In the era of big data, the rapid expansion of computing capacities in automatic data generation and acquisition brings data of unprecedented size and complexity, and raises a series of scientific challenges such as storage bottleneck and algorithmic scalability (Zhou et al., 2014). To overcome the difficulty, some approaches for generating scalable approximate algorithms have been introduced in the literature such as low-rank approximations of kernel matrices for kernel principal component analysis (Schölkopf et al., 1998; Bach, 2013), incomplete Cholesky decomposition (Fine, 2002), early-stopping of iterative optimization algorithms for gradient descent methods (Yao et al., 2007; Raskutti et al., 2014; Lin et al., 2016), and greedy-type algorithms. Another method proposed recently is distributed learning based on a divide-and-conquer approach and a particular learning algorithm implemented in individual machines (Zhang et al., 2015; Shamir and Srebro, 2014). This method produces distributed learning algorithms consisting of three steps: partitioning the data into disjoint subsets, applying a particular learning algorithm implemented in an individual machine to each data subset to produce an individual output (function), and synthesizing a global output by utilizing some average of the individual outputs. This method can significantly reduce computing time and lower single-machine memory requirements. For practical applications in medicine, finance, business and some other areas, the data are often stored naturally across multiple servers in a distributive way and are not combined for reasons of protecting privacy and avoiding high costs. In such situations, the first step of data partitioning is not needed. It has been observed in many practical applications that when the number of data subsets is not too large, the divide-and-conquer approach does not cause noticeable loss of performance, compared with the learning scheme which processes the whole data on a single big machine. Theoretical attempts have been recently made in (Zhang et al., 2013, 2015) to derive learning rates for distributed learning with least squares regularization schemes under certain assumptions.

This paper aims at error analysis of the *distributed learning* with regularized least squares and its approximation to the algorithm processing the whole data in one single machine. Recall (Cristianini and Shawe-Taylor, 2000; Evgeniou et al., 2000) that in a reproducing kernel Hilbert space (RKHS) $(\mathcal{H}_K, \|\cdot\|_K)$ induced by a Mercer kernel K on an input metric space $\mathcal{X}$, with a sample $D = \{(x_i, y_i)\}_{i=1}^N \subset \mathcal{X} \times \mathcal{Y}$ where $\mathcal{Y} = \mathbb{R}$ is the output space, the least squares regularization scheme can be stated as

$$f_{D,\lambda} = \arg\min_{f \in \mathcal{H}_K} \left\{ \frac{1}{|D|} \sum_{(x,y)\in D} (f(x) - y)^2 + \lambda \|f\|_K^2 \right\}. \tag{1}$$

Here $\lambda > 0$ is a regularization parameter and $|D| =: N$ is the cardinality of D. This learning algorithm is also called kernel ridge regression in statistics and has been well studied in learning theory. See e.g. (De Vito et al., 2005; Caponnetto and De Vito, 2007; Steinwart et al., 2009; Bauer et al., 2007; Smale and Zhou, 2007; Steinwart and Christmann, 2008). The regularization scheme (1) can be explicitly solved by using a standard matrix inversion technique, which requires costs of $\mathcal{O}(N^3)$ in time and $\mathcal{O}(N^2)$ in memory. However, this matrix inversion technique may not conquer challenges on storages or computations arising from big data.

The distributed learning algorithm studied in this paper starts with partitioning the data set D into m disjoint subsets $\{D_j\}_{j=1}^m$. Then it assigns each data subset D_j to one machine or processor to produce a local estimator $f_{D_j,\lambda}$ by the least squares regularization scheme (1). Finally, these local estimators are communicated to a central processor, and a global estimator $\overline{f}_{D,\lambda}$ is synthesized by taking a weighted average

$$\overline{f}_{D,\lambda} = \sum_{j=1}^m \frac{|D_j|}{|D|} f_{D_j,\lambda} \tag{2}$$

of the local estimators $\{f_{D_j,\lambda}\}_{j=1}^m$. This algorithm has been studied with a matrix analysis approach in (Zhang et al., 2015) where some error analysis has been conducted under some eigenfunction assumptions for the integral operator associated with the kernel, presenting error bounds in expectation.

JMLR 18(92):1-31, 2017

In this paper we shall use a novel integral operator approach to prove that $\overline{f}_{D,\lambda}$ is a good approximation of $f_{D,\lambda}$. We present a representation of the difference $\overline{f}_{D,\lambda} - f_{D,\lambda}$ in terms of empirical integral operators, and analyze the error $\overline{f}_{D,\lambda} - f_{D,\lambda}$ in expectation without any eigenfunction assumptions. As a by-product, we present the best learning rates in expectation for the least squares regularization scheme (1) in a general setting, which surprisingly has not been done for a general kernel in the literature (see detailed comparisons below).

2. Main Results

Our analysis is carried out in the standard least squares regression framework with a Borel probability measure ρ on $\mathcal{Z} := \mathcal{X} \times \mathcal{Y}$, where the input space $\mathcal{X}$ is a compact metric space. The sample D is independently drawn according to ρ. The Mercer kernel $K : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ defines an integral operator L_K on $\mathcal{H}_K$ as

$$L_K(f) = \int_{\mathcal{X}} K_x f(x) d\rho_X, \qquad f \in \mathcal{H}_K, \tag{3}$$

where K_x is the function $K(\cdot, x)$ in $\mathcal{H}_K$ and ρ_X is the marginal distribution of ρ on $\mathcal{X}$.

2.1 Error Bounds for the Distributed Learning Algorithm

Our error bounds in expectation for the distributed learning algorithm (2) require the uniform boundedness condition for the output y, that is, for some constant $M > 0$, there holds $|y| \le M$ almost surely. Our bounds are stated in terms of the approximation error

$$\|f_\lambda - f_\rho\|_\rho, \tag{4}$$

where f_λ is the data-free limit of (1) defined by

$$f_\lambda = \arg\min_{f \in \mathcal{H}_K} \left\{ \int_{\mathcal{Z}} (f(x) - y)^2 d\rho + \lambda \|f\|_K^2 \right\}, \tag{5}$$

$\|\cdot\|_\rho$ denotes the norm of $L^2_{\rho_X}$, the Hilbert space of square integrable functions with respect to ρ_X, and f_ρ is the regression function (conditional mean) of ρ defined by

$$f_\rho(x) = \int_{\mathcal{Y}} y d\rho(y|x), \qquad x \in \mathcal{X},$$

with $\rho(\cdot|x)$ being the conditional distribution of ρ induced at $x \in \mathcal{X}$.

Since K is continuous, symmetric and positive semidefinite, L_K is a compact positive operator of trace class and $L_K + \lambda I$ is invertible. Define a quantity measuring the complexity of $\mathcal{H}_K$ with respect to ρ_X, the *effective dimension* (Zhang, 2005), to be the trace of the operator $(L_K + \lambda I)^{-1} L_K$ as

$$\mathcal{N}(\lambda) = \mathrm{Tr}\left((L_K + \lambda I)^{-1} L_K \right), \qquad \lambda > 0. \tag{6}$$

In Section 6 we shall prove the following first main result of this paper concerning error bounds in expectation of $\overline{f}_{D,\lambda} - f_{D,\lambda}$ in $\mathcal{H}_K$ and in $L^2_{\rho_X}$. Denote $\kappa = \sup_{x \in \mathcal{X}} \sqrt{K(x,x)}$.

Theorem 1 *Assume $|y| \le M$ almost surely. If $|D_j| = \frac{N}{m}$ for $j = 1, \ldots, m$, then we have*

$$E \left\| \overline{f}_{D,\lambda} - f_{D,\lambda} \right\|_\rho \le C_\kappa \left\{ M\sqrt{\lambda m}\mathcal{C}_m \left\{ 1 + \sqrt{m\mathcal{C}_m} \right\} + \frac{\|f_\rho - f_\lambda\|_\rho}{\sqrt{N\lambda}} m \left(\sqrt{\frac{\mathcal{N}(\lambda)}{N\lambda}} + \sqrt{m}\mathcal{C}_m \right) \right\}$$

and

$$E \left\| \overline{f}_{D,\lambda} - f_{D,\lambda} \right\|_K \le C_\kappa \left\{ M\sqrt{m}\mathcal{C}_m \left\{ 1 + \sqrt{m\mathcal{C}_m} \right\} + \frac{\|f_\rho - f_\lambda\|_\rho}{\sqrt{N\lambda}} m \left(\sqrt{\frac{\mathcal{N}(\lambda)}{N\lambda}} + \sqrt{m}\mathcal{C}_m \right) \right\},$$

where C_κ is a constant depending only on κ, and $\mathcal{C}_m$ is the quantity given in terms of $m, N, \lambda, \mathcal{N}(\lambda)$ by

$$\mathcal{C}_m := \frac{m}{(N\lambda)^2} + \frac{\mathcal{N}(\lambda)}{N\lambda}.$$

To derive explicit learning rates from the general error bounds in Theorem 1, one can quantify the increment of $\mathcal{N}(\lambda)$ by the following *capacity assumption*, a characteristic of the complexity of the hypothesis space (Caponnetto and De Vito, 2007; Blanchard and Krämer, 2010),

$$\mathcal{N}(\lambda) \le c\lambda^{-\beta}, \qquad \forall \lambda > 0 \tag{7}$$

for some constants $\beta > 0$ and $c > 0$. Let $\{(\lambda_\ell, \varphi_\ell)\}_\ell$ be a set of normalized eigenpairs of L_K on $\mathcal{H}_K$ with $\{\varphi_\ell\}_\ell$ being an orthonormal basis of $\mathcal{H}_K$ and $\{\lambda_\ell\}_\ell$ arranged in a non-increasing order. A sufficient condition for the capacity assumption (7) with $0 < \beta < 1$ is $\lambda_\ell = O(\ell^{-1/\beta})$, which can be found in, e.g. Caponnetto and De Vito (2007).

Remark 2 *The sufficient condition $\lambda_\ell = O(\ell^{-1/\beta})$ with the index $\beta = \frac{d}{2\tau} < 1$ is satisfied by the Sobolev space $W^\tau(B(\mathbb{R}^d))$ with the smoothness index $\tau > d/2$ on a ball $B(\mathbb{R}^d)$ of the Euclidean space $\mathbb{R}^d$ when the marginal distribution ρ_X is the uniform distribution on $B(\mathbb{R}^d)$, see (Steinwart et al., 2009; Edmunds and Triebel, 1996).*

Condition (7) with $\beta = 1$ always holds true with the choice of the constant $c = \kappa^2$. In fact, the eigenvalues of the operator $(L_K + \lambda I)^{-1} L_K$ are $\{\frac{\lambda_\ell}{\lambda_\ell + \lambda}\}_\ell$. So its trace is given by $\mathcal{N}(\lambda) = \sum_\ell \frac{\lambda_\ell}{\lambda_\ell + \lambda} \le \sum_\ell \frac{\lambda_\ell}{\lambda} = \frac{\mathrm{Tr}(L_K)}{\lambda} \le \kappa^2 \lambda^{-1}$.

In the existing literature on learning rates for the classical least squares algorithm (1), the regularization parameter λ is often taken to satisfy the restriction $\frac{\mathcal{N}(\lambda)}{N\lambda} = O(1)$ as in (Caponnetto and De Vito, 2007) up to a logarithmic factor or in (Steinwart et al., 2009) under some assumptions on (K, ρ_X) (see (14) below). Here, to derive learning rates for $E \left\| \overline{f}_{D,\lambda} - f_{D,\lambda} \right\|_\rho$ with $m \ge 1$ corresponding to the distributed learning algorithm (2), we consider λ to satisfy the following restriction with some constant $C_0 > 0$,

$$0 < \lambda \le C_0 \quad \text{and} \quad \frac{m\mathcal{N}(\lambda)}{N\lambda} \le C_0. \tag{8}$$

Corollary 3 *Assume $|y| \le M$ almost surely. If $|D_j| = \frac{N}{m}$ for $j = 1, \ldots, m$, and λ satisfies (8), then we have*

$$E \left\| \overline{f}_{D,\lambda} - f_{D,\lambda} \right\|_\rho \le \widetilde{C}_\kappa \sqrt{\frac{\mathcal{N}(\lambda)}{N\lambda}} \left\{ M\sqrt{\lambda} + \frac{m\|f_\rho - f_\lambda\|_\rho}{\sqrt{N\lambda}} \right\}$$

and

$$E\left\|\overline{f}_{D,\lambda}-f_{D,\lambda}\right\|_K \le \widetilde{C}_\kappa \sqrt{\frac{\mathcal{N}(\lambda)}{N\lambda}}\left\{M+\frac{m\|f_\rho-f_\lambda\|_\rho}{\sqrt{N\lambda}}\right\},$$

where $\widetilde{C}_\kappa$ is a constant depending only on κ, C_0, and the largest eigenvalue of L_K.

In the special case that $f_\rho \in \mathcal{H}_K$, the approximation error can be bounded as $\|f_\lambda - f_\rho\|_\rho \le \|f_\rho\|_K \sqrt{\lambda}$. A more general *regularity condition* can be imposed for the regression function as

$$f_\rho = L_K^r(g_\rho) \quad \text{for some } g_\rho \in L^2_{\rho_X},\ r>0, \tag{9}$$

where the integral operator L_K is regarded as a compact positive operator on $L^2_{\rho_X}$ and its rth power L_K^r is well defined for any $r>0$. The condition (9) means f_ρ lies in the range of L_K^r, and the special case $f_\rho \in \mathcal{H}_K$ corresponds to the choice $r=1/2$. It implies $\|f_\lambda - f_\rho\|_\rho \le \lambda^r \|g_\rho\|_\rho$ by Lemma 21 below. Thus, under condition (9), we obtain from Corollary 3, by choosing λ to minimize the order of the error bound subject to the restriction (8), the following nice convergence rates for the error $\left\|\overline{f}_{D,\lambda}-f_{D,\lambda}\right\|$ of the distributed learning algorithm (2).

Corollary 4 *Assume regularity condition (9) for some $0<r\le 1$, capacity assumption (7) with $\beta=\frac{1}{2\alpha}$ for some $\alpha>0$, and $|y|\le M$ almost surely. If $|D_j|=\frac{N}{m}$ for $j=1,\dots,m$ with*

$$m \le N^{\frac{\alpha\max\{2r,1\}+\frac{1}{2}+2\alpha(r-1)}{2\alpha\max\{2r,1\}+1+2\alpha(r-1)}}, \tag{10}$$

and $\lambda=\left(\frac{m}{N}\right)^{\frac{2\alpha}{2\alpha\max\{2r,1\}+1}}$, then we have

$$E\left\|\overline{f}_{D,\lambda}-f_{D,\lambda}\right\|_\rho \le \widetilde{C}_{\kappa,c,r}\frac{1}{\sqrt{m}}\left(\frac{m}{N}\right)^{\frac{\alpha\max\{2r,1\}}{2\alpha\max\{2r,1\}+1}}$$

and

$$E\left\|\overline{f}_{D,\lambda}-f_{D,\lambda}\right\|_K \le \widetilde{C}_{\kappa,c,r}\frac{1}{\sqrt{m}}\left(\frac{m}{N}\right)^{\frac{\alpha\max\{2r-1,0\}}{2\alpha\max\{2r,1\}+1}},$$

where $\widetilde{C}_{\kappa,c,r}$ is a constant independent of N or m.

In particular, when $f_\rho\in\mathcal{H}_K$ and $m\le N^{\frac{1}{2+2\alpha}}$, taking $\lambda=\left(\frac{m}{N}\right)^{\frac{2\alpha}{2\alpha+1}}$ yields the rates $E\left\|\overline{f}_{D,\lambda}-f_{D,\lambda}\right\|_\rho \le \widetilde{C}_{\kappa,c,r}N^{-\frac{\alpha}{2\alpha+1}}m^{-\frac{1}{4\alpha+2}}$ and $E\left\|\overline{f}_{D,\lambda}-f_{D,\lambda}\right\|_K \le \widetilde{C}_{\kappa,c,r}\frac{1}{\sqrt{m}}$.

Remark 5 *In Corollary 4, we present learning rates in both $\mathcal{H}_K$ and $L^2_{\rho_X}$ norms. The rates with respect to the $L^2_{\rho_X}$ norm provide estimates for the generalization ability of the algorithm for regression. The rates with respect to the $\mathcal{H}_K$ norm give error estimates with respect to the uniform metric due to the relation $\|f\|_\infty \le \kappa\|f\|_K$, and might be used to solve some mismatch problems in learning theory where the generalization ability of learning algorithms is measured with respect to a probability measure μ different from ρ_X.*

Remark 6 *The learning rates in Corollary 4 are stated for the norms of the difference $\overline{f}_{D,\lambda}-f_{D,\lambda}$ which reflects the variance of the distributed learning algorithm (2). These rates decrease as m increases (subject to the restriction (10)) and thereby the regularization parameter λ increases, which is different from the learning rates presented for $E\left\|\overline{f}_{D,\lambda}-f_\rho\right\|_\rho$ in (Zhang et al., 2015). To derive learning rates for $E\left\|\overline{f}_{D,\lambda}-f_\rho\right\|_\rho$ by our analysis, the regularization parameter λ should be independent of m, as shown in Corollary 11 below.*

2.2 Optimal Learning Rates for Least Squares Regularization Scheme

The second main result of this paper is optimal learning rates in expectation for the least squares regularization scheme (1). We can even relax the uniform boundedness to a *moment condition* that for some constant $p\ge 1$,

$$\sigma_\rho^2 \in L^p_{\rho_X}, \tag{11}$$

where σ_ρ^2 is the conditional variance defined by $\sigma_\rho^2(x)=\int_{\mathcal{Y}}(y-f_\rho(x))^2\,d\rho(y|x)$.

The following learning rates in expectation for the least squares regularization scheme (1) will be proved in Section 5. The existence of f_λ is ensured by $E[y^2]<\infty$.

Theorem 7 *Assume $E[y^2]<\infty$ and moment condition (11) for some $1\le p\le\infty$. Then we have*

$$E\left[\|f_{D,\lambda}-f_\rho\|_\rho\right] \le \left(2+56\kappa^4+57\kappa^2\right)(1+\kappa)\left(1+\frac{1}{(N\lambda)^2}+\frac{\mathcal{N}(\lambda)}{N\lambda}\right)$$
$$\left\{\left(1+\frac{1}{\sqrt{N\lambda}}\right)\|f_\lambda-f_\rho\|_\rho+\sqrt{\left\|\sigma_\rho^2\right\|_p}\left(\frac{\mathcal{N}(\lambda)}{N}\right)^{\frac{1}{2}(1-\frac{1}{p})}\left(\frac{1}{N\lambda}\right)^{\frac{1}{2p}}\right\}. \tag{12}$$

If the parameters satisfy $\frac{\mathcal{N}(\lambda)}{N\lambda}=O(1)$, we have the following explicit bound.

Corollary 8 *Assume $E[y^2]<\infty$ and moment condition (11) for some $1\le p\le\infty$. If λ satisfies (8) with $m=1$, then we have*

$$E\left[\|f_{D,\lambda}-f_\rho\|_\rho\right]=O\left(\|f_\lambda-f_\rho\|_\rho+\left(\frac{\mathcal{N}(\lambda)}{N}\right)^{\frac{1}{2}(1-\frac{1}{p})}\left(\frac{1}{N\lambda}\right)^{\frac{1}{2p}}\right).$$

In particular, if $p=\infty$, that is, the conditional variances are uniformly bounded, then

$$E\left[\|f_{D,\lambda}-f_\rho\|_\rho\right]=O\left(\|f_\lambda-f_\rho\|_\rho+\sqrt{\frac{\mathcal{N}(\lambda)}{N}}\right).$$

In particular, when regularity condition (9) is satisfied, we have the following learning rates in expectation.

Corollary 9 *Assume $E[y^2]<\infty$, moment condition (11) for some $1\le p\le\infty$, and regularity condition (9) for some $0<r\le 1$. If the capacity assumption $\mathcal{N}(\lambda)=O(\lambda^{-\frac{1}{2\alpha}})$ holds with some $\alpha>0$, then by taking $\lambda=N^{-\frac{2\alpha}{2\alpha\max\{2r,1\}+1}}$ we have*

$$E\left[\|f_{D,\lambda}-f_\rho\|_\rho\right]=O\left(N^{-\frac{2r\alpha}{2\alpha\max\{2r,1\}+1}+\frac{1}{2p}\frac{2\alpha-1}{2\alpha\max\{2r,1\}+1}}\right).$$

In particular, when $p=\infty$ (the conditional variances are uniformly bounded), we have

$$E\left[\|f_{D,\lambda}-f_\rho\|_\rho\right]=O\left(N^{-\frac{2r\alpha}{2\alpha\max\{2r,1\}+1}}\right).$$

Remark 10 *It was shown in (Caponnetto and De Vito, 2007; Steinwart et al., 2009; Bauer et al., 2007) that under the condition of Corollary 9 with $p = \infty$ and $r \in [\frac{1}{2}, 1]$, the best learning rate, called minimax lower rate of convergence, for learning algorithms with output functions in $\mathcal{H}_K$ is $O\left(N^{-\frac{2r\alpha}{4\alpha r+1}}\right)$. So the convergence rate we obtain in Corollary 9 is optimal.*

Combining bounds for $\left\|\overline{f}_{D,\lambda} - f_{D,\lambda}\right\|_\rho$ and $\|f_{D,\lambda} - f_\rho\|_\rho$, we shall prove in Section 6 the following learning rates in expectation for the distributed learning algorithm (2) for regression.

Corollary 11 *Assume $|y| \le M$ almost surely and regularity condition (9) for some $\frac{1}{2} < r \le 1$. If the capacity assumption $\mathcal{N}(\lambda) = O(\lambda^{-\frac{1}{2\alpha}})$ holds with some $\alpha > 0$, $|D_j| = \frac{N}{m}$ for $j = 1, \ldots, m$, and m satisfies the restriction*

$$m \le N^{\frac{2\alpha(2r-1)}{4\alpha r+1}}, \tag{13}$$

then by taking $\lambda = N^{-\frac{2\alpha}{4\alpha r+1}}$, we have

$$E\left[\left\|\overline{f}_{D,\lambda} - f_\rho\right\|_\rho\right] = O\left(N^{-\frac{2\alpha r}{4\alpha r+1}}\right).$$

Remark 12 *Corollary 11 shows that distributed learning with the least squares regularization scheme in a RKHS can achieve the optimal learning rates in expectation, provided that m satisfies the restriction (13). It should be pointed out that our error analysis is carried out under regularity condition (9) with $1/2 < r \le 1$ while the work in (Zhang et al., 2015) focused on the case with $r = 1/2$. When r approaches $1/2$, the number m of local processors under the restriction (13) reduces to 1, which corresponds to the non-distributed case. In our follow-up work, we will consider to relax the restriction (13) in a semi-supervised learning framework by using additional unlabelled data, as done in (Caponnetto and Yao, 2010). The main contribution of our analysis for distributed learning in this paper is to remove an eigenfunction assumption in (Zhang et al., 2015) by using a novel second order decomposition for a difference of operator inverses.*

Remark 13 *In Corollary 11 and Corollary 9, the choice of the regularization parameter λ is independent of the number m of local processors. This is consistent with the results in (Zhang et al., 2015). There have been several approaches for selecting the regularization parameter λ in regularization schemes in the literature including cross-validation (Györfy et al., 2002; Blanchard and Krämer, 2016) and the balancing principle (De Vito et al., 2010). For practical applications of distributed learning algorithms, how to choose λ and m (except the situations when the data are stored naturally in a distributive way) is crucial. Though we only consider the theoretical topic of error analysis in this paper, it would be interesting to develop parameter selection methods for distributed learning.*

3. Comparisons and Discussion

The least squares regularization scheme (1) is a classical algorithm for regression and has been extensively investigated in statistics and learning theory. There is a vast literature on

this topic. Here for a general kernel beyond those for the Sobolev spaces, we compare our results with the best learning rates in the existing literature.

Under the assumption that the orthogonal projection $f_{\mathcal{H}}$ of f_ρ in $L^2_{\rho_X}$ onto the closure of $\mathcal{H}_K$ satisfies regularity condition (9) for some $\frac{1}{2} \le r \le 1$, and that the eigenvalues $\{\lambda_i\}_i$ of L_K satisfy $\lambda_i \approx i^{-2\alpha}$ with some $\alpha > 1/2$, it was proved in (Caponnetto and De Vito, 2007) that

$$\lim_{\tau\to\infty} \limsup_{N\to\infty} \sup_{\rho\in\mathcal{P}(\alpha)} \text{Prob}\left[\|f_{D,\lambda_N} - f_{\mathcal{H}}\|_\rho^2 > \tau\lambda_N^{2r}\right] = 0,$$

where

$$\lambda_N = \begin{cases} N^{-\frac{2\alpha}{4\alpha r+1}}, & \text{if } \frac{1}{2} < r \le 1, \\ \left(\frac{\log N}{N}\right)^{\frac{2\alpha}{2\alpha+1}}, & \text{if } r = \frac{1}{2}, \end{cases}$$

and $\mathcal{P}(\alpha)$ denotes a set of probability measures ρ satisfying some moment decay condition (which is satisfied when $|y| \le M$). This learning rate in probability is stated with a limit as $\tau \to \infty$ and it has a logarithmic factor in the case $r = \frac{1}{2}$. In particular, to guarantee $\|f_{D,\lambda_N} - f_{\mathcal{H}}\|_\rho^2 \le \tau_\eta \lambda_N^{2r}$ with confidence $1-\eta$ by this result, one needs to restrict $N \ge N_\eta$ to be large enough and has the constant τ_η depending on η to be large enough. Using existing tools for error analysis including those in (Caponnetto and De Vito, 2007), we develop a novel second order decomposition technique for a difference of operator inverses in this paper, and succeed in deriving the optimal learning rate in expectation in Corollary 9 by removing the logarithmic factor in the case $r = \frac{1}{2}$.

Under the assumption that $|y| \le M$ almost surely, the eigenvalues $\{\lambda_i\}_i$ satisfying $\lambda_i \le ai^{-2\alpha}$ with some $\alpha > 1/2$ and $a > 0$, and for some constant $C > 0$, the pair (K, ρ_X) satisfying

$$\|f\|_\infty \le C\|f\|_K^{\frac{1}{2\alpha}}\|f\|_\rho^{1-\frac{1}{2\alpha}} \tag{14}$$

for every $f \in \mathcal{H}_K$, it was proved in (Steinwart et al., 2009) that for some constant $c_{\alpha,C}$ depending only on α and C, with confidence $1-\eta$, for any $0 < \lambda \le 1$,

$$\|\pi_M(f_{D,\lambda}) - f_\rho\|_\rho^2 \le 9\mathcal{A}_2(\lambda) + c_{\alpha,C}\frac{a^{1/(2\alpha)}M^2\log(3/\eta)}{\lambda^{1/(2\alpha)}N}.$$

Here π_M is the projection onto the interval $[-M, M]$ defined (Chen et al., 2004; Wu et al., 2006) by

$$\pi_M(f)(x) = \begin{cases} M, & \text{if } f(x) > M, \\ f(x), & \text{if } |f(x)| \le M, \\ -M, & \text{if } f(x) < -M, \end{cases}$$

and $\mathcal{A}_2(\lambda)$ is the approximation error defined by

$$\mathcal{A}_2(\lambda) = \inf_{f\in\mathcal{H}_K}\left\{\|f - f_\rho\|_\rho^2 + \lambda\|f\|_K^2\right\}.$$

When $f_\rho \in \mathcal{H}_K$, $\mathcal{A}_2(\lambda) = O(\lambda)$ and the choice $\lambda_N = N^{\frac{2\alpha}{2\alpha+1}}$ gives a learning rate of order $\|f_{D,\lambda_N} - f_\rho\|_\rho = O\left(N^{-\frac{\alpha}{2\alpha+1}}\right)$. Here one needs to impose the condition (14) for the functions spaces $L^2_{\rho_X}$ and $\mathcal{H}_K$, and to take the projection onto $[-M, M]$. Our learning rates

in Corollary 9 do not require such a condition for the function spaces, nor do we take the projection. Let us mention the fact from (Steinwart et al., 2009; Mendelson and Neeman, 2010) that condition (14) is satisfied when $\mathcal{H}_K$ is a Sobolev space on a domain of a Euclidean space and ρ_X is the uniform distribution, or when the eigenfunctions $\{\varphi_\ell/\sqrt{\lambda_\ell} : \lambda_\ell > 0\}$ of L_K normalized in $L^2_{\rho_X}$ are uniformly bounded. Recall that $\|\varphi_\ell\|_{L^2_{\rho_X}} = \sqrt{\lambda_\ell}$ since $\lambda_\ell = \lambda_\ell\|\varphi_\ell\|_K^2 = \langle\lambda_\ell\varphi_\ell, \varphi_\ell\rangle_K = \langle L_K\varphi_\ell, \varphi_\ell\rangle_K$ equals

$$\langle\int_{\mathcal{X}} K_x\varphi_\ell(x)d\rho_X(x), \varphi_\ell\rangle_K = \int_{\mathcal{X}} \varphi_\ell(x)\varphi_\ell(x)d\rho_X(x) = \|\varphi_\ell\|^2_{L^2_{\rho_X}}.$$

Learning rates for the least squares regularization scheme (1) in the $\mathcal{H}_K$-metric have been investigated in (Smale and Zhou, 2007).

For the distributed learning algorithm (2) with subsets $\{D_j\}_{j=1}^m$ of equal size, under the assumption that for some constants $2 < k \le \infty$ and $A < \infty$, the eigenfunctions $\{\varphi_i\}_i$ satisfy

$$\begin{cases} \sup_{\lambda_i>0} E\left[\left|\frac{\varphi_i(x)}{\sqrt{\lambda_i}}\right|^{2k}\right] \le A^{2k}, & \text{when } k < \infty, \\ \sup_{\lambda_i>0} \left\|\frac{\varphi_i(x)}{\sqrt{\lambda_i}}\right\|_\infty \le A, & \text{when } k = \infty, \end{cases} \tag{15}$$

and that $f_\rho \in \mathcal{H}_K$ and $\lambda_i \le ai^{-2\alpha}$ for some $\alpha > 1/2$ and $a > 0$, it was proved in (Zhang et al., 2015) that for $\lambda = N^{-\frac{2\alpha}{2\alpha+1}}$ and m satisfying the restriction

$$m \le c_\alpha \begin{cases} \left(\frac{N^{\frac{2(k-4)\alpha-k}{2\alpha+1}}}{A^{4k}\log^k N}\right)^{\frac{1}{k-2}}, & \text{when } k < \infty \\ \frac{N^{\frac{2\alpha-1}{2\alpha+1}}}{A^4\log N}, & \text{when } k = \infty \end{cases} \tag{16}$$

with a constant c_α depending only on α, there holds $E\left[\left\|\overline{f}_{D,\lambda} - f_\rho\right\|_\rho^2\right] = O\left(N^{-\frac{2\alpha}{2\alpha+1}}\right)$. This interesting result was achieved by a matrix analysis approach for which the eigenfunction assumption (15) played an essential role.

It might be challenging to check the eigenfunction assumption (15) involving the integral operator $L_K = L_{K,\rho_X}$ for the pair (K, ρ_X). To our best knowledge, besides the case of finite dimensional RKHSs, there exist in the literature only three classes of pairs (K, ρ_X) proved satisfying this eigenfunction assumption: the first class (Steinwart et al., 2009) is the Sobolev reproducing kernels on Euclidean domains together with the unform measures ρ_X, the second (Williamson et al., 2001) is periodical kernels, and the third class can be constructed by a Mercer type expansion

$$K(x, y) = \sum_i \lambda_i \frac{\varphi_i(x)}{\sqrt{\lambda_i}}\frac{\varphi_i(y)}{\sqrt{\lambda_i}}, \tag{17}$$

where $\{\frac{\varphi_i(x)}{\sqrt{\lambda_i}}\}_i$ is an orthonormal system in $L^2_{\rho_X}$. An example of a C^∞ Mercer kernel was presented in (Zhou, 2002, 2003) to show that only the smoothness of the Mercer kernel does not guarantee the uniform boundedness of the eigenfunctions $\{\frac{\varphi_i(x)}{\sqrt{\lambda_i}}\}_i$. Furthermore, it was shown in (Gittens and Mahoney, 2016) that these normalized eigenfunctions associated with radial basis kernels tend to be localized when the radial basis parameters are made smaller, which raises a practical concern for the uniform boundedness assumption on the eigenfunctions.

Remark 14 *To see how the eigenfunctions $\{\varphi_i(x)\}_i$ change with the marginal distribution, we consider a different measure μ induced by a nonnegative function $P \in L^2_{\rho_X}$ as $d\mu = P(x)d\rho_X$. An eigenpair (λ, φ) of the integral operator $L_{K,\mu}$ associated with the pair (K, μ) with $\lambda > 0$ satisfies*

$$L_{K,\mu}\varphi = \int_{\mathcal{X}} K(\cdot, x)\varphi(x)P(x)d\rho_X = \sum_{\lambda_i>0} \lambda_i \frac{\varphi_i}{\sqrt{\lambda_i}}\int_{\mathcal{X}} \frac{\varphi_i(x)}{\sqrt{\lambda_i}}\varphi(x)P(x)d\rho_X = \lambda\varphi.$$

We introduce an index set $I := \{i : \lambda_i > 0\}$, a possibly infinite matrix

$$\mathbb{K}^P = \left(\lambda_i \int_{\mathcal{X}} \frac{\varphi_i(x)}{\sqrt{\lambda_i}}P(x)\frac{\varphi_j(x)}{\sqrt{\lambda_j}}d\rho_X\right)_{i,j\in I}, \tag{18}$$

and express φ in terms of the orthonormal basis $\{\varphi_i\}_{i\in I}$ as $\varphi = \sum_{i\in I}\frac{c_i}{\sqrt{\lambda_i}}\varphi_i$ where the sequence $c = (c_i)_{i\in I}$ is given by $c_i = \langle\varphi, \frac{\varphi_i}{\sqrt{\lambda_i}}\rangle_{L^2_{\rho_X}} = \sqrt{\lambda_i}\langle\varphi, \varphi_i\rangle_K$. Then the eigenpair (λ, φ) satisfies

$$L_{K,\mu}\varphi = \lambda\varphi \quad\Longleftrightarrow\quad \sum_{i\in I}\frac{\varphi_i}{\sqrt{\lambda_i}}\sum_{j\in I}\left(\mathbb{K}^P\right)_{i,j}c_j = \lambda\sum_{i\in I}\frac{c_i}{\sqrt{\lambda_i}}\varphi_i \quad\Longleftrightarrow\quad \mathbb{K}^P c = \lambda c.$$

Thus the eigenpairs of the integral operator $L_{K,\mu}$ associated with (K, μ) can be characterized by those of the possibly infinite matrix $\mathbb{K}^P$ defined by (18). Finding the eigenpairs of $\mathbb{K}^P$ is an interesting question involving matrix analysis in linear algebra and multiplier operators in harmonic analysis. Note that when $P \equiv 1$ corresponding to $\mu = \rho_X$, $\mathbb{K}^P$ is diagonal with diagonal entries $\{\lambda_i\}_i$ and its eigenvectors yield eigenfunctions $\{\varphi_i\}_i$.

From the above observation, we can see that the marginal distribution ρ_X plays an essential role in the eigenfunction assumption (15) which might be difficult to check for a general marginal distribution ρ_X. For example, it is even unknown whether any of the Gaussian kernels on $\mathcal{X} = [0, 1]^d$ satisfies the eigenfunction assumption (15) when ρ_X is a general Borel measure.

Our learning rates stated in Corollary 4 or Corollary 11 do not require the eigenfunction assumption (15). Moreover, our restriction (10) for the number m of local processors in Corollary 4 is more general than (16) when α is close to $1/2$: with $r = 1/2$ corresponding to the condition $f_\rho \in \mathcal{H}_K$, our restriction (10) in Corollary 4 is $m \le N^{\frac{1}{4+6\alpha}}$ with the power index tending to $\frac{1}{7}$ while the restriction in (16) with $k = \infty$ takes the form $m \le c_\alpha\frac{N^{\frac{2\alpha-1}{2\alpha+1}}}{A^4\log N}$ with the power index tending to 0 as $\alpha \to \frac{1}{2}$. Note that the learning rates stated in Corollary 4 are for the difference $\overline{f}_{D,\lambda} - f_{D,\lambda}$ between the output function of the distributed learning algorithm (2) and that of the algorithm (1) using the whole data. In the special case of $r = \frac{1}{2}$, we can see that $E\left\|\overline{f}_{D,\lambda} - f_{D,\lambda}\right\|_\rho \le \widetilde{C}_{\kappa,c,r}N^{-\frac{\alpha}{2\alpha+1}}m^{-\frac{1}{4\alpha+2}}$, achieved by choosing $\lambda = \left(\frac{m}{N}\right)^{\frac{2\alpha}{2\alpha+1}}$, is smaller as m becomes larger. Here the dependence of λ on m is crucial for achieving this convergence rate of the sample error: if we fix λ and N, the error bounds for $E\left\|\overline{f}_{D,\lambda} - f_{D,\lambda}\right\|$ stated in Theorem 1 and Corollary 3 become larger as m increases. On the other hand, as one expects, increasing the number m of local processors would increase

the approximation error for the regression problem, which can also be seen from the bound with $\lambda = \left(\frac{m}{N}\right)^{\frac{2\alpha}{2\alpha+1}}$ stated in Theorem 7. The result in Corollary 11 with $r > \frac{1}{2}$ compensates and gives the optimal learning rate $E\left[\left\|\overline{f}_{D,\lambda} - f_\rho\right\|_\rho\right] = O\left(N^{-\frac{2r\alpha}{4\alpha r+1}}\right)$ by restricting m as in (13).

Besides the divide-and-conquer technique, there are many other approaches in the literature to reduce the computational complexity in handling big data. These include the localized learning (Meister and Steinwart, 2016), Nyström regularization (Bach, 2013; Rudi et al., 2015), and online learning (Dekel et al., 2012). The divide-and-conquer technique has the advantage of reducing the single-machine complexity of both space and time without a significant lost of prediction power.

It is an important and interesting problem how the big data are decomposed for distributed learning. Here we only study the approach of random decomposition, and the data subsets are regarded as being drawn from the same distribution. There should be better decomposition strategies for some practical applications. For example, intuitively data points should be divided according to their spatial distribution so that the learning process would yield locally optimal predictors, which could then be synthesized to the output function. See (Thomann et al., 2016).

In this paper, we consider the regularized least squares with Mercer kernels. Our results might be extended to more general kernels. A natural class consists of bounded and positive semidefinite kernels as studied in (Steinwart and Scovel, 2012). By means of the Mercer type expansion (17), one needs some assumptions on the system $\{\frac{\varphi_i(x)}{\sqrt{\lambda_i}}\}_i$, the domain $\mathcal{X}$, and the measure ρ_X to relax the continuity of the kernel while keeping compactness of the integral operator. How to minimize the assumptions and to maximize the scope of applications of the framework such as the situation of an input space $\mathcal{X}$ without a metric (Shen et al., 2014; De Vito et al., 2013) is a valuable question to investigate.

Here we only consider distributed learning with the regularized least squares. It would be of great interest and value to develop the theory for distributed learning with other algorithms such as spectral algorithms (Bauer et al., 2007), empirical feature-based learning (Guo and Zhou, 2012; Guo et al., 2017; Shi et al., 2011), the minimum error entropy principle (Hu et al., 2015; Fan et al., 2016), and randomized Kaczmarz algorithms (Lin and Zhou, 2015).

Remark 15 *After the submission of this paper, in our follow-up paper by Z. C. Guo, S. B. Lin, and D. X. Zhou entitled "Learning theory of distributed spectral algorithms" published in Inverse Problems, error analysis and optimal learning rates for distributed learning with spectral algorithms were derived. In late 2016, we learned that similar analysis was carried out for classical (non-distributed) spectral algorithms implemented in one machine by G. Blanchard and N. Mücke in a paper entitled "Optimal rates for regularization of statistical inverse learning problems" (arXiv:1604.04054, April 2016), and by L. H. Dicker, D. P. Foster, and D. Hsu in a paper entitled "Kernel ridge vs. principal component regression: minimax bounds and adaptibility of regularization operators" (arXiv:1605.08839, May 2016). We are indebted to one of the referees for pointing this out to us.*

4. Second Order Decomposition of Operator Differences and Norms

Our error estimates are achieved by a novel second order decomposition of operator differences in our integral operator approach. We approximate the integral operator L_K by the empirical integral operator $L_{K,D(x)}$ on $\mathcal{H}_K$ defined with the input data set $D(x) = \{x_i\}_{i=1}^N = \{x : (x,y) \in D \text{ for some } y \in \mathcal{Y}\}$ as

$$L_{K,D(x)}(f) = \frac{1}{|D|}\sum_{x\in D(x)} f(x)K_x = \frac{1}{|D|}\sum_{x\in D(x)} \langle f, K_x\rangle_K K_x, \qquad f \in \mathcal{H}_K, \tag{19}$$

where the reproducing property $f(x) = \langle f, K_x\rangle_K$ for $f \in \mathcal{H}_K$ is used. Since K is a Mercer kernel, $L_{K,D_j(x)}$ is a finite-rank positive operator and $L_{K,D_j(x)} + \lambda I$ is invertible.

The operator difference in our study is that of the inverses of two operators defined by

$$Q_{D(x)} = \left(L_{K,D(x)} + \lambda I\right)^{-1} - \left(L_K + \lambda I\right)^{-1}. \tag{20}$$

If we denote $A = L_{K,D(x)} + \lambda I$ and $B = L_K + \lambda I$, then our second order decomposition for the operator difference $Q_{D(x)}$ is a special case of the following second order decomposition for the difference $A^{-1} - B^{-1}$.

Lemma 16 *Let A and B be invertible operators on a Banach space. Then we have*

$$A^{-1} - B^{-1} = B^{-1}\{B - A\}B^{-1} + B^{-1}\{B - A\}A^{-1}\{B - A\}B^{-1}. \tag{21}$$

Proof We can decompose the operator $A^{-1} - B^{-1}$ as

$$A^{-1} - B^{-1} = B^{-1}\{B - A\}A^{-1}. \tag{22}$$

This is the first order decomposition.

Write the last term A^{-1} as $B^{-1} + (A^{-1} - B^{-1})$ and apply another first order decomposition similar to (22) as

$$A^{-1} - B^{-1} = A^{-1}\{B - A\}B^{-1}.$$

It follows from (22) that

$$A^{-1} - B^{-1} = B^{-1}\{B - A\}\left\{B^{-1} + A^{-1}\{B - A\}B^{-1}\right\}.$$

Then the desired identity (21) is verified. The lemma is proved. ■

To demonstrate how the second order decomposition leads to tight error bounds for the classical least squares regularization scheme (1) with the output function $f_{D,\lambda}$, we recall the following formula (see e.g. (Caponnetto and De Vito, 2007; Smale and Zhou, 2007))

$$f_{D,\lambda} - f_\lambda = \left(L_{K,D(x)} + \lambda I\right)^{-1}\Delta_D, \quad \Delta_D := \frac{1}{|D|}\sum_{z\in D}\xi_\lambda(z) - E[\xi_\lambda], \tag{23}$$

where Δ_D is induced by the random variables ξ_λ with values in the Hilbert space $\mathcal{H}_K$ defined as

$$\xi_\lambda(z) = (y - f_\lambda(x))K_x, \qquad z = (x,y) \in \mathcal{Z}. \tag{24}$$

Then we can express $f_{D,\lambda} - f_\lambda$ by means of the notation $Q_{D(x)} = \left(L_{K,D(x)} + \lambda I\right)^{-1} - (L_K + \lambda I)^{-1}$ as

$$f_{D,\lambda} - f_\lambda = \left[Q_{D(x)}\right] \Delta_D + (L_K + \lambda I)^{-1} \Delta_D.$$

Due to the identity between the $L^2_{\rho_X}$ norm and the $\mathcal{H}_K$ metric

$$\|g\|_\rho = \|L_K^{\frac{1}{2}} g\|_K, \qquad \forall g \in L^2_{\rho_X}, \tag{25}$$

we can estimate the error $\|f_{D,\lambda} - f_\lambda\|_\rho = \|L_K^{\frac{1}{2}} (f_{D,\lambda} - f_\lambda)\|_K$ by bounding the $\mathcal{H}_K$ norm of the following expression obtained from the second order decomposition (21) with $B - A = L_K - L_{K,D(x)}$

$$\begin{aligned} L_K^{\frac{1}{2}} \left[Q_{D(x)}\right] \Delta_D &= \left\{L_K^{\frac{1}{2}} (L_K + \lambda I)^{-\frac{1}{2}}\right\} \left\{(L_K + \lambda I)^{-\frac{1}{2}} \left\{L_K - L_{K,D(x)}\right\}\right\} (L_K + \lambda I)^{-1} \Delta_D \\ &+ \left\{L_K^{\frac{1}{2}} (L_K + \lambda I)^{-\frac{1}{2}}\right\} \left\{(L_K + \lambda I)^{-\frac{1}{2}} \left\{L_K - L_{K,D(x)}\right\}\right\} \left(L_{K,D(x)} + \lambda I\right)^{-1} \\ &\quad \left\{\left\{L_K - L_{K,D(x)}\right\} (L_K + \lambda I)^{-\frac{1}{2}}\right\} \left\{(L_K + \lambda I)^{-\frac{1}{2}} \Delta_D\right\}. \end{aligned}$$

Combining this expression with the operator norm bound $\left\|L_K^{\frac{1}{2}} (L_K + \lambda I)^{-\frac{1}{2}}\right\| \leq 1$ and the notation

$$\Xi_D = \left\|(L_K + \lambda I)^{-\frac{1}{2}} \left\{L_K - L_{K,D(x)}\right\}\right\| \tag{26}$$

for convenience, we find

$$\begin{aligned} \left\|L_K^{\frac{1}{2}} \left[Q_{D(x)}\right] \Delta_D\right\|_K &\leq \Xi_D \left\|(L_K + \lambda I)^{-1} \Delta_D\right\|_K + \Xi_D \left\|\left(L_{K,D(x)} + \lambda I\right)^{-1}\right\| \\ &\quad \Xi_D \left\|(L_K + \lambda I)^{-\frac{1}{2}} \Delta_D\right\|_K. \end{aligned}$$

By decomposing $(L_K + \lambda I)^{-1} \Delta_D$ as $(L_K + \lambda I)^{-\frac{1}{2}} (L_K + \lambda I)^{-\frac{1}{2}} \Delta_D$ and using the bounds $\left\|\left(L_{K,D(x)} + \lambda I\right)^{-1}\right\| \leq \frac{1}{\lambda}$, $\left\|(L_K + \lambda I)^{-\frac{1}{2}}\right\| \leq 1/\sqrt{\lambda}$, we know that

$$\left\|L_K^{\frac{1}{2}} \left[Q_{D(x)}\right] \Delta_D\right\|_K \leq \left(\frac{\Xi_D}{\sqrt{\lambda}} + \frac{\Xi_D^2}{\lambda}\right) \left\|(L_K + \lambda I)^{-\frac{1}{2}} \Delta_D\right\|_K \tag{27}$$

and

$$\|f_{D,\lambda} - f_\lambda\|_\rho \leq \left(\frac{\Xi_D}{\sqrt{\lambda}} + \frac{\Xi_D^2}{\lambda} + 1\right) \left\|(L_K + \lambda I)^{-\frac{1}{2}} \Delta_D\right\|_K. \tag{28}$$

Thus the classical least squares regularization scheme (1) can be analyzed after estimating the operator norm $\Xi_D = \left\|(L_K + \lambda I)^{-\frac{1}{2}} \left\{L_K - L_{K,D(x)}\right\}\right\|$ and the function norm $\left\|(L_K + \lambda I)^{-\frac{1}{2}} \Delta_D\right\|_K$. In the following two lemmas, to be proved in the appendix, these norms are estimated in terms of effective dimensions by methods in the existing literature (Caponnetto and De Vito, 2007; Bauer et al., 2007; Blanchard and Krämer, 2010).

Lemma 17 *Let D be a sample drawn independently according to ρ. Then the following estimates for the operator norm $\left\|(L_K + \lambda I)^{-\frac{1}{2}} \left\{L_K - L_{K,D(x)}\right\}\right\|$ hold.*

(a) $E\left[\left\|(L_K + \lambda I)^{-\frac{1}{2}} \left\{L_K - L_{K,D(x)}\right\}\right\|^2\right] \leq \frac{\kappa^2 \mathcal{N}(\lambda)}{|D|}$.

(b) For any $0 < \delta < 1$, with confidence at least $1 - \delta$, there holds

$$\left\|(L_K + \lambda I)^{-\frac{1}{2}} \left\{L_K - L_{K,D(x)}\right\}\right\| \leq \mathcal{B}_{|D|,\lambda} \log(2/\delta), \tag{29}$$

where we denote the quantity

$$\mathcal{B}_{|D|,\lambda} = \frac{2\kappa}{\sqrt{|D|}} \left\{\frac{\kappa}{\sqrt{|D|\lambda}} + \sqrt{\mathcal{N}(\lambda)}\right\}. \tag{30}$$

(c) For any $d > 1$, there holds

$$\left\{E\left[\left\|(L_K + \lambda I)^{-\frac{1}{2}} \left\{L_K - L_{K,D(x)}\right\}\right\|^d\right]\right\}^{\frac{1}{d}} \leq (2d\Gamma(d) + 1)^{\frac{1}{d}} \mathcal{B}_{|D|,\lambda},$$

where Γ is the Gamma function defined for $d > 0$ by $\Gamma(d) = \int_0^\infty u^{d-1} \exp\{-u\}\, du$.

Lemma 18 *Let D be a sample drawn independently according to ρ and g be a measurable bounded function on $\mathcal{Z}$ and ξ_g be the random variable with values in $\mathcal{H}_K$ defined by $\xi_g(z) = g(z) K_x$ for $z = (x, y) \in \mathcal{Z}$. Then the following statements hold.*

(a) $E\left[\left\|(L_K + \lambda I)^{-1/2} (K_x)\right\|_K^2\right] = \mathcal{N}(\lambda)$.

(b) For almost every $x \in \mathcal{X}$, there holds $\left\|(L_K + \lambda I)^{-1/2} (K_x)\right\|_K \leq \frac{\kappa}{\sqrt{\lambda}}$.

(c) For any $0 < \delta < 1$, with confidence at least $1 - \delta$, there holds

$$\left\|(L_K + \lambda I)^{-1/2} \left(\frac{1}{|D|} \sum_{z \in D} \xi_g(z) - E\left[\xi_g\right]\right)\right\|_K \leq \frac{2\|g\|_\infty \log(2/\delta)}{\sqrt{|D|}} \left\{\frac{\kappa}{\sqrt{|D|\lambda}} + \sqrt{\mathcal{N}(\lambda)}\right\}.$$

Remark 19 *In the existing literature, the first order decomposition (22) was used. To bound the norm of $\left(L_{K,D(x)} + \lambda I\right)^{-1} \Delta_D$ by this approach, one needs to either use the brute force estimate $\left\|\left(L_{K,D(x)} + \lambda I\right)^{-1}\right\| \leq \frac{1}{\lambda}$ leading to suboptimal learning rates, or applying the approximation of L_K by $L_{K,D(x)}$ which is valid only with confidence and leads to confidence-based estimates with λ depending on the confidence level. In our second order decomposition, we decompose the inverse operator $\left(L_{K,D(x)} + \lambda I\right)^{-1}$ further after the first order decomposition (22). This leads to finer estimates with an additional factor $\|(B - A) B^{-\frac{1}{2}}\|$ in the second term of the bound (21) and gives the refined error bound (28).*

5. Deriving Error Bounds for Least Squares Regularization Scheme

In this section we prove our main result on error bounds for the least squares regularization scheme (1), which illustrates how to apply the second order decomposition (21) for operator differences in our integral operator approach.

Proposition 20 *Assume $E[y^2] < \infty$ and moment condition (11) for some $1 \le p \le \infty$. Then*

$$E\left[\|f_{D,\lambda} - f_\lambda\|_\rho\right] \le \left(2 + 56\kappa^4 + 57\kappa^2\right)\left(1 + \frac{1}{(|D|\lambda)^2} + \frac{\mathcal{N}(\lambda)}{|D|\lambda}\right) \left\{\kappa^{\frac{1}{p}}\sqrt{\left\|\sigma_\rho^2\right\|_p}\left(\frac{\mathcal{N}(\lambda)}{|D|}\right)^{\frac{1}{2}(1-\frac{1}{p})}\left(\frac{1}{|D|\lambda}\right)^{\frac{1}{2p}} + \kappa\frac{\|f_\lambda - f_\rho\|_\rho}{\sqrt{|D|\lambda}}\right\}.$$

Proof We apply the error bound (28) and the Schwarz inequality to get

$$E\left[\|f_{D,\lambda} - f_\lambda\|_\rho\right] \le \left\{E\left[\left(1 + \frac{\Xi_D}{\sqrt{\lambda}} + \frac{\Xi_D^2}{\lambda}\right)^2\right]\right\}^{1/2}\left\{E\left[\left\|(L_K + \lambda I)^{-1/2}\Delta_D\right\|_K^2\right]\right\}^{1/2}. \tag{31}$$

The first factor in the above bound involves $\Xi_D = \left\|(L_K + \lambda I)^{-\frac{1}{2}}\left\{L_K - L_{K,D(x)}\right\}\right\|$ and it can be estimated by applying Lemma 17 as

$$\begin{aligned}\left\{E\left[\left(1 + \frac{\Xi_D}{\sqrt{\lambda}} + \frac{\Xi_D^2}{\lambda}\right)^2\right]\right\}^{1/2} &\le 1 + \left\{E\left[\frac{\Xi_D^2}{\lambda}\right]\right\}^{1/2} + \left\{E\left[\frac{\Xi_D^4}{\lambda^2}\right]\right\}^{1/2} \\ &\le 1 + \left\{\frac{\kappa^2\mathcal{N}(\lambda)}{|D|\lambda}\right\}^{1/2} + \left\{\frac{49\mathcal{B}^4_{|D|,\lambda}}{\lambda^2}\right\}^{1/2} \\ &\le 2 + \frac{56\kappa^4}{(|D|\lambda)^2} + \frac{57\kappa^2\mathcal{N}(\lambda)}{|D|\lambda}. \end{aligned} \tag{32}$$

To deal with the factor in the bound (31), we separate $\Delta_D = \frac{1}{|D|}\sum_{z\in D}\xi_\lambda(z) - E[\xi_\lambda]$ as

$$\Delta_D = \Delta_D' + \Delta_D'',$$

where

$$\Delta_D' := \frac{1}{|D|}\sum_{z\in D}\xi_0(z), \quad \Delta_D'' := \frac{1}{|D|}\sum_{z\in D}\left(\xi_\lambda - \xi_0\right)(z) - E[\xi_\lambda]$$

are induced by another random variable ξ_0 with values in the Hilbert space $\mathcal{H}_K$ defined by

$$\xi_0(z) = (y - f_\rho(x))K_x, \qquad z = (x, y) \in \mathcal{Z}. \tag{33}$$

Then the second factor in (31) can be separated as

$$\begin{aligned}&\left\{E\left[\left\|(L_K + \lambda I)^{-1/2}\Delta_D\right\|_K^2\right]\right\}^{1/2} \\ &\le \left\{E\left[\left\|(L_K + \lambda I)^{-1/2}\Delta_D'\right\|_K^2\right]\right\}^{1/2} + \left\{E\left[\left\|(L_K + \lambda I)^{-1/2}\Delta_D''\right\|_K^2\right]\right\}^{1/2}. \end{aligned} \tag{34}$$

Let us bound the first term of (34). Observe that

$$(L_K + \lambda I)^{-1/2}\Delta_D' = \sum_{z\in D}\frac{1}{|D|}(y - f_\rho(x))\left(L_K + \lambda I\right)^{-1/2}(K_x).$$

Each term in this expression is unbiased because $\int_{\mathcal{Y}}(y - f_\rho(x))\,d\rho(y|x) = 0$. This unbiasedness and the independence tell us that

$$\begin{aligned}\left\{E\left[\left\|(L_K + \lambda I)^{-1/2}\Delta_D'\right\|_K^2\right]\right\}^{1/2} &= \left\{\frac{1}{|D|}E\left[\left\|(y - f_\rho(x))\left[(L_K + \lambda I)^{-1/2}\right](K_x)\right\|_K^2\right]\right\}^{1/2} \\ &= \left\{\frac{1}{|D|}E\left[\sigma_\rho^2(x)\left\|\left[(L_K + \lambda I)^{-1/2}\right](K_x)\right\|_K^2\right]\right\}^{1/2}. \end{aligned} \tag{35}$$

If $\sigma_\rho^2 \in L^\infty$, then $\sigma_\rho^2(x) \le \left\|\sigma_\rho^2\right\|_\infty$ and by Lemma 18 we have

$$\left\{E\left[\left\|(L_K + \lambda I)^{-1/2}\Delta_D'\right\|_K^2\right]\right\}^{1/2} \le \sqrt{\left\|\sigma_\rho^2\right\|_\infty}\sqrt{\mathcal{N}(\lambda)/|D|}.$$

If $\sigma_\rho^2 \in L^p_{\rho_X}$ with $1 \le p < \infty$, we take $q = \frac{p}{p-1}$ ($q = \infty$ for $p = 1$) satisfying $\frac{1}{p} + \frac{1}{q} = 1$ and apply the Hölder inequality $E[|\xi\eta|] \le (E[|\xi|^p])^{1/p}(E[|\eta|^q])^{1/q}$ to $\xi = \sigma_\rho^2$, $\eta = \left\|(L_K + \lambda I)^{-1/2}(K_x)\right\|_K^2$ to find

$$E\left[\sigma_\rho^2(x)\left\|\left[(L_K + \lambda I)^{-1/2}\right](K_x)\right\|_K^2\right] \le \left\|\sigma_\rho^2\right\|_p\left\{E\left[\left\|\left[(L_K + \lambda I)^{-1/2}\right](K_x)\right\|_K^{2q}\right]\right\}^{1/q}.$$

But

$$\left\|\left[(L_K + \lambda I)^{-1/2}\right](K_x)\right\|_K^{2q-2} \le \left(\kappa/\sqrt{\lambda}\right)^{2q-2}$$

and $E\left[\left\|(L_K + \lambda I)^{-1/2}(K_x)\right\|_K^2\right] = \mathcal{N}(\lambda)$ by Lemma 18. So we have

$$\begin{aligned}\left\{E\left[\left\|(L_K + \lambda I)^{-1/2}\Delta_D'\right\|_K^2\right]\right\}^{1/2} &\le \left\{\frac{1}{|D|}\left\|\sigma_\rho^2\right\|_p\left\{\frac{\kappa^{2q-2}}{\lambda^{q-1}}\mathcal{N}(\lambda)\right\}^{1/q}\right\}^{1/2} \\ &= \sqrt{\left\|\sigma_\rho^2\right\|_p}\kappa^{\frac{1}{p}}\left(\frac{\mathcal{N}(\lambda)}{|D|}\right)^{\frac{1}{2}(1-\frac{1}{p})}\left(\frac{1}{|D|\lambda}\right)^{\frac{1}{2p}}. \end{aligned}$$

Combining the above two cases, we know that for either $p = \infty$ or $p < \infty$, the first term of (34) can be bounded as

$$\left\{E\left[\left\|(L_K + \lambda I)^{-1/2}\Delta_D'\right\|_K^2\right]\right\}^{1/2} \le \sqrt{\left\|\sigma_\rho^2\right\|_p}\kappa^{\frac{1}{p}}\left(\frac{\mathcal{N}(\lambda)}{|D|}\right)^{\frac{1}{2}(1-\frac{1}{p})}\left(\frac{1}{|D|\lambda}\right)^{\frac{1}{2p}}.$$

The second term of (34) can be bounded easily as

$$\left\{E\left[\left\|(L_K+\lambda I)^{-1/2}\Delta''_D\right\|_K^2\right]\right\}^{1/2} \leq \frac{1}{\sqrt{|D|}}\left\{E\left[(f_\rho(x)-f_\lambda(x))^2\left\|(L_K+\lambda I)^{-1/2}(K_x)\right\|_K^2\right]\right\}^{1/2}$$
$$\leq \frac{1}{\sqrt{|D|}}\left\{E\left[(f_\rho(x)-f_\lambda(x))^2\frac{\kappa^2}{\lambda}\right]\right\}^{1/2}=\frac{\kappa\|f_\rho-f_\lambda\|_\rho}{\sqrt{|D|\lambda}}.$$

Putting the above estimates for the two terms of (34) into (31) and applying the bound (32) involving Ξ_D, we know that $E\left[\|f_{D,\lambda}-f_\lambda\|_\rho\right]$ is bounded by

$$\left(2+\frac{56\kappa^4}{(|D|\lambda)^2}+\frac{57\kappa^2\mathcal{N}(\lambda)}{|D|\lambda}\right)\left(\sqrt{\left\|\sigma_\rho^2\right\|_p}\kappa^{\frac{1}{p}}\left(\frac{\mathcal{N}(\lambda)}{|D|}\right)^{\frac{1}{2}(1-\frac{1}{p})}\left(\frac{1}{|D|\lambda}\right)^{\frac{1}{2p}}+\frac{\kappa\|f_\rho-f_\lambda\|_\rho}{\sqrt{|D|\lambda}}\right).$$

Then our desired error bound follows. The proof of the proposition is complete. ■

Proof of Theorem 7 Combining Proposition 20 with the triangle inequality $\|f_{D,\lambda}-f_\rho\|_\rho \leq \|f_{D,\lambda}-f_\lambda\|_\rho+\|f_\lambda-f_\rho\|_\rho$, we know that

$$E\left[\|f_{D,\lambda}-f_\rho\|_\rho\right] \leq \|f_\lambda-f_\rho\|_\rho+\left(2+56\kappa^4+57\kappa^2\right)\left(1+\frac{1}{(|D|\lambda)^2}+\frac{\mathcal{N}(\lambda)}{|D|\lambda}\right)$$
$$\left\{\kappa^{\frac{1}{p}}\sqrt{\left\|\sigma_\rho^2\right\|_p}\left(\frac{\mathcal{N}(\lambda)}{|D|}\right)^{\frac{1}{2}(1-\frac{1}{p})}\left(\frac{1}{|D|\lambda}\right)^{\frac{1}{2p}}+\frac{\kappa}{\sqrt{|D|\lambda}}\|f_\lambda-f_\rho\|_\rho\right\}.$$

Then the desired error bound holds true, and the proof of Theorem 7 is complete. ■

Proof of Corollary 8 By the definition of effective dimension,

$$\mathcal{N}(\lambda)=\sum_\ell\frac{\lambda_\ell}{\lambda_\ell+\lambda}\geq\frac{\lambda_1}{\lambda_1+\lambda}.$$

Combining this with the restriction (8) with $m=1$, we find $\mathcal{N}(\lambda)\geq\frac{\lambda_1}{\lambda_1+C_0}$ and $N\lambda\geq\frac{\lambda_1}{(\lambda_1+C_0)C_0}$. Putting these and the restriction (8) with $m=1$ into the error bound (12), we know that

$$E\left[\|f_{D,\lambda}-f_\rho\|_\rho\right]\leq\left(2+56\kappa^4+57\kappa^2\right)(1+\kappa)\left(1+\frac{(\lambda_1+C_0)^2C_0^2}{\lambda_1^2}+C_0\right)$$
$$\left\{\left(1+\sqrt{(\lambda_1+C_0)C_0/\lambda_1}\right)\|f_\lambda-f_\rho\|_\rho+\sqrt{\left\|\sigma_\rho^2\right\|_p}\left(\frac{\mathcal{N}(\lambda)}{N}\right)^{\frac{1}{2}(1-\frac{1}{p})}\left(\frac{1}{N\lambda}\right)^{\frac{1}{2p}}\right\}.$$

Then the desired bound follows. The proof of Corollary 8 is complete. ■

To prove Corollary 9, we need the following bounds (Smale and Zhou, 2007) for $\|f_\lambda-f_\rho\|_\rho$ and $\|f_\lambda-f_\rho\|_K$.

Lemma 21 *Assume regularity condition (9) with $0<r\leq 1$. There holds*

$$\|f_\lambda-f_\rho\|_\rho\leq\lambda^r\|g_\rho\|_\rho. \tag{36}$$

Furthermore, if $1/2\leq r\leq 1$, then we have

$$\|f_\lambda-f_\rho\|_K\leq\lambda^{r-1/2}\|g_\rho\|_\rho. \tag{37}$$

Proof of Corollary 9 By Lemma 21, regularity condition (9) with $0<r\leq 1$ implies

$$\|f_\lambda-f_\rho\|_\rho\leq\lambda^r\|g_\rho\|_\rho.$$

If

$$\mathcal{N}(\lambda)\leq C_0\lambda^{-\frac{1}{2\alpha}},\qquad\forall\lambda>0$$

for some constant $C_0\geq 1$, then the choice $\lambda=N^{-\frac{2\alpha}{2\alpha\max\{2r,1\}+1}}$ yields

$$\frac{\mathcal{N}(\lambda)}{N\lambda}\leq\frac{C_0\lambda^{-\frac{1}{2\alpha}-1}}{N}=C_0N^{\frac{2\alpha+1}{2\alpha\max\{2r,1\}+1}-1}\leq C_0.$$

So (8) with $m=1$ is satisfied. With this choice we also have

$$\left(\frac{\mathcal{N}(\lambda)}{N}\right)^{\frac{1}{2}(1-\frac{1}{p})}\left(\frac{1}{N\lambda}\right)^{\frac{1}{2p}} \leq C_0^{\frac{1}{2}(1-\frac{1}{p})}N^{-\frac{2\alpha\max\{2r,1\}}{2\alpha\max\{2r,1\}+1}\frac{1}{2}(1-\frac{1}{p})}N^{-\frac{2\alpha\max\{2r,1\}+1-2\alpha}{2\alpha\max\{2r,1\}+1}\frac{1}{2p}}$$
$$=C_0^{\frac{1}{2}(1-\frac{1}{p})}N^{-\frac{\alpha\max\{2r,1\}}{2\alpha\max\{2r,1\}+1}+\frac{1}{2p}\frac{2\alpha-1}{2\alpha\max\{2r,1\}+1}}.$$

Putting these estimates into Corollary 8, we know that

$$E\left[\|f_{D,\lambda}-f_\rho\|_\rho\right] = O\left(N^{-\frac{2\alpha r}{2\alpha\max\{2r,1\}+1}}+N^{-\frac{\alpha\max\{2r,1\}}{2\alpha\max\{2r,1\}+1}+\frac{1}{2p}\frac{2\alpha-1}{2\alpha\max\{2r,1\}+1}}\right)$$
$$=O\left(N^{-\frac{\alpha\min\{2r,\max\{2r,1\}\}}{2\alpha\max\{2r,1\}+1}+\frac{1}{2p}\frac{2\alpha-1}{2\alpha\max\{2r,1\}+1}}\right).$$

But we find

$$\min\{2r,\max\{2r,1\}\}=2r$$

by discussing the two different cases $0<r<\frac{1}{2}$ and $\frac{1}{2}\leq r\leq 1$. Then our conclusion follows immediately. The proof of Corollary 9 is complete. ■

6. Proof of Error Bounds for the Distributed Learning Algorithm

To analyze the error $\overline{f}_{D,\lambda}-f_{D,\lambda}$ for distributed learning, we recall the notation $Q_{D(x)}=\left(L_{K,D(x)}+\lambda I\right)^{-1}-(L_K+\lambda I)^{-1}$ for the difference of inverse operators and use the notation $Q_{D_j(x)}$ involving the data subset D_j. The empirical integral operator $L_{K,D_j(x)}$ is defined with D replaced by the data subset D_j. For our error analysis for the distributed learning algorithm (2), we need the following error decomposition for $\overline{f}_{D,\lambda}-f_{D,\lambda}$.

Lemma 22 *Assume $E[y^2] < \infty$. For $\lambda > 0$, we have*

$$\begin{aligned}\overline{f}_{D,\lambda} - f_{D,\lambda} &= \sum_{j=1}^{m} \frac{|D_j|}{|D|} \left[\left(L_{K,D_j(x)} + \lambda I \right)^{-1} - \left(L_{K,D(x)} + \lambda I \right)^{-1} \right] \Delta_j \\ &= \sum_{j=1}^{m} \frac{|D_j|}{|D|} \left[Q_{D_j(x)} \right] \Delta_j' + \sum_{j=1}^{m} \frac{|D_j|}{|D|} \left[Q_{D_j(x)} \right] \Delta_j'' - \left[Q_{D(x)} \right] \Delta_D, \quad (38)\end{aligned}$$

where

$$\Delta_j := \frac{1}{|D_j|} \sum_{z \in D_j} \xi_\lambda(z) - E[\xi_\lambda], \quad \Delta_D := \frac{1}{|D|} \sum_{z \in D} \xi_\lambda(z) - E[\xi_\lambda],$$

and

$$\Delta_j' := \frac{1}{|D_j|} \sum_{z \in D_j} \xi_0(z), \quad \Delta_j'' := \frac{1}{|D_j|} \sum_{z \in D_j} \left(\xi_\lambda - \xi_0 \right)(z) - E[\xi_\lambda].$$

Proof Recall the expression (23) for $f_{D,\lambda} - f_\lambda$. When the data subset D_j is used, we have

$$f_{D_j,\lambda} - f_\lambda = \left(L_{K,D_j(x)} + \lambda I \right)^{-1} \Delta_j.$$

So we know that

$$\overline{f}_{D,\lambda} - f_\lambda = \sum_{j=1}^{m} \frac{|D_j|}{|D|} \left\{ f_{D_j,\lambda} - f_\lambda \right\} = \sum_{j=1}^{m} \frac{|D_j|}{|D|} \left(L_{K,D_j(x)} + \lambda I \right)^{-1} \Delta_j.$$

We can decompose Δ_D as

$$\Delta_D = \frac{1}{|D|} \sum_{z \in D} \xi_\lambda(z) - E[\xi_\lambda] = \sum_{j=1}^{m} \frac{|D_j|}{|D|} \left\{ \frac{1}{|D_j|} \sum_{z \in D_j} \xi_\lambda(z) - E[\xi_\lambda] \right\} = \sum_{j=1}^{m} \frac{|D_j|}{|D|} \Delta_j$$

in the expression (23) for $f_{D,\lambda} - f_\lambda$ and find

$$f_{D,\lambda} - f_\lambda = \sum_{j=1}^{m} \frac{|D_j|}{|D|} \left(L_{K,D(x)} + \lambda I \right)^{-1} \Delta_j.$$

Then the first desired expression for $\overline{f}_{D,\lambda} - f_{D,\lambda}$ follows.

By adding and subtracting the operator $(L_K + \lambda I)^{-1}$, writing $\Delta_j = \Delta_j' + \Delta_j''$, and noting $E[\xi_0] = 0$, we know that the first expression implies (38). This proves Lemma 22. ∎

Before proving our first main result on the error $\overline{f}_{D,\lambda} - f_{D,\lambda}$ in the $\mathcal{H}_K$ metric and L_ρ^2 metric, we state the following more general result which allows different sizes for data subsets $\{D_j\}$.

Theorem 23 *Assume that for some constant $M > 0$, $|y| \le M$ almost surely. Then we have*

$$E\left[\left\| \overline{f}_{D,\lambda} - f_{D,\lambda} \right\|_\rho \right] \le C_\kappa' M \sqrt{\lambda} \left\{ \sum_{j=1}^{m} \left(\frac{|D_j|}{|D|} \right)^2 \left(\mathcal{S}_{|D_j|,\lambda}^2 + \mathcal{S}_{|D_j|,\lambda}^3 \right) \right\}^{\frac{1}{2}} + C_\kappa' \sum_{j=1}^{m} \frac{|D_j|}{|D|}$$
$$\frac{\|f_\rho - f_\lambda\|_\rho}{\sqrt{|D_j|\lambda}} \left(\sqrt{\frac{\mathcal{N}(\lambda)}{|D_j|\lambda}} + \mathcal{S}_{|D_j|,\lambda} \right) + C_\kappa' \left(\sqrt{\frac{\mathcal{N}(\lambda)}{|D|\lambda}} + \mathcal{S}_{|D|,\lambda} \right) \left(M \sqrt{\frac{\mathcal{N}(\lambda)}{|D|}} + \frac{\|f_\rho - f_\lambda\|_\rho}{\sqrt{|D|\lambda}} \right)$$

and

$$E\left[\left\| \overline{f}_{D,\lambda} - f_{D,\lambda} \right\|_K \right] \le C_\kappa' M \left\{ \sum_{j=1}^{m} \left(\frac{|D_j|}{|D|} \right)^2 \left(\mathcal{S}_{|D_j|,\lambda}^2 + \mathcal{S}_{|D_j|,\lambda}^3 \right) \right\}^{\frac{1}{2}} + C_\kappa' \sum_{j=1}^{m} \frac{|D_j|}{|D|}$$
$$\frac{\|f_\rho - f_\lambda\|_\rho}{\sqrt{|D_j|\lambda}} \left(\sqrt{\frac{\mathcal{N}(\lambda)}{|D_j|\lambda}} + \mathcal{S}_{|D_j|,\lambda} \right) + C_\kappa' \left(\sqrt{\frac{\mathcal{N}(\lambda)}{|D|\lambda}} + \mathcal{S}_{|D|,\lambda} \right) \left(M \sqrt{\frac{\mathcal{N}(\lambda)}{|D|\lambda}} + \frac{\|f_\rho - f_\lambda\|_\rho}{\sqrt{|D|\lambda}} \right),$$

where C_κ' is a constant depending only on κ, and $\mathcal{S}_{|D_j|,\lambda}$ is the quantity given by

$$\mathcal{S}_{|D_j|,\lambda} = \frac{1}{|D_j|^2 \lambda^2} + \frac{\mathcal{N}(\lambda)}{|D_j|\lambda}.$$

Proof Recall the expression (38) for $\overline{f}_{D,\lambda} - f_{D,\lambda}$ in Lemma 22. It enables us to express

$$L_K^{1/2} \left\{ \overline{f}_{D,\lambda} - f_{D,\lambda} \right\} = J_1 + J_2 + J_3, \quad (39)$$

where the terms J_1, J_2, J_3 are given by

$$J_1 = \sum_{j=1}^{m} \frac{|D_j|}{|D|} \left[L_K^{1/2} Q_{D_j(x)} \right] \Delta_j', \; J_2 = \sum_{j=1}^{m} \frac{|D_j|}{|D|} \left[L_K^{1/2} Q_{D_j(x)} \right] \Delta_j'', \; J_3 = - \left[L_K^{1/2} Q_{D(x)} \right] \Delta_D.$$

These three terms will be dealt with separately in the following.

For the first term J_1 of (39), each summand with $j \in \{1, \ldots, m\}$ can be expressed as $\sum_{z \in D_j} \frac{1}{|D|} (y - f_\rho(x)) \left[L_K^{1/2} Q_{D_j(x)} \right] (K_x)$, and is unbiased because $\int_{\mathcal{Y}} y - f_\rho(x) d\rho(y|x) = 0$. The unbiasedness and the independence tell us that

$$E\left[\|J_1\|_K \right] \le \left\{ E\left[\|J_1\|_K^2 \right] \right\}^{1/2} \le \left\{ \sum_{j=1}^{m} \left(\frac{|D_j|}{|D|} \right)^2 E\left[\left\| \left[L_K^{1/2} Q_{D_j(x)} \right] \Delta_j' \right\|_K^2 \right] \right\}^{1/2}. \quad (40)$$

Let $j \in \{1, \ldots, m\}$. The estimate (27) derived from the second order decomposition (21) yields

$$\left\| \left[L_K^{1/2} Q_{D_j(x)} \right] \Delta_j' \right\|_K^2 \le \left(\frac{\Xi_{D_j}}{\sqrt{\lambda}} + \frac{\Xi_{D_j}^2}{\lambda} \right)^2 \left\| (L_K + \lambda I)^{-1/2} \Delta_j' \right\|_K^2. \quad (41)$$

Now we apply the formula

$$E[\xi] = \int_0^\infty \text{Prob}\,[\xi > t]\,dt \tag{42}$$

to estimate the expected value of (41). By Part (b) of Lemma 17, for $0 < \delta < 1$, there exists a subset $\mathcal{Z}_{\delta,1}^{|D_j|}$ of $\mathcal{Z}^{|D_j|}$ of measure at least $1-\delta$ such that

$$\Xi_{D_j} \le \mathcal{B}_{|D_j|,\lambda} \log(2/\delta), \qquad \forall D_j \in \mathcal{Z}_{\delta,1}^{|D_j|}. \tag{43}$$

Applying Part (c) of Lemma 18 to $g(z) = y - f_\rho(x)$ with $\|g\|_\infty \le 2M$ and the data subset D_j, we know that there exists another subset $\mathcal{Z}_{\delta,2}^{|D_j|}$ of $\mathcal{Z}^{|D_j|}$ of measure at least $1-\delta$ such that

$$\left\|(L_K+\lambda I)^{-1/2}\,\Delta_j'\right\|_K \le \frac{2M}{\kappa}\mathcal{B}_{|D_j|,\lambda}\log(2/\delta), \qquad \forall D_j \in \mathcal{Z}_{\delta,2}^{|D_j|}.$$

Combining this with (43) and (41), we know that for $D_j \in \mathcal{Z}_{\delta,1}^{|D_j|} \cap \mathcal{Z}_{\delta,2}^{|D_j|}$,

$$\left\|\left[L_K^{1/2}Q_{D_j(x)}\right]\Delta_j'\right\|_K^2 \le \left(\frac{\mathcal{B}_{|D_j|,\lambda}^2}{\lambda} + \frac{\mathcal{B}_{|D_j|,\lambda}^4}{\lambda^2}\right)\left(\frac{M}{\kappa}\right)^2 \mathcal{B}_{|D_j|,\lambda}^2 \left(2\log(2/\delta)\right)^6.$$

Since the measure of the set $\mathcal{Z}_{\delta,1}^{|D_j|} \cap \mathcal{Z}_{\delta,2}^{|D_j|}$ is at least $1-2\delta$, by denoting

$$\mathcal{C}_{|D_j|,\lambda} = 64\left(\frac{\mathcal{B}_{|D_j|,\lambda}^2}{\lambda} + \frac{\mathcal{B}_{|D_j|,\lambda}^4}{\lambda^2}\right)\left(\frac{M}{\kappa}\right)^2 \mathcal{B}_{|D_j|,\lambda}^2,$$

we see that

$$\text{Prob}\left[\left\|\left[L_K^{1/2}Q_{D_j(x)}\right]\Delta_j'\right\|_K^2 > \mathcal{C}_{|D_j|,\lambda}\left(\log(2/\delta)\right)^6\right] \le 2\delta.$$

For $0 < t < \infty$, the equation $\mathcal{C}_{|D_j|,\lambda}\left(\log(2/\delta)\right)^6 = t$ has the solution

$$\delta_t = 2\exp\left\{-\left(t/\mathcal{C}_{|D_j|,\lambda}\right)^{1/6}\right\}.$$

When $\delta_t < 1$, we have

$$\text{Prob}\left[\left\|\left[L_K^{1/2}Q_{D_j(x)}\right]\Delta_j'\right\|_K^2 > t\right] \le 2\delta_t = 4\exp\left\{-\left(t/\mathcal{C}_{|D_j|,\lambda}\right)^{1/6}\right\}.$$

This inequality holds trivially when $\delta_t \ge 1$ since the probability is at most 1. Thus we can apply the formula (42) to the nonnegative random variable $\xi = \left\|\left[L_K^{1/2}Q_{D_j(x)}\right]\Delta_j'\right\|_K^2$ and obtain

$$E\left[\left\|\left[L_K^{1/2}Q_{D_j(x)}\right]\Delta_j'\right\|_K^2\right] = \int_0^\infty \text{Prob}\,[\xi > t]\,dt \le \int_0^\infty 4\exp\left\{-\left(t/\mathcal{C}_{|D_j|,\lambda}\right)^{1/6}\right\}dt$$

which equals $24\Gamma(6)\mathcal{C}_{|D_j|,\lambda}$. Therefore,

$$E\left[\|J_1\|_K\right] \le \left\{\sum_{j=1}^m \left(\frac{|D_j|}{|D|}\right)^2 24\Gamma(6)\mathcal{C}_{|D_j|,\lambda}\right\}^{1/2}$$
$$\le 1536\sqrt{5}\kappa M\left\{\sum_{j=1}^m \left(\frac{|D_j|}{|D|}\right)^2 \lambda\left(\frac{\kappa^2}{|D_j|^2\lambda^2} + \frac{\mathcal{N}(\lambda)}{|D_j|\lambda}\right)^2\left\{1 + 8\kappa^2\left(\frac{\kappa^2}{|D_j|^2\lambda^2} + \frac{\mathcal{N}(\lambda)}{|D_j|\lambda}\right)\right\}\right\}^{1/2}.$$

For the second term J_2 of (39), we apply (27) again and obtain

$$\left\|\left[L_K^{1/2}Q_{D_j(x)}\right]\Delta_j''\right\|_K \le \left(\frac{\Xi_{D_j}}{\sqrt{\lambda}} + \frac{\Xi_{D_j}^2}{\lambda}\right)\left\|(L_K+\lambda I)^{-1/2}\,\Delta_j''\right\|_K.$$

Applying the Schwarz inequality and Lemmas 17 and 18, we get

$$\begin{aligned}
E\left[\left\|\left[L_K^{1/2}Q_{D_j(x)}\right]\Delta_j''\right\|_K\right] &\le \left\{E\left[\left(\frac{\Xi_{D_j}}{\sqrt{\lambda}} + \frac{\Xi_{D_j}^2}{\lambda}\right)^2\right]\right\}^{1/2} \\
&\quad \frac{1}{\sqrt{|D_j|}}\left\{E\left[(f_\rho(x) - f_\lambda(x))^2\left\|(L_K+\lambda I)^{-1/2}(K_x)\right\|_K^2\right]\right\}^{1/2} \\
&\le \left(\left\{\frac{\kappa^2\mathcal{N}(\lambda)}{|D_j|\lambda}\right\}^{1/2} + \left\{\frac{49\mathcal{B}_{|D_j|,\lambda}^4}{\lambda^2}\right\}^{1/2}\right)\frac{\kappa\|f_\rho - f_\lambda\|_\rho}{\sqrt{|D_j|\lambda}} \\
&\le \left(\kappa\sqrt{\frac{\mathcal{N}(\lambda)}{|D_j|\lambda}} + 56\kappa^2\left(\frac{\kappa^2}{(|D_j|\lambda)^2} + \frac{\mathcal{N}(\lambda)}{|D_j|\lambda}\right)\right)\frac{\kappa\|f_\rho - f_\lambda\|_\rho}{\sqrt{|D_j|\lambda}}.
\end{aligned}$$

It follows that

$$E\left[\|J_2\|_K\right] \le \sum_{j=1}^m \frac{|D_j|}{|D|}\frac{\kappa\|f_\rho - f_\lambda\|_\rho}{\sqrt{|D_j|\lambda}}\left(\kappa\sqrt{\frac{\mathcal{N}(\lambda)}{|D_j|\lambda}} + 56\kappa^2\left(\frac{\kappa^2}{(|D_j|\lambda)^2} + \frac{\mathcal{N}(\lambda)}{|D_j|\lambda}\right)\right).$$

The last term J_3 of (39) has been handled by (27) and in the proof of Proposition 20 by ignoring the summand 1 in the bound (31), and we find from the trivial bound $\left\|\sigma_\rho^2\right\|_\infty \le 4M^2$ with $p = \infty$ that

$$E\left[\|J_3\|_K\right] \le \left(\kappa\sqrt{\frac{\mathcal{N}(\lambda)}{|D|\lambda}} + 56\kappa^2\left(\frac{\kappa^2}{(|D|\lambda)^2} + \frac{\mathcal{N}(\lambda)}{|D|\lambda}\right)\right)\left(2M\left(\frac{\mathcal{N}(\lambda)}{|D|}\right)^{\frac{1}{2}} + \frac{\kappa\|f_\rho - f_\lambda\|_\rho}{\sqrt{|D|\lambda}}\right).$$

Combining the above estimates for the three terms of (39), we see that the desired error bound in the $L^2_{\rho_X}$ metric holds true.

The estimate in the $\mathcal{H}_K$ metric follows from the steps in deriving the error bound in the $L^2_{\rho_X}$ metric except that in the representation (39) the operator $L_K^{1/2}$ in the front disappears. This change gives an additional factor $1/\sqrt{\lambda}$, the bound for the operator $(L_K+\lambda I)^{-1/2}$, and proves the desired error bound in the $\mathcal{H}_K$ metric. ■

Remark 24 *A crucial step in the above error analysis for the distributed learning algorithm is to use the unbiasedness and independence to get (40) where the norm is squared in the expected value. Thus we can obtain the optimal learning rates in expectation for the distributed learning algorithm (2) but have difficulty in getting rates in probability. It would be interesting to derive error bounds in probability by combining our second order decomposition technique with some analysis in the literature (Caponnetto and De Vito, 2007; Blanchard and Krämer, 2010; Steinwart and Christmann, 2008; Wu and Zhou, 2008).*

Proof of Theorem 1 Since $|D_j| = \frac{N}{m}$ for $j = 1, \ldots, m$, the bound in Theorem 23 in the $L^2_{\rho_X}$ metric can be simplified as

$$\begin{aligned}
E\left[\left\|\overline{f}_{D,\lambda} - f_{D,\lambda}\right\|_\rho\right] &\le C'_\kappa M\sqrt{\lambda}\sqrt{m}\left(\frac{m}{(N\lambda)^2} + \frac{\mathcal{N}(\lambda)}{N\lambda}\right)\left\{1 + \sqrt{m}\left(\frac{m}{(N\lambda)^2} + \frac{\mathcal{N}(\lambda)}{N\lambda}\right)^{\frac{1}{2}}\right\} \\
&\quad + C'_\kappa \frac{\|f_\rho - f_\lambda\|_\rho}{\sqrt{N\lambda}} m\left(\sqrt{\frac{\mathcal{N}(\lambda)}{N\lambda}} + \frac{m\sqrt{m}}{(N\lambda)^2} + \frac{\sqrt{m}\mathcal{N}(\lambda)}{N\lambda}\right) \\
&\quad + C'_\kappa\left(\frac{\|f_\rho - f_\lambda\|_\rho}{\sqrt{N\lambda}} + M\sqrt{\frac{\mathcal{N}(\lambda)}{N}}\right)\left(\sqrt{\frac{\mathcal{N}(\lambda)}{N\lambda}} + \frac{1}{(N\lambda)^2} + \frac{\mathcal{N}(\lambda)}{N\lambda}\right) \\
&\le C'_\kappa M(\sqrt{m}+1)\sqrt{\lambda}\left(\frac{m}{(N\lambda)^2} + \frac{\mathcal{N}(\lambda)}{N\lambda}\right)\left\{1 + \sqrt{m}\left(\frac{m}{(N\lambda)^2} + \frac{\mathcal{N}(\lambda)}{N\lambda}\right)^{\frac{1}{2}}\right\} \\
&\quad + C'_\kappa \frac{\|f_\rho - f_\lambda\|_\rho}{\sqrt{N\lambda}}(m+1)\left(\sqrt{\frac{\mathcal{N}(\lambda)}{N\lambda}} + \frac{m\sqrt{m}}{(N\lambda)^2} + \frac{\sqrt{m}\mathcal{N}(\lambda)}{N\lambda}\right) \\
&\le 2C'_\kappa M\sqrt{\lambda}\mathcal{C}_m\left\{\sqrt{m} + m\sqrt{\mathcal{C}_m}\right\} + 2C'_\kappa\frac{\|f_\rho - f_\lambda\|_\rho}{\sqrt{N\lambda}} m\left(\sqrt{\frac{\mathcal{N}(\lambda)}{N\lambda}} + \sqrt{m}\mathcal{C}_m\right).
\end{aligned}$$

Then the desired error bound in the $L^2_{\rho_X}$ metric with $C_\kappa = 2C'_\kappa$ follows. The proof for the error bound in the $\mathcal{H}_K$ metric is similar. The proof of Theorem 1 is complete. ■

Proof of Corollary 3 As in the proof of Corollary 8, the restriction (8) implies $\mathcal{N}(\lambda) \ge \frac{\lambda_1}{\lambda_1 + C_0}$ and $N\lambda \ge \frac{m\lambda_1}{(\lambda_1 + C_0)C_0}$. It follows that

$$\frac{m}{(N\lambda)^2} \le \frac{(\lambda_1 + C_0)C_0}{\lambda_1}\frac{1}{N\lambda} \le \frac{(\lambda_1 + C_0)^2 C_0}{\lambda_1^2}\frac{\mathcal{N}(\lambda)}{N\lambda}$$

and with $\widetilde{C}'_\kappa := \frac{(\lambda_1 + C_0)^2 C_0}{\lambda_1^2} + 1$,

$$\mathcal{C}_m \le \widetilde{C}'_\kappa \frac{\mathcal{N}(\lambda)}{N\lambda}.$$

Putting these bounds into Theorem 1 and applying the restriction $\frac{m\mathcal{N}(\lambda)}{N\lambda} \le C_0$, we know that

$$\begin{aligned}
E\left\|\overline{f}_{D,\lambda} - f_{D,\lambda}\right\|_\rho &\le C_\kappa\left(\widetilde{C}'_\kappa\right)^{\frac{3}{2}}\sqrt{\frac{\mathcal{N}(\lambda)}{N\lambda}}\left(1 + \sqrt{\frac{m\mathcal{N}(\lambda)}{N\lambda}}\right)\left\{M\sqrt{\frac{m\mathcal{N}(\lambda)}{N}} + \frac{m\|f_\rho - f_\lambda\|_\rho}{\sqrt{N\lambda}}\right\} \\
&\le C_\kappa\left(\widetilde{C}'_\kappa\right)^{\frac{3}{2}}\left(1 + \sqrt{C_0}\right)\sqrt{\frac{\mathcal{N}(\lambda)}{N\lambda}}\left\{M\sqrt{C_0}\sqrt{\lambda} + \frac{m\|f_\rho - f_\lambda\|_\rho}{\sqrt{N\lambda}}\right\}
\end{aligned}$$

and

$$E\left\|\overline{f}_{D,\lambda} - f_{D,\lambda}\right\|_K \le C_\kappa\left(\widetilde{C}'_\kappa\right)^{\frac{3}{2}}\left(1 + \sqrt{C_0}\right)\sqrt{\frac{\mathcal{N}(\lambda)}{N\lambda}}\left\{M\sqrt{C_0} + \frac{m\|f_\rho - f_\lambda\|_\rho}{\sqrt{N\lambda}}\right\}.$$

Then the desired error bounds hold by taking the constant $\widetilde{C}_\kappa = C_\kappa\left(\widetilde{C}'_\kappa\right)^{\frac{3}{2}}\left(1 + \sqrt{C_0}\right)^2$. This proves Corollary 3. ■

Proof of Corollary 4 If

$$\mathcal{N}(\lambda) \le C_0\lambda^{-\frac{1}{2\alpha}}, \qquad \forall \lambda > 0$$

for some constant $C_0 \ge 1$, then the choice $\lambda = \left(\frac{m}{N}\right)^{\frac{2\alpha}{2\alpha\max\{2r,1\}+1}}$ satisfies (8). With this choice we also have

$$\frac{m\mathcal{N}(\lambda)}{N\lambda} \le C_0\left(\frac{m}{N}\right)^{\frac{2\alpha(\max\{2r,1\}-1)}{2\alpha\max\{2r,1\}+1}}.$$

Since regularity condition (9) yields $\|f_\lambda - f_\rho\|_\rho \le \|g_\rho\|_\rho\lambda^r$ by Lemma 21, we have by Corollary 3,

$$\begin{aligned}
E\left\|\overline{f}_{D,\lambda} - f_{D,\lambda}\right\|_\rho &\le \widetilde{C}_\kappa\sqrt{C_0}\frac{1}{\sqrt{m}}\left(\frac{m}{N}\right)^{\frac{\alpha(\max\{2r,1\}-1)}{2\alpha\max\{2r,1\}+1}}\left(\|g_\rho\|_\rho\left(\frac{m}{N}\right)^{\frac{2\alpha}{2\alpha\max\{2r,1\}+1}(r-\frac{1}{2})}\frac{m}{\sqrt{N}}\right. \\
&\quad \left. + M\left(\frac{m}{N}\right)^{\frac{\alpha}{2\alpha\max\{2r,1\}+1}}\right).
\end{aligned}$$

The inequality $\left(\frac{m}{N}\right)^{\frac{2\alpha}{2\alpha\max\{2r,1\}+1}(r-\frac{1}{2})}\frac{m}{\sqrt{N}} \le \left(\frac{m}{N}\right)^{\frac{\alpha}{2\alpha\max\{2r,1\}+1}}$ is equivalent to

$$m^{1+\frac{2\alpha}{2\alpha\max\{2r,1\}+1}(r-1)} \le N^{\frac{1}{2}+\frac{2\alpha}{2\alpha\max\{2r,1\}+1}(r-1)}$$

and it can be expressed as (10). Since (10) is valid, we have

$$E\left\|\overline{f}_{D,\lambda} - f_{D,\lambda}\right\|_\rho \le \widetilde{C}_\kappa\sqrt{C_0}\left(\|g_\rho\|_\rho + M\right)\frac{1}{\sqrt{m}}\left(\frac{m}{N}\right)^{\frac{\alpha\max\{2r,1\}}{2\alpha\max\{2r,1\}+1}}.$$

This proves the first desired convergence rate. The second rate follows easily. This proves Corollary 4. ■

Proof of Corollary 11 By Corollary 9, with the choice $\lambda = N^{-\frac{2\alpha}{4\alpha r+1}}$, we can immediately bound $\|f_{D,\lambda} - f_\rho\|_\rho$ as

$$E\left[\|f_{D,\lambda} - f_\rho\|_\rho\right] = O\left(N^{-\frac{2\alpha r}{4\alpha r+1}}\right).$$

The assumption $\mathcal{N}(\lambda) = O(\lambda^{-\frac{1}{2\alpha}})$ tells us that for some constant $C_0 \ge 1$,

$$\mathcal{N}(\lambda) \le C_0\lambda^{-\frac{1}{2\alpha}}, \qquad \forall \lambda > 0.$$

So the choice $\lambda = N^{-\frac{2\alpha}{4\alpha r+1}}$ yields

$$\frac{m\mathcal{N}(\lambda)}{N\lambda} \le C_0\frac{m\lambda^{-\frac{1+2\alpha}{2\alpha}}}{N} = C_0 m N^{\frac{1+2\alpha}{4\alpha r+1}-1} = C_0 m N^{\frac{2\alpha(1-2r)}{4\alpha r+1}}. \tag{44}$$

If m satisfies (13), then (8) is valid, and by Corollary 3,

$$\begin{aligned} E\left\|\overline{f}_{D,\lambda}-f_{D,\lambda}\right\|_\rho &\le \widetilde{C}_\kappa\sqrt{C_0}N^{\frac{\alpha(1-2r)}{4\alpha r+1}}\left(\lambda^r\|g_\lambda\|_\rho\frac{m}{\sqrt{N\lambda}}+M\sqrt{\lambda}\right)\\ &\le \widetilde{C}_\kappa\sqrt{C_0}\Big(\|g_\lambda\|_\rho+M\Big)\lambda^r\left(\frac{mN^{\frac{\alpha(1-2r)}{4\alpha r+1}}}{\sqrt{N\lambda}}+N^{\frac{\alpha(1-2r)}{4\alpha r+1}}\lambda^{\frac12-r}\right)\\ &= \widetilde{C}_\kappa\sqrt{C_0}\Big(\|g_\lambda\|_\rho+M\Big)N^{-\frac{2\alpha r}{4\alpha r+1}}\left(mN^{-\frac{2\alpha(2r-1)+\frac12}{4\alpha r+1}}+1\right). \end{aligned}$$

Since (13) is satisfied, we have

$$E\left\|\overline{f}_{D,\lambda}-f_{D,\lambda}\right\|_\rho \le 2\widetilde{C}_\kappa\sqrt{C_0}\Big(\|g_\lambda\|_\rho+M\Big)N^{-\frac{2\alpha r}{4\alpha r+1}},$$

and thereby

$$E\left[\left\|\overline{f}_{D,\lambda}-f_\rho\right\|_\rho\right]=O\left(N^{-\frac{2\alpha r}{4\alpha r+1}}\right).$$

This proves Corollary 11. ∎

Appendix

This appendix provides detailed proofs of the norm estimates stated in Lemmas 17 and 18 involving the approximation of L_K by $L_{K,D(x)}$. To this end, we need the following probability inequality for vector-valued random variables in (Pinelis, 1994).

Lemma 25 *For a random variable ξ on $(\mathcal{Z},\rho)$ with values in a separable Hilbert space $(H,\|\cdot\|)$ satisfying $\|\xi\|\le\widetilde{M}<\infty$ almost surely, and a random sample $\{z_i\}_{i=1}^s$ independent drawn according to ρ, there holds with confidence $1-\widetilde{\delta}$,*

$$\left\|\frac1s\sum_{i=1}^s[\xi(z_i)-E(\xi)]\right\|\le\frac{2\widetilde{M}\log(2/\widetilde{\delta})}{s}+\sqrt{\frac{2E(\|\xi\|^2)\log(2/\widetilde{\delta})}{s}}. \tag{45}$$

Proof of Lemma 17 We apply Lemma 25 to the random variable η_1 defined by

$$\eta_1(x)=(L_K+\lambda I)^{-1/2}\langle\cdot,K_x\rangle_K K_x,\qquad x\in\mathcal{X} \tag{46}$$

It takes values in $HS(\mathcal{H}_K)$, the Hilbert space of Hilbert-Schmidt operators on $\mathcal{H}_K$, with inner product $\langle A,B\rangle_{HS}=\mathrm{Tr}(B^TA)$. Here Tr denotes the trace of a (trace-class) linear operator. The norm is given by $\|A\|_{HS}^2=\sum_i\|Ae_i\|_K^2$ where $\{e_i\}$ is an orthonormal basis

of $\mathcal{H}_K$. The space $HS(\mathcal{H}_K)$ is a subspace of the space of bounded linear operators on $\mathcal{H}_K$, denoted as $(L(\mathcal{H}_K),\|\cdot\|)$, with the norm relations

$$\|A\|\le\|A\|_{HS},\qquad \|AB\|_{HS}\le\|A\|_{HS}\|B\|. \tag{47}$$

Now we use effective dimensions to estimate norms involving η_1. The random variable η_1 defined by (46) has mean $E(\eta_1)=(L_K+\lambda I)^{-1/2}L_K$ and sample mean $(L_K+\lambda I)^{-1/2}L_{K,D(x)}$. Recall the set of normalized (in $\mathcal{H}_K$) eigenfunctions $\{\varphi_i\}_i$ of L_K. It is an orthonormal basis of $\mathcal{H}_K$. If we regard L_K as an operator on $L^2_{\rho_X}$, the normalized eigenfunctions in $L^2_{\rho_X}$ are $\{\frac{1}{\sqrt{\lambda_i}}\varphi_i\}_i$ and they form an orthonormal basis of the orthogonal complement of the eigenspace associated with eigenvalue 0. By the Mercer Theorem, we have the following uniform convergent Mercer expansion

$$K(x,y)=\sum_i\lambda_i\frac{1}{\sqrt{\lambda_i}}\varphi_i(x)\frac{1}{\sqrt{\lambda_i}}\varphi_i(y)=\sum_i\varphi_i(x)\varphi_i(y). \tag{48}$$

Take the orthonormal basis $\{\varphi_i\}_i$ of $\mathcal{H}_K$. By the definition of the HS norm, we have

$$\|\eta_1(x)\|_{HS}^2=\sum_i\left\|(L_K+\lambda I)^{-1/2}\langle\cdot,K_x\rangle_K K_x\varphi_i\right\|_K^2.$$

For a fixed i,

$$\langle\cdot,K_x\rangle_K K_x\varphi_i=\varphi_i(x)K_x,$$

and $K_x\in\mathcal{H}_K$ can be expended by the orthonormal basis $\{\varphi_\ell\}_\ell$ as

$$K_x=\sum_\ell\langle\varphi_\ell,K_x\rangle_K\varphi_\ell=\sum_\ell\varphi_\ell(x)\varphi_\ell. \tag{49}$$

Hence

$$\begin{aligned}\|\eta_1(x)\|_{HS}^2 &= \sum_i\left\|\varphi_i(x)\sum_\ell\varphi_\ell(x)\left(L_K+\lambda I\right)^{-1/2}\varphi_\ell\right\|_K^2\\ &= \sum_i\left\|\varphi_i(x)\sum_\ell\varphi_\ell(x)\frac{1}{\sqrt{\lambda_\ell+\lambda}}\varphi_\ell\right\|_K^2=\sum_i\left(\varphi_i(x)\right)^2\sum_\ell\frac{\left(\varphi_\ell(x)\right)^2}{\lambda_\ell+\lambda}.\end{aligned}$$

Combining this with (48), we see that

$$\|\eta_1(x)\|_{HS}^2=K(x,x)\sum_\ell\frac{\left(\varphi_\ell(x)\right)^2}{\lambda_\ell+\lambda},\qquad\forall x\in\mathcal{X} \tag{50}$$

and

$$E\left[\|\eta_1(x)\|_{HS}^2\right]\le\kappa^2E\left[\sum_\ell\frac{\left(\varphi_\ell(x)\right)^2}{\lambda_\ell+\lambda}\right]=\kappa^2\sum_\ell\frac{\int_{\mathcal{X}}\left(\varphi_\ell(x)\right)^2d\rho_X}{\lambda_\ell+\lambda}.$$

But

$$\int_{\mathcal{X}}\left(\varphi_\ell(x)\right)^2d\rho_X=\|\varphi_\ell\|_{L^2_{\rho_X}}^2=\left\|\sqrt{\lambda_\ell}\frac{1}{\sqrt{\lambda_\ell}}\varphi_\ell\right\|_{L^2_{\rho_X}}^2=\lambda_\ell. \tag{51}$$

So we have

$$E\left[\|\eta_1\|_{HS}^2\right] \leq \kappa^2 \sum_\ell \frac{\lambda_\ell}{\lambda_\ell+\lambda} = \kappa^2 \mathrm{Tr}\left(\left(L_K+\lambda I\right)^{-1} L_K\right) = \kappa^2 \mathcal{N}(\lambda) \tag{52}$$

and

$$E\left\|\frac{1}{|D|}\sum_{x\in D(x)} \eta_1(x) - E[\eta_1]\right\|_{HS}^2 = E\left[\left\|\left(L_K+\lambda I\right)^{-1/2}\left\{L_K - L_{K,D(x)}\right\}\right\|_{HS}^2\right] \leq \frac{\kappa^2\mathcal{N}(\lambda)}{|D|}.$$

Then our desired inequality in Part (a) follows from the first inequality of (47).

From (49) and (50), we find a bound for η_1 as

$$\|\eta_1(x)\|_{HS} \leq \kappa \frac{1}{\sqrt{\lambda}} \sqrt{\sum_\ell \left(\varphi_\ell(x)\right)^2} \leq \frac{\kappa}{\sqrt{\lambda}}\sqrt{K(x,x)} \leq \frac{\kappa^2}{\sqrt{\lambda}}, \qquad \forall x \in \mathcal{X}.$$

Applying Lemma 25 to the random variable η_1 with $\widetilde{M} = \frac{\kappa^2}{\sqrt{\lambda}}$, we know by (47) that with confidence at least $1-\delta$,

$$\begin{aligned}\left\|E[\eta_1] - \frac{1}{|D|}\sum_{x\in D(x)}\eta_1(x)\right\| &\leq \left\|E[\eta_1] - \frac{1}{|D|}\sum_{x\in D(x)}\eta_1(x)\right\|_{HS} \\ &\leq \frac{2\kappa^2\log(2/\delta)}{|D|\sqrt{\lambda}} + \sqrt{\frac{2\kappa^2\mathcal{N}(\lambda)\log(2/\delta)}{|D|}}.\end{aligned}$$

Writing the above bound by taking a factor $\frac{2\kappa\log(2/\delta)}{\sqrt{|D|}}$, we get the desired bound (29).

Recall $\mathcal{B}_{|D|,\lambda}$ defined by (30). Apply the formula (42) for nonnegative random variables to $\xi = \left\|\left(L_K+\lambda I\right)^{-1/2}\left\{L_K - L_{K,D(x)}\right\}\right\|^d$ and use the bound

$$\mathrm{Prob}\left[\xi > t\right] = \mathrm{Prob}\left[\xi^{\frac{1}{d}} > t^{\frac{1}{d}}\right] \leq 2\exp\left\{-\frac{t^{\frac{1}{d}}}{\mathcal{B}_{|D|,\lambda}}\right\}$$

derived from (29) for $t \geq \log^d 2\mathcal{B}_{|D|,\lambda}$. We find

$$E\left[\left\|\left(L_K+\lambda I\right)^{-1/2}\left\{L_K - L_{K,D(x)}\right\}\right\|^d\right] \leq \log^d 2\mathcal{B}_{|D|,\lambda} + \int_0^\infty 2\exp\left\{-\frac{t^{\frac{1}{d}}}{\mathcal{B}_{|D|,\lambda}}\right\} dt.$$

The second term on the right-hand side of above equation equals $2d\mathcal{B}_{|D|,\lambda}^d \int_0^\infty u^{d-1}\exp\{-u\}\,du$. Then the desired bound in Part (c) follows from $\int_0^\infty u^{d-1}\exp\{-u\}\,du = \Gamma(d)$ and the lemma is proved. ■

Proof of Lemma 18 Consider the random variable η_2 defined by

$$\eta_2(z) = \left(L_K+\lambda I\right)^{-1/2}(K_x), \qquad z=(x,y)\in\mathcal{Z}. \tag{53}$$

It takes values in $\mathcal{H}_K$. By (49), it satisfies

$$\|\eta_2(z)\|_K = \left\|\left(L_K+\lambda I\right)^{-1/2}\left(\sum_\ell \varphi_\ell(x)\varphi_\ell\right)\right\|_K = \left(\sum_\ell \frac{(\varphi_\ell(x))^2}{\lambda_\ell+\lambda}\right)^{1/2}.$$

So

$$E\left[\left\|\left(L_K+\lambda I\right)^{-1/2}(K_x)\right\|_K^2\right] = E\left[\sum_\ell \frac{(\varphi_\ell(x))^2}{\lambda_\ell+\lambda}\right] = \mathcal{N}(\lambda).$$

This is the statement of Part (a).

We also see from (49) that for $x\in\mathcal{X}$,

$$\|\eta_2(z)\|_K = \left(\sum_\ell \frac{(\varphi_\ell(x))^2}{\lambda_\ell+\lambda}\right)^{1/2} \leq \frac{1}{\sqrt{\lambda}}\left(\sum_\ell (\varphi_\ell(x))^2\right)^{1/2} = \frac{1}{\sqrt{\lambda}}\sqrt{K(x,x)} \leq \frac{\kappa}{\sqrt{\lambda}}.$$

This verifies the statement of Part (b).

For Part (c), we consider another random variable η_3 defined by

$$\eta_3(z) = \left(L_K+\lambda I\right)^{-1/2}(g(z)K_x), \qquad z=(x,y)\in\mathcal{Z}. \tag{54}$$

It takes values in $\mathcal{H}_K$ and satisfies

$$\|\eta_3(z)\|_K = |g(z)|\left\|\left(L_K+\lambda I\right)^{-1/2}(K_x)\right\|_K = |g(z)|\left(\sum_\ell \frac{(\varphi_\ell(x))^2}{\lambda_\ell+\lambda}\right)^{1/2}.$$

So

$$\|\eta_3(z)\|_K \leq \frac{\kappa\|g\|_\infty}{\sqrt{\lambda}}, \qquad z\in\mathcal{Z}$$

and

$$E\left[\|\eta_3\|_K^2\right] \leq \|g\|_\infty^2 E\left[\sum_\ell \frac{(\varphi_\ell(x))^2}{\lambda_\ell+\lambda}\right] = \|g\|_\infty^2 \mathcal{N}(\lambda).$$

Applying Lemma 25 verifies the statement in Part (c). The proof of the lemma is complete. ■

Abstract

We study the problem of identifying *unreliable* and *adversarial* workers in crowdsourcing systems where workers (or users) provide labels for tasks (or items). Most existing studies assume that worker responses follow specific probabilistic models; however, recent evidence shows the presence of workers adopting non-random or even malicious strategies. To account for such workers, we suppose that workers comprise a mixture of honest and adversarial workers. *Honest* workers may be reliable or unreliable, and they provide labels according to an unknown but explicit probabilistic model. *Adversaries* adopt labeling strategies different from those of honest workers, whether probabilistic or not. We propose two reputation algorithms to identify unreliable honest workers and adversarial workers from *only* their responses. Our algorithms assume that honest workers are in the majority, and they classify workers with outlier label patterns as adversaries. Theoretically, we show that our algorithms successfully identify unreliable honest workers, workers adopting deterministic strategies, and worst-case *sophisticated* adversaries who can adopt arbitrary labeling strategies to degrade the accuracy of the inferred task labels. Empirically, we show that filtering out outliers using our algorithms can significantly improve the accuracy of several state-of-the-art label aggregation algorithms in real-world crowdsourcing datasets.

Keywords: crowdsourcing, reputation, adversary, outliers

1. Introduction

The growing popularity of online crowdsourcing services like Amazon Mechanical Turk and CrowdFlower has made it easy to collect low-cost labels from the crowd to generate training datasets for machine learning applications. Unfortunately, these labels are typically of low quality because of unintentional or intentional inaccuracies introduced by unreliable and malicious workers (Kittur et al., 2008; Le et al., 2010). Determining correct labels of tasks from such noisy labels is challenging because the reliabilities or qualities of workers are often unknown. While one may use "gold standard" tasks—whose true label is already known—to identify low-reliability workers (Snow et al., 2008; Downs et al., 2010; Le et al., 2010), accessing true labels for a sufficient number of tasks can be difficult and expensive. To address these challenges, a common solution is to use *redundancy* (Sheng et al., 2008), that is, collecting multiple labels for each task and assigning multiple tasks to each worker. Given the redundant labels, most existing studies make specific probabilistic assumptions on how individual workers provide labels and propose techniques to infer true task labels given workers' responses. Common probabilistic models include the one-coin model (Zhang et al., 2014), two-coin model (Raykar and Yu, 2012), and the general Dawid-Skene model (Dawid and Skene, 1979). For example, the "one-coin" model assumes that each worker w provides the correct label to an assigned task with probability p_w and (an) incorrect label with probability $1 - p_w$. The parameter p_w thus measures the reliability of worker w.

While most existing work relies on explicit probabilistic models, recent studies (Vuurens et al., 2011; Difallah et al., 2012) and anecdotal evidence show that worker labeling strategies may not be probabilistic in practice. For instance, for binary classification tasks, workers may adopt strategies that: (a) uniformly label all tasks $+1$ if it is known that $+1$ labels are more prevalent than -1 among true labels in the corpus of tasks; [1] (b) provide accurate labels to the first few tasks and random labels to remaining ones; and (c) systematically provide $+1$ labels to certain types of tasks and -1 to other types. Vuurens et al. (2011) recently provided real-world empirical evidence of similar worker strategies. In addition, workers may be malicious and may adopt sophisticated strategies for explicitly altering inferred labels of tasks. For instance, Wang et al. (2014) showed that malicious crowdsourcing campaigns, called "crowdturfing", are increasing in popularity in both dedicated and generic crowdsourcing websites (Motoyama et al., 2011; Wang et al., 2012). Further, evidence indicates the presence of malicious users in online content rating systems (such as Digg, Amazon, and Yelp) in which users can choose items to rate and the ratings are public. Specifically, users have been observed to explicitly alter the popularity of advertisements and phishing articles (Tran et al., 2009) and collaboratively target products on Amazon (Mukherjee et al., 2012).

This paper focuses on the problem of explicitly identifying *unreliable* and *adversarial* workers in crowdsourced labeling tasks by using only the labels provided by workers as an input. We consider a general crowdsourcing setting in which users/workers provide labels to items/tasks. The setting may be a crowdsourced classification application (such as Mechanical Turk) in which labels are collected for tasks by assigning [2] them to workers; or a public crowdsourcing system (such as Digg, Amazon, or Yelp) in which users provide labels/ratings to a collection of items they choose. For brevity, we use the generic terms "worker" and "task" for both types of applications. We make the following assumptions. The tasks have binary true labels in the set $\{-1, +1\}$; for cases in which the notion of true task labels is subjective, we consider it to be the population's majority opinion. We distinguish between two types of workers: *honest* and *adversarial*. The population of workers is mostly honest, with adversaries comprising a "small" fraction. Honest workers provide responses according

1. Note that the one-coin model cannot capture this strategy, but the more general two-coin model (Raykar and Yu, 2012) can
2. Workers can still choose from among assigned tasks; however, the assignment can be done to ensure that the graph representing workers' assignment to tasks has particular structures—see Section 4.1.

to a well-defined probabilistic model, say, M (e.g. the one-coin model introduced above), and therefore, they *can make mistakes*. However, the model M is not known. Motivated by the presence of non-random worker strategies, we go beyond standard probabilistic models and consider a much broader class of *adversarial* worker strategies. Specifically, adversaries adopt strategies different from those of honest workers, whether probabilistic or not, that is, their responses are not generated according to model M. Further, different adversaries may adopt distinct strategies.

Our work differs from most prior literature (Dawid and Skene, 1979; Smyth et al., 1995; Whitehill et al., 2009; Raykar et al., 2010; Welinder et al., 2010; Ghosh et al., 2011; Karger et al., 2011; Liu et al., 2012; Zhou et al., 2012; Dalvi et al., 2013; Zhang et al., 2014) that primarily focused on designing label aggregation algorithms to maximize the accuracy of recovered task labels. Only a few studies have explicitly focused on identifying unreliable workers based on their responses; these either relied on access to true task labels (Snow et al., 2008; Downs et al., 2010; Le et al., 2010) or did not assume any form of adversarial behavior (Vuurens et al., 2011; Raykar and Yu, 2012; Hovy et al., 2013). We aim to identify unreliable and adversarial workers using *only* their responses and do not assume access to any true task labels. Furthermore, to the best of our knowledge, we are unaware of previous studies that have addressed the problem of identifying adversarial workers who can adopt *arbitrary* strategies in crowdsourcing systems. Refer to Section 1.2 for further discussion on this aspect.

For the above setting, we design a scoring algorithm that computes "reputation scores" for workers to indicate the degree to which their labeling patterns are adversarial. We base our algorithms on the intuition that as the population is mostly honest and adversaries' labeling patterns differ from those of honest workers, adversary labeling patterns should be statistical outliers. The reputation score then indicates the degree to which a worker's labeling pattern is a statistical outlier. The adversaries identified by our algorithms may be discarded or processed separately depending on the application. Section 5 shows that discarding adversary labels can enable standard label aggregation algorithms to infer true task labels more accurately.

We note that the problem of identifying unreliable honest workers and adversaries from only their responses is nontrivial, especially because we cannot access true labels for any of the tasks. In particular, even in the simple and commonly observed case where adversaries always provide the label $+1$, the natural approach of classifying workers who only give $+1$ labels as adversaries can have arbitrarily bad performance (see Lemma 2). Furthermore, because we do not restrict the adversary strategy in any way, differentiating them from honest workers can be difficult. In fact, we show (see Theorem 14) that by carefully choosing their responses, *sophisticated* adversarial workers can render themselves *indistinguishable* from honest ones and ensure that the true labels of some fraction of tasks cannot be inferred better than a random guess.

1.1 Main contributions

Our work makes algorithmic, theoretical, and empirical contributions: [3]

3. This work expands on the results described in a previous version (Jagabathula et al., 2014)

Algorithmic contributions. Our main algorithmic contribution is a reputation algorithm that is designed to identify outlier labeling patterns. This algorithm takes as inputs the set of workers, set of tasks, and binary labels provided by each worker. Each worker may label only a subset of the tasks. Because the algorithm makes no specific assumptions on the worker labeling strategies, it identifies outliers by *penalizing* workers for the number of "conflicts" they are involved in. Specifically, suppose each task receives both $+1$ and -1 labels. For each task t_j, the algorithm maintains the number d_j^+ of $+1$ labels, number d_j^- of -1 labels, and a penalty budget of 2. Intuitively, if $d_j^+ > d_j^-$, then the worker assigning -1 to t_j is "more" of an outlier than a worker assigning label $+1$. Accordingly, the algorithm makes the following decisions: (a) how much of the penalty budget to allocate to each worker for each task and (b) how to aggregate the penalties allocated to each worker to arrive at the final reputation score.

We propose two algorithms that differ in how they make these two decisions. The first algorithm (Algorithm 1) performs a "soft" assignment: it allocates a penalty of $1/d_j^+$ (resp. $1/d_j^-$) to every worker who has provided the label $+1$ (resp. -1) to task t_j and computes the net penalty as the average of the penalties allocated across all tasks assigned to a worker. [4] The second algorithm (Algorithm 2) performs a "hard" assignment: instead of spreading the penalty score of 1 over all workers who provide the label $+1$ (resp. -1), it identifies one "representative" worker among the workers who provide the label $+1$ (resp. -1) to task t_j and allocates the entire penalty of 1 to the representative worker. The net penalty for the worker is computed by summing the accrued penalties across all assigned tasks. If the representative worker is chosen uniformly at random, then a worker who agrees with the majority is less likely to be chosen and therefore less likely to receive the penalty. However, we show that it is more appropriate to choose the representative worker in a "load-balanced" fashion by using the concept of *optimal semi-matching* (Harvey et al., 2003), where the semi-matching is defined on the bipartite graph between the workers and tasks, in which every worker is connected to the tasks that it has labeled. Both penalty assignments are based on the intuition that when there are more honest workers than adversaries, the former are more likely to agree with the majority and therefore receive lower penalties.

Theoretical contributions. We analyze our algorithms under three settings: (a) there are no adversaries and honest workers adopt the one-coin model; (b) honest workers adopt the one-coin model and adversaries, the Uniform strategy in which they label all assigned tasks $+1$; and (c) honest workers adopt the spammer-hammer model (Karger et al., 2011) and the adversaries are *sophisticated*, having infinite computational capacity and knowledge of honest workers' labels. For the first two settings, we derive guarantees for the soft-penalty algorithm and show that these guarantees extend to a random, normalized approximation of the hard-penalty algorithm; we analyze this approximation because the hard-penalty algorithm is not analytically tractable in these settings. For the last setting, we show that the hard-penalty algorithm is robust to sophisticated adversary strategies but the soft-penalty algorithm is vulnerable. Specifically, the example at the end of Section 3.1 shows an instance of an adversary strategy for which the soft-penalty algorithm misclassifies

4. We do not explicitly define the reputation score. It can be interpreted as the inverse of the net penalty—higher the penalty, the lower is the reputation, and vice-versa.

all adversaries as honest. We also show (see Lemma 13) that existing label aggregation algorithms can perform very poorly in the presence of sophisticated adversaries.

For the first two settings, we analyze our algorithms under a standard probabilistic model for crowdsourcing in which there are n workers; the worker-task assignment graph is (l, r)-regular, that is, each worker labels l tasks and each task is labeled by r workers; and the population is described by three parameters: fraction q of honest workers, fraction γ of tasks with $+1$ true labels, and average reliability μ of honest workers under the one-coin model. Recall that the reliability of an honest worker is defined as the probability of providing the correct response for any given task. This setup best represents the setting of crowdsourced classification in which tasks may be assigned according to an (l, r)-regular graph. An (l, r)-regular graph is analytically tractable, and Karger et al. (2014) showed that it achieves order-optimal performance (with respect to the best combination of task assignment and inference algorithm) when given a task assignment budget. We derive the expected penalties received by honest and adversarial workers and bound the asymptotic *error rate* or *misclassification rate* of a threshold classifier: given a penalty threshold θ, the threshold classifier classifies a worker as honest if its penalty is less than or equal to θ and as adversarial otherwise. Then, the misclassification rate is defined as the expected fraction of errors made by this classifier. This is non-trivial, especially because the natural approach that classifies all workers that provide only $+1$ labels as adversaries can have a misclassification rate arbitrarily close to 1 (see Lemma 2).

For the last setting, we make no assumptions on the structure of the worker-task assignment graph and derive performance guarantees as a function of the graph structure. This setup is reflective of public crowdsourced settings in which workers choose which tasks to label and the assumption of sophisticated adversaries is most relevant.

Formally, we establish the following results:

1. *No adversaries.* We show that the penalties assigned by the soft-penalty algorithm are consistent with worker reliabilities in the one-coin model—the higher the reliability, the lower is the penalty (see Theorem 3). When $l = \log n$ and r is constant, we show that the misclassification rate scales as $O(1/n^{2\varepsilon^2})$ for some small enough $\varepsilon \in (0, \frac{1}{\sqrt{2}})$ as $n \to \infty$, where a worker is said to be misclassified if it has high reliability (exceeding a threshold) but is classified as adversarial (see Theorem 6). In other words, our algorithm classifies all highly reliable workers as honest as $n \to \infty$. For this, the number of labels collected from each worker must tend to infinity, but only logarithmically in n.

2. Uniform *adversaries.* We derive necessary and sufficient conditions under which the soft-penalty algorithm assigns lower expected penalties to honest workers than to adversaries (see Theorem 4). Our conditions essentially require a sufficient majority of honest workers; specifically, for fixed μ and γ, we need the fraction of honest workers $q > \max\left\{1/2, h_\mu^{-1}\left(\gamma/(1-\gamma)\right)\right\}$, where $h_\mu^{-1}(\cdot)$ is an increasing function (see Theorem 4). This result shows that as γ increases, it becomes harder to separate honest workers from adversaries. This is because as the proportion γ of tasks with true labels $+1$ increases, the adversaries (who always provide the label $+1$) become more accurate, making it harder to distinguish them from honest workers. Further, when $l = \log n$ and r is constant, we show that the misclassification rate scales as $O(1/n^{2\varepsilon^2})$ for adversaries and as $F(\tilde{\mu}) + O(1/n^{2\varepsilon^2})$ for honest workers, for some $\tilde{\mu} < \mu$ and small enough $\varepsilon > 0$ as $n \to \infty$ (see Theorem 10). Here, $F(\cdot)$ is the cumulative distribution function (CDF) of honest workers' reliabilities. Our result essentially shows that asymptotically, we correctly classify all adversaries and honest workers with above average reliabilities. We argue that the presence of the term $F(\tilde{\mu})$ is necessary because it is difficult to distinguish low-reliability honest workers from adversaries.

3. *Sophisticated adversaries.* We suppose that the goal of sophisticated adversaries is to maximize the number of tasks they *affect*, that is, cause to receive labels different from those they would have received otherwise. When honest workers are perfectly reliable, we show that k sophisticated adversaries can render themselves indistinguishable from k honest workers, so that a random guess misclassifies workers with probability (1/2). We use this to provide a lower bound on the minimum number of tasks that k adversaries can affect (the true label cannot be inferred better than a random guess) *irrespective* of the label aggregation algorithm used to aggregate the worker labels (as long as it is agnostic to worker/task identities). The bound depends on the graph structure between honest workers and tasks (see Theorem 14 for details). Our result is valid across different labeling patterns and a large class of label aggregation algorithms, and therefore, it provides *fundamental* limits on the damage that k adversaries can cause. Furthermore, we propose a label aggregation algorithm (Algorithm 3) utilizing worker reputations computed by the hard-penalty algorithm and prove the existence of an upper bound on the worst-case number of affected tasks (see Theorem 17), under the assumption that honest workers adopt the popular spammer-hammer model. This combined with the result of Theorem 14 shows that our proposed label aggregation algorithm is optimal (up to a constant factor) in recovering the true labels of tasks.

Empirical contributions. We conducted two numerical studies to demonstrate the practical value of our methods (see Section 5). The first study illustrates a concrete application of our methods. With five real-world crowdsourcing datasets, it shows that *discarding* the labels of adversaries identified by our methods allows standard label aggregation algorithms to infer true task labels more accurately. These improvements are demonstrated for the following six label aggregation algorithms: (a) simple majority, (b) expectation-maximization (EM) for the two-coin model (Raykar and Yu, 2012), (c) KOS (Karger et al., 2011), (d) a normalized variant of KOS [5], (e) spectral EM (Zhang et al., 2014), and (f) regularized minimax conditional entropy (Zhou et al., 2015). Our results show that by removing up to 10 workers, our methods can improve predictive accuracy by 9.8% on average. These improvements suggest that the label patterns of discarded workers do not conform to standard probabilistic models.

The second study is designed to complement our theoretical analysis. By using synthetic data, we show that both soft- and hard-penalty algorithms successfully identify Uniform adversaries who label all assigned tasks $+1$ and low-reliability honest workers when the worker-task assignment graph has a power-law degree distribution. These degree distributions commonly arise in crowdsourcing systems when workers organically choose the

5. This variant was designed to capture non-uniform worker and task degrees because the standard KOS algorithm is designed to operate on (l, r)-regular worker-task assignment graphs.

tasks to label, with some workers labeling many tasks and some tasks receiving many labels (Franklin et al., 2011). This study also offers insights into the settings under which the soft- or hard-penalty algorithm is appropriate; specifically, these algorithms are more appropriate when the adversaries have lower and higher degrees, respectively.

1.2 Related Work

Our work is part of the literature on crowdsourcing that proposes statistical techniques to exploit the redundancy in collected labels to simultaneously infer the latent reliabilities of workers and true task labels. In particular, our work is related to three broad streams. The first stream focuses on "crowdsourced classification", namely, inferring underlying true labels of tasks when workers adopt specific probabilistic labeling strategies. Our reputation algorithm can work in conjunction with any of these methods, possibly by filtering out low reputation workers. The second stream proposes methods to explicitly filter out low-reliability workers; it is similar in spirit to our approach. The third stream focuses on methods to address sophisticated attacks in online settings; it is related to our treatment of sophisticated adversaries.

Crowdsourced classification. The literature on crowdsourced classification is vast. Most studies are based on the worker model proposed by Dawid and Skene (1979), which is a generalization of the one-coin model to tasks with more than two categories. The standard solution is to use the expectation-maximization (EM) algorithm (or its variants) to estimate worker reliability parameters and true task labels (Smyth et al., 1995; Raykar et al., 2010). The methods proposed in Liu et al. (2012) and Chen et al. (2013) take a Bayesian approach by assuming different priors over the worker reliability parameters. Whitehill et al. (2009) included task difficulty as an additional parameter in the model, and Welinder et al. (2010) studied a model with multi-dimensional latent variables for each worker, such as competence, expertise, and bias. Zhou et al. (2012, 2015) introduced a natural generalization of the Dawid-Skene model that captures tasks with differing difficulties and proposed a minimax entropy based approach which works well in real datasets. Although most of these approaches show improved performance on real-world datasets, they offer no theoretical guarantees on the resulting estimates of true task labels and model parameters.

From a theoretical perspective, the crowdsourced classification problem has been studied in two distinct regimes: *dense* and *sparse*. In the *dense* regime, it is assumed that each worker has a certain probability of labeling each task. As the problem size (or number of workers) increases, each task receives an increasing number of responses; therefore, the true labels of all tasks are eventually identified correctly (with high probability). The theoretical analysis therefore focuses on identifying the rate at which the algorithm estimates converge to the true task labels under different settings. The dense regime was first studied by Ghosh et al. (2011), who proposed a spectral method to infer task labels. More recently, Gao and Zhou (2016) studied the minimax optimal error rate of a projected EM algorithm under the one-coin model, and Li and Yu (2014) provided upper bounds on the error rate of weighted majority voting algorithms for the Dawid-Skene model. Zhang et al. (2014) showed that the EM algorithm for the Dawid-Skene model achieves the optimal convergence rate when initialized using a spectral method.

In the *sparse* regime, each task is assigned a "small" number of workers, that is, of size $O(1)$, so that the accuracy does not increase with problem size. Karger et al. (2014) were the first to analyze this scenario; they proposed an iterative message-passing algorithm for estimating true task labels as well as a task assignment scheme that minimizes the total price that must be paid to achieve an overall target accuracy. They showed that their algorithm is optimal by comparing it against an oracle estimator that knows the reliability of every worker. Dalvi et al. (2013) proposed methods based on singular-value decomposition (SVD) and analyzed the consistency of their estimators for the one-coin model. Recently, Khetan and Oh (2016) analyzed the "Generalized Dawid-Skene Model" introduced by Zhou et al. and showed that spectral approaches achieve near-optimal performance, whereas Ok et al. (2016) proved that belief propagation (BP) is optimal, that is, it matches the performance of the MAP estimator, under the one-coin model when each worker is assigned at most two tasks. In our theoretical analysis, we focus on this regime. The key distinction of our work from previous studies is that we focus on characterizing the misclassification rate of our algorithm in classifying workers, as opposed to the accuracy of recovering true task labels.

Detecting Unreliable/Adversarial workers. Some studies have aimed to explicitly detect and/or remove unreliable workers based on observed labels. One approach is to use "gold standard" tasks, that is, tasks whose true labels are already known, to identify low-reliability workers (Snow et al., 2008; Downs et al., 2010; Le et al., 2010). However, accessing true task labels can be difficult and might involve additional payment. In this work, we do not assume access to any gold standard tasks and identify adversarial workers based only on the provided labels. Vuurens et al. (2011) defined scores customized to specific adversary strategies to identify and remove them. Similarly, Hovy et al. (2013) modeled the worker population as consisting of two types—those who always provide the correct label and spammers who provide uniformly random labels—and estimated each worker's trustworthiness by using the observed labels. In contrast to these studies, we allow adversaries to adopt arbitrary strategies. Ipeirotis et al. (2010) proposed a method for quantifying worker quality by transforming the observed labels into soft posterior labels based on the estimated *confusion matrix* (Dawid and Skene, 1979). Similar to our work, their approach computes an expected cost for each worker, where the higher the cost, the lower is the worker's quality. Raykar and Yu (2012) proposed an empirical Bayesian algorithm to eliminate workers whose labels are not correlated with the true label (called *spammers*), and estimated consensus labels from the remaining workers. Both of these works rely on the Dawid-Skene model, whereas our algorithms do not assume knowledge of the probabilistic model used by workers. Some studies have tried to quantify the price of having adversarial workers under some restricted settings. Ghosh et al. (2011) (in the dense regime) and Karger et al. (2013) (in the sparse regime) considered malicious workers who can collude and provide arbitrary responses to degrade the performance of the aggregation algorithms and showed that their approaches are robust to manipulation by a small constant fraction of such adversaries. However, both these works assume specific structures on the worker-task assignment graph and do not consider adversaries who can adapt their responses based on the labels submitted by honest workers. Our analysis considers *arbitrary* worker-task assignment graphs, and we allow adversaries to choose their labels based on observed honest workers' responses.

Sybil attacks. Finally, our work is also broadly related to the rich literature on identifying *Sybil* identities in online social networks. Most such schemes (Yu et al., 2006, 2008; Danezis and Mittal, 2009; Tran et al., 2011; Viswanath et al., 2012) use the graph (or trust) structure between users to limit the corruptive influences of *Sybil attacks* (see Viswanath et al., 2010 for a nice overview). In our context, there is no information about the network structure or trust relationships between workers, and because most crowdsourcing tasks involve some form of payment, it is harder to launch Sybil attacks by forging financial credentials like credit cards or bank accounts.

2. Setup

We consider the following broad setting. There is a set $\mathcal{T} = \{t_1, t_2, \ldots, t_m\}$ of m tasks such that each task t_j is associated with a latent ground-truth binary label $y_j \in \{-1, +1\}$. We elicit binary labels for these tasks from a set $W = \{w_1, w_2, \ldots, w_n\}$ of n workers. Each worker typically labels only a subset of the tasks, and we generically say that the subset of tasks is *assigned* to the worker. We represent this assignment by using a bipartite graph $\mathcal{B} = (W \cup \mathcal{T}, E)$ with workers on one side, tasks on the other side, and an edge $(w_i, t_j) \in E$ indicating that task t_j is assigned to worker w_i. We call $\mathcal{B}$ the *worker-task assignment graph* and suppose that the assignment is pre-specified.

Each worker w_i provides a binary response [6] $w_i(t_j) \in \{-1, +1\}$ for each task t_j assigned to it. We encode the responses as the *response matrix* $\mathcal{L} \in \{-1, 0, +1\}^{|W| \times |\mathcal{T}|}$ such that $\mathcal{L}_{ij} = w_i(t_j)$, for all $1 \leq i \leq n$ and $1 \leq j \leq m$, where we set $w_i(t_j) = 0$ for any task t_j not assigned to worker w_i. $W_j \subseteq W$ denotes the set of workers who labeled task t_j and $\mathcal{T}_i \subseteq \mathcal{T}$, the set of tasks assigned to worker w_i. Let d_j^+ (resp. d_j^-) denote the number of workers labeling task t_j as $+1$ (resp. -1).

Worker model. We assume that the population of workers comprises two disjoint classes: *honest* and *adversarial*. That is, $W = H \cup A$ with $H \cap A = \emptyset$, where H is the set of honest workers and A, the set of adversarial workers. The class memberships of the workers are latent, so we do not know whether a worker is honest. Honest workers provide (noisy) labels according to an unknown but explicit probabilistic model (such as the one-coin model). Adversarial workers are those whose labeling strategy does not conform to this probabilistic model; they can adopt arbitrary (deterministic or probabilistic) strategies. If honest workers adopt the one-coin model, example adversary strategies include (a) the *uniform strategy*, in which the worker arbitrarily provides uniform responses $+1$ or -1 to all assigned tasks irrespective of the true label; (b) *smart strategy*, in which the adversary is smart and chooses the uniform label in accordance with the population prevalence of the true labels so that if more than 50% of tasks are a priori known to have label -1, then the worker chooses -1 as the uniform label and vice-versa; or (c) *sophisticated strategy*, in which the worker adopts strategies specifically designed to cause the maximum "damage" (see Section 4.2 for details).

Most existing works only focus on honest workers, whereas our approach also considers adversarial workers. Furthermore, our definition of "adversary" is intentionally broader than common definitions to accommodate a wide range of labeling strategies. In fact, some of the abovementioned example adversary strategies may be accommodated by extensions of the one-coin model; for example, the uniform strategy is captured by the two-coin model (Raykar and Yu, 2012), and the smart strategy can be accommodated by allowing worker reliability parameters to depend on the population prevalence of the task labels. While such case-by-case extensions are feasible in theory, they do not extend to general adversary strategies, including sophisticated strategies specifically designed to inflict the maximum "damage".

6. We use the terms "label" and "response" interchangeably.

Given the broad definition of adversaries, our approach is to design a general algorithm to *identify* adversarial workers. The adversaries identified using our algorithm may be filtered out or investigated further, depending on the application. Specifically, our objective is to solve the following problem:

Problem 1 *Given a set of workers $W = H \cup A$, tasks $\mathcal{T}$, and response matrix $\mathcal{L}$, identify the subset of adversarial workers A.*

We describe a reputation-based algorithm that only relies on the response matrix $\mathcal{L}$ to detect adversaries. The algorithm relies on detecting workers whose labeling patterns are statistical *outliers* among the population of workers.

3. Reputation Algorithms

We now describe the proposed algorithm for identifying adversarial workers given the response matrix $\mathcal{L}$. We suppose that no side information is available on the workers' identities (e.g., a social network or worker-level demographic information), and therefore, the algorithm must solely rely on the response patterns given by workers. Our approach is to compute a "reputation" or "trust" score for each worker as a measure of the degree to which their response pattern is a statistical outlier or an anomaly. Workers with low reputation scores are significant outliers and are identified as adversaries.

To compute a worker's reputation, the algorithm relies on the number of *conflicts* the worker is involved in. A worker is involved in a conflict if its response to an assigned task is in disagreement with those of other workers. Note that tasks with a consensus opinion, that is, those having all $+1$ or -1 labels, do not provide any *discriminative* information about the workers who labeled the task. In other words, we cannot distinguish between honest and adversarial workers from just this specific task. Therefore, we focus on tasks that lack consensus, that is, those having a mix of $+1$ and -1 labels. We call this subset of tasks the *conflict set* $\mathcal{T}_{cs}$, and workers who respond to tasks in this set are all involved in conflicts. A conflict typically indicates the presence of low-reliability honest workers (who tend to make mistakes) or adversaries. In the ideal case, when all honest workers are perfectly reliable, a conflict necessarily means the presence of an adversarial worker. In this case, the number of conflicts a worker is involved in can serve as a rough indicator of the possibility of this worker being an adversary. However, when honest workers are not perfect and make mistakes, a conflict indicates only a *chance* of the presence of an adversary. Then, simply counting the number of conflicts may over-penalize honest workers who label a large number of tasks.

To overcome this issue, we propose two penalty allocation techniques, resulting in two variants of our algorithm: (a) *soft-penalty* and (b) *hard-penalty*.

3.1 Soft Penalty

In the *soft-penalty* algorithm (see Algorithm 1), for any task t_j in the conflict set, we allocate a penalty of $1/d_j^+$ and $1/d_j^-$ to all workers who provide the label $+1$ and -1 for t_j, respectively. Then, for each worker, we compute the *net penalty* by averaging the penalties across all assigned (conflict) tasks.

The above allocation of penalties implicitly rewards agreements among worker responses by making the penalty inversely proportional to the number of other workers that agree with a worker. In particular, if a worker agrees with the majority opinion on some task, then it is allocated a lower penalty than a worker who disagrees with the majority. Further, averaging normalizes for the number of tasks labeled by any worker. The algorithm relies on the following intuition for allocating penalties: assuming the average reliability of honest workers to be $> \frac{1}{2}$, we expect that honest workers provide the correct response to the assigned tasks on average. Furthermore, because there are more honest workers than adversaries, we expect the majority response to be the same as the true label of the task for most tasks. Therefore, we expect that the above allocation of penalties assigns lower penalties to high-reliability honest workers and higher penalties to low-reliability honest *and* adversarial workers. We formalize this intuition in Section 4, where we prove theoretical guarantees for the soft-penalty algorithm. We show that the soft-penalty algorithm performs well in identifying low-reliability honest workers as well as adversarial workers employing deterministic strategies (see Theorems 3, 4, 6, and 10). Our results demonstrate the asymptotic consistency of the soft-penalty algorithm in identifying adversaries under standard assumptions on the structure of the worker-task assignment graph.

Although the soft-penalty algorithm can successfully identify adversarial workers adopting certain types of strategies, its performance depends on the complexity of these strategies. If adversarial workers are non-colluding and adopt non-deliberate strategies, then the soft-penalty algorithm can identify them from the observed responses. However, this algorithm could be manipulated by more sophisticated adversaries who can collude together and adapt their labeling strategy to target certain tasks to lower their penalty scores. In particular, the soft-penalty algorithm treats each task in isolation when assigning penalties; therefore, it is susceptible to attack by determined adversaries who can cleverly decide their responses based on honest workers' labels and the structure of the worker-task assignment graph to cause maximum "damage". For example, suppose that the subgraph of $\mathcal{B}$ between honest workers and tasks is r-right regular, that is, each task receives labels from exactly r honest workers (such graphs are commonly used in practice, see Karger et al., 2014 and Ok et al., 2016), and all honest workers are perfectly reliable. Now, suppose that there are $k > r$ adversaries and that each adversary provides the incorrect response to *all* tasks. Then, every task has r correct responses, all provided by honest workers, and k incorrect responses, all provided by adversaries, resulting in net penalties of $1/r$ for each honest worker and $1/k$ for each adversary (note that the degree of the workers does not affect the net penalty because the penalty received from each task is the same). Because $k > r$, adversaries receive lower penalties than do honest workers. Therefore, filtering out k workers with the highest penalties will always filter out honest workers. Furthermore, natural aggregation algorithms (such as simple majority or weighted majority with penalties as weights) result

in incorrect labels for all tasks (see Lemma 13). In fact, for such worst-case adversaries, we can establish the following result:

Theoretical Result (Refer to Theorem 14). *Given any collection of honest worker responses, there exists an adversary strategy that can achieve a lower bound on the fraction of tasks whose true labels cannot be inferred correctly (better than a random guess) by* ***any*** *label aggregation algorithm that is agnostic to the worker and task identities.*

Section 4.2.2 provides a formal description of the result. The proof relies on the fact that sophisticated adversaries can render themselves *indistinguishable* from honest workers by carefully choosing their responses. This shows that identifying such worst-case adversarial workers can be difficult. To deal with such adversarial behavior, we use the *hard-penalty* algorithm.

Algorithm 1 soft penalty

1: **Input:** W, $\mathcal{T}$, and $\mathcal{L}$
2: For every task $t_j \in \mathcal{T}_{cs}$, allocate penalty s_{ij} to each worker $w_i \in W_j$ as follows:

$$s_{ij} = \begin{cases} \frac{1}{d_j^+}, & \text{if } \mathcal{L}_{ij} = +1 \\ \frac{1}{d_j^-}, & \text{if } \mathcal{L}_{ij} = -1 \end{cases}$$

3: **Output:** Net penalty of worker w_i:

$$pen(w_i) = \frac{\sum_{t_j \in \mathcal{T}_i \cap \mathcal{T}_{cs}} s_{ij}}{|\mathcal{T}_i \cap \mathcal{T}_{cs}|}$$

Algorithm 2 hard penalty

1: **Input:** W, $\mathcal{T}$, and $\mathcal{L}$
2: Create a bipartite graph $\mathcal{B}^{cs}$ as follows: (i) Each worker $w_i \in W$ is represented by a node on the left (ii) Each task $t_j \in \mathcal{T}_{cs}$ is represented by two nodes on the right, t_j^+ and t_j^- (iii) Add the edge (w_i, t_j^+) if $\mathcal{L}_{ij} = +1$ or edge (w_i, t_j^-) if $\mathcal{L}_{ij} = -1$
3: Compute an optimal semi-matching $\mathcal{M}$ on $\mathcal{B}^{cs}$
4: **Output:** Net penalty of worker w_i: $pen(w_i) = deg_{\mathcal{M}}(w_i)$

3.2 Hard Penalty

To deal with sophisticated adversaries, we propose a *hard* penalty allocation scheme (Algorithm 2) in which the penalty allocation for a particular task takes into account the structure of the worker-task assignment graph and the responses of other workers on *all* other tasks. In particular, instead of distributing the penalty evenly across all workers that respond to a given task, this algorithm chooses two "representative" workers to penalize for each conflict task: one each among those who provide the label $+1$ and -1. The representative workers are chosen in a load-balanced manner to "spread" the penalty across all workers and thereby avoid over-penalizing workers who provide labels for a large number of tasks. The net penalty of each worker is the sum of penalties accrued across all (conflict) tasks assigned to this worker. Intuitively, such a hard allocation of penalties will penalize workers with higher degrees (i.e. large number of assigned tasks) and many conflicts (who are potential worst-case adversaries), thereby leading to a low reputation.

To choose representative workers in a load-balanced fashion, we use the concept of *optimal semi-matchings* (Harvey et al., 2003) in bipartite graphs. For a bipartite graph $G = (V_1 \cup V_2, E)$, a *semi-matching* in G is a set of edges $M \subseteq E$ such that each vertex in V_2 is incident to exactly one edge in M (note that vertices in V_1 could be incident to

multiple edges in M). A semi-matching generalizes the notion of matchings on bipartite graphs. The optimal semi-matching is the semi-matching with the minimum *cost*. We use the common degree-based cost function defined as follows: for each $u \in V_1$, let $deg_M(u)$ denote the *degree* of u, that is, the number of edges in M that are incident to u, and let $cost_M(u)$ be defined as

$$cost_M(u) := \sum_{i=1}^{deg_M(u)} i = \frac{deg_M(u) \cdot (deg_M(u)+1)}{2}$$

Then, an *optimal semi-matching* is one that minimizes $\sum_{u \in V_1} cost_M(u)$. Intuitively, an optimal semi-matching *fairly* matches V_2 vertices across V_1 vertices such that the "load" on any V_1 vertex is minimized. The above notion of cost is motivated by the load balancing problem for scheduling tasks on machines. Specifically, consider a set of unit-time tasks T and a set of machines P. Suppose that each task t can be processed on a subset of machines; this can be specified as a bipartite graph between T and P. On any given machine, the tasks are executed one after the other in series. An optimal semi-matching can be thought of as an assignment of tasks to the machines such that the *flow-time*, that is, average completion time of a task, is minimized. See (Harvey et al., 2003) for more details.

To determine the representative workers for each task, we compute the optimal semi-matching in the following augmented worker-task assignment graph: we split each task t_j into two copies, t_j^+ and t_j^-, and connect worker w_i to t_j^+ or t_j^- depending on whether this worker labeled the task $+1$ or -1, respectively. By definition, the optimal semi-matching yields two representative workers for each task t_j—one connected to t_j^+ and the other connected to t_j^-. As in the soft-penalty algorithm, we only consider conflict tasks when creating this augmented bipartite graph. The worker degrees in the optimal semi-matching then constitute their net penalties. Algorithm 2 describes the hard-penalty algorithm.

3.3 Connection between soft-penalty and hard-penalty algorithms

Although the hard- and soft-penalty algorithms appear different, the latter can be interpreted as a random, normalized variant of the former. Specifically, suppose we choose a random semi-matching M in the augmented worker-task assignment graph $\mathcal{B}^{cs}$, defined in Algorithm 2, and assign the penalty $deg_M(w_i)/deg_{\mathcal{B}^{cs}}(w_i)$ to worker w_i, where $deg_{\mathcal{B}^{cs}}(w_i)$ is the degree of worker w_i in $\mathcal{B}^{cs}$. When the random semi-matching is constructed by mapping each copy t_j^+ (or t_j^-) of task t_j uniformly at random to a worker connected to it, the probability that it will be mapped to worker $w_i \in W_j$ is equal to $1/deg_{\mathcal{B}^{cs}}(t_j^+)$ (or $1/deg_{\mathcal{B}^{cs}}(t_j^-)$), or equivalently, $1/d_j^+$ (or $1/d_j^-$). Therefore, the expected degree $\mathbb{E}[deg_M(w_i)]$ of worker w_i is equal to $\sum_{t_j \in \mathcal{T}_i \cap \mathcal{T}_{cs}} s_{ij}$, where $s_{ij} = 1/d_j^+$ if $\mathcal{L}_{ij} = +1$ and $1/d_j^-$ if $\mathcal{L}_{ij} = -1$. Because the degree $deg_{\mathcal{B}^{cs}}(w_i)$ of worker w_i is equal to $|\mathcal{T}_i \cap \mathcal{T}_{cs}|$, it follows that the expected penalty of worker w_i is equal to $\mathbb{E}[deg_M(w_i)]/deg_{\mathcal{B}^{cs}}(w_i) = \sum_{t_j \in \mathcal{T}_i \cap \mathcal{T}_{cs}} s_{ij} / |\mathcal{T}_i \cap \mathcal{T}_{cs}|$, which is exactly the penalty allocated by the soft-penalty algorithm. It thus follows that the expected penalties under the above random, normalized variant of the hard-penalty algorithm are equal to the penalties allocated by the soft-penalty algorithm. When all workers are assigned the same number of tasks, the expected penalty assigned by the random hard-penalty algorithm is equal to the penalty assigned by the soft-penalty algorithm, but scaled by a constant factor.

With the above interpretation of the soft-penalty algorithm, it follows that the hard-penalty algorithm differs from the soft-penalty algorithm in two key aspects: it (a) does not normalize the penalties by degrees and (b) uses optimal semi-matchings as opposed to random semi-matchings. The absence of degree-based normalization of the penalties results in significant penalization of high-degree workers. The use of the optimal semi-matching results in a more balanced allocation of penalties by optimizing a global objective function. Both of these effects make the hard-penalty algorithm conservative and robust to sophisticated adversary strategies, as established theoretically in Section 4. The above connection also suggests that the random, normalized variant of the hard-penalty algorithm should have performance similar to that of the soft-penalty algorithm. We explore this aspect theoretically at the end of Section 4.1.

4. Theoretical Results

Our reputation algorithms are analytically tractable, and we establish their theoretical properties below. Our analysis is aimed at deriving the conditions under which our algorithms separate adversaries from honest workers. We use uppercase boldface letters (say, $\boldsymbol{X}$) to denote random variables, unless it is clear from the context. The proofs of all results are given in Appendix A.

4.1 Soft-penalty algorithm: common adversary strategies

First, we analyze the performance of the soft-penalty algorithm. We assume that honest workers adopt the one-coin model, where each worker w is characterized by parameter $\mu_w \in [0,1]$ that specifies the probability that w provides the correct response for any task. We choose this model because it is the simplest non-trivial model to analyze, and it has been widely studied in existing literature (Ghosh et al., 2011; Dalvi et al., 2013; Karger et al., 2014; Zhang et al., 2014; Gao and Zhou, 2016). We focus on two settings: (a) the classical setting in which there are no adversaries ($A = \emptyset$) and (b) the setting in which adversaries adopt the Uniform strategy.

Definition 1 (Uniform strategy) *Every adversarial worker provides the same $+1$ response to all tasks assigned to it.*

We consider the Uniform strategy because of its ubiquity and simplicity. It is commonly observed in practice (Vuurens et al., 2011), and our analysis of real-world datasets (discussed in detail in Section 5) reveals that a significant fraction of workers ($\approx 30\%, 17\%$, and 9% of workers in the `stage2, task2`, and `temp` datasets, respectively) provide uniform labels for all assigned tasks. Note that it is not captured by the standard one-coin model, in which workers assign the label y_j or $-y_j$ to task t_j, where y_j is the true label. It can be adopted by both "lazy" and "smart" adversaries. Lazy workers adopt this strategy to maximize the number of tasks they label and the corresponding payment they obtain. Smart adversaries adopt this strategy if it is known a priori that the prevalence (or proportion) γ of tasks with true labels $+1$ is large, say, above 90%. For instance, medical images showing tumors contain a large proportion of benign ones and a correspondingly small proportion of malignant ones,

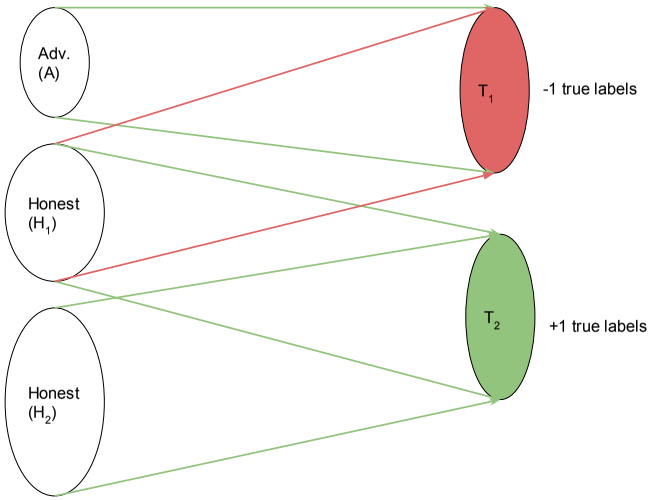

Figure 1: Example where filtering workers who give only +1 labels performs poorly

leading a "smart" worker to label all assigned images as benign without carefully considering each image. Therefore, the Uniform strategy actually comprises a spectrum of strategies of varying degrees of "smartness", with higher values of γ indicating smarter strategies.

A natural way to identify adversaries who adopt the Uniform strategy is to classify all workers who have labeled *all* assigned tasks +1 as adversaries. However, we show that this approach can have arbitrarily large *misclassification rate*, because it may misclassify almost all (asymptotic fraction approaching 1) perfectly reliable honest workers as adversarial.

Lemma 2 (Hardness of identifying Uniform adversarial workers) *Consider a simple binary classifier $\hat{\boldsymbol{I}}_{\text{natural}}(\cdot)$ as follows:*

$$\hat{\boldsymbol{I}}_{\text{natural}}(w_i) = \begin{cases} \textit{adversarial}, & \textit{if } w_i \textit{ gives all } +1 \textit{ labels} \\ \textit{honest}, & \textit{o.w.} \end{cases}$$

Then, the misclassification rate, that is, fraction of incorrectly classified workers, of the above classifier can be arbitrarily close to 1.

Proof Suppose the collection of tasks partitions into two sets, T_1 and T_2, consisting of tasks that have true labels -1 and $+1$, respectively (see Figure 1). The adversary A follows the Uniform strategy and labels all tasks in T_1 as $+1$. There are two groups of honest workers—H_1 and H_2—who are perfectly reliable, that is, they always provide the correct label. The workers in H_1 label all tasks in $T_1 \cup T_2$, and workers in H_2 label only the tasks in T_2. Now, because honest workers H_2 give only +1 labels, the classifier $\hat{\boldsymbol{I}}_{\text{natural}}$ misclassifies

all honest workers in H_2 as adversaries. In other words, we have

$$\frac{1}{|H_1 \cup H_2|} \sum_{h \in H_1 \cup H_2} \mathbf{1}\left[\hat{\boldsymbol{I}}_{\text{natural}}(h) \neq \textit{honest}\right] = \frac{|H_2|}{|H_1 \cup H_2|}$$

where $\mathbf{1}[\cdot]$ denotes the indicator function. Suppose H_2 comprises a large fraction of honest workers, that is, $|H_2| = (1-\rho)\,|H_1 \cup H_2|$ for some "small" $\rho > 0$. Then, it follows from the above equation that the misclassification rate of the natural classifier $\hat{\boldsymbol{I}}_{\text{natural}}(\cdot)$ is $1-\rho$, which can be arbitrarily close to 1. ■

The above lemma shows that the problem of identifying adversaries is nontrivial even for the Uniform strategy case, and our analysis below provides precise conditions under which we can identify such adversarial workers. In particular, for the the scenario outlined in the proof above, our soft-penalty algorithm assigns a penalty of $\frac{1}{|A|}$ to adversaries, $\frac{1}{|H_1|}$ to honest workers in H_1, and zero penalty to honest workers in H_2 (because they are not part of any conflicts). Consequently, as long as $|H_1| > |A|$, our algorithm correctly separates out honest workers from adversaries by choosing a threshold $\theta \in \left(\frac{1}{|H_1|}, \frac{1}{|A|}\right)$ and classifying all workers with penalty $> \theta$ as adversarial.

Because the performance of the algorithm depends on the specific crowdsourced classification instance (worker-task assignment graph, true task labels, reliabilities of honest workers), we conduct a probabilistic analysis under a natural generative model. For our analysis, we focus on worker-task assignment graphs $\mathcal{B}$ that are (l, r)-regular, in which each worker is assigned l tasks and each task is labeled by r workers. These assignment graphs are analytically tractable and have been shown by Karger et al. (2014) to achieve order-optimal performance (with respect to the best combination of task assignment and inference algorithm) when given a certain budget for task assignment. To generate the crowdsourcing instance, we use the probabilistic model of crowdsourced labeling proposed by Karger et al. (2014) but extended to incorporate adversarial workers:

Generative model. Suppose the fraction $q \in (0, 1]$ of honest workers, number of tasks m, number of workers n, worker degree $l > 1$, and task degree $r > 1$ are fixed. Let $\gamma \in [0, 1]$ denote the prevalence (or proportion) of tasks with true labels $+1$ and $F(\cdot)$, the cumulative distribution function (CDF) of the honest worker reliabilities under the one-coin model, with $\mu \in [0, 1]$ denoting the mean. Sample a crowdsourced classification instance as follows:

1. *Worker-task assignment graph:* Assign m tasks to n workers using the *configuration model*—take $n \cdot l$ half-edges for worker nodes and $m \cdot r$ half-edges for the task nodes, pick a random permutation of worker half-edges, and map them to task half-edges.

2. *True task labels:* For each task t_j, sample the true label $\boldsymbol{Y}_j \in \{-1, +1\}$ independently according to the Bernoulli distribution with $\Pr[\boldsymbol{Y}_j = +1] = \gamma$.

3. *Worker identities:* For each worker w_i, set its identity to *honest* with probability q and *adversarial* with probability $1 - q$.

4. *Honest worker reliabilities and responses:* If w_i is honest, sample its reliability $\boldsymbol{M}_i = \mu_i$ from the distribution $F(\cdot)$. For each task t_j assigned to w_i, set the response $w_i(t_j)$ to $\boldsymbol{Y}_j$ with probability μ_i and $-\boldsymbol{Y}_j$ with probability $1 - \mu_i$.

5. *Adversarial worker responses:* If w_i is adversarial, set the response $w_i(t_j) = +1$ for all tasks t_j assigned to w_i.

The above generative model may be justified as follows. First, the *configuration model* is a simple random construction to generate graphs that is popular in random graph literature (Bollobás, 2001). It may result in a graph with multi-edges (where two nodes are connected by more than one edge); however, the number of double-edges converges to a Poisson distribution with mean $(l-1)(r-1)/2$ (see Bollobás, 2001). Therefore, the proportion of nodes with multi-edges is $\approx lr/n$, which tends to zero as $n \to \infty$ as long as $l = o(n)$ and r is constant.

The model for true task labels, worker identities, and reliabilities may be justified by supposing that the m tasks $\mathcal{T} = \{t_1, \ldots, t_m\}$ are drawn from a "large" population of tasks with a prevalence γ of $+1$ tasks and workers are drawn from a "large" population with a proportion $1-q$ of adversaries and a proportion q of honest workers, whose reliabilities have the distribution $F(\cdot)$. Then, the distributional assumptions for the true task labels, worker identities, and honest worker reliabilities will be met when the task assignment is randomized and there is no distinction between sampling with and without replacement because of the large population sizes. The model for generating honest worker responses is the standard one-coin model. See Karger et al. (2014) for a detailed discussion of the settings under which the above probabilistic model is reasonable.

For our theoretical analysis, we assume that non-conflict tasks (with all $+1$ or -1 labels) are *not* ignored/dropped for the purposes of penalty computation. This assumption makes the analysis less cumbersome and may be justified by noting that for a large enough r, the probability that a task will be non-conflict is low. Even if a task is non-conflict, we expect little impact from its inclusion because the penalty from this task will be $1/r$, which is negligible for large values of r. We also tested this assertion numerically and observed negligible differences in the performances of the two variants (with and without dropping high-degree non-conflict tasks) of the soft-penalty algorithm (see Section 5).

4.1.1 Analysis of expected penalties

We first analyze the expected penalties received by honest and adversarial workers under the abovementioned generative model and identify the conditions for population parameters q, μ, and γ under which honest workers receive lower expected penalties. Let $\mathbf{PEN}_i$ denote the penalty assigned by the soft-penalty algorithm to worker w_i; note that it is a random variable under the abovementioned generative model.

First, we focus on the classical setting in which there are no adversarial workers; therefore, $A = \emptyset$. We obtain the following result:

Theorem 3 (Reputations consistent with reliabilities) *When $q = 1$ (i.e., there are no adversarial workers) and $\mu > \frac{1}{2}$, we have*

$$\mathbb{E}\left[\mathbf{PEN}_i \mid \boldsymbol{M}_i = \mu_1\right] < \mathbb{E}\left[\mathbf{PEN}_i \mid \boldsymbol{M}_i = \mu_2\right] \iff \mu_1 > \mu_2$$

for any worker w_i.

Theorem 3 shows that the expected reputation scores are consistent with honest workers' reliabilities: as the honest worker's reliability decreases, the expected penalty increases,

that is, the expected reputation score decreases. As honest worker reliabilities capture their propensities to make mistakes, our algorithm flags workers who are prone to making mistakes, as desired. Consequently, filtering out low-reputation workers filters out workers with low reliabilities (we make this claim precise in Section 4.1.2 below).

Next, we consider the case in which $A \neq \emptyset$ and there is a fraction $1-q$ of workers who are adversarial and adopt the Uniform strategy. Let p_h and p_a denote the expected penalties that a worker receives conditioned on being honest and adversarial, respectively, that is,

$$p_h = \mathbb{E}\left[\mathbf{PEN}_i \mid w_i \text{ is honest }\right] \quad \text{and} \quad p_a = \mathbb{E}\left[\mathbf{PEN}_i \mid w_i \text{ is adversarial }\right]$$

Because of symmetry, these expectations do not depend on worker indices. Then, we obtain the following result:

Theorem 4 (Penalties under Uniform strategy) *When $q < 1$, $\mu > \frac{1}{2}$, and the adversaries adopt the* Uniform *strategy, we obtain*

$$p_h < p_a \iff \left(q\mu > \frac{1}{2} \quad \text{and} \quad \frac{\mu}{1-\mu} \cdot h(\mu, q) > \frac{\gamma}{1-\gamma}\right)$$

where $h(\mu, q)$ is a strictly increasing function in q for a fixed μ, and it is defined as

$$h(\mu, q) = \frac{g(1-Q) - g(Q)}{g(P) - g(1-P)} \text{ where } P := q\mu + (1-q), Q := 1 - q\mu, \text{ and } g(x) := \frac{1-x^r}{r \cdot (1-x)}.$$

The above result reveals the conditions for the parameters q, μ, and γ under which the soft-penalty algorithm is successful in assigning lower penalties to honest workers than to adversaries.

To understand this, we first focus on the condition $q\mu > 1/2$. Note that because $\mu \leq 1$, this condition implies that the population must consist of more honest workers than adversaries ($q > 1/2$). This is because our algorithm is designed to identify "outlier" response patterns—those which deviate from the majority—and for adversaries to be declared outliers, they must necessarily be in the minority.

Furthermore, note that the necessary condition $\mu > 1/(2q)$ implies that for our algorithm to be successful, the average reliability μ of the honest workers must be "large enough"; specifically, it must exceed $\frac{1}{2q}$ (for a fixed q). To obtain an intuitive understanding of this condition (the proof is given in Appendix A.1.2), note the following. Consider a task with true label $+1$. Then, in expectation, there are $rq\mu$ honest workers and $(1-q) \cdot r$ adversaries who provide the response $+1$ and $rq \cdot (1-\mu)$ honest workers who provide the response -1. Now, the adversaries will agree with the majority if and only if $r \cdot (q\mu + (1-q)) \geq rq \cdot (1-\mu)$, that is, $\mu \geq 1 - 1/(2q)$. Similarly, when the true label of a task is -1, then in expectation, there are $r \cdot (q \cdot (1-\mu) + (1-q))$ workers providing $+1$ label and $rq\mu$ workers providing -1 label. Again, the adversaries will be in the majority in expectation if and only if $\mu \leq 1/(2q)$. It thus follows that if $\mu \in [1 - \frac{1}{2q}, \frac{1}{2q}]$, then the adversaries are always in majority in expectation, and therefore, they will receive a lower penalty. Because $\mu > 1/2$ and $1 - \frac{1}{2q} \leq 1/2$, a necessary condition for the worker to receive a lower penalty when being honest is therefore $\mu > \frac{1}{2q}$, that is, $q\mu > \frac{1}{2}$.

Now assuming that the first condition is met, that is, $q\mu > 1/2$, we focus on the second condition: $\frac{\mu}{1-\mu} \cdot h(\mu, q) > \frac{\gamma}{1-\gamma}$. When $\gamma = 1$, this condition is not met (unless $\mu = 1$), and therefore, honest workers receive higher expected penalties than adversaries. This is because if all tasks have a true label $+1$, then in expectation, there is a fraction $q\mu + 1 - q > 1/2$ (because $q\mu > 1/2$) of workers providing the label $+1$ to each task, implying that the adversaries always agree with the majority label for each task. As a result, our algorithm filters out honest workers; however, it must be noted that adversaries actually have higher (perfect) reliabilities in this special case. Similarly, when $\mu = 1$, that is, honest workers are perfectly reliable, the condition is always met because honest workers are in the majority at each task (in expectation); specifically, when the true label is $+1$, all responses are $+1$, and when the true label is -1, all honest workers (a fraction $q > 1/2$) provide the label -1.

Next, we investigate the performance of our algorithm as the adversary strategies become "smarter". As noted above, the Uniform strategy comprises a spectrum of strategies of varying degrees of "smartness", with higher values of γ indicating smarter strategies.

Corollary 5 (Penalties under smarter adversary strategies) *Suppose $\mu > \frac{1}{2}$ is fixed and $q\mu > \frac{1}{2}$. Then, it follows that*

$$p_h < p_a \iff q > h_\mu^{-1}\left(\frac{\gamma}{1-\gamma}\right)$$

where $h_\mu(q) := \frac{\mu}{1-\mu} \cdot h(\mu, q)$ and $h_\mu^{-1}(\cdot)$ is the inverse of $h_\mu(\cdot)$. In other words, for fixed $\mu > \frac{1}{2}$, we require a minimum fraction of honest workers to ensure that adversaries receive a higher penalty than honest workers, and this fraction increases as γ increases.

The above result shows that as the adversary strategies become smarter, it becomes more difficult to distinguish them from honest workers. Specifically, because $h_\mu^{-1}(\cdot)$ is a strictly increasing function, we require honest workers to have a larger majority as γ increases to ensure that they receive lower expected penalties than adversaries.

4.1.2 Asymptotic identification of adversaries and honest workers

Assuming that the expected penalties of adversaries and honest workers are separated, we now derive the asymptotic error rates, defined as the expected fraction of errors, of the soft-penalty algorithm as $n \to \infty$ when (1) there are no adversaries and (2) adversaries adopt the Uniform strategy.

To analyze the error rates, we consider the following threshold-classifier $\hat{\boldsymbol{I}}_\theta(\cdot)$ based on the soft-penalty algorithm: given a penalty threshold $\theta \in \mathbb{R}$, define the binary classifier

$$\hat{\boldsymbol{I}}_\theta(w_i) = \begin{cases} \text{honest}, & \text{if } \mathbf{PEN}_i \le \theta \\ \text{adversarial}, & \text{o.w.} \end{cases}$$

Let $\boldsymbol{I}(w_i)$ denote the latent true identity of worker w_i. Note that both $\boldsymbol{I}(w_i)$ and $\hat{\boldsymbol{I}}_\theta(w_i)$ are random variables under our generative model.

As above, we first consider the case in which there are no adversaries, that is, $q = 1$, so that $\boldsymbol{I}(w_i) = \textit{honest}$ for all workers w_i. In this case, Theorem 3 shows that workers with

higher reliabilities receive lower expected penalties. Furthermore, we now show that the threshold classifier correctly classifies high-reliability workers as honest with high probability as $n \to \infty$:

Theorem 6 (Identification of high-reliability workers) *Suppose $q = 1$ and $\mu > \frac{1}{2}$. Given $\theta \in (0,1)$ and $\varepsilon \in (0, \frac{1}{\sqrt{2}})$ such that $\theta - \varepsilon \in (g(1-\mu), g(\mu))$, define $\hat{\mu}(\theta) := \frac{g(\mu)+\varepsilon-\theta}{g(\mu)-g(1-\mu)}$, where the function $g(\cdot)$ was defined in Theorem 4. Then, under the generative model, we obtain*

$$\frac{1}{n}\sum_{i=1}^{n} \Pr\left(\hat{\boldsymbol{I}}_\theta(w_i) \neq \boldsymbol{I}(w_i) \text{ and } \boldsymbol{M}_i > \hat{\mu}(\theta)\right) \le \frac{l^2 r^2}{n-1} + \exp\left(-\frac{2l\varepsilon^2}{(1-1/r)^2}\right)$$

When $l = \log n$ and r is fixed, we obtain

$$\frac{1}{n}\sum_{i=1}^{n} \Pr\left(\hat{\boldsymbol{I}}_\theta(w_i) \neq \boldsymbol{I}(w_i) \text{ and } \boldsymbol{M}_i > \hat{\mu}(\theta)\right) = O\left(\frac{1}{n^{2\varepsilon^2}}\right) \text{ as } n \to \infty$$

Theorem 6 provides an upper bound for the *error rate* or *misclassification rate* of the threshold classifier. We say that the classifier makes an *error* if it classifies a worker whose reliability is higher than $\hat{\mu}(\theta)$ as adversarial, and the misclassification rate is defined as the expected fraction of errors. As $n \to \infty$, the first term, $l^2 r^2/(n-1)$, in the error bound goes to 0 as long as $l = o(\sqrt{n})$. With the task degree r fixed, the second term goes to zero as long as $l \to \infty$ when $n \to \infty$. Upon combining these two observations, it follows that taking $l = \log n$ yields the error bound of $O(1/n^{2\varepsilon^2})$ for a fixed $\varepsilon \in (0, \frac{1}{\sqrt{2}})$ and r, as $n \to \infty$. In other words, our result shows that as long as we collect $\log n$ labels from each worker and a fixed number of labels for each task, we will classify workers with reliabilities higher than $\hat{\mu}(\theta)$ as honest with a high probability as $n \to \infty$. Although the number of labels collected from each worker must tend to infinity, it must only grow logarithmically in the total number of workers n. Finally, if the population reliability μ is known, we can determine the value of threshold θ for a given reliability threshold $\hat{\mu}(\theta)$.

The proof of Theorem 6 relies on establishing that the worker penalties are concentrated around their respective expectations, for which we need the worker-task assignment graph $\mathcal{B}$ to be locally tree-like:

Definition 7 (Locally tree-like assignment graphs) *An (l, r)-regular worker-task assignment graph $\mathcal{B}$ is said to be D-locally tree-like at a worker node w_i if the subgraph $\mathcal{B}_{w_i,D}$, consisting of nodes at a distance of at most D from w_i, is a tree.*

For our purposes, it suffices to have $\mathcal{B}_{w_i,2}$ be a tree. Note that the subgraph $\mathcal{B}_{w_i,2}$ consists of the worker node w_i; tasks labeled by w_i, that is, the set $\mathcal{T}_i$; and workers $\bigcup_{j\in\mathcal{T}_i} W_j$ who labeled the tasks in $\mathcal{T}_i$. Karger et al. (2014) show that a random construction of the assignment graph using the configuration model ensures that $\mathcal{B}_{w,2}$ is a tree with a high probability as $n \to \infty$ for a randomly chosen worker w.

Lemma 8 (Random construction ensures local tree-structure) *If $\mathcal{B}$ is random (l, r)-regular constructed according to the configuration model, then for a randomly chosen worker $\boldsymbol{w}$*

$$\Pr\left(\mathcal{B}_{\boldsymbol{w},2} \text{ is not a tree}\right) \le \frac{l^2 r^2}{n-1}$$

The proof of the above lemma is in Appendix A.2.1 and it follows the arguments in Karger et al. (2014). Based on the result of Lemma 8, the proof of Theorem 6 proceeds in two steps. First, whenever the configuration model generates an assignment graph $\mathcal{B}$ that is not locally tree-like, we immediately declare an error, incurring an error probability that is bounded above by $l^2r^2/(n-1)$; this yields the first term in the error bound. Second, when $\mathcal{B}_{w_i,2}$ is indeed a tree, we obtain the second term in the error bound by invoking the following concentration result:

Lemma 9 (Concentration of honest worker penalties) *Suppose that $q = 1$ and $\mathcal{B}_{w_i,2}$ is a tree. Under the generative model and for a fixed reliability $\boldsymbol{M}_i = \mu_i$, given any $\varepsilon > 0$, the penalty assigned to honest worker w_i concentrates as*

$$\Pr\left(\mathbf{PEN}_i \geq \mathbb{E}[\mathbf{PEN}_i \mid \boldsymbol{M}_i = \mu_i] + \varepsilon \,\middle|\, \boldsymbol{M}_i = \mu_i\right) \leq \exp\left(\frac{-2l\epsilon^2}{(1-1/r)^2}\right)$$

Note that the above lemma holds for *any* fixed value of reliability μ_i. The proof of the above result relies on expressing the penalty scores as an average of l random variables and then invoking Hoeffding's concentration bound. The local tree-like property of the assignment graph $\mathcal{B}$ at worker node w_i ensures that the l random variables are mutually independent (which is required for Hoeffding's inequality).

Next, we consider the case in which there is a fraction $1-q$ of workers who are adversaries and adopt the Uniform strategy. Theorem 4 above provides the necessary and sufficient conditions for an honest worker to receive a lower expected penalty than an adversary, that is, for $p_h < p_a$. Under these conditions, we obtain the following result:

Theorem 10 (Identification of honest and adversarial workers) *Suppose $p_h < p_a$ and let $\theta \in (p_h + \varepsilon, p_a - \varepsilon)$ for some ε small enough such that $0 < \epsilon < (p_a - p_h)/2$. Then, under the generative model we obtain*

$$\frac{1}{n}\sum_{i=1}^{n} \Pr\left(\hat{\boldsymbol{I}}_\theta(w_i) \neq \boldsymbol{I}(w_i) \,\middle|\, \boldsymbol{I}(w_i) = \textit{honest}\right) \leq \frac{l^2r^2}{n-1} + \exp\left(-\frac{2l\varepsilon^2}{(1-1/r)^2}\right) + F\left(\hat{\mu}(q,\theta)\right)$$

$$\frac{1}{n}\sum_{i=1}^{n} \Pr\left(\hat{\boldsymbol{I}}_\theta(w_i) \neq \boldsymbol{I}(w_i) \,\middle|\, \boldsymbol{I}(w_i) = \textit{adversarial}\right) \leq \frac{l^2r^2}{n-1} + \exp\left(-\frac{2l\varepsilon^2}{(1-1/r)^2}\right)$$

where $\hat{\mu}(q,\theta)$ is such that $\hat{\mu}(1,\theta) = \hat{\mu}(\theta)$ and $\hat{\mu}(q,\theta) < \mu$ for all $q \in (0,1]$ and $\theta \in (p_h + \varepsilon, p_a - \varepsilon)$.

When $l = \log n$ and r is fixed, we obtain

$$\frac{1}{n}\sum_{i=1}^{n} \Pr\left(\hat{\boldsymbol{I}}_\theta(w_i) \neq \boldsymbol{I}(w_i) \,\middle|\, \boldsymbol{I}(w_i) = \textit{honest}\right) = O\left(\frac{1}{n^{2\varepsilon^2}}\right) + F\left(\hat{\mu}(q,\theta)\right)$$

$$\frac{1}{n}\sum_{i=1}^{n} \Pr\left(\hat{\boldsymbol{I}}_\theta(w_i) \neq \boldsymbol{I}(w_i) \,\middle|\, \boldsymbol{I}(w_i) = \textit{adversarial}\right) = O\left(\frac{1}{n^{2\varepsilon^2}}\right)$$

The precise expression for $\hat{\mu}(q,\theta)$ is involved and is given in Appendix A.2.4. Theorem 10 provides the misclassification rate of our algorithm when the population parameters q, μ, and γ satisfy the conditions of Theorem 4, ensuring that honest workers receive a lower expected penalty than adversaries. Following the arguments from the discussion under Theorem 6 above, it can be seen that when $l = \log n$ and r is fixed, the fraction of adversaries that is misclassified is $O(1/n^{2\varepsilon^2})$. On the other hand, the fraction of honest workers that is misclassified scales as $O(1/n^{2\varepsilon^2}) + F(\hat{\mu}(q,\theta))$. The first term tends to zero as $n \to \infty$. The second term denotes the probability that honest worker reliability is less than or equal to $\hat{\mu}(q,\theta)$. In other words, our algorithm misclassifies low-reliability workers as adversaries. In the special case when all honest workers have the same reliability μ, it immediately follows that the probability density function is a point mass at μ, from which it follows that $F(\hat{\mu}(q,\theta)) = 0$ because $\hat{\mu}(q,\theta) < \mu$. In this case, the misclassification error for the honest workers also tends to zero as $n \to \infty$.

We note that the dependence of the honest worker misclassification rate on $F\left(\hat{\mu}(q,\theta)\right)$ is fundamental to our algorithm. As an example, consider the case when the reliability distribution is a two-point distribution with probability mass μ at 1 and the remaining $1-\mu$ mass at 0. This distribution results in two types of honest workers: workers who always provide the correct response and those that always provide the incorrect response. Note that the average reliability under this distribution is μ. Let p_0 and p_1 denote the expected penalties under our generative model for a worker conditioned on being honest with reliabilities 0 and 1, respectively. Then, it follows from Lemma 19 in the Appendix that

$$\begin{aligned} p_1 &= \gamma \cdot g(1-P) + (1-\gamma) \cdot g(Q) \\ p_a &= \gamma \cdot g(1-P) + (1-\gamma) \cdot g(1-Q) \\ p_0 &= \gamma \cdot g(P) + (1-\gamma) \cdot g(1-Q) \end{aligned}$$

From Theorem 4, it follows that $P > 1/2$ and $Q < 1/2$ is necessary to ensure $p_h < p_a$. Combined with the fact that $g(\cdot)$ is increasing, this implies that $g(Q) < g(1-Q)$ and $g(1-P) < g(P)$. As a result, we obtain $p_1 < p_a < p_0$. It now follows that when $n \to \infty$, the penalties of honest workers with reliability 0 concentrate around p_0, and consequently, they are classified as adversarial whenever the threshold $\theta < p_a$, resulting in a misclassification error of $1-\mu$. However, it should be noted that honest workers classified as adversaries indeed have low reliabilities.

Similar to the proof of Theorem 6 above, the proof of Theorem 10 proceeds in two steps. The first term in the error bound of Theorem 10 comes from Lemma 8 because we immediately declare an error whenever the assignment graph is not locally tree-like. The second term comes from the case when $\mathcal{B}_{w_i,2}$ is indeed a tree by invoking the following concentration result:

Lemma 11 (Concentration of worker penalties) *Suppose that $q < 1$ and $\mathcal{B}_{w_i,2}$ is a tree. Under the generative model, given any reliability value $\hat{\mu} \in (0,1)$ and $\varepsilon > 0$, the penalty assigned to worker w_i concentrates as*

$$\Pr\left(\mathbf{PEN}_i \geq \mathbb{E}[\mathbf{PEN}_i \mid \boldsymbol{M}_i = \hat{\mu}] + \varepsilon \,\middle|\, \boldsymbol{I}(w_i) = \textit{honest}\right) \leq \exp\left(\frac{-2l\epsilon^2}{(1-1/r)^2}\right) + F(\hat{\mu})$$

and

$$\Pr\left(\mathbf{PEN}_i \leq p_a - \varepsilon \;\middle|\; \boldsymbol{I}(w_i) = \textit{adversarial}\right) \leq \exp\left(\frac{-2l\epsilon^2}{(1-1/r)^2}\right)$$

The proof of the above result is similar to that of Lemma 9. For the case of adversarial workers, we use Hoeffding's argument to establish the concentration. For the case of honest workers, the first term follows directly from Lemma 9 when w_i has reliability $\mu_i > \hat{\mu}$ and the second term is the probability that the reliability $\mu_i \leq \hat{\mu}$.

The above results establish that the soft-penalty algorithm successfully identifies low-reliability honest workers and adversaries adopting the Uniform strategy asymptotically with high probability. Note that all results also extend to the random, normalized variant of the hard-penalty algorithm mentioned in Section 3.3, where the expectation is taken over the generative model *and* the randomized hard-penalty algorithm (see Appendix A.3).

We would like to note that similar results can be derived if it is assumed that honest workers employ the two-coin model (instead of the one-coin model assumed in the preceding analysis). However, the precise error bounds require significantly more notation to explain, without adding too much in terms of insights. Instead, we evaluate the performance of our algorithm for the two-coin model in the numerical experiments and show that it is still able to identify uniform adversaries and low-reliability honest workers (see Section 5.1).

4.2 Hard-penalty algorithm: sophisticated adversary strategies

In the preceding analysis, we focused on common adversary strategies in which adversaries were not intentionally malicious. However, existing studies provide ample evidence for the presence of workers with malicious intent in public crowdsourcing systems, where workers choose which tasks to label and the worker labels are public. These workers are usually hired online by an attacker (Wang et al., 2012) to create fake accounts and manipulate ratings/reviews to alter the aggregate ratings or rankings received by tasks. Specific examples include workers on Digg altering the "popularity" of advertisements and phishing articles (Tran et al., 2009), fake review groups collaboratively targeting products on Amazon (Mukherjee et al., 2012), workers providing fake ratings and reviews to alter the aggregate ratings of restaurants on Yelp (Molavi Kakhki et al., 2013), and malicious crowd behavior in online surveys (Gadiraju et al., 2015). Refer to the recent work by Wang et al. (2014) for more examples. Motivated by these examples, we study settings with *sophisticated adversaries*, who are defined as follows:

Definition 12 (Sophisticated adversaries) *Sophisticated adversaries provide responses with the objective of maximizing the number of tasks whose inferred labels are different from the labels they would otherwise have received from any label aggregation algorithm. They are computationally unbounded and colluding, and they possess knowledge about the labels provided by honest workers; therefore, they can adopt arbitrary response strategies.*

Our definition allows sophisticated adversaries to not just be malicious but also be capable of executing the most complex strategies. In practice, an adversary may adopt feasible strategies with varying complexities depending on the application context and their objectives. Focusing on the most sophisticated adversary makes our analysis broadly applicable,

independent of the application context. Further, we do not restrict the structure of the worker-task assignment graph because unlike in a crowdsourced-classification task, we have no control on which tasks each worker labels.

We first note that existing label aggregation algorithms can have arbitrarily bad performance in the presence of sophisticated adversaries, even if we assume that all honest workers are perfectly reliable:

Lemma 13 (Hardness of recovering true task labels) *Suppose honest workers are perfectly reliable, that is, they always provide the correct response. Let the assignment graph between honest workers and tasks be such that each task receives responses from at most $r > 1$ honest workers. Suppose there are $k > r$ sophisticated adversaries, and each adversary provides the incorrect label on all tasks. Then, both the simple majority and EM (initialized by majority estimates) label aggregation algorithms output the incorrect label for all tasks.*

Note that the above lemma characterizes the performance of label aggregation algorithms, which are designed to infer true task labels as opposed to identifying adversarial workers. Because sophisticated adversaries aim to maximize the number of tasks whose inferred labels are incorrect, the lemma shows that for standard label aggregation algorithms like simple majority and EM, the adversaries can cause arbitrarily bad "damage". Consequently, in our theoretical analysis below, we focus on the accuracy of label aggregation algorithms in the presence of sophisticated adversaries, as opposed to the misclassification rate, as was done in Section 4.1.

Lemma 13 holds for r-right regular graphs, that is, each task receives exactly r honest worker labels, which are commonly used in practice (see the discussion in Section 4.1). Therefore, standard label aggregation algorithms can have very poor accuracy in recovering true task labels in the presence of sophisticated adversaries. In fact, we can actually establish something much stronger—in the presence of sophisticated adversaries, there exists a lower bound on the number of tasks whose true label cannot be inferred correctly (better than random guess) *irrespective* of the label aggregation algorithm used to aggregate the worker responses.

4.2.1 Lower bound on number of tasks that receive incorrect labels

To state our result, we need the following additional notation. We represent any label aggregation algorithm as a *decision rule* $\boldsymbol{R} : \mathcal{L} \to \{-1, +1\}^m$, which maps the observed labeling matrix $\mathcal{L}$ to a set of output labels for each task. Because of the absence of any auxiliary information about the workers or the tasks, the class of decision rules, say $\mathcal{C}$, is invariant to permutations of the identities of workers and/or tasks. More precisely, $\mathcal{C}$ denotes the class of decision rules that satisfy $\boldsymbol{R}(P\mathcal{L}Q) = \boldsymbol{R}(\mathcal{L})Q$ for any $n \times n$ permutation matrix P and $m \times m$ permutation matrix Q. We say that a task is *affected* if a decision rule outputs the incorrect label for the task, and we define the *quality* of a decision rule $\boldsymbol{R}(\cdot)$ as the *worst-case* number of affected tasks over all possible true labelings of the tasks and adversary strategies given a *fixed* set of honest worker responses. Fixing the responses provided by honest workers allows isolation of the effect of the adversary strategy on the accuracy of the decision rule. Considering the worst-case over all possible true task labelings makes the quality metric robust to ground-truth assignments, which are typically application specific.

To formally define the quality, let $\mathcal{B}_H$ denote the subgraph of the worker-task assignment graph restricted to honest workers H and $\boldsymbol{y} = (y_1, y_2, \ldots, y_m)$ denote the vector of true labels for the tasks. Because the number of affected tasks depends on the actual honest worker responses, we focus on the case when all the honest workers are perfectly reliable, that is, they always provide the correct response. Focusing on completely reliable honest workers allows us to isolate the impact of adversaries because any misidentification is caused by the presence of adversaries. Finally, let $\mathcal{S}_k$ denote the strategy space of $k < |H|$ adversaries, where each strategy $\sigma \in \mathcal{S}_k$ specifies the $k \times m$ response matrix given by the adversaries. Because we do not restrict the adversary strategy in any way, it follows that $\mathcal{S}_k = \{-1, 0, +1\}^{k \times m}$. The *quality* of a decision rule $\boldsymbol{R} \in \mathcal{C}$ is then defined as

$$\mathrm{Aff}(\boldsymbol{R}, \mathcal{B}_H, k) = \max_{\sigma \in \mathcal{S}_k, \boldsymbol{y} \in \{-1,+1\}^m} \left| \left\{ t_j \in \mathcal{T} \colon R_{t_j}^{\boldsymbol{y},\sigma} \neq y_j \right\} \right|$$

where $R_t^{\boldsymbol{y},\sigma} \in \{-1, +1\}$ is the label output by the decision rule $\boldsymbol{R}$ for task t when the true label vector is $\boldsymbol{y}$ and the adversary strategy is σ. Note that our notation $\mathrm{Aff}(\boldsymbol{R}, \mathcal{B}_H, k)$ makes the dependence of the quality measure on the honest worker subgraph $\mathcal{B}_H$ and the number of adversaries k explicit.

We obtain the following result, which establishes a lower bound on the quality of any decision rule:

Theorem 14 (Lower bound on number of affected tasks) *Suppose that $|A| = k$ and all honest workers provide correct responses. Let $\mathrm{PreIm}(\mathcal{T}')$ denote the set of honest workers who label at least one task in $\mathcal{T}' \subseteq \mathcal{T}$. Then, given any honest worker-task assignment graph $\mathcal{B}_H$, there exists an adversary strategy $\sigma^* \in \mathcal{S}_k$ that is independent of any decision rule $\boldsymbol{R} \in \mathcal{C}$, such that*

$$\max_{\boldsymbol{y} \in \{-1,+1\}^m} \mathrm{Aff}(\boldsymbol{R}, \sigma^*, \boldsymbol{y}) \geq L \quad \forall \boldsymbol{R} \in \mathcal{C}, \quad \textit{where}$$

$$L := \frac{1}{2} \cdot \left(\max_{\substack{\mathcal{T}' \subseteq \mathcal{T}: \\ |\mathrm{PreIm}(\mathcal{T}')| \leq k}} |\mathcal{T}'| \right)$$

and $\mathrm{Aff}(\boldsymbol{R}, \sigma^*, \boldsymbol{y})$ denotes the number of affected tasks under adversary strategy σ^*, decision rule $\boldsymbol{R}$, and true label vector $\boldsymbol{y}$ (with the assumption that the maximum over an empty set is zero). In particular, this means that $\mathrm{Aff}(\boldsymbol{R}, \mathcal{B}_H, k) \geq L$ for all decision rules $\boldsymbol{R} \in \mathcal{C}$. In addition, there exist honest worker-task assignment graphs such that σ^* renders the adversaries A indistinguishable from a set of k honest workers, so that a random guess misclassifies $2k$ workers with probability $(1/2)$.

We describe the main idea of the proof. The proof proceeds in two steps: (i) we provide an explicit construction of adversary strategy σ^* that depends only on $\mathcal{B}_H$ and (ii) we show the existence of two possible true labelings $\tilde{\boldsymbol{y}} \neq \boldsymbol{y}$ such that $\boldsymbol{R}$ outputs exactly the same labels in both scenarios. The adversary labeling strategy we construct uses the idea of *indistinguishability*, which captures the fact that by carefully choosing their responses, adversaries can render themselves indistinguishable from honest workers. In the simple case

when there is only one honest worker, the adversary simply flips the response provided by the honest worker, so that each task will have two labels of opposite parity. It can be argued that because there is no other discriminatory information, it is impossible for any decision rule $\boldsymbol{R} \in \mathcal{C}$ to distinguish the honest worker from the adversary and to therefore identify the true label of any task (better than a random guess). We extend this to the general case, where the adversary "targets" at most k honest workers and derives a strategy based on the subgraph of $\mathcal{B}_H$ restricted to the targeted workers. The resultant strategy can be shown to result in incorrectly identified labels for at least L tasks for some ground-truth label assignment.

Note that Theorem 14 holds for *any* honest worker-task assignment graph $\mathcal{B}_H$. This is particularly remarkable given that the analysis of aggregation algorithms becomes extremely complicated for general graphs (a fact observed in previous studies; see Dalvi et al., 2013). The bound L itself depends on the structure of $\mathcal{B}_H$, and therefore, it can be difficult to interpret in general. However, it becomes interpretable for (r, γ, α)-bipartite expanders, as defined next.

Definition 15 (Expanders) *An honest worker-task assignment graph $\mathcal{B}_H = (H \cup \mathcal{T}; E)$, with edges E between the honest workers H and tasks $\mathcal{T}$, is (r, γ, α)-bipartite expander if (i) $\mathcal{B}_H$ is r-right regular, that is, each task is labeled by r honest workers and (ii) for all $\mathcal{T}' \subseteq \mathcal{T}$ such that $|\mathcal{T}'| \leq \gamma |\mathcal{T}|$, the pre-image of $\mathcal{T}'$ satisfies $|\mathrm{PreIm}(\mathcal{T}')| \geq \alpha |\mathcal{T}'|$, where $\mathrm{PreIm}(\mathcal{T}')$ is the set of all honest workers who label at least one task in $\mathcal{T}'$.*

Note that the definition entails that $\alpha \leq r$. We have the following corollary of Theorem 14 when $\mathcal{B}_H$ is (r, γ, α)-bipartite expander.

Corollary 16 (Lower bound for expanders) *Suppose $\mathcal{B}_H$ is (r, γ, α)-bipartite expander. Then, k adversary identities can affect at least L tasks such that $\lfloor \frac{k}{r} \rfloor \leq 2L \leq \lceil \frac{k}{\alpha} \rceil$, provided $\lceil \frac{k}{\alpha} \rceil + 1 < \gamma \cdot |\mathcal{T}|$. Furthermore, given any constant r, there exists $\gamma > 0$ such that a uniformly random $\mathcal{B}_H$ is $(r, \gamma, r-2)$-bipartite expander with probability at least $1/2$, in which case the lower bound $L = \frac{1}{2} \lceil \frac{k}{r-2} \rceil$.*

The proof is provided in Appendix A.5. The above statement says that if the honest worker-task assignment graph $\mathcal{B}_H$ is constructed randomly, then k adversary identities can affect at least $\frac{1}{2} \lfloor \frac{k}{r} \rfloor$ tasks. The bound implies that the ability of the adversaries to affect tasks increases linearly as the number of identities k increases. Further, the damage that k adversaries can do decreases inversely with the number of honest workers r who provide labels for each task. Both implications are intuitive. As can be seen from the proof, the lower bound $\frac{1}{2} \lfloor \frac{k}{r} \rfloor$ on L in Corollary 16 holds for all r-right regular graphs, even if they are not expanders.

Having established the above lower bound and in light of Lemma 13, the natural question to ask is as follows: does there exist a label aggregation algorithm for which we can prove an upper bound on the number of affected tasks, irrespective of the strategy employed by the sophisticated adversaries? Below, we show such a label aggregation algorithm that is a natural extension of the hard-penalty algorithm.

4.2.2 Accuracy of hard-penalty algorithm

We introduce the *penalty-based label aggregation* algorithm (see Algorithm 3) for our analysis, which is a natural extension of the hard-penalty algorithm to also perform label aggregation:

Algorithm 3 penalty-based label aggregation

1: **Input:** W, $\mathcal{T}$, and $\mathcal{L}$
2: Perform steps 2 and 3 of the hard-penalty algorithm
3: For each task t_j, let $w_{t_j^+}, w_{t_j^-}$ be worker nodes that task nodes t_j^+, t_j^- are respectively mapped to in optimal semi-matching $\mathcal{M}$ in Step 2
4: **Output**

$$\hat{y}_j = \begin{cases} +1 & \text{if } deg_{\mathcal{M}}(w_{t_j^+}) < deg_{\mathcal{M}}(w_{t_j^-}) \\ -1 & \text{if } deg_{\mathcal{M}}(w_{t_j^+}) > deg_{\mathcal{M}}(w_{t_j^-}) \\ \leftarrow \{-1,+1\} & \text{otherwise} \end{cases}$$

(here $\hat{y}_j$ refers to the output label for task t_j and $\leftarrow \{-1,+1\}$ means that $\hat{y}_j$ is drawn uniformly at random from $\{-1,+1\}$)

For our analysis, we consider the following model for honest worker responses that is based on the *spammer-hammer* model popularly used in previous studies (Karger et al., 2011; Liu et al., 2012; Ok et al., 2016; Khetan and Oh, 2016): $0 \leq \varepsilon < 1$ fraction of honest workers are "spammers," that is, they make mistakes in their responses, and the remaining $1-\varepsilon$ fraction are "hammers," that is, they are perfectly reliable and always provide the correct response. In the theorem below, $\mathcal{B}_H^{cs}$ refers to the bipartite graph created as follows: (i) each honest worker h is represented by a node on the left; (ii) each task $t_j \in \mathcal{T}$ is represented by (at most) two nodes on the right, t_j^+ and t_j^-; and (iii) add the edge (h, t_j^+) (resp. (h, t_j^-)) if honest worker h labels task t_j as $+1$ (resp. -1). Then, we can show the following:

Theorem 17 (Accuracy of penalty-based label aggregation) *Suppose that $|A| = k$ and let $\varepsilon \in [0,1)$ denote the fraction of honest workers who make mistakes in their responses. Furthermore, let $d_1 \geq d_2 \geq \cdots \geq d_{|H|}$ denote the degrees of honest workers in the optimal semi-matching on $\mathcal{B}_H^{cs}$. For any true labeling $\boldsymbol{y}$ of the tasks and under Algorithm 3 (with the convention that $d_i = 0$ for $i > |H|$):*

1. *If $\varepsilon = 0$, there exists an adversary strategy σ^* such that the number of affected tasks is at least $\frac{1}{2}\sum_{i=1}^{k-1} d_i$*
2. *Assuming that each task receives at least one correct response from the honest workers, no adversary strategy can affect more than U tasks where*
   (a) $U = \sum_{i=1}^{k+\varepsilon\cdot|H|} d_i$, *when at most one adversary provides correct responses*
   (b) $U = \sum_{i=1}^{2k+\varepsilon\cdot|H|} d_i$, *in the general case*

A few remarks are in order. First, it can be shown that for optimal semi-matchings, the degree sequence $d_1, d_2, \ldots, d_{|H|}$ is unique (see the proof in Appendix A.7), and therefore, the bounds in the theorem above are uniquely defined given $\mathcal{B}_H^{cs}$. The result of Theorem 17 provides both a lower and upper bound for the number of tasks that can be affected by k adversaries under the penalty-based label aggregation algorithm, irrespective of the adversary strategy. This is remarkable, especially because we established that existing label aggregation algorithms can be arbitrarily bad (Lemma 13). Assuming honest workers are always correct, that is, $\varepsilon = 0$, our characterization is reasonably tight when all but (at most) one adversary provide incorrect responses. In this case, the gap between the upper and a constant factor of the lower bound is d_k, which can be "small" for large enough k. However, our characterization is loose in the general case when adversaries can provide arbitrary responses. Here, the gap is $\sum_{i=k}^{2k} d_i$; we attribute this to our proof technique and conjecture that the upper bound of $\sum_{i=1}^{k} d_i$ also applies to the more general case. When $\varepsilon > 0$, the upper bound U increases because there are more incorrect responses and, in turn, the scope for adversaries to affect a larger number of tasks.

One might wonder whether we could perform a similar analysis for the case when honest workers follow the one-coin model. Given the complexity of analyzing optimal semi-matchings, our current proof technique does not readily extend to this scenario, and therefore, there is an opportunity to improve the analysis in future work.

Optimality of penalty-based label aggregation. We now compare the upper bound U in Theorem 17 to the lower bound L in Theorem 14 in the case when honest workers are perfectly reliable, that is, $\varepsilon = 0$. We show that (see Appendix A.8) when the degrees $d_1, d_2, \ldots, d_{|H|}$ are all distinct, $L \geq \frac{1}{2}\sum_{i=1}^{k-1} d_i$. Combined with Theorem 14, this shows that k adversaries can affect at least $\frac{1}{2}\sum_{i=1}^{k-1} d_i$ tasks *irrespective* of the label aggregation algorithm used to aggregate the worker responses. From Theorem 17, we also have that under the penalty-based label aggregation algorithm, k adversaries can affect at most $U = \sum_{i=1}^{2k} d_i \leq 3(\sum_{i=1}^{k-1} d_i)$ tasks (as long as $k \geq 2$). Therefore, our algorithm achieves constant factor optimality in recovering the true labels of tasks *irrespective* of the adversary's strategy.

5. Numerical analysis

We conducted two empirical studies to demonstrate the practical value of our methods. The first study illustrates a concrete real-world application of our methodology. By using standard crowdsourcing datasets (as described below), it shows that filtering out the adversaries identified by our methods allows existing label aggregation algorithms to infer true task labels more accurately. Such improvements in accuracy by *discarding* labels from certain workers suggests that their label patterns do not conform to standard probabilistic assumptions. Although not illustrated in our study, instead of being filtered out, the adversary labels may also be used by fitting a model different from that of honest workers in applications where such assumptions are reasonable. The second study is designed to assess the ability of our methods to successfully identify adversaries and low-reliability honest workers. It is a simulation study in which we injected a standard crowdsourcing task with "spammers" (workers who label a task $+1$ and -1 with probability $1/2$ each irrespective of the true label) and workers adopting the Uniform strategy. It demonstrates that both soft- and hard-penalty algorithms successfully identify adversaries and low-reliability

honest workers when the worker-task assignment graph has a power-law degree distribution for workers and tasks, thus complementing the results in Section 4.1 which focused on (l, r)-regular worker-task assignment graphs.

For the purposes of our studies, we focused on the following six label aggregation algorithms: (a) simple majority algorithm MV; (b) EM algorithm for the two-coin model (Raykar and Yu, 2012); (c) KOS algorithm (Karger et al., 2014); (d) KOS(NORM), a normalized variant of KOS in which messages are scaled by the corresponding worker and task degrees to account for non-regular node degrees in the assignment graph (see Appendix B for the precise description); (e) SPEC-EM, the spectral EM algorithm of Zhang et al. (2014); and (f) MMCE, the regularized minimax conditional entropy approach of Zhou et al. (2015). We implemented both variants of our reputation algorithm: (a) soft-penalty (SOFT) and (b) hard-penalty (HARD). As removing workers alters the penalties of the remaining workers, we filtered the workers iteratively. In each iteration, we recomputed the penalties of the remaining workers, removed the worker with the highest penalty, and repeated until a prespecified number of workers was removed. [7]

Finally, as mentioned in Section 4.1, we implemented two variants of the soft-penalty algorithm: one in which non-conflict tasks are dropped for assigning worker penalties and another in which they are retained. The results were essentially the same, so we only report the results for the variant in which the non-conflict tasks were dropped.

Dataset	Workers	Tasks	Responses
rte	164	800	8000
temp	76	462	4620
stage2	68	711	2035
task2	386	2269	12435
tweets	66	1000	4977

Table 1: Summary of real datasets used in the experiments

5.1 Accuracy improvements on real-world crowdsourcing datasets

We focused on the following standard datasets:

- `stage2` and `task2`: consisting of a collection of topic-document pairs labeled as relevant or non-relevant by workers on Amazon Mechanical Turk (see Tang and Lease, 2011). These datasets were collected as part of the TREC 2011 crowdsourcing track.
- `rte` and `temp`: consisting of annotations by Amazon Mechanical Turk workers for different natural language processing (NLP) tasks. `rte` consists of binary judgments for textual entailment (whether one sentence can be inferred from another) and `temp` for temporal ordering of events (see Snow et al., 2008).
- `tweets`: consisting of sentiment (positive or negative) labels for 1000 tweets (see Mozafari et al., 2014).

7. The performance was similar for the non-iterative variant discussed in Section 3—we report the results for the iterative version because it had marginally better performance.

As inferring the reliabilities of workers who labeled very few tasks [8] is difficult, we preprocessed the datasets to remove all workers who labeled less than three tasks. Table 1 shows summary statistics of the datasets after our preprocessing.

Table 2 reports the accuracies of various label aggregation algorithms for inferring true task labels. For each benchmark label aggregation algorithm, the column BASE reports the accuracy of the algorithm in isolation. The columns SOFT and HARD report the best accuracy of the algorithms for filtering $k = 1, 2, \ldots, 10$ workers using the soft- and hard-penalty algorithms, respectively; the numbers in parentheses indicate the k value for which we observed the best performance. [9]

Algorithm	rte			temp			stage2			task2			tweets		
	BASE	SOFT	HARD	BASE	SOFT	HARD	BASE	SOFT	HARD	BASE	SOFT	HARD	BASE	SOFT	HARD
MV	91.9	92.1(7)	**92.5(3)**	93.9	93.9	**94.4(5)**	74.3	75.4(1)	**80.5(2)*****	64.2	64.2	**67.8(10)*****	69.6	69.8(4)	**73.3(1)*****

MMCE	92.5	92.9(9)	**93.2(3)**	94.4	94.4	94.4	57.0	58.5(5)	**73.3(10)*****	66.1	66.1	**66.9(10)**	72.7	72.7	72.7

Table 2: **Percentage accuracy** in recovering true labels of benchmark algorithms in isolation and when combined with our modified reputation algorithms. For each benchmark, the best-performing combination is highlighted in bold. The number in parentheses represents the number of workers filtered by our reputation algorithm (an absence indicates that no performance improvement was achieved while removing upto 10 workers with the highest penalties). The p-values, according to a two-sided paired t-test, are denoted as * $p < 0.1$, ** $p < 0.05$, and *** $p < 0.01$.

The key conclusion we draw is that filtering out workers flagged by our algorithms as adversaries boosts the predictive accuracy of state-of-the-art aggregation algorithms significantly across the datasets: the average improvement in accuracy for MV is 3.7%, EM is 3.4%, KOS is 30.2%, KOS(NORM) is 4.4%, SPEC-EM is 12.6%, and MMCE is 4.7% when using the hard-penalty algorithm. The improvement is large for KOS because it is designed for regular graphs (with all workers having the same degree and all tasks having the same degree) and suffers in performance on real-world graphs that are not regular. Second, we note that our methods can boost the performance of the MV and KOS algorithms to the level of the popular EM algorithm. The MV algorithm is simple to implement, and the KOS algorithm is designed for scenarios where the underlying assignment graph is random (l, r)-regular and has strong theoretical guarantees and robustness to different initializations (Karger et al., 2014). Our results suggest that implementing the MV and KOS algorithms in conjunction with our reputation algorithms can allow us to obtain their respective simplicity and robustness along with strong practical performance (even for irregular graphs) comparable

8. The datasets `stage2`, `task2`, and `tweets` contain several workers who provided responses for only a single task.
9. The performance was robust to the choice of k. We matched or improved the accuracy of the underlying label aggregation algorithm in 66% and 70% of cases on average for the soft- and hard-penalty algorithm, respectively.

to that of the EM algorithm. [10] Finally, because discarding the labels of certain workers improves the predictive accuracy, our results suggest that standard probabilistic models (including the two-coin model) are insufficient to capture the labeling patterns of workers in real-world datasets.

To gain insights into the types of workers identified by our algorithms, we conducted a qualitative analysis of the labeling patterns of the workers that were filtered out. We observed the following key types:

1. Workers who labeled at least 10 tasks, of which more than 95% had the same label. For instance, our algorithms detected six such workers in the `temp` dataset, five in the `task2` dataset, and one in the `tweets` dataset. For the `stage2` dataset, we detected two workers who gave all $+1$ labels and one worker who gave all but a single response as -1; it should be noted that the empirically calculated prevalence γ of $+1$ tasks in the `stage2` dataset was 0.83, potentially suggesting that the two workers who gave all $+1$ labels were adopting "smart" strategies.

2. Workers who provide labels independent of true task labels. For instance, we detected four such workers in the `rte` dataset, seven workers in the `temp` dataset, seven in the `task2` dataset, three in the `stage2` dataset, and one in the `tweets` dataset, whose label patterns are such that the empirical fractions $\hat{\alpha}$ and $\hat{\beta}$ of correct responses among the tasks with true labels $+1$ and -1, respectively, satisfy $|\hat{\alpha}+\hat{\beta}-1| \leq 0.05$. Raykar and Yu (2012) showed that such workers effectively assign a label of $+1$ with probability $\hat{\alpha}$ and -1 with probability $1-\hat{\alpha}$ independent of the true task label.

3. Workers with skewed reliabilities. Such workers were accurate on tasks with one type of true label, say, $+1$, but not on others, say, tasks with true label -1. Such label patterns of workers may be indicative of tasks that require subjective assessments. For instance, we found four workers in the `tweets` dataset and two workers in `stage2` dataset that had skewed reliabilities. In the `tweets` dataset, workers were asked to rate the sentiment of a tweet as being positive or negative. As the notion of tweet sentiment can be subjective, workers with biased views of the sentiment make systematic errors on one type of task. A similar explanation applies to the `stage2` dataset, in which workers were asked to label a topic-document pair as relevant or not, requiring a potentially subjective assessment. See Kamar et al. (2015) for more examples.

In summary, our reputation algorithms are successful in identifying adversarial workers adopting a broad set of strategies. Furthermore, although not reported, the empirical reliabilities of the workers filtered out using our algorithms were on average *lower* than those of unfiltered workers. This suggests that the labels our algorithms discard are from low-reliability workers who provide little to no information about the true task labels; this explains the improved accuracy we obtain.

10. Note that the EM algorithm can also have theoretical guarantees with appropriate initializations (see Gao and Zhou, 2016 and Zhang et al. 2014).

5.2 Identifying low-reliability honest workers and adversaries

We use a simulation study to show that our reputation algorithms successfully identify low-reliability honest workers and adversaries when the worker-task assignment graphs have power-law degree distributions for the worker and task nodes. Such graph structures are common in many real-world crowdsourcing scenarios (Franklin et al., 2011). The results of the simulation study complement the theoretical results presented in Section 4.1 for (l, r)-regular assignment graphs, which show that the soft-penalty algorithm successfully identifies low-reliability honest workers and adversaries adopting the Uniform strategy.

For our study, we used the following broad procedure: (a) generate a random crowdsourcing instance from the ground-truth model, (b) generate synthetic responses from the workers for a sample of tasks, (c) filter out workers with the highest penalties according to our reputation algorithms, and (d) compute the *precision*, that is, the fraction of filtered-out workers who are adversarial and who have low empirical reliabilities.

Setup of study. We considered a total of $n = 100$ workers. The probability q that a worker is honest was set to 0.7; therefore, on average, there are 30 adversaries among the 100 workers. The prevalence γ of $+1$ tasks was set to 0.5. We sampled worker degrees according to a power-law distribution (with exponent $a = 2.5$) with the minimum degree equal to 5, and then, we used the Python networkx library (Hagberg et al., 2008) to generate the worker-task assignment graph.[11] Note that the number of tasks m is determined from the total number of workers and the sampled worker degrees.

As the worker degrees are skewed, the performance of the algorithms is influenced by the adversary degrees. To capture this, we considered two scenarios: (a) adversaries have high degrees and (b) adversaries have low degrees. To ensure that adversaries on average have high degrees, we set worker w in the sampled worker-task assignment graph to be honest with probability $q_w = q \cdot (d_{\max} - d_w)/(d_{\max} - d_{\text{avg}})$ and to be adversarial with probability $1 - q_w$, where d_w is the degree of worker w and $d_{\max}$, $d_{\min}$, and d_{avg} are the maximum, minimum, and average degrees, respectively. Similarly, to ensure that adversaries on average have lower degrees, we set $q_w = q \cdot (d_w - d_{\min})/(d_{\text{avg}} - d_{\min})$. See Appendix B for details.

For each scenario, after the worker-task assignment graph and worker identities were sampled, we generated the crowdsourcing instances as follows: (a) set the true label y_j of each task t_j to be $+1$ with probability $1/2$ and -1 with probability $1/2$; (b) for each honest worker w, sample its reliability μ_w u.a.r from the interval $[0.8, 1.0)$, and set its response to each assigned task t_j to be the true label y_j with probability μ_w and $-y_j$ with probability $1-\mu_w$; and (c) generate responses from adversarial workers according to the chosen strategy. We focused on two adversary strategies: (a) Spammer—label each task $+1$ or -1 with prob. $1/2$ and (b) Uniform—label every assigned task $+1$. The first strategy reflects the setting of Theorem 3 because it is captured by the one-coin model, and the second strategy reflects the setting of Theorem 4.

Results. Table 3 reports the *precisions* of the SOFT and HARD algorithms when (iteratively) removing 10 workers. The precision is defined as the fraction of filtered-out workers who are either adversarial or honest with empirical reliabilities less than 0.85 (which is less

11. Specifically, we used the following function: `https://networkx.github.io/documentation/networkx-1.10/reference/generated/networkx.algorithms.bipartite.generators.preferential_attachment_graph.html`.

	Spammer		Uniform	
	Low Deg	High Deg	Low Deg	High Deg
SOFT	**90.03**	88.70	**77.13**	69.57
HARD	89.00	**93.83**	73.43	**76.73**

Table 3: The *precisions* of the soft- and hard-penalty algorithms in identifying low-reliability honest workers and adversaries when filtering 10 workers. The rows SOFT and HARD correspond to the soft- and hard-penalty algorithms, respectively. The columns Spammer and Uniform correspond to the two adversary strategies, and for each adversary strategy, the columns "Low Deg" and "High Deg" refer to the scenarios in which low- and high-degree workers, respectively, are more likely to be adversaries. Refer to the text for more details.

than the mean $\mu = 0.9$ of the honest worker reliability distribution), where the empirical reliability of an honest worker is equal to the fraction of its responses that were correct. The table reports the precision of the algorithms for the two adversary strategies, Spammer and Uniform, under the two scenarios: Low Deg, in which low-degree workers are more likely to be adversaries, and High Deg, in which high-degree workers are more likely to be adversaries. For each combination of adversary strategy and scenario, the reported numbers are the precision values averaged over 300 randomly generated instances.

We draw the following key conclusions. First, our algorithms have precision values $> 69\%$ in all scenarios, indicating that they are successful in identifying adversaries and low-reliability honest workers when the worker and task degrees have a power-law distribution. This finding complements the results of Theorem 6 and Theorem 10, which establish a similar result when the worker-task assignment graph is (l, r)-regular. Second, our results offer insights into the settings under which the soft- or hard-penalty algorithm is appropriate. Generally, we observe that the hard-penalty algorithm is more appropriate when the adversaries have higher degrees, whereas the soft-penalty algorithm is more appropriate when the adversaries have lower degrees. We also note that when the adversaries have labeling patterns (such as Spammer) that are probabilistically similar to those of honest workers, the soft-penalty algorithm has a performance comparable to that of the hard-penalty algorithm even when the adversaries have high degrees.

6. Conclusions

This study investigated the problem of identifying a broad class of adversarial workers in crowdsourced systems, when the population of workers consists of a mixture of honest workers and adversaries. Honest workers may be reliable or unreliable, and they provide labels according to a well-defined probabilistic model. The adversaries adopt strategies different from those of honest workers, whether probabilistic or not. Under this setting, we make algorithmic, theoretical, and empirical contributions. The key algorithmic contribution is the design of two reputation-based algorithms—soft-penalty and hard-penalty algorithms—that analyze workers' label patterns and assign a reputation score to each worker that indicate

the degree to which the labeling pattern is a statistical outlier. Under standard probabilistic assumptions, we show that the reputation scores assigned by the soft-penalty algorithm are consistent with worker reliabilities (probability that a worker provides the true task label) when there are no adversaries. We also show that under appropriate conditions, the soft-penalty algorithm can asymptotically separate adversaries from honest workers when adversaries adopt deterministic strategies. When adversaries are sophisticated, we derive a lower bound for the number of tasks that k adversaries can affect (true label cannot be inferred better than a random guess) and a corresponding upper bound for the number of affected tasks under the hard-penalty algorithm. Empirically, we show that our algorithm can be used to significantly enhance the accuracy of existing label aggregation algorithms in real-world crowdsourcing datasets.

To the best of our knowledge, our work is the first to consider general worker strategies in crowdsourced labeling tasks. Our work opens the doors for several exciting future directions. Both of our penalty-based algorithms assume that the task labels are binary; analyzing natural extensions of our algorithms to multi-class settings is an interesting direction. Because our algorithm allows the identification of adversarial workers, it could be combined with adaptive techniques to recruit more workers (Ramesh et al., 2012) and identify the right workers (Li et al., 2014). Finally, applying our outlier detection technique to ensemble learning approaches, in which outputs from multiple learning algorithms are combined, could be a promising future direction; indeed there has already been some work in this space (Wang and Yeung, 2014).

Appendix A. Proofs of the theorems

In this section, we describe the proofs of all our theoretical results, starting with the results stated in section 4.1.1.

A.1 Analysis of Expected Penalties under the soft-penalty algorithm

First, we introduce some additional notation. Let $\mathbb{P}_{ih}[E]$ (resp. $\mathbb{P}_{ia}[E]$) denote the probability of some event E conditioned on the fact that worker w_i is honest (resp. adversarial). Similarly, $\mathbb{E}_{ih}[\boldsymbol{X}]$ (resp. $\mathbb{E}_{ia}[\boldsymbol{X}]$) denotes the conditional expectation of the random variable $\boldsymbol{X}$ given the event that worker w_i is honest (resp. adversarial). Also, let $f(\cdot)$ denote the probability density function (PDF) of the worker reliability distribution. Recall the definitions $P := q\mu + (1-q)$, $Q := 1 - q\mu$, and the function $g(x) := \frac{1-x^r}{r(1-x)}$, and note that $g(\cdot)$ is *strictly increasing* on $(0,1)$. Let $\mathbf{1}[A]$ denote the indicator variable taking value 1 if A is true and 0 otherwise. Let $\boldsymbol{D}_j^+$ (resp. $\boldsymbol{D}_j^-$) denote the number of workers who label task t_j as $+1$ (resp -1). In other words, $\boldsymbol{D}_j^+ = \sum_{w_i \in W_j} \mathbf{1}[\boldsymbol{W}_{ij} = +1]$ and $\boldsymbol{D}_j^- = \sum_{w_i \in W_j} \mathbf{1}[\boldsymbol{W}_{ij} = -1]$, where recall that W_j denotes the set of workers who labeled task t_j. Here, $\boldsymbol{W}_{ij}$ represents the label assigned by worker w_i to task t_j. Finally, let $\mathrm{Bin}(n,p)$ denote the Binomial distribution with parameters n and p.

We begin by proving some important lemmas that will be repeatedly used in the proofs below.

Lemma 18 *Under the generative model in section 4.1, the probability that worker w_i provides response $+1$ for a task t_j is given by*

$$\Pr[\boldsymbol{W}_{ij} = +1 \,\big|\, \boldsymbol{Y}_j = +1] = P$$
$$\Pr[\boldsymbol{W}_{ij} = +1 \,\big|\, \boldsymbol{Y}_j = -1] = Q$$

Furthermore, conditioned on $\boldsymbol{Y}_j = +1$ or $\boldsymbol{Y}_j = -1$, the random variables $\mathbf{1}[\boldsymbol{W}_{ij} = +1]$ are i.i.d. for all $w_i \in W_j$. As a result, it follows that $\boldsymbol{D}_j^+ \,\big|\, \boldsymbol{Y}_j = +1 \sim \mathrm{Bin}(r,P)$ and $\boldsymbol{D}_j^+ \,\big|\, \boldsymbol{Y}_j = -1 \sim \mathrm{Bin}(r,Q)$.

Proof Consider the case when $\boldsymbol{Y}_j = +1$:

$$\begin{aligned}
&\Pr[\boldsymbol{W}_{ij} = +1 \,\big|\, \boldsymbol{Y}_j = +1] \\
&= \mathbb{P}_{ih}[\boldsymbol{W}_{ij} = +1 \,\big|\, \boldsymbol{Y}_j = +1] \cdot \Pr[w_i \text{ is honest} \,\big|\, \boldsymbol{Y}_j = +1] \\
&+ \mathbb{P}_{ia}[\boldsymbol{W}_{ij} = +1 \,\big|\, \boldsymbol{Y}_j = +1] \cdot \Pr[w_i \text{ is adversarial} \,\big|\, \boldsymbol{Y}_j = +1] \\
&= \left(\int_0^1 \mathbb{P}_{ih}[\boldsymbol{W}_{ij} = +1 \,\big|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{Y}_j = +1] \cdot f(\mu_i) d\mu_i \right) q + 1 \cdot (1-q) \\
&= \left(\int_0^1 \mu_i f(\mu_i) d\mu_i \right) q + (1-q) \\
&= q\mu + (1-q) = P,
\end{aligned}$$

where the first term of the second equality follows from the law of total expectation, the second term because the adversary always labels a task $+1$, and the third equality follows from the definition of honest worker reliability $\boldsymbol{M}_i$.

Furthermore, it follows from our generative process that conditioned on $\boldsymbol{Y}_j = +1$, the labels from any two workers $w_i \neq w_{i'}$ for task t_j are generated independently. Therefore, we have shown that, conditioned on $\boldsymbol{Y}_j = +1$, the random variables $\mathbf{1}[\boldsymbol{W}_{ij} = +1]$ are independently and identically distributed with probability P of taking the value 1. Because $\boldsymbol{D}_j^+ = \sum_{w_i \in W_j} \mathbf{1}[\boldsymbol{W}_{ij} = +1]$ and $|W_j| = r$, it follows that $\boldsymbol{D}_j^+ \,\big|\, \boldsymbol{Y}_j = +1$ is a sum of r i.i.d. Bernoulli random variables and, hence, $\boldsymbol{D}_j^+ \,\big|\, \boldsymbol{Y}_j = +1 \sim \mathrm{Bin}(r,P)$.

A similar argument shows that $\Pr[\boldsymbol{W}_{ij} = +1 \,\big|\, \boldsymbol{Y}_j = -1] = Q$ and consequently $\boldsymbol{D}_j^+ \,\big|\, \boldsymbol{Y}_j = -1 \sim \mathrm{Bin}(r,Q)$. ■

Lemma 19 *Under the generative model in section 4.1, suppose that worker w_i is honest with a sampled reliability μ_i and let $\boldsymbol{S}_{ij}$ denote the penalty received by w_i from task $t_j \in \mathcal{T}_i$ in the* soft-penalty *algorithm. Then, we can show*

$$\mathbb{E}_{ih}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{M}_i = \mu_i] = \gamma\Big(\mu_i \cdot g(1-P) + (1-\mu_i) \cdot g(P)\Big) + (1-\gamma)\Big(\mu_i \cdot g(Q) + (1-\mu_i) \cdot g(1-Q)\Big)$$

Similarly, if worker w_i is adversarial, then we have:

$$\mathbb{E}_{ia}[\boldsymbol{S}_{ij}] = \gamma \cdot g(1-P) + (1-\gamma) \cdot g(1-Q)$$

Proof We begin with the case when w_i is honest. Using the law of total expectation, we have:

$$\begin{aligned}
&\mathbb{E}_{ih}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{M}_i = \mu_i] \\
&= \sum_{v_1, v_2 \in \{-1,+1\}} \mathbb{E}_{ih}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{W}_{ij} = v_1; \boldsymbol{Y}_j = v_2] \cdot \mathbb{P}_{ih}[\boldsymbol{W}_{ij} = v_1; \boldsymbol{Y}_j = v_2 \,\big|\, \boldsymbol{M}_i = \mu_i]
\end{aligned}$$

We first consider the case when $v_1 = +1$ and $v_2 = +1$. In this case, because worker w_i assigns label $+1$ to task t_j (i.e., $\boldsymbol{W}_{ij} = +1$), the penalty $\boldsymbol{S}_{ij}$ assigned by the task to the worker is equal to $1/\boldsymbol{D}_j^+$. Furthermore, because $\boldsymbol{Y}_j = +1$ and $\mathbf{1}[\boldsymbol{W}_{ij} = +1] = 1$, it follows from the arguments in Lemma 18 that $\boldsymbol{D}_j^+ - 1$ is distributed as $\mathrm{Bin}(r-1,P)$. We can now

write

$$\begin{aligned}
&\mathbb{E}_{ih}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{W}_{ij} = +1; \boldsymbol{Y}_j = +1] \\
=&\mathbb{E}_{ih}\left[1/\boldsymbol{D}_j^+ \,\middle|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{W}_{ij} = +1; \boldsymbol{Y}_j = +1\right] \\
=&\sum_{k=0}^{r-1} \frac{1}{1+k}\binom{r-1}{k} \cdot P^k(1-P)^{r-1-k} \\
=&\frac{1}{r} \cdot \sum_{k=0}^{r-1} \binom{r}{k+1} \cdot P^k(1-P)^{r-1-k} \\
=&\frac{1}{rP} \cdot \sum_{k'=1}^{r} \binom{r}{k'} \cdot P^{k'}(1-P)^{r-k'} \\
=&\frac{1-(1-P)^r}{rP} = g(1-P),
\end{aligned}$$

where the third equality follows because $\frac{1}{k+1} \cdot \binom{r-1}{k} = \frac{1}{r} \cdot \binom{r}{k+1}$, the fifth equality follows because $\sum_{k'=0}^{r} \binom{r}{k'} \cdot P^{k'}(1-P)^{r-k'} = 1$, and the last equality follows from the definition of the function $g(\cdot)$.

Furthermore, $\mathbb{P}_{ih}[\boldsymbol{W}_{ij} = +1, \boldsymbol{Y}_j = +1 \,\big|\, \boldsymbol{M}_i = \mu_i] = \mathbb{P}_{ih}[\boldsymbol{W}_{ij} = +1 \,\big|\, \boldsymbol{Y}_j = +1; \boldsymbol{M}_i = \mu_i] \cdot \mathbb{P}_{ih}[\boldsymbol{Y}_j = +1 \,\big|\, \boldsymbol{M}_i = \mu_i] = \mu_i \cdot \gamma$. We have thus shown that

$$\mathbb{E}_{ih}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{W}_{ij} = +1; \boldsymbol{Y}_j = +1] \cdot \mathbb{P}_{ih}[\boldsymbol{W}_{ij} = +1; \boldsymbol{Y}_j = +1 \,\big|\, \boldsymbol{M}_i = \mu_i] = g(1-P) \cdot \mu_i\gamma$$

The case when $v_1 = -1$ and $v_2 = +1$ (i.e., $\boldsymbol{W}_{ij} = -1$ and $\boldsymbol{Y}_j = +1$) follows a symmetric argument. In particular, because worker w_i assigns the label -1 to task t_j, the penalty $\boldsymbol{S}_{ij}$ that is assigned is equal to $1/\boldsymbol{D}_j^-$. Furthermore, it follows from the arguments in Lemma 18 that $\boldsymbol{D}_j^- - 1$ is distributed as $\mathrm{Bin}(r-1, 1-P)$. It now follows from a symmetric argument (by replacing P by $1-P$ above) that $\mathbb{E}_{ih}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{W}_{ij} = -1; \boldsymbol{Y}_j = +1] = g(P)$ and $\mathbb{P}_{ih}[\boldsymbol{Y}_j = +1; \boldsymbol{W}_{ij} = +1 \,\big|\, \boldsymbol{M}_i = \mu_i] = \gamma \cdot (1-\mu_i)$. We have thus shown that

$$\mathbb{E}_{ih}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{W}_{ij} = -1; \boldsymbol{Y}_j = +1] \cdot \mathbb{P}_{ih}[\boldsymbol{W}_{ij} = -1; \boldsymbol{Y}_j = +1 \,\big|\, \boldsymbol{M}_i = \mu_i] = g(P) \cdot (1-\mu_i)\gamma$$

Replacing P by Q, μ_i by $1-\mu_i$, and γ by $1-\gamma$ yields the expressions for the other two cases. In particular,

$$\begin{aligned}
&\mathbb{E}_{ih}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{W}_{ij} = +1; \boldsymbol{Y}_j = -1] \cdot \mathbb{P}_{ih}[\boldsymbol{Y}_j = -1; \boldsymbol{W}_{ij} = +1 \,\big|\, \boldsymbol{M}_i = \mu_i] \\
&= g(1-Q) \cdot (1-\gamma) \cdot (1-\mu_i) \\
&\mathbb{E}_{ih}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{W}_{ij} = -1; \boldsymbol{Y}_j = -1] \cdot \mathbb{P}_{ih}[\boldsymbol{Y}_j = -1; \boldsymbol{W}_{ij} = -1 \,\big|\, \boldsymbol{M}_i = \mu_i] \\
&= g(Q) \cdot (1-\gamma) \cdot \mu_i
\end{aligned}$$

Combining the above, we obtain

$$\mathbb{E}_{ih}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{M}_i = \mu_i] = \gamma\Big(\mu_i \cdot g(1-P) + (1-\mu_i) \cdot g(P)\Big) + (1-\gamma)\Big(\mu_i \cdot g(Q) + (1-\mu_i) \cdot g(1-Q)\Big)$$

We now consider the case when worker w_i is an adversary. Because adversaries always assign the label $+1$, we need to consider only two cases: $\boldsymbol{Y}_j = +1$ and $\boldsymbol{Y}_j = -1$. The conditional expectations of the penalties in both cases are identical to those above: $\mathbb{E}_{ia}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{W}_{ij} = +1; \boldsymbol{Y}_j = +1] = g(1-P)$ and $\mathbb{E}_{ia}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{W}_{ij} = +1; \boldsymbol{Y}_j = -1] = g(1-Q)$. Further, we have $\mathbb{P}_{ia}[\boldsymbol{W}_{ij} = +1; \boldsymbol{Y}_j = +1] = \gamma$ and $\mathbb{P}_{ia}[\boldsymbol{W}_{ij} = +1; \boldsymbol{Y}_j = -1] = 1-\gamma$. Combining these, we obtain

$$\mathbb{E}_{ia}[\boldsymbol{S}_{ij}] = \gamma \cdot g(1-P) + (1-\gamma) \cdot g(1-Q)$$

The result of the lemma now follows. ■

We are now ready to prove the theorems.

A.1.1 Proof of Theorem 3

First, note that if $q = 1$ then $P = \mu$ and $Q = 1-\mu$. Also, since all workers are honest, we remove the explicit conditioning on worker w_i being honest. Then the expected penalty allocated to a worker w_i with a reliability μ_i:

$$\begin{aligned}
&\mathbb{E}[\mathbf{PEN}_i \,\big|\, \boldsymbol{M}_i = \mu_i] = \frac{1}{l}\sum_{j \in \mathcal{T}_i} \mathbb{E}[\boldsymbol{S}_{ij} \,\big|\, \boldsymbol{M}_i = \mu_i] \\
&= \gamma\Big(\mu_i \cdot g(1-P) + (1-\mu_i) \cdot g(P)\Big) + (1-\gamma)\Big(\mu_i \cdot g(Q) + (1-\mu_i) \cdot g(1-Q)\Big) \\
&\text{(using lemma 19)} \\
&= \gamma\Big(\mu_i \cdot g(1-\mu) + (1-\mu_i) \cdot g(\mu)\Big) + (1-\gamma)\Big(\mu_i \cdot g(1-\mu) + (1-\mu_i) \cdot g(\mu)\Big) \\
&= g(\mu) - \mu_i \cdot (g(\mu) - g(1-\mu))
\end{aligned}$$

Since $g(\cdot)$ is strictly increasing on $(0,1)$ and $\mu > \frac{1}{2}$, we have that $\mu > 1-\mu$ and consequently $g(\mu) - g(1-\mu) > 0$. The claim then follows.

A.1.2 Proof of Theorem 4

For an honest worker w_i, we have that

$$
\begin{aligned}
&p_h := \mathbb{E}_{ih}[\mathbf{PEN}_i] \\
&= \frac{1}{l}\sum_{j\in\mathcal{T}_i}\mathbb{E}_{ih}[\boldsymbol{S}_{ij}] \\
&= \frac{1}{l}\sum_{j\in\mathcal{T}_i}\int_0^1 \mathbb{E}_{ih}[\boldsymbol{S}_{ij}\,\Big|\,\boldsymbol{M}_i=\mu_i]f(\mu_i)d\mu_i \;\text{ (law of total expectation)} \\
&= \int_0^1 \Big(\gamma\cdot(\mu_i\cdot g(1-P)+(1-\mu_i)\cdot g(P))+(1-\gamma)\cdot(\mu_i\cdot g(Q)+(1-\mu_i)\cdot g(1-Q))\Big)f(\mu_i)d\mu_i \\
&\text{(using lemma 19)} \\
&= \gamma\Big(\mu\cdot g(1-P)+(1-\mu)\cdot g(P)\Big)+(1-\gamma)\Big(\mu\cdot g(Q)+(1-\mu)\cdot g(1-Q)\Big) \\
&\text{(since } \int_0^1 \mu_i f(\mu_i)d\mu_i=\mu\text{)}
\end{aligned}
$$

Similarly, when worker w_i is adversarial,

$$
\begin{aligned}
p_a &:= \mathbb{E}_{ia}[\mathbf{PEN}_i] \\
&= \frac{1}{l}\sum_{j\in\mathcal{T}_i}\mathbb{E}_{ia}[\boldsymbol{S}_{ij}] \\
&= \frac{1}{l}\sum_{j\in\mathcal{T}_i}\gamma\cdot g(1-P)+(1-\gamma)\cdot g(1-Q) \quad \text{(using lemma 19)} \\
&= \gamma\cdot g(1-P)+(1-\gamma)\cdot g(1-Q)
\end{aligned}
$$

Suppose $q\mu \le 1/2$, then we have that $Q = 1-q\mu \ge 1/2$ and $P > Q \ge 1/2$. Further, because $g(\cdot)$ is strictly increasing, it follows that $g(1-P)-g(P) < 0$ and $g(1-Q)-g(Q) \le 0$. Given this, and using the expressions for the expected penalty computed above, we have that:

$$
\begin{aligned}
&p_a - p_h \\
&= \gamma\cdot(1-\mu)\cdot\underbrace{(g(1-P)-g(P))}_{<0}+(1-\gamma)\cdot\mu\cdot\underbrace{(g(1-Q)-g(Q))}_{\le 0} \\
&\le 0
\end{aligned}
$$

Therefore, $q\mu > \frac{1}{2}$ is a *necessary* condition for $p_h < p_a$. Assuming this condition is met, we derive the second condition:

$$
\begin{aligned}
p_a > p_h &\iff p_a - p_h > 0 \\
&\iff \gamma\cdot(1-\mu)\cdot\Big(g(1-P)-g(P)\Big)+(1-\gamma)\cdot\mu\Big(g(1-Q)-g(Q)\Big) > 0 \\
&\iff (1-\gamma)\cdot\mu\Big(g(1-Q)-g(Q)\Big) > \gamma\cdot(1-\mu)\cdot\Big(g(P)-g(1-P)\Big) \\
&\iff \frac{\mu}{1-\mu}\frac{\Big(g(1-Q)-g(Q)\Big)}{\Big(g(P)-g(1-P)\Big)} > \frac{\gamma}{1-\gamma} \\
&\text{(since } P > q\mu > \frac{1}{2} \text{ and } Q = 1-q\mu < \frac{1}{2}\text{)}
\end{aligned}
$$

Consider the function $h(\mu,q) = \frac{g(1-Q)-g(Q)}{g(P)-g(1-P)}$ in the regime $q\mu > \frac{1}{2}$. Note that as q increases, Q decreases (since $\frac{\partial Q}{\partial q} = -\mu < 0$) and therefore $g(1-Q)-g(Q)$ (strictly) increases. Similarly, P decreases as q increases (since $\frac{\partial P}{\partial q} = \mu - 1 \le 0$) and therefore $g(P)-g(1-P)$ decreases. It follows that $h(\mu,q)$ is a *strictly* increasing function of q. The result of the theorem now follows.

A.1.3 Proof of Corollary 5

Since $q\mu > \frac{1}{2}$, we have that $P > \frac{1}{2}$ and $Q < \frac{1}{2}$. From the proof of theorem 4 above, we have

$$
\begin{aligned}
p_a > p_h &\iff \frac{\mu}{1-\mu}h(\mu,q) > \frac{\gamma}{1-\gamma} \\
&\iff h_\mu(q) > \frac{\gamma}{1-\gamma} \\
&\iff q > h_\mu^{-1}\Big(\frac{\gamma}{1-\gamma}\Big) \\
&\text{(since } h_\mu(q) \text{ is strictly increasing)}
\end{aligned}
$$

A.2 Asymptotic identification of honest and adversarial workers

We begin with the proof of the lemma establishing the locally-tree like property of the worker-task assignment graph.

A.2.1 Proof of Lemma 8

We adapt the proof from Karger et al. Consider the following (discrete time) random process that generates the random graph $\mathcal{B}_{\boldsymbol{w},2}$ starting from the root node $\boldsymbol{w}$. In the first step, we connect l task nodes to node $\boldsymbol{w}$ according to the configuration model, where l half-edges are matched to a randomly chosen subset of mr task half-edges of size l. Let α_1 denote the probability that the resulting graph is *not* a tree, that is, at least one pair

of edges are connected to the same task node. Since there are $\binom{l}{2}$ pairs and each pair of half-edges is connected to the same task node with probability $\frac{r-1}{mr-1}$, we have that:

$$\alpha_1 \leq \binom{l}{2}\frac{r-1}{mr-1} \leq \frac{l^2}{2m} = \frac{lr}{2n}$$

where we use the fact that $(a-1)/(b-1) \leq a/b$ for all $a \leq b$ and the relation $mr = nl$. Next, define $\beta_2 \equiv \Pr[\mathcal{B}_{\boldsymbol{w},2}$ is not a tree $\big|\ \mathcal{B}_{\boldsymbol{w},1}$ is a tree$]$ so that we have:

$$\Pr\left(\mathcal{B}_{\boldsymbol{w},2} \text{ is not a tree}\right) \leq \alpha_1 + \beta_2$$

We can similarly bound β_2. For generating $\mathcal{B}_{\boldsymbol{w},2}$ conditioned on $\mathcal{B}_{\boldsymbol{w},1}$ being a tree, there are $l\hat{r}$ half-edges where $\hat{r} = r-1$. Among the $\binom{l\hat{r}}{2}$ pairs of these half-edges, each pair will be connected to the same worker with probability $\frac{l-1}{l(n-1)-1}$ and therefore:

$$\begin{aligned}\beta_2 &\leq \frac{l^2\hat{r}^2}{2}\frac{l-1}{l(n-1)-1} \\ &\leq \frac{l^2\hat{r}^2}{2}\frac{l}{l(n-1)} = \frac{l^2\hat{r}^2}{2(n-1)}\end{aligned}$$

Combining this with the above, we get that

$$\Pr[\mathcal{B}_{\boldsymbol{w},2} \text{ is not a tree}] \leq \alpha_1 + \beta_2 \leq \frac{lr}{2n} + \frac{l^2\hat{r}^2}{2(n-1)} \leq \frac{l^2r^2}{n-1}$$

A.2.2 Proof of Lemma 9

Consider an honest worker w_i with a given reliability μ_i. Recall that the penalty assigned to w_i is of the form:

$$\mathbf{PEN}_i = \frac{1}{l}\sum_{j\in\mathcal{T}_i} \boldsymbol{S}_{ij}$$

where $\boldsymbol{S}_{ij} = \frac{1}{\boldsymbol{D}_j^+}$ if $\boldsymbol{W}_{ij} = +1$ and $\boldsymbol{S}_{ij} = \frac{1}{\boldsymbol{D}_j^-}$ when $\boldsymbol{W}_{ij} = -1$. For any two tasks $t_j \neq t_{j'} \in \mathcal{T}_i$ note that $\boldsymbol{W}_{ij}$ and $\boldsymbol{W}_{ij'}$ are independent, conditioned on the reliability $\boldsymbol{M}_i$. This is because

for $(v_1, v_2) \in \{-1, +1\}$:

$$\begin{aligned}&\Pr[\boldsymbol{W}_{ij} = v_1; \boldsymbol{W}_{ij'} = v_2 \,|\, \boldsymbol{M}_i = \mu_i] \\ &= \sum_{(x_1,x_2)\in\{-1,+1\}} \Pr[\boldsymbol{W}_{ij} = v_1; \boldsymbol{W}_{ij'} = v_2 \,|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{Y}_j = x_1; \boldsymbol{Y}_{j'} = x_2] \Pr[\boldsymbol{Y}_j = x_1; \boldsymbol{Y}_{j'} = x_2] \\ &(\text{ since the true task labels are independent of } \boldsymbol{M}_i) \\ &= \Big(\Pr[\boldsymbol{W}_{ij} = v_1 \,|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{Y}_j = +1]\Pr[\boldsymbol{Y}_j = +1] \\ &+ \Pr[\boldsymbol{W}_{ij} = v_1 \,|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{Y}_j = -1]\Pr[\boldsymbol{Y}_j = -1]\Big)\times \\ &\Big(\Pr[\boldsymbol{W}_{ij'} = v_2 \,|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{Y}_{j'} = +1]\Pr[\boldsymbol{Y}_{j'} = +1] \\ &+ \Pr[\boldsymbol{W}_{ij'} = v_2 \,|\, \boldsymbol{M}_i = \mu_i; \boldsymbol{Y}_{j'} = -1]\Pr[\boldsymbol{Y}_{j'} = -1]\Big) \\ &= \Pr[\boldsymbol{W}_{ij} = v_1 \,|\, \boldsymbol{M}_i = \mu_i] \cdot \Pr[\boldsymbol{W}_{ij'} = v_2 \,|\, \boldsymbol{M}_i = \mu_i]\end{aligned}$$

Note that third equality makes use of the fact that $\boldsymbol{W}_{ij}$ (resp. $\boldsymbol{W}_{ij'}$) is independent of all other random variables conditioned on the reliability $\boldsymbol{M}_i$ and the true label $\boldsymbol{Y}_j$ (resp. $\boldsymbol{Y}_{j'}$). The argument above can be extended for any subset of random variables $\boldsymbol{W}_{ij_1}, \boldsymbol{W}_{ij_2}, \ldots, \boldsymbol{W}_{ij_i}$. Further, if the worker-task assignment graph is 2-locally tree-like at w_i, there is no other overlap in the set of workers labeling the tasks $t_j, t_{j'}$ apart from w_i. This combined with the above claim shows that the random variables $\{\boldsymbol{S}_{ij} : j \in \mathcal{T}_i\}$ are *mutually independent* under our generative model. Further, note that $\frac{1}{r} \leq \boldsymbol{S}_{ij} \leq 1$ for any task $t_j \in \mathcal{T}_i$, i.e the random variables $\boldsymbol{S}_{ij}$ are bounded. Then, we can apply Hoeffding's inequality to bound the difference between $\mathbf{PEN}_i$ and $\mathbb{E}[\mathbf{PEN}_i \,\big|\, \boldsymbol{M}_i = \mu_i]$ for any $\varepsilon > 0$:

$$\Pr\left(\mathbf{PEN}_i \geq \mathbb{E}[\mathbf{PEN}_i \mid \boldsymbol{M}_i = \mu_i] + \varepsilon \,\Big|\, \boldsymbol{M}_i = \mu_i\right) \leq \exp\left(\frac{-2l\varepsilon^2}{(1-1/r)^2}\right)$$

A.2.3 Proof of Theorem 6

Suppose we draw a random worker $\boldsymbol{w}$ uniformly from the set of workers W. Then we want to compute the average probability of error, which is the probability that we misclassify a randomly chosen worker:

$$\frac{1}{n}\sum_{i=1}^{n}\Pr\left(\boldsymbol{I}(w_i) \neq \hat{\boldsymbol{I}}_\theta(w_i) \text{ and } \boldsymbol{M}_i > \hat{\mu}(\theta)\right) = \Pr\left(\boldsymbol{I}(\boldsymbol{w}) \neq \hat{\boldsymbol{I}}_\theta(\boldsymbol{w}) \text{ and } \boldsymbol{M}_{\boldsymbol{w}} > \hat{\mu}(\theta)\right)$$

Let $\mathbf{PEN}_{\boldsymbol{w}}$ denote the penalty received by the worker $\boldsymbol{w}$. Recall the expression for the expected penalty received by an honest worker from the proof of theorem 3 above, $\mathbb{E}[\mathbf{PEN}_{\boldsymbol{w}} \,\big|\, \boldsymbol{M}_{\boldsymbol{w}} = \mu_{\boldsymbol{w}}] = g(\mu) - \mu_{\boldsymbol{w}} \cdot (g(\mu) - g(1-\mu))$. Based on the definition of $\hat{\mu}(\theta)$ in the theorem it follows that $p_{\hat{\mu}(\theta)} := \mathbb{E}[\mathbf{PEN}_{\boldsymbol{w}} \,\big|\, \boldsymbol{M}_{\boldsymbol{w}} = \hat{\mu}(\theta)] = \theta - \varepsilon$.

We upper bound the probability $\Pr\left(\boldsymbol{I}(\boldsymbol{w}) \neq \hat{\boldsymbol{I}}_\theta(\boldsymbol{w}) \text{ and } \boldsymbol{M}_{\boldsymbol{w}} > \hat{\mu}(\theta)\right)$ in two steps. First, if $\mathcal{B}_{\boldsymbol{w},2}$ is not a tree, we suppose that we always declare w_i as adversarial, thereby making an error. So supposing $\mathcal{B}_{\boldsymbol{w},2}$ is a tree, the probability that we misclassify $\boldsymbol{w}$ is given by

$$
\begin{aligned}
&\Pr(\mathbf{PEN}_{\boldsymbol{w}} > \theta \text{ and } \boldsymbol{M}_{\boldsymbol{w}} > \hat{\mu}(\theta)) \\
&= \Pr(\mathbf{PEN}_{\boldsymbol{w}} > p_{\hat{\mu}(\theta)} + \varepsilon \text{ and } \boldsymbol{M}_{\boldsymbol{w}} > \hat{\mu}(\theta)) \\
&= \int_{\hat{\mu}(\theta)}^{1} \Pr\left(\mathbf{PEN}_{\boldsymbol{w}} > p_{\hat{\mu}(\theta)} + \varepsilon \,\middle|\, \boldsymbol{M}_{\boldsymbol{w}} = \tilde{\mu}\right) f(\tilde{\mu}) d\tilde{\mu} \\
&\leq \int_{\hat{\mu}(\theta)}^{1} \Pr\left(\mathbf{PEN}_{\boldsymbol{w}} > \mathbb{E}[\mathbf{PEN}_{\boldsymbol{w}} \mid \boldsymbol{M}_{\boldsymbol{w}} = \tilde{\mu}] + \varepsilon \,\middle|\, \boldsymbol{M}_{\boldsymbol{w}} = \tilde{\mu}\right) f(\tilde{\mu}) d\tilde{\mu} \\
&(\text{since } \tilde{\mu} > \hat{\mu}(\theta) \implies \mathbb{E}[\mathbf{PEN}_{\boldsymbol{w}} \mid \boldsymbol{M}_{\boldsymbol{w}} = \tilde{\mu}] < p_{\hat{\mu}(\theta)}) \\
&\leq \int_{\hat{\mu}(\theta)}^{1} \exp\left(\frac{-2l\varepsilon^2}{(1-1/r)^2}\right) f(\tilde{\mu}) d\tilde{\mu} \\
&(\text{from lemma 9 above}) \\
&\leq \exp\left(\frac{-2l\varepsilon^2}{(1-1/r)^2}\right)
\end{aligned}
$$

Finally, combining all the claims above, we have

$$
\begin{aligned}
&\frac{1}{n}\sum_{i=1}^{n} \Pr\left(\boldsymbol{I}(w_i) \neq \hat{\boldsymbol{I}}_\theta(w_i) \text{ and } \boldsymbol{M}_i > \hat{\mu}(\theta)\right) \\
&= \Pr\left(\boldsymbol{I}(\boldsymbol{w}) \neq \hat{\boldsymbol{I}}_\theta(\boldsymbol{w}) \text{ and } \boldsymbol{M}_{\boldsymbol{w}} > \hat{\mu}(\theta)\right) \\
&\leq \Pr(\mathcal{B}_{\boldsymbol{w},2} \text{ is not a tree }) \cdot 1 + \Pr\left(\boldsymbol{I}(\boldsymbol{w}) \neq \hat{\boldsymbol{I}}_\theta(\boldsymbol{w}) \text{ and } \boldsymbol{M}_{\boldsymbol{w}} > \hat{\mu}(\theta) \,\middle|\, \mathcal{B}_{\boldsymbol{w},2} \text{ is a tree }\right) \cdot 1 \\
&\leq \frac{l^2 r^2}{n-1} + \exp\left(\frac{-2l\varepsilon^2}{(1-1/r)^2}\right)
\end{aligned}
$$

and the first part of the theorem follows. For the second part, when $l = \log n$ and r is fixed, note that

$$
\exp\left(\frac{-2l\varepsilon^2}{(1-1/r)^2}\right) = \exp\left(\frac{-2\log n\varepsilon^2}{(1-1/r)^2}\right) = \exp\left(\log\left(\frac{1}{n}\right)^{\frac{2\varepsilon^2}{(1-1/r)^2}}\right) = O\left(\frac{1}{n^{2\varepsilon^2}}\right)
$$

In addition, because $\varepsilon < \frac{1}{\sqrt{2}} \implies 2\varepsilon^2 < 1$, it follows that $\frac{\log^2 n \cdot r^2}{n-1} = O\left(\frac{1}{n^{2\varepsilon^2}}\right)$ and the claim follows.

A.2.4 Proof of Theorem 10

We follow a similar line of reasoning to that of theorem 6. As before, if $\mathcal{B}_{\boldsymbol{w},2}$ is not a tree, we suppose that the worker is always misclassified.

First, we focus on **honest** workers. Given a threshold θ, choose the reliability threshold such that $\mathbb{E}[\mathbf{PEN}_i \mid \boldsymbol{M}_i = \hat{\mu}(q,\theta)] = \theta - \varepsilon$ where the expected penalty for an honest worker

conditioned on reliability was computed in lemma 19. Specifically, we have the following expression for $\hat{\mu}(q,\theta)$:

$$
\begin{aligned}
&\gamma\Big(\hat{\mu}(q,\theta)\cdot g(1-P) + (1-\hat{\mu}(q,\theta))\cdot g(P)\Big) + (1-\gamma)\Big(\hat{\mu}(q,\theta)\cdot g(Q) + (1-\hat{\mu}(q,\theta))\cdot g(1-Q)\Big) \\
&= \theta - \varepsilon \implies \\
&\Big(\gamma g(1-P) - \gamma g(P) + (1-\gamma)g(Q) - (1-\gamma)g(1-Q)\Big)\hat{\mu}(q,\theta) \\
&= \theta - \varepsilon - \gamma g(P) - (1-\gamma)g(1-Q) \implies \\
&\hat{\mu}(q,\theta) = \frac{\gamma g(P) + (1-\gamma)g(1-Q) + \varepsilon - \theta}{\gamma\cdot(g(P)-g(1-P)) + (1-\gamma)\cdot(g(1-Q)-g(Q))}
\end{aligned}
$$

Note that such a threshold always exists since (1) $\theta - \varepsilon > p_h = \mathbb{E}[\mathbf{PEN}_i \mid \boldsymbol{M}_i = \mu]$ (2) $\mathbb{E}[\mathbf{PEN}_i \mid \boldsymbol{M}_i = \mu_i]$ (strictly) increases as μ_i decreases and (3) $\mathbb{E}[\mathbf{PEN}_i \mid \boldsymbol{M}_i = 0] \geq p_a > \theta > \theta - \varepsilon$. In particular, this means that $\hat{\mu}(q,\theta) < \mu$. Further, observe that if $q = 1$, then we have $\hat{\mu}(1,\theta) = \hat{\mu}(\theta)$.

Then, the probability that we misclassify a randomly chosen honest worker is given by

$$
\Pr(\mathbf{PEN}_{\boldsymbol{w}} > \theta \,\Big|\, \boldsymbol{w} \text{ is honest }) \leq \Pr\left(\mathbf{PEN}_{\boldsymbol{w}} \geq \mathbb{E}[\mathbf{PEN}_{\boldsymbol{w}} \mid \boldsymbol{M}_{\boldsymbol{w}} = \hat{\mu}(q,\theta)] + \varepsilon \,\middle|\, \boldsymbol{w} \text{ is honest }\right)
$$

The claim then follows from the result of lemma 11 below.

When $\boldsymbol{w}$ is **adversarial**, the probability that we misclassify $\boldsymbol{w}$ is given by

$$
\Pr(\mathbf{PEN}_{\boldsymbol{w}} \leq \theta \mid \boldsymbol{w} \text{ is adversarial}) \leq \Pr(\mathbf{PEN}_{\boldsymbol{w}} \leq p_a - \varepsilon \mid \boldsymbol{w} \text{ is adversarial}) \leq \exp\left(\frac{-2l\varepsilon^2}{(1-1/r)^2}\right)
$$

where the first inequality follows since $\theta < p_a - \varepsilon$ and the second follows from the result of lemma 11 below.

Coming to the second part of the theorem, first observe that the expected penalties p_h and p_a lie between 0 and 1. As a result, we have that $\varepsilon < (p_a - p_h)/2 \leq \frac{1}{2} \implies 2\varepsilon^2 < 1$ and the claim follows from the sequence of arguments in the proof of theorem 6 above.

A.2.5 Proof of Lemma 11

Suppose that worker w_i is **honest** and let $p_{\hat{\mu}} = \mathbb{E}[\mathbf{PEN}_i \,\big|\, \boldsymbol{M}_i = \hat{\mu}]$. We have the following (conditioned on $\mathcal{B}_{w_i,2}$ being a tree):

$$
\begin{aligned}
&\Pr(\mathbf{PEN}_i \geq p_{\hat{\mu}} + \epsilon \,\big|\, w_i \text{ is honest }) \\
&= \int_0^1 \Pr(\mathbf{PEN}_i \geq p_{\hat{\mu}} + \epsilon \,\big|\, w_i \text{ is honest and } \boldsymbol{M}_i = \mu_i) f(\mu_i) d\mu_i \\
&= \int_0^{\hat{\mu}} \Pr(\mathbf{PEN}_i \geq p_{\hat{\mu}} + \epsilon \,\big|\, w_i \text{ is honest and } \boldsymbol{M}_i = \mu_i) f(\mu_i) d\mu_i \\
&+ \int_{\hat{\mu}}^1 \Pr(\mathbf{PEN}_i \geq p_{\hat{\mu}} + \epsilon \,\big|\, w_i \text{ is honest and } \boldsymbol{M}_i = \mu_i) f(\mu_i) d\mu_i \\
&\leq \int_0^{\hat{\mu}} f(\mu_i) d\mu_i \\
&+ \int_{\hat{\mu}}^1 \Pr(\mathbf{PEN}_i \geq \mathbb{E}[\mathbf{PEN}_i \mid \boldsymbol{M}_i = \mu_i] + \epsilon \,\big|\, w_i \text{ is honest and } \boldsymbol{M}_i = \mu_i) f(\mu_i) d\mu_i \\
&(\text{ since } \mu_i \geq \hat{\mu} \implies \mathbb{E}[\mathbf{PEN}_i \mid \boldsymbol{M}_i = \mu_i] \leq p_{\hat{\mu}}) \\
&\leq F(\hat{\mu}) + \exp\left(\frac{-2l\varepsilon^2}{(1-1/r)^2}\right) \\
&(\text{ from lemma 9})
\end{aligned}
$$

When w_i is an **adversary**, note that her responses $\{\boldsymbol{W}_{ij} \,:\, j \in \mathcal{T}_i\}$ are trivially independent since adversarial workers always respond with $+1$ on all assigned tasks. Further, since $\mathcal{B}_{w_i,2}$ is locally tree-like, there is no other overlap in the set of workers labeling any two tasks $t_j, t_{j'} \in \mathcal{T}_i$ apart from w_i. As a result, the assigned penalties $\{\boldsymbol{S}_{ij} \,:\, j \in \mathcal{T}_i\}$ are *mutually independent* and using the Hoeffding's inequality we can establish the concentration bound for adversarial workers:

$$
\Pr[\mathbf{PEN}_i \leq p_a - \varepsilon \,\big|\, w_i \text{ is adversarial}] \leq \exp\left(\frac{-2l^2\varepsilon^2}{\sum_{j=1}^{l}(1-1/r)^2}\right) = \exp\left(\frac{-2l\varepsilon^2}{(1-1/r)^2}\right)
$$

A.3 Extension to random, normalized hard-penalty

Here, we show that the theoretical results proved above for the soft-penalty algorithm extend to the random, normalized variant of the hard-penalty algorithm mentioned in section 3.3. First, we focus on the expected penalties. Since the penalty algorithm is randomized, the expectation also takes into account the randomness in the algorithm. As above, if $\boldsymbol{S}_{ij}$ denotes the penalty received by worker w_i from task t_j, then we have that $\boldsymbol{S}_{ij} \in \{0, 1\}$. Further, conditioned on the fact that $\boldsymbol{W}_{ij} = +1$, we have that $\mathbb{E}[\boldsymbol{S}_{ij} \mid \boldsymbol{W}_{ij} = +1] = \mathbb{E}[\frac{1}{\boldsymbol{D}_j^+} \mid \boldsymbol{W}_{ij} = +1]$ using the law of iterated expectations. Similarly, for the case when $\boldsymbol{W}_{ij} = -1$. Then, using the arguments above it is easy to see that the expressions for the expected penalties are the same.

Moving on to the concentration results, observe that $\boldsymbol{S}_{ij}$ depends *only* on $\boldsymbol{W}_{ij}$ and $\boldsymbol{D}_j^+$ (and consequently, $\boldsymbol{D}_j^-$). This is because when $\boldsymbol{W}_{ij} = +1$, we have

$$
(\boldsymbol{S}_{ij} \mid \boldsymbol{W}_{ij} = +1) = \begin{cases} 1 & \text{w.p. } 1/\boldsymbol{D}_j^+ \\ 0 & \text{w.p. } 1 - 1/\boldsymbol{D}_j^+ \end{cases}
$$

Similarly, for the case when $\boldsymbol{W}_{ij} = -1$. Now, when $\mathcal{B}$ is locally tree-like at worker node w_i, the arguments in lemma 9 and 11 establish that the random variables $\{\boldsymbol{S}_{ij} \,:\, t_j \in \mathcal{T}_i\}$ are still mutually independent conditioned on the identity of worker w_i (this also relies on the fact that each task is treated independently when computing the random semi-matching). Therefore, we can apply the Hoeffding's bound to establish the concentration of the penalties under the random, normalized variant of the hard-penalty algorithm around the expected values.

A.4 Proof of Lemma 13

For the simple majority algorithm, it is easy to see that each task has k incorrect responses and at most $r < k$ correct responses and consequently, it outputs the incorrect label for all tasks.

For the expectation-maximization (EM) algorithm, recall that the generative model for worker ratings was as follows: the true task labels are sampled from a population with $\gamma \in [0, 1]$ fraction of tasks having $+1$ true label. Each worker w_i has reliability parameter $\mu_i \in [0, 1]$, which specifies the probability that w_i provides the correct label on any task. Then, given the response matrix $\mathcal{L}$, the log-likelihood of the parameters, $\boldsymbol{\Theta} = (\mu_1, \mu_2, \cdots, \mu_n, \gamma)$ under this generative model can be written as:

$$
\log \Pr[\mathcal{L} \mid \boldsymbol{\Theta}] = \sum_{j=1}^{m} \log\left(a_j \cdot \gamma + b_j \cdot (1-\gamma)\right)
$$

where $M(j)$ is the set of workers who label task t_j and

$$
\begin{aligned}
a_j &= \prod_{i \in M(j)} {\mu_i}^{\mathbf{1}[\mathcal{L}_{ij}=+1]} \cdot (1-\mu_i)^{\mathbf{1}[\mathcal{L}_{ij}=-1]} \\
b_j &= \prod_{i \in M(j)} (1-\mu_i)^{\mathbf{1}[\mathcal{L}_{ij}=+1]} \cdot {\mu_i}^{\mathbf{1}[\mathcal{L}_{ij}=-1]}
\end{aligned}
$$

The objective is to find the model parameters $\boldsymbol{\Theta}^*$ that maximize the log-likelihood, i.e. $\boldsymbol{\Theta}^* = \arg\max_{\boldsymbol{\Theta}} \log \Pr[\mathcal{L} \mid \Theta]$. The EM algorithm computes the maximum likelihood estimates (MLE) of the model parameters by introducing the latent true label of each task, denoted by the vector $\boldsymbol{y} = [y_1, y_2, \ldots, y_m]$. The complete data log-likelihood can then be written as:

$$
\log \Pr[\mathcal{L}, \boldsymbol{y} \mid \boldsymbol{\Theta}] = \sum_{j=1}^{m} \left(y_j \log(a_j\gamma) + (1-y_j)\log(1-\gamma)b_j\right) \tag{1}
$$

Each iteration x of the EM algorithm consists of two steps:

- **E-step:** Given the response matrix $\mathcal{L}$ and the current estimate of the model parameters $\mathbf{\Theta}^{(x)}$, the conditional expectation of the complete data log-likelihood is computed as

$$\mathbb{E}\left\{\log \Pr[\mathcal{L}, \boldsymbol{y} \mid \mathbf{\Theta}^{(x)}]\right\} = \sum_{j=1}^{m} \left(\gamma_j^{(x)} \log(a_j^{(x)}\gamma^{(x)}) + (1-\gamma_j^{(x)}) \log(1-\gamma^{(x)}) b_j^{(x)}\right)$$

where the expectation is w.r.t to $\Pr[\boldsymbol{y} \mid \mathcal{L}; \mathbf{\Theta}^{(x)}]$ and $\gamma_j^{(x)} = \Pr[y_j = +1 \mid \mathcal{L}; \mathbf{\Theta}^{(x)}]$. Using Bayes theorem, we can compute

$$\begin{aligned}\gamma_j^{(x)} &= \frac{\Pr[\{\mathcal{L}_{ij} \quad : \quad i \in M(j)\} \mid y_j = +1; \mathbf{\Theta}^{(x)}] \cdot \Pr[y_j = +1 \mid \mathbf{\Theta}^{(x)}]}{\Pr[\{\mathcal{L}_{ij} \quad : \quad i \in M(j)\} \mid \mathbf{\Theta}^{(x)}]} \\ &= \frac{a_j^{(x)}\gamma^{(x)}}{a_j^{(x)}\gamma^{(x)} + b_j^{(x)}(1-\gamma^{(x)})}\end{aligned} \tag{2}$$

where the first equality follows from the fact that labels for different tasks t_j are independent of each other and the second equality follows from the law of total probability.

- **M-step:** Based on the current posterior estimates of the true labels $\gamma_j^{(x)}$ and the response matrix $\mathcal{L}$, the model parameters are updated by maximizing $\mathbb{E}\left\{\log \Pr[\mathcal{L}, \boldsymbol{y} \mid \mathbf{\Theta}^{(x)}]\right\}$, which can be shown to be a lower bound on the data log-likelihood (equation (1)). The prevalence of positive tasks γ is updated as:

$$\gamma^{(x+1)} = \frac{\sum_{j=1}^{m} \gamma_j^{(x)}}{m} \tag{3}$$

Similarly, the parameter μ_i is updated as:

$$\mu_i^{(x+1)} = \frac{\sum_{j \in N(i)} \left(\mathbf{1}[\mathcal{L}_{ij} = +1]\gamma_j^{(x)} + \mathbf{1}[\mathcal{L}_{ij} = -1](1-\gamma_j^{(x)})\right)}{|N(i)|} \tag{4}$$

where $N(i)$ is the set of tasks assigned to worker w_i.

These two steps are iterated until convergence of the log-likelihood $\log \Pr[\mathcal{L} \mid \mathbf{\Theta}]$. After convergence, the true labels of the tasks are estimated as:

$$\hat{y}_j = 2 \cdot \mathbf{1}[\gamma_j^{(K)} \geq 0.5] - 1 \tag{5}$$

where K is the number of iterations to convergence.

Since the original problem is non-convex, the EM algorithm converges to a local optimum in general. Its performance critically depends on the initialization of the posterior estimates $\gamma_j^{(0)}$ for each task t_j. A popular approach is to use the majority estimate (see Raykar and Yu (2012)), given by $\gamma_j^{(0)} := \frac{\sum_{i \in M(j)} \mathbf{1}[\mathcal{L}_{ij}=+1]}{|M(j)|}$. We show that this initialization results in incorrect labels for all the tasks.

Suppose that the true labels for all tasks are $+1$, i.e $y_j = +1$ for all $1 \leq j \leq m$. Then all honest worker labels are $+1$ and adversary labels are -1. Further, since each task has more adversary than honest labels, we have that $\gamma_j^{(0)} < 0.5$ for all $1 \leq j \leq m$. Given this, it easy to see from equation (4) that $\mu_i^{(1)} < 0.5$ whenever w_i is honest and $\mu_i^{(1)} > 0.5$ for all adversarial workers w_i. In addition, we have $\gamma^{(1)} < 0.5$ which follows from equation (3). With these estimates, we update the posterior probabilities γ_j for each task t_j. Again, it follows that $\gamma_j^{(1)} < 0.5$ for all $1 \leq j \leq m$, using the update rule in equation (2). The above sequence of claims shows that $\gamma_j^{(x)} < 0.5$ for all iterations $x \geq 1$ and consequently, $\hat{y}_j = -1$ for all tasks t_j (using equation (5)). Therefore, the EM algorithm outputs incorrect labels for all tasks.

Now, let us consider the general case. If we initialize using the majority estimate, we obtain that $\gamma_j^{(0)} > 0.5$ for all tasks with true label $y_j = -1$ and $\gamma_j^{(0)} < 0.5$ for all tasks with $y_j = +1$. Then, it follows from equation (4) that $\mu_i^{(1)} < 0.5$ for all honest workers w_i and $\mu_i^{(1)} > 0.5$ for adversarial workers w_i. In addition, if we look at the update equations (3) and (4) together, we also get that $\mu_i^{(1)} \geq \max(1-\gamma^{(1)}, \gamma^{(1)})$ for all adversaries w_i. To see this, first note that adversaries label on all the tasks, so that $|N(i)| = m$ for an adversarial worker w_i. Next, let $N_+(i)$ and $N_-(i)$ denote the set of tasks for which adversary w_i labels $+1$ and -1 respectively. If $N_+(i)$ is empty, then we have $\mu_i^{(1)} = 1-\gamma^{(1)}$. Also, since we have all adversary labels as -1, we have $\gamma_j^{(0)} < 0.5$ for all $1 \leq j \leq m$ and therefore $\gamma^{(1)} < 1-\gamma^{(1)}$. Therefore, in this case we have $\mu_i^{(1)} \geq \max(1-\gamma^{(1)}, \gamma^{(1)})$. A symmetric argument can be applied when $N_-(i)$ is empty. So suppose that both $N_+(i)$ and $N_-(i)$ are non-empty, then we have from equation (4):

$$\begin{aligned}\mu_i^{(1)} &= \frac{\sum_{j \in N(i)} \left(\mathbf{1}[\mathcal{L}_{ij} = +1]\gamma_j^{(0)} + \mathbf{1}[\mathcal{L}_{ij} = -1](1-\gamma_j^{(0)})\right)}{|N(i)|} \\ &= \frac{\sum_{j \in N_+(i)} \gamma_j^{(0)} + \sum_{j \in N_-(i)} (1-\gamma_j^{(0)})}{m} \\ &> \frac{\sum_{j \in N_+(i)} \gamma_j^{(0)} + \sum_{j \in N_-(i)} \gamma_j^{(0)}}{m} \\ &\quad \text{(since } \gamma_j^{(0)} < 0.5 \text{ if adversaries label } t_j \text{ as } -1\text{)} \\ &= \frac{\sum_{j \in N(i)} \gamma_j^{(0)}}{m} \\ &= \gamma^{(1)}\end{aligned}$$

where the last equality follows from equation (3). Similarly, we can show that $\mu_i^{(1)} > 1-\gamma^{(1)}$ and the claim follows.

Now, let $M_h(j)$ and $M_a(j)$ denote the set of honest and adversarial workers labeling task t_j. Consider a task t_j for which the true label $y_j = -1$. Now, we have two cases:

Case 1: $\gamma^{(1)} \geq 0.5$. First observe that since $\mu_i^{(1)} < 0.5$ for all honest workers w_i, we have $\mu_i^{(1)} < 1 - \mu_i^{(1)}$ for all honest workers w_i. Similarly, we have $1 - \mu_i^{(1)} < \mu_i^{(1)}$ for all

adversarial workers w_i. Then, we have

$$\begin{aligned} b_j^{(1)} \cdot (1-\gamma^{(1)}) &= \left(\prod_{i \in M(j)} (1-\mu_i^{(1)})^{\mathbf{1}[\mathcal{L}_{ij}=+1]} \cdot (\mu_i^{(1)})^{\mathbf{1}[\mathcal{L}_{ij}=-1]} \right) \cdot (1-\gamma^{(1)}) \\ &= \prod_{i \in M_h(j)} \mu_i^{(1)} \cdot \prod_{i \in M_a(j)} (1-\mu_i^{(1)}) \cdot (1-\gamma^{(1)}) \\ &\quad \text{(since honest worker response is } -1 \text{ and adversary response is } +1) \\ &< \prod_{i \in M_h(j)} (1-\mu_i^{(1)}) \cdot \prod_{i \in M_a(j)} \mu_i^{(1)} \cdot \gamma^{(1)} \\ &= a_j^{(1)} \cdot \gamma^{(1)} \end{aligned}$$

where the inequality follows from the observation above and the fact that $\gamma^{(1)} \geq 0.5$. Using equation (2), it follows that $\gamma_j^{(1)} > 0.5$.

Case 2: $\gamma^{(1)} < 0.5$. In this scenario, we have:

$$\begin{aligned} & b_j^{(1)} \cdot (1-\gamma^{(1)}) \\ &= \left(\prod_{i \in M(j)} (1-\mu_i^{(1)})^{\mathbf{1}[\mathcal{L}_{ij}=+1]} \cdot (\mu_i^{(1)})^{\mathbf{1}[\mathcal{L}_{ij}=-1]} \right) \cdot (1-\gamma^{(1)}) \\ &= \prod_{i \in M_h(j)} \mu_i^{(1)} \cdot \prod_{i \in M_a(j)} (1-\mu_i^{(1)}) \cdot (1-\gamma^{(1)}) \\ &= \prod_{i \in M_h(j)} \mu_i^{(1)} \cdot (1-\mu_{w_{i_1}}^{(1)}) \cdot (1-\gamma^{(1)}) \cdot \prod_{i \in M_a(j) \setminus \{i_1\}} (1-\mu_i^{(1)}) \\ &\quad \text{(where } w_{i_1} \text{ is some adversarial worker)} \\ &\leq \prod_{i \in M_h(j)} \mu_i^{(1)} \cdot \mu_{w_{i_1}}^{(1)} \cdot \gamma^{(1)} \cdot \prod_{i \in M_a(j) \setminus \{i_1\}} (1-\mu_i^{(1)}) \\ &\quad \Big(\text{since } 1-\gamma^{(1)} \leq \mu_{w_{i_1}}^{(1)} \text{ because } w_{i_1} \text{ is adversarial; see discussion before Case 1} \Big) \\ &< \prod_{i \in M_h(j)} (1-\mu_i^{(1)}) \cdot \mu_{w_{i_1}}^{(1)} \cdot \gamma^{(1)} \cdot \prod_{i \in M_a(j) \setminus \{i_1\}} \mu_i^{(1)} \\ &\quad \text{(from Case 1 above)} \\ &= a_j^{(1)} \cdot \gamma^{(1)} \end{aligned}$$

Consequently, in both cases, the posterior probability $\gamma_j^{(1)} > 0.5$ given that the true label was $y_j = -1$. A symmetric argument shows that $\gamma_j^{(1)} < 0.5$ if $y_j = +1$. Then, the above sequence of claims establishes that this remains true for all iterations in the future. Finally, step (5) implies that the output label is incorrect for all tasks.

A.5 Proof of Theorem 14

We prove the result for the the case when there exists at least one subset $\mathcal{T}' \subseteq \mathcal{T}$ such that $\text{PreIm}(\mathcal{T}') \leq k$. Otherwise, the lower bound $L = 0$ by definition and the result of the theorem is trivially true.

Let H^* denote the set $\text{PreIm}(\mathcal{T}^*)$ where

$$\mathcal{T}^* \stackrel{\text{def}}{=} \underset{\mathcal{T}' \subseteq \mathcal{T}:\ |\text{PreIm}(\mathcal{T}')| \leq k}{\arg\max} \left| \mathcal{T}' \right|.$$

We construct an adversary strategy σ^* under which at least L tasks are affected for some true labeling of the tasks, for any decision rule $R \in \mathcal{C}$. Specifically for a fixed honest worker-task assignment graph $\mathcal{B}_H$ and ground-truth labeling $\boldsymbol{y}$ of the tasks, consider the following adversary strategy (that depends on the obtained honest worker responses): letting $H^* = \{h_1, h_2, \ldots, h_{|H^*|}\}$ and the set of adversaries $A = \{a_1, a_2, \ldots, a_k\}$, we have (recall the notation in Section 2)

$$a_i(t) = \begin{cases} -h_i(t) & \text{if } t \in \mathcal{T}^* \\ h_i(t) & \text{otherwise} \end{cases} \qquad \forall i = 1, 2, \ldots, |H^*| \tag{6}$$

In other words, the adversaries label *flip* the labels of the honest workers H^* for tasks in $\mathcal{T}^*$ and *copy* their responses for all other tasks. Note that since $|H^*| \leq k$ by construction, the above strategy is feasible. In addition, if $|H^*| < k$, then we only use $|H^*|$ of the k adversary identities. Let $\mathcal{L}(\boldsymbol{y})$ denote the $n \times m$ labeling matrix obtained for this adversary strategy, where we explicitly denote the dependence on the true label vector $\boldsymbol{y}$. Here n denotes the total number of workers.

Now consider the scenario in which the true labels of all tasks in $\mathcal{T}^*$ were reversed, let this ground-truth be denoted as $\tilde{\boldsymbol{y}}$. Let $\tilde{h}(t)$ denote the response of honest worker h for task t in the new scenario. Since, honest workers always respond correctly, we have that:

$$\tilde{h}(t) = \begin{cases} -h(t) & \text{if } t \in \mathcal{T}^* \\ h(t) & \text{otherwise} \end{cases} \qquad \forall\ h \in H \tag{7}$$

Correspondingly, according to the adversary labeling strategy σ^* described above, the adversary responses would also change. In particular, using $\tilde{a}_i(t)$ to denote the adversary response in the new scenario, we have

$$\tilde{a}_i(t) = \begin{cases} -\tilde{h}_i(t) & \text{if } t \in \mathcal{T}^* \\ \tilde{h}_i(t) & \text{otherwise} \end{cases} \qquad \forall i = 1, 2, \ldots, |H^*| \tag{8}$$

Finally, let $\mathcal{L}(\tilde{\boldsymbol{y}})$ denote the labeling matrix in this new scenario. We now argue that $\mathcal{L}(\tilde{\boldsymbol{y}}) = P\mathcal{L}(\boldsymbol{y})$ for some $n \times n$ permutation matrix P. In order to see this, for any worker w (honest or adversary), let $r(w)$ and $\tilde{r}(w)$ respectively denote the row vectors in matrices $\mathcal{L}(\boldsymbol{y})$ and $\mathcal{L}(\tilde{\boldsymbol{y}})$. We show that $\mathcal{L}(\tilde{\boldsymbol{y}})$ can be obtained from $\mathcal{L}(\boldsymbol{y})$ through a permutation of the rows.

First observe that for any honest worker $h \notin H^*$, we must have by definition of PreIm that $h(t) = 0$ for any $t \in \mathcal{T}^*$. Thus, it follows from equation (7) that $\tilde{h}(t) = -h(t) = 0 = h(t)$

for any $t \in \mathcal{T}^*$. Furthermore, $\tilde{h}(t) = h(t)$ for any $t \notin \mathcal{T}^*$ by (7). Therefore, we have that $\tilde{r}(h) = r(h)$ for any $h \notin H^*$. Next, consider an honest worker $h_i \in H^*$ for some i. It can be argued that $\tilde{r}(h_i) = r(a_i)$. To see this, for any task $t \notin \mathcal{T}^*$, we have by equation (7) that $\tilde{h}_i(t) = h_i(t) = a_i(t)$, where the second equality follows from equation (6). Similarly, for any $t \in \mathcal{T}^*$, we have $\tilde{h}_i(t) = -h_i(t) = a_i(t)$ again using equation (6). Thus, we have shown that the rows $\tilde{r}(h_i) = r(a_i)$ for any $1 \leq i \leq |H^*|$. A symmetric argument shows that $\tilde{r}(a_i) = r(h_i)$ for all $1 \leq i \leq |H^*|$. Consequently, $\mathcal{L}(\tilde{\boldsymbol{y}})$ is obtained from $\mathcal{L}(\boldsymbol{y})$ by swapping rows corresponding to h_i with a_i for all $i = 1, 2, \ldots, |H^*|$.

Now that we have shown $\mathcal{L}(\tilde{\boldsymbol{y}}) = P\mathcal{L}(\boldsymbol{y})$ for some permutation matrix P, it follows from the fact that $R \in \mathcal{C}$ that $R(\mathcal{L}(\tilde{\boldsymbol{y}})) = R(\mathcal{L}(\boldsymbol{y}))$. Thus, the labels output by R for all tasks in $\mathcal{T}^*$ is the same under both scenarios. As a result, it follows that $\text{Aff}(R, \sigma^*, \boldsymbol{y}) + \text{Aff}(R, \sigma^*, \tilde{\boldsymbol{y}}) = |\mathcal{T}^*| = 2 * L$ and therefore, either $\text{Aff}(R, \sigma^*, \boldsymbol{y}) \geq L$ or $\text{Aff}(R, \sigma^*, \tilde{\boldsymbol{y}}) \geq L$.

In other words, there exists a ground-truth task labeling for which the number of affected tasks is at least L, and since we take a maximum over all possible ground-truth labelings, the result of the theorem follows. Further, any decision rule that outputs labels randomly in case of ties (i.e equal number of $+1$ and -1 responses) will achieve the lower bound L, including the simple majority decision rule.

Misclassification of workers. Since we allow the sophisticated adversaries to adopt arbitrary strategies, we need to assume some characteristic property that helps to identify honest workers. In the theorem we assumed that all honest workers are perfectly reliable, so that they agree with each other on their labels for all tasks. Given this, any ML algorithm that is trying to separate honest workers from the sophisticated adversaries will output two groups of workers, say W_1, W_2 such that $W_1 \cup W_2 = H \cup A$ and $W_1 \cap W_2 = \phi$. Further, let us suppose that the algorithm has knowledge of k—the number of sophisticated adversaries, so that the output satisfies $|W_1| = n - k$ and $|W_2| = k$ where $|H \cup A| = n$. We call an output (W_1, W_2) *valid* if all workers in W_1 agree with each other on their labels for all tasks. Note that the "true" output $W_1 = H$ and $W_2 = A$ is valid. We argue that for the above adversary strategy, the output $W_1 = (H \setminus H^*) \cup A$ and $W_2 = H^*$ is also valid, where H^* is as defined in the proof above.

To see this, note that the algorithm can identify the set $\mathcal{T}^*$ of tasks for which there are conflicts, i.e. both $+1$ and -1 labels, and partition the set of workers labeling these tasks into two groups where workers in each group agree on their label for all tasks. Now, one of these groups consists of adversarial workers A and the other honest workers, corresponding to the set H^* above. The remaining workers correspond to the set $H \setminus H^*$. Now, if we consider the output $W_1 = (H \setminus H^*) \cup A$, any two workers in W_1 indeed agree with each other on their labels for all tasks. This is because, by the definition of PreIm, workers in $H \setminus H^*$ *only* label tasks in the set $\mathcal{T} \setminus \mathcal{T}^*$. Further, since adversaries agree with honest workers H^* on these tasks (refer to the strategy above) and honest workers are perfectly reliable, this means that adversaries A and honest workers $H \setminus H^*$ also agree with each other on their labels for all tasks in $\mathcal{T} \setminus \mathcal{T}^*$. Consequently, we have that the output $((H \setminus H^*) \cup A, H^*)$ is also *valid*. Further note that this is the only other valid output, since honest workers H^* and adversaries A do *not* agree with each other on their labels for tasks in $\mathcal{T}^*$ and therefore, cannot be placed together in the set W_1.

Finally, since the ML algorithm does not have any other information, it cannot distinguish between the two valid outputs described above, so that a random guess will misclassify $2k$ workers with probability $(1/2)$.

A.5.1 Proof of Corollary 16

We first prove that $2L \geq \lfloor \frac{k}{r} \rfloor$. Consider $\mathcal{T}' \subseteq \mathcal{T}$ such that $|\mathcal{T}'| = \lfloor \frac{k}{r} \rfloor$, note that we can always choose such a $\mathcal{T}'$ since $k < |H| \leq r \cdot |\mathcal{T}| \implies k/r < |\mathcal{T}|$. Since $\mathcal{B}_H$ is r-right regular, the pre-image of $\mathcal{T}'$ in $\mathcal{B}_H$ satisfies $|\text{PreIm}(\mathcal{T}')| \leq r|\mathcal{T}'| = r\lfloor \frac{k}{r} \rfloor \leq k$. In other words, any subset of tasks of size $\lfloor \frac{k}{r} \rfloor$ has a pre-image of size at most k. By the definition of L, we have that $2L \geq \lfloor \frac{k}{r} \rfloor$.

For the upper-bound, consider any $\mathcal{T}' \subset \mathcal{T}$ such that $|\mathcal{T}'| = e$ where $e := \lceil \frac{k}{\alpha} \rceil + 1$. Since $e < \gamma|\mathcal{T}|$, by the expander property we have that $|PreIm(\mathcal{T}')| \geq \alpha|\mathcal{T}'| = \alpha \cdot e \geq \alpha \cdot (\frac{k}{\alpha} + 1) > k$. This means that any subset $\mathcal{T}'$ of size *at least* e has a pre-image of size strictly greater than k, since the size of the pre-image can only increase with the addition of more tasks. Therefore, this implies that $2L \leq \lceil \frac{k}{\alpha} \rceil$.

For the second part of the corollary, refer to Theorem 4.4 in Chapter 4 of Vadhan et al. (2012).

A.6 Proof of Theorem 17

Before we can prove the theorem, we need the following definitions and lemmas.

Definition 20 *A bipartite graph $G = (V_1, V_2, E)$ is termed* **degenerate** *if the following condition is satisfied:*

$$|V_1| > |V_2|$$

Definition 21 *A bipartite graph $G = (V_1, V_2, E)$ is termed* **growth** *if the following condition is satisfied:*

$$\forall \ V \subseteq V_1, \ \ |V| \leq |\text{Img}(V)|$$

where $\text{Img}(V) = \{v_2 \in V_2 \mid \exists v \in V \ \text{ s.t. } (\text{v}, \text{v}_2) \in \text{E}\}$*, i.e. the set of neighboring nodes of V.*

Lemma 22 *Any bipartite graph can be decomposed into degenerate and growth sub-graphs where there are cross-edges only between the left nodes of the growth component and the right nodes of the degenerate component.*

Proof Let $G = (V_1, V_2, E)$ be a given bipartite graph. Define V^* to be the largest subset of V_1 such that $|V^*| > |\text{Img}_G(V^*)|$ where Img_G denotes the image in the graph G. If no such V^* exists then the graph is already growth and we are done. If $V^* = V_1$ then the graph is degenerate and again we are done. Else, we claim that the sub-graph J of G restricted to $V_1 \setminus V^*$ on the left and $V_2 \setminus \text{Img}_G(V^*)$ on the right is growth. Suppose not, then there exists a subset V' of nodes on the left such that $|V'| > |\text{Img}_J(V')|$ where $\text{Img}_J(V') \subseteq V_2 \setminus \text{Img}_G(V^*)$ denotes the image of V' in the sub-graph J. But then, we can add V' to V^* to get a larger degenerate sub-graph in G which contradicts our choice of

V^*. To see this, consider the set $V^* \cup V'$ on the left and $\text{Img}_G(V^*) \cup \text{Img}_J(V')$ on the right. We have $|V^* \cup V'| = |V^*| + |V'| > |\text{Img}_G(V^*)| + |\text{Img}_J(V')| = |\text{Img}_G(V^* \cup V')|$. Also, note that the only cross-edges are between $V_1 \setminus V^*$ and $\text{Img}_G(V^*)$. The claim then follows. ■

Lemma 23 *Let $G = (V_1, V_2, E)$ be a bipartite graph and suppose that M is* any *semi-matching on G. Further, let $J = (V_1, V_2', E')$ be the subgraph of G restricted to only the nodes $V_2' \subseteq V_2$ on the right. Starting with $M' \subseteq M$, we can use algorithm $\mathcal{A}_{SM2}$ in Harvey et al. (2003) to obtain an optimal semi-matching $\mathcal{N}$ for the subgraph J. Let the nodes in V_1 be indexed such that $deg_M(1) \geq deg_M(2) \geq \ldots \geq deg_M(|V_1|)$ and indexed again such that $deg_{\mathcal{N}}(1) \geq deg_{\mathcal{N}}(2) \geq \ldots \geq deg_{\mathcal{N}}(|V_1|)$. Then for any $1 \leq s \leq |V_1|$, we have $\sum_{i=1}^{s} deg_{\mathcal{N}}(i) \leq \sum_{i=1}^{s} deg_M(i)$, i.e. the sum of the top s-degrees can only decrease as we go from M to $\mathcal{N}$.*

Proof Note that if we restrict M to just the nodes V_2', we get a feasible semi-matching M' on the subgraph J. Algorithm $\mathcal{A}_{SM2}$ proceeds by the iterated removal of cost-reducing paths. Note that when a cost-reducing path is removed, load is transferred from a node with larger degree (in the current semi-matching) to a node with strictly smaller degree. To see this, let $P = (v_1^{(1)}, v_2^{(1)}, v_1^{(2)}, \ldots, v_1^{(d)})$ be a cost-reducing path (see section 2.1 in Harvey et al. (2003)) in some semi-matching $\bar{M}$ on J. This means that $deg_{\bar{M}}(v_1^{(1)}) > deg_{\bar{M}}(v_1^{(d)}) + 1$. When we eliminate the cost-reducing path P, the degree of $v_1^{(1)}$ decreases by 1 and that of $v_1^{(d)}$ increases by 1, but still the new degree of $v_1^{(d)}$ is strictly lower than the old degree of $v_1^{(1)}$. In other words, if $d_1^{\text{bef}} \geq d_2^{\text{bef}} \geq \ldots \geq d_{|V_1|}^{\text{bef}}$ and $d_1^{\text{aft}} \geq d_2^{\text{aft}} \geq \ldots \geq d_{|V_1|}^{\text{aft}}$ be the degree sequence (in the current semi-matching) before and after the removal of a cost-reducing path, then $\sum_{i=1}^{s} d_i^{\text{aft}} \leq \sum_{i=1}^{s} d_i^{\text{bef}}$ for any $1 \leq s \leq |V_1|$. Since this invariant is satisfied after every iteration of algorithm $\mathcal{A}_{SM2}$, it holds at the beginning and the end, and we have

$$\sum_{i=1}^{s} deg_{\mathcal{N}}(i) \leq \sum_{i=1}^{s} deg_{M'}(i) \tag{9}$$

Finally, observe that when we restrict M to only the set V_2', the sum of the top s-degrees can only *decrease*, i.e.

$$\sum_{i=1}^{s} deg_{M'}(i) \leq \sum_{i=1}^{s} deg_M(i) \tag{10}$$

Combining equations (9) and (10), the result follows. ■

Lemma 24 *Let $G = (V_1, V_2, E)$ be a bipartite graph and suppose that M is* any *semi-matching on G. Further, let $J = (V_1 \cup V_3, V_2, E')$ be the supergraph of G obtained by adding nodes V_3 on the left and edges $E' \setminus E$ to G. Starting with M, we can use algorithm $\mathcal{A}_{SM2}$ in Harvey et al. (2003) to obtain an optimal semi-matching $\mathcal{N}$ for the supergraph J. Let the nodes in V_1 be indexed such that $deg_M(1) \geq deg_M(2) \geq \ldots \geq deg_M(|V_1|)$ and the nodes in $V_1 \cup V_3$ indexed again such that $deg_{\mathcal{N}}(1) \geq deg_{\mathcal{N}}(2) \geq \ldots \geq deg_{\mathcal{N}}(|V_1 \cup V_3|)$. Then for any $1 \leq s \leq |V_1 \cup V_3|$, we have $\sum_{i=1}^{s} deg_{\mathcal{N}}(i) \leq \sum_{i=1}^{s} deg_M(i)$, i.e. the sum of the top s-degrees can only decrease as we go from M to $\mathcal{N}$.*

Proof Note that M is a feasible semi-matching for the graph J, with all nodes in V_3 having degree 0. We can repeat the argument from the previous lemma to show that if $d_1^{\text{bef}} \geq d_2^{\text{bef}} \geq \ldots \geq d_{|V_1 \cup V_3|}^{\text{bef}}$ and $d_1^{\text{aft}} \geq d_2^{\text{aft}} \geq \ldots \geq d_{|V_1 \cup V_3|}^{\text{aft}}$ be the degree sequence (in the current semi-matching) before and after the removal of any cost-reducing path, then $\sum_{i=1}^{s} d_i^{\text{aft}} \leq \sum_{i=1}^{s} d_i^{\text{bef}}$ for any $1 \leq s \leq |V_1 \cup V_3|$. The result then follows. ■

Notation for the proofs. Let $\mathcal{T}^+$ denote the set $\{t^+ : t \in \mathcal{T}\}$, and similarly $\mathcal{T}^-$ denote the set $\{t^- : t \in \mathcal{T}\}$, these are "task copies". Now partition the set of task copies $\mathcal{T}^+ \cup \mathcal{T}^-$ as $E \cup F$ such that for any task t, if the **true** label is $+1$, we put t^+ in E and t^- in F, otherwise, we put t^- in E and t^+ in F. Thus, E contains task copies with *true* labels while F contains task copies with *incorrect* labels. Let $F' \subseteq F$ denote the set of tasks for which honest workers provide incorrect responses, and denote the optimal semi-matching on the graph $\mathcal{B}_H^{cs}$ by $\mathcal{M}_H$. Without loss of generality, suppose that honest workers are indexed such that $d_1 \geq d_2 \geq \cdots \geq d_{|H|}$ where d_h denotes the degree of honest worker h in semi-matching $\mathcal{M}_H$.

Part 1. Adversary strategy that affects at least $\frac{1}{2}\sum_{i=1}^{k-1} d_i$ tasks

If $\varepsilon = 0$, there are no conflicts in the responses provided by honest workers, and therefore the bipartite graph $\mathcal{B}_H^{cs}$ contains just "true" task copies E on the right.

Given this, the adversaries *target* honest workers $\{1, 2, \ldots, k-1\}$: for each i, adversary a_i labels opposite to worker h_i (i.e. provides the incorrect response) on every task that h_i is mapped to in the semi-matching $\mathcal{M}_H$. Furthermore, the adversary uses its last identity a_k to provide the incorrect response on every task $t \in \mathcal{T}$ for which one of the first $k-1$ adversaries have not already labeled on. We argue that under the penalty-based aggregation algorithm, this adversary strategy results in incorrect labels for at least $\frac{1}{2}\sum_{i=1}^{k-1} d_i$ tasks. To see this, first note that the conflict set $\mathcal{T}_{cs} = \mathcal{T}$. Further, the bipartite graph $\mathcal{B}^{cs}$ decomposes into two disjoint subgraphs: bipartite graph $\mathcal{B}^{cs}(E)$ between H and E and semi-matching $M(F)$ between A and F that represents the adversary labeling strategy (it is a semi-matching because there is exactly one adversary that labels each task). Since the bipartite graph $\mathcal{B}^{cs}$ decomposes into two disjoint bipartite graphs, computing the optimal semi-matching on $\mathcal{B}^{cs}$ is equivalent to separately computing optimal semi-matchings on $\mathcal{B}^{cs}(E)$ and M_F. The argument above says that $\mathcal{B}^{cs}(E)$ is nothing but the graph $\mathcal{B}_H^{cs}$ defined in the theorem statement and therefore $\mathcal{M}_H$ is the optimal semi-matching on $\mathcal{B}^{cs}(E)$. Given that $M(F)$ is already a semi-matching by construction, the optimal semi-matching on $\mathcal{B}^{cs}$ is the disjoint union of $\mathcal{M}_H$ and $M(F)$. It is easy to see that in the resultant semi-matching, honest worker h_i and adversary a_i have the same degrees for $i = 1, 2, \ldots, k-1$. Hence, for every task mapped to honest worker h_i for $i = 1, 2, \ldots, k-1$ in the optimal semi-matching, the algorithm outputs a random label, and therefore outputs the correct label for at most half of these tasks. Thus, the above adversary strategy results in incorrect labels for at least $\frac{1}{2}\sum_{i=1}^{k-1} d_i$ tasks.

Part 2. Upper Bound on number of affected tasks

To simplify the exposition, we assume in the arguments below that the optimal semi-matching in the HARD PENALTY algorithm is computed for the entire task set and not just

the conflict set $\mathcal{T}_{cs}$. However, the bounds provided still hold as a result of lemma 23 above. Consequently, we abuse notation and use $\mathcal{B}^{cs}$ to denote the following bipartite graph in the remainder of the discussion: each worker w is represented by a node on the left, each task t is represented by at most two nodes on the right – t^+ and t^- – and we add an edge (w, t^+) if worker w labels task t as $+1$ and edge (w, t^-) if w labels t as -1. Then, it is easy to see that the subgraph of $\mathcal{B}^{cs}$ restricted to just the honest workers H on the left and task copies $E \cup F'$ on the right, is nothing but the graph $\mathcal{B}^{cs}_H$ defined in the theorem statement. Consequently, $\mathcal{M}_H$ is a feasible semi-matching for the subgraph $\mathcal{B}^{cs}(E \cup F')$, which is obtained by restricting $\mathcal{B}^{cs}$ to nodes $E \cup F'$ on the right. Further, we can assume that the adversary labeling strategy is always a semi-matching, i.e. there is at most one adversary response for any task. If the adversary labeling strategy is not a semi-matching, they can replace it with an alternate strategy where they only label for tasks to which they will be mapped in the optimal semi-matching (the adversaries can compute this since they have knowledge of the honest workers' responses). The optimal semi-matching doesn't change (otherwise it contradicts the optimality of the original semi-matching) and hence neither does the number of affected tasks.

We first state the following important lemma:

Lemma 25 *For any adversary labeling strategy, let $\mathcal{B}^{cs}(E \cup F')$ denote the bipartite graph $\mathcal{B}^{cs}$ restricted to all the workers $W = H \cup A$ on the left and, "true" task copies E as well as subset F' of the "incorrect" task copies F on the right. Let $\mathcal{M}$ be the optimal semi-matching on the bipartite graph $\mathcal{B}^{cs}$ and $\mathcal{M}(E \cup F') \subset M$ be the semi-matching $\mathcal{M}$ restricted to only the task copies $E \cup F'$. Then, $\mathcal{M}(E \cup F')$ is an optimal semi-matching for the sub-graph $\mathcal{B}^{cs}(E \cup F')$.*

Proof First observe that if $F' = F$, then the statement is trivially true. So we can assume $F' \subset F$. Suppose the statement is not true and let $\mathcal{N}(E \cup F')$ denote the optimal semi-matching on $\mathcal{B}^{cs}(E \cup F')$. We use $d_w(K)$ to denote the degree of worker w in a semi-matching K. Note that, $d_a(\mathcal{N}(E \cup F')) \leq d_a(\mathcal{M}(E \cup F')) \leq d_a(\mathcal{M})$ for all adversaries $a \in A$, where the first inequality follows from the fact that the adversary strategy is a semi-matching and the second inequality is true because $\mathcal{M}(E \cup F') \subset \mathcal{M}$. The adversaries who do not provide any responses for the task copies $E \cup F'$ will have degrees 0 in the semi-matchings $\mathcal{N}(E \cup F')$ and $\mathcal{M}(E \cup F')$ but the inequality is still satisfied. Now, since $\mathcal{N}(E \cup F')$ is an optimal semi-matching and $\mathcal{M}(E \cup F')$ is not, we have that

$$cost(\mathcal{N}(E \cup F')) < cost(\mathcal{M}(E \cup F')) \Rightarrow$$
$$\sum_{h \in H} d_h^2(\mathcal{N}(E \cup F')) + \sum_{a \in A} d_a^2(\mathcal{N}(E \cup F')) < \sum_{h \in H} d_h^2(\mathcal{M}(E \cup F')) + \sum_{a \in A} d_a^2(\mathcal{M}(E \cup F'))$$

Now, consider the semi-matching $\mathcal{N}$ on $\mathcal{B}^{cs}$ where we start with the semi-matching $\mathcal{N}(E \cup F')$ and then map the remaining task copies in $\mathcal{B}^{cs}$ (which belong to the set $F \setminus F'$) to the adversaries which they were assigned to in $\mathcal{M}$. We claim that $cost(\mathcal{N}) < cost(\mathcal{M})$ which is

a contradiction since $\mathcal{M}$ was assumed to be an optimal semi-matching on $\mathcal{B}^{cs}$. To see this:

$$\begin{aligned}
&cost(\mathcal{M}) - cost(\mathcal{N}) \\
&= \sum_{h \in H} d_h^2(\mathcal{M}) + \sum_{a \in A} d_a^2(\mathcal{M}) - \left(\sum_{h \in H} d_h^2(\mathcal{N}) + \sum_{a \in A} d_a^2(\mathcal{N}) \right) \\
&= \sum_{h \in H} d_h^2(\mathcal{M}(E \cup F')) + \sum_{a \in A} \left(d_a(\mathcal{M}(E \cup F')) + \Delta_a \right)^2 \\
&- \left(\sum_{h \in H} d_h^2(\mathcal{N}(E \cup F')) + \sum_{a \in A} \left(d_a(\mathcal{N}(E \cup F')) + \Delta_a \right)^2 \right) \\
&\Big(\text{where } \Delta_a \stackrel{\text{def}}{=} d_a(\mathcal{M}) - d_a(\mathcal{M}(E \cup F')) \geq 0 \Big) \\
&= \left(\sum_{h \in H} d_h^2(\mathcal{M}(E \cup F')) + \sum_{a \in A} d_a^2(\mathcal{M}(E \cup F')) - \sum_{h \in H} d_h^2(\mathcal{N}(E \cup F')) - \sum_{a \in A} d_a^2(\mathcal{N}(E \cup F')) \right) \\
&+ 2 \sum_{a \in A} \left(d_a(\mathcal{M}(E \cup F')) - d_a(\mathcal{N}(E \cup F')) \right) * \Delta_a > 0 \\
&\big(\text{since } d_a(\mathcal{M}(E \cup F')) \geq d_a(\mathcal{N}(E \cup F')) \text{ as stated above} \big)
\end{aligned}$$

Therefore, $\mathcal{M}(E \cup F')$ is an optimal semi-matching for the sub-graph $\mathcal{B}^{cs}(E \cup F')$. ■

Part 2a. Adversaries only provide incorrect responses or one adversary provides correct responses

Adversaries only provide incorrect responses. Let us begin with the case when all adversaries only provide incorrect responses.

Lemma 26 *Suppose that $\varepsilon = 0$ and adversaries only provide incorrect responses. Let M be an* arbitrary *semi-matching on the bipartite graph $\mathcal{B}^{cs}$ and suppose that this semi-matching is used in the* penalty-based aggregation *Algorithm to compute the true labels of the tasks. Further, let $b_1 \geq b_2 \geq \cdots \geq b_{|H|}$ denote the degrees of the honest workers in this semi-matching where b_i is the degree of honest worker h_i. Then, the number of affected tasks is at most $\sum_{i=1}^{k} b_i$.*

Proof It follows from the assumption that $\varepsilon = 0$ and that adversaries only provide incorrect responses, that there are no cross-edges between nodes H and F as well as A and E in the bipartite graph $\mathcal{B}^{cs}$. Thus, for any adversary labeling strategy, we can decompose $\mathcal{B}^{cs}$ into *disjoint* bipartite graphs $\mathcal{B}^{cs}(E)$ and $\mathcal{B}^{cs}(F)$, where $\mathcal{B}^{cs}(E)$ is the subgraph consisting of honest workers H and task copies E and $\mathcal{B}^{cs}(F)$ is the subgraph between the adversaries A and the task copies F. This further means that the semi-matching M is a disjoint union of semi-matchings on $\mathcal{B}^{cs}(E)$ and $\mathcal{B}^{cs}(F)$. Let the semi-matchings on the subgraphs be termed as $M(E)$ and $M(F)$ respectively. Further, let $T_{\text{aff}} \subseteq \mathcal{T}$ denote the set of tasks that are affected under this strategy of the adversaries and when the semi-matching M is used to compute the penalties of the workers in the penalty-based aggregation algorithm.

We claim that $|T_{\text{aff}}| \leq \sum_{i=1}^{k} b_i$. To see this, for each adversary $a \in A$, let $H(a) \subset H$ denote the set of honest workers who have "lost" to a i.e., for each worker $h \in H(a)$ there exists some task $t \in \mathcal{T}_{cs}$ such that h is mapped to the *true* copy of t in $M(E)$, a is mapped to the *incorrect* copy of t in $M(F)$, and the degree of h in $M(E)$ is greater than or equal to the degree of a in $M(F)$. Of course, $H(a)$ may be empty. Let $\bar{A}$ denote the set of adversaries $\{a \in A \colon H(a) \neq \emptyset\}$ and let $\bar{H}$ denote the set of honest workers $\bigcup_{a \in \bar{A}} H(a)$. Now define a bipartite graph between the nodes $\bar{A}$ and $\bar{H}$ with an edge between $a \in \bar{A}$ and $h \in \bar{H}$ if and only if $h \in H(a)$. This bipartite graph can be decomposed into degenerate and growth subgraphs by lemma 22 above. In the growth subgraph, by Hall's condition, we can find a perfect matching from adversaries to honest workers. Let (A_1, H_1) with $A_1 \subseteq \bar{A}$ and $H_1 = \text{Img}(A_1)$ be the degenerate component. The number of tasks that adversaries in A_1 affect is bounded above by $\sum_{h \in \text{Img}(A_1)} b_h$. Similarly, for $A_2 = \bar{A} \setminus A_1$, we can match each adversary to a *distinct* honest worker whose degree in $M(E)$ is greater than or equal to the degree of the adversary in $M(F)$. We can bound the number of affected tasks caused due to the adversaries in A_2 by the sum of their degrees, which in turn is bounded above by the sum of the degrees of honest workers that the adversaries are matched to. Let H_2 denote the set of honest workers matched to adversaries in the perfect matching. Thus, we have upper bounded the number of affected tasks by $\sum_{h \in H_1 \cup H_2} b_h$. It is easy to see that $|H_1 \cup H_2| \leq k$. Therefore, $\sum_{h \in H_1 \cup H_2} b_h \leq \sum_{i=1}^{k} b_i$. Therefore, the number of affected tasks $|T_{\text{aff}}|$ is at most $\sum_{i=1}^{k} b_i$. ■

We now extend the above lemma to the case when $\varepsilon \neq 0$.

Lemma 27 *Suppose that adversaries only provide incorrect responses. Let M be an* arbitrary *semi-matching on the bipartite graph $\mathcal{B}^{cs}$ and suppose that this semi-matching is used in the* penalty-based aggregation *Algorithm to compute the true labels of the tasks. Further, let $b_1 \geq b_2 \geq \cdots \geq b_{|H|}$ denote the degrees of the honest workers in this semi-matching where b_i is the degree of honest worker h_i. Then, the number of affected tasks is at most $\sum_{i=1}^{k+\varepsilon \cdot |H|} b_i$.*

Proof Since honest workers can make mistakes, there are cross-edges between H and F in the bipartite graph $\mathcal{B}^{cs}$. Observe that there are two kinds of affected tasks in this case: (1) tasks that adversaries "win" against honest workers, say $T_{\text{aff}}(A)$, similar to those in the previous lemma and (2) tasks that are affected when 2 honest workers are compared in the final step of the penalty-based aggregation algorithm, say $T_{\text{aff}}(H)$. We can repeat the argument from lemma 26 above to bound $|T_{\text{aff}}(A)|$ by the sum of the degrees of (some) k honest workers, say H_k, in semi-matching M. Further, we can bound $|T_{\text{aff}}(H)|$ by the sum of the degrees of honest workers who make mistakes, in the semi-matching M. By assumption, there are at most $\varepsilon \cdot |H|$ such workers. Now if any of these workers belong to H_k, then we have already accounted for their degree. Consequently, we have that $|T_{\text{aff}}(H)| + |T_{\text{aff}}(A)|$ is upper bounded by the sum of the degrees of the top $k + \varepsilon \cdot |H|$ honest workers in the semi-matching M, which establishes the result. ■

Since the above lemmas are true for *any* choice of semi-matching M, they hold in particular for the optimal semi-matching on $\mathcal{B}^{cs}$. Therefore, it gives us an upper bound on the number of affected tasks when the adversaries only provide incorrect responses.

One adversary provides correct responses. Next consider the case when there is exactly 1 adversary that provides correct responses and all other adversaries only provide incorrect responses. Let $\mathcal{M}$ be the optimal semi-matching on the bipartite graph $\mathcal{B}^{cs}$ resulting from such an adversary strategy and let $\bar{a}$ denote the adversary who provides correct responses. Observe that we can repeat the argument from lemma 27 above to get an upper bound on the number of affected tasks that the adversaries "win" against honest workers as well as those that honest workers who make mistakes "win" against other honest workers. Let T_1 be the collection of such tasks. In the proof of lemma 26, there are two possible scenarios: either we obtain a perfect matching between the k adversaries and some k honest workers in which case we have accounted for all of the affected tasks that come from adversaries winning (against honest workers or $\bar{a}$). In the other scenario, when the degenerate component is non-empty, we have at most $k-1$ honest workers on the right and we bound the number of tasks that adversaries "win" by the sum of the degrees of these honest workers. Note however that we may be missing out on some of the affected tasks, namely those that the adversary $\bar{a}$ "loses" against *other adversaries* (the losses against honest workers who make mistakes are already accounted for). The tasks that we might be missing out on correspond exactly to the task copies in E that the adversary $\bar{a}$ is mapped to in the optimal semi-matching $\mathcal{M}$.

Next observe that in both scenarios above—all adversaries provide incorrect responses and exactly one adversary provides correct responses—we can upper bound the total number of affected tasks by the sum of the degrees of some $k + \varepsilon \cdot |H|$ workers in the optimal semi-matching $\mathcal{M}$ restricted to just the task copies $E \cup F'$ on the right (since honest workers provide responses only on these tasks), which we denote as $\mathcal{M}(E \cup F')$. Lemma 25 tells us that $\mathcal{M}(E \cup F')$ is, in fact, the optimal semi-matching on the subgraph $\mathcal{B}^{cs}(E \cup F')$ between workers W and the task copies $E \cup F'$. In addition, lemma 24 tells us that this sum is at most $\sum_{i=1}^{k+\varepsilon \cdot |H|} d_i$ (by starting with $\mathcal{M}_H$ as a feasible semi-matching) and the bound follows.

Part 2b. Adversaries can provide arbitrary responses

Consider the general case when all adversaries can provide arbitrary responses. First recall that lemma 27 was applicable to any semi-matching and in fact, we can use the argument even when adversaries provide correct responses. Formally, consider an arbitrary adversary strategy resulting in an optimal semi-matching $\mathcal{M}$ on $\mathcal{B}^{cs}$. Let $\mathcal{M}(E \cup F')$ denote the semi-matching M restricted to just the task copies $E \cup F'$. Suppose that the set of affected tasks T_{aff} under this adversary strategy is such that $T_{\text{aff}} = T_{\text{aff}}(A_1) \cup T_{\text{aff}}(H) \cup T_{\text{aff}}(A_2)$ where $T_{\text{aff}}(A_1)$ are the tasks that the adversaries "win" against honest workers, $T_{\text{aff}}(H)$ are the tasks that honest workers who make mistakes "win" (against other honest workers and/or adversaries) and $T_{\text{aff}}(A_2)$ are the tasks that are affected when 2 adversaries are compared against each other in the final step of the penalty-based aggregation algorithm. We can then utilize the argument in lemma 27 to bound $|T_{\text{aff}}(H)| + |T_{\text{aff}}(A_1)|$ by the sum of the degrees of (some) $k + \varepsilon \cdot |H|$ honest workers in the optimal semi-matching $\mathcal{M}$ (the

tasks affected when honest workers who make mistakes win against adversaries are also accounted). Further, we can bound $|T_{\text{aff}}(A_2)|$ by the sum of the degrees of the adversaries in the semi-matching $\mathcal{M}(E)$, which is the semi-matching $\mathcal{M}$ restricted to task copies E.

Let $A(H) \subseteq A$ denote the adversaries that have non-zero degrees in semi-matching $\mathcal{M}(E)$, i.e. they are mapped to some task copy in E in semi-matching $\mathcal{M}$. The above sequence of claims implies that we can bound the number of affected tasks $|T_{\text{aff}}|$ by the sum of the degrees of the top $s = k + \varepsilon \cdot |H| + |A(H)|$ workers in the semi-matching $\mathcal{M}(E \cup F')$, which is $\mathcal{M}$ restricted to the task copies $E \cup F'$ (because honest workers, by assumption, only provide responses on task copies $E \cup F'$ and the semi-matching $\mathcal{M}(E) \subseteq \mathcal{M}(E \cup F')$). Now, we claim that this itself is upper bounded by the sum of the degrees of the top s honest workers in the optimal semi-matching $\mathcal{M}_H$ on the bipartite graph $\mathcal{B}^{cs}_H$. To see this, start with $\mathcal{M}_H$ as a feasible semi-matching from workers W to task copies $E \cup F'$ (recall that it is feasible since we assume that each task has at least one correct response from honest workers). Then, lemma 24 tells us that the sum of the degrees of the top s workers in the optimal semi-matching on $\mathcal{B}^{cs}(E \cup F')$ is at most the sum of the degrees of the top s honest workers in $\mathcal{M}_H$. Further, lemma 25 tells us that the optimal semi-matching on the subgraph $\mathcal{B}^{cs}(E \cup F')$ is precisely the semi-matching $\mathcal{M}(E \cup F')$. This shows that we can bound the number of affected tasks by $\sum_{i=1}^{s} d_i$. Finally, note that $|A(H)| \leq k \Rightarrow s \leq 2k + \varepsilon \cdot |H|$ and hence, we can bound the total number of affected tasks by $\sum_{i=1}^{2k+\varepsilon\cdot|H|} d_i$.

A.7 Uniqueness of degree-sequence in optimal semi-matchings

In the arguments above, we have implicitly assumed some sort of uniqueness for the optimal semi-matching on any bipartite graph. Clearly its possible to have multiple optimal semi-matchings for a given bipartite graph. However, we prove below that the degree sequence of the vertices is unique across all optimal semi-matchings and hence our bounds still hold without ambiguity.

Lemma 28 *Let M and M' be two optimal semi-matchings on a bipartite graph $G = (V_1, V_2, E)$ with $|V_1| = n$ and let $d_1 \geq d_2 \cdots \geq d_n$ and $d'_1 \geq d'_2 \geq \cdots d'_n$ be the degree sequence for the V_1-vertices in M and M' respectively. Then, $d_i = d'_i \ \forall\ 1 \leq i \leq n$, or in other words, any two optimal semi-matchings have the same degree sequence.*

Proof Let s be the smallest index such that $d_s \neq d'_s$, note that we must have $s < n$ since we have that $\sum_{j=1}^{n} d'_j = \sum_{j=1}^{n} d_j$. This means that we have $d_j = d'_j\ \forall j < s$. Without loss of generality, assume that $d'_s > d_s$. Now, $\exists q \in \mathbb{N}$ such that $d'^q_s > d^q_s + \sum_{j=s+1}^{n} d^q_j$ and since $d_j = d'_j\ \forall j < s$, we have that $\sum_{j=1}^{n} d'^q_j \geq \sum_{j=1}^{l} d'^q_j > \sum_{j=1}^{n} d^q_j$. But, this is a contradiction since an optimal semi-matching minimizes the $\mathcal{L}_p$ norm of the degree-vector of V_1-vertices for any $p \geq 1$ (Section 3.4 in Harvey et al. (2003)). Hence, we have that $d_i = d'_i\ \forall i$. ■

A.8 Relation between Lower bound L and Optimal semi-matching degrees

We prove here the relationship between the lower bound L in theorem 14 and the honest worker degrees $d_1, d_2, \ldots, d_{|H|}$ in the optimal semi-matching on the bipartite graph $\mathcal{B}^{cs}_H$.

Lemma 29 *Suppose that honest workers are perfectly reliable and let $d_1 > d_2 > \cdots > d_{|H|}$ denote the degrees of the honest workers in the optimal semi-matching $\mathcal{M}_H$ on $\mathcal{B}^{cs}_H$. Then the lower bound L in theorem 14 is such that $L \geq \sum_{i=1}^{k-1} d_i$.*

Proof Let $T_1, T_2, \ldots, T_{k-1}$ denote the set of tasks that are mapped to honest workers $h_1, h_2, \ldots, h_{k-1}$ in $\mathcal{M}_H$ and $T := \bigcup_{j=1}^{k-1} T_j$. Now, we claim that for any $t \in T$, the only honest workers that provide responses for t are amongst $h_1, h_2, \ldots, h_k$. In other words, $\text{PreIm}(T) \subseteq \{h_1, h_2, \ldots, h_k\}$. Suppose not, so that there exists $h_i \in \text{PreIm}(T)$ such that $i > k$. This would contradict the fact that $\mathcal{M}_H$ is an optimal semi-matching. Specifically, Theorem 3.1 in Harvey et al. (2003) shows that a semi-matching M is optimal if and only if there is no *cost-reducing path* relative to M. A cost-reducing path $P = (h^{(1)}, t^{(1)}, h^{(2)}, \ldots h^{(d)})$ for a semi-matching M on $\mathcal{B}^{cs}_H$ is an alternating sequence of honest workers and tasks such that $t^{(x)}$ is mapped to $h^{(x)}$ in the semi-matching M for all $1 \leq x \leq d-1$ and $deg_M(h^{(1)}) > deg_M(h^{(d)}) + 1$. Here $deg_M()$ denotes the degree of a node in the semi-matching M (see section 2.1 in Harvey et al. (2003) for a precise definition). Since $i > k$, we have that $d_s > d_i + 1$ for all $s \in \{1, 2, \ldots, k-1\}$, which introduces a cost-reducing path. Therefore, we have that $\text{PreIm}(T) \subseteq \{h_1, h_2, \ldots, h_k\}$. Now

$$|T| = |\bigcup_{j=1}^{k-1} T_j| = \sum_{j=1}^{k-1} |T_j| = \sum_{j=1}^{k-1} d_j$$

where we have used the property of a semi-matching that a given task is mapped to only one worker. Using the definition of the lower bound L, it follows that $L \geq |T| = \sum_{i=1}^{k-1} d_i$. ■

Appendix B. Experimental Details

In this section we describe the details of our experimental setup discussed in section 5. We start with the benchmark algorithms.

EM algorithm. We consider the EM algorithm proposed by Raykar and Yu (2012). The worker model they consider is as follows: for each worker w_i, her accuracy is modeled separately for positive and negative tasks (referred to as the "two-coin" model). For a task t_j with true label $+1$, the *sensitivity* (true positive rate) for worker w_i is defined as:

$$\alpha_i := \Pr[w_i(t_j) = +1 \,\Big|\, y_j = +1]$$

Similarly, the *specificity* (1- false positive rate) is defined as:

$$\beta_i := \Pr[w_i(t_j) = -1 \,\Big|\, y_j = -1]$$

Let $\boldsymbol{\Theta} = [\left\{(\alpha_i, \beta_i) \,\Big|\, i \in [n]\right\}, \gamma]$ denote the set of all parameters. For ease of exposition, we assume that the worker-task assignment graph is complete, i.e. all workers provide responses for all items, but the algorithm can be immediately extended to the case of

incomplete graphs. Given the response matrix $\mathcal{L}$, the log-likelihood of the parameters Θ can be written as:

$$\log Pr[\mathcal{L} \Big| \boldsymbol{\Theta}] = \sum_{j=1}^{m} \log \left(\prod_{i=1}^{n} \alpha_i^{\mathbf{1}[\mathcal{L}_{ij}=+1]} \cdot (1-\alpha_i)^{\mathbf{1}[\mathcal{L}_{ij}=-1]} \cdot \gamma + \prod_{i=1}^{n} (1-\beta_i)^{\mathbf{1}[\mathcal{L}_{ij}=+1]} \cdot \beta_i^{\mathbf{1}[\mathcal{L}_{ij}=-1]} \cdot (1-\gamma) \right)$$

The MLE of the parameters can be computed by introducing the latent true label of each task, denoted by the vector $\boldsymbol{y} = [y_1, y_2, \ldots, y_m]$. The complete data log-likelihood can then be written as:

$$\log Pr[\mathcal{L}, \boldsymbol{y} \Big| \boldsymbol{\Theta}] = \sum_{j=1}^{m} \Big(y_j \log(a_j \gamma) + (1-y_j) \log(1-\gamma) b_j \Big) \tag{11}$$

where

$$a_j = \prod_{i=1}^{n} \alpha_i^{\mathbf{1}[\mathcal{L}_{ij}=+1]} \cdot (1-\alpha_i)^{\mathbf{1}[\mathcal{L}_{ij}=-1]}$$
$$b_j = \prod_{i=1}^{n} (1-\beta_i)^{\mathbf{1}[\mathcal{L}_{ij}=+1]} \cdot \beta_i^{\mathbf{1}[\mathcal{L}_{ij}=-1]}$$

Each iteration of the EM algorithm consists of two steps:

- **E-step:** Given the response matrix $\mathcal{L}$ and the current estimate of the model parameters $\boldsymbol{\Theta}^{(k)}$, the conditional expectation of the complete data log-likelihood is computed as

  $$\mathbb{E}\left\{ \log \Pr[\mathcal{L}, \boldsymbol{y} \Big| \boldsymbol{\Theta}^{(k)}] \right\} = \sum_{j=1}^{m} \Big(\gamma_j^{(k)} \log(a_j^{(k)} \gamma^{(k)}) + (1-\gamma_j^{(k)}) \log(1-\gamma^{(k)}) b_j^{(k)} \Big)$$

  where the expectation is w.r.t to $\Pr[\boldsymbol{y} \Big| \mathcal{L}; \boldsymbol{\Theta}^{(k)}]$ and $\gamma_j^{(k)} = \Pr[y_j = +1 \Big| \mathcal{L}; \boldsymbol{\Theta}^{(k)}]$. Using Bayes theorem, we can compute

  $$\gamma_j^{(k)} \propto \Pr[\mathcal{L}_{1j}, \mathcal{L}_{2j}, \ldots, \mathcal{L}_{nj} \Big| y_j = +1; \boldsymbol{\Theta}^{(k)}] \cdot \Pr[y_j = +1 \Big| \boldsymbol{\Theta}^{(k)}] = \frac{a_j^{(k)} \gamma^{(k)}}{a_j^{(k)} \gamma^{(k)} + b_j^{(k)} (1-\gamma^{(k)})}$$

- **M-step:** Based on the current posterior estimates of the true labels $\gamma_j^{(k)}$ and the response matrix $\mathcal{L}$, the model parameters are updated by maximizing $\mathbb{E}\left\{ \log \Pr[\mathcal{L}, \boldsymbol{y} \Big| \boldsymbol{\Theta}^{(k)}] \right\}$, which can be shown to be a lower bound on the data log-likelihood (eq 11). The prevalence of positive tasks γ is updated as:

  $$\gamma^{(k+1)} = \frac{\sum_{j=1}^{m} \gamma_j^{(k)}}{m}$$

Similarly, the parameters α_i, β_i are updated as:

$$\alpha_i^{(k+1)} = \frac{\sum_{j=1}^{m} \mathbf{1}[\mathcal{L}_{ij} = +1] \gamma_j^{(k)}}{\sum_{j=1}^{m} \gamma_j^{(k)}}$$
$$\beta_i^{(k+1)} = \frac{\sum_{j=1}^{m} \mathbf{1}[\mathcal{L}_{ij} = -1] (1-\gamma_j^{(k)})}{\sum_{j=1}^{m} (1-\gamma_j^{(k)})}$$

These two steps are iterated until convergence of the log-likelihood $\Pr[\mathcal{L} \Big| \boldsymbol{\Theta}]$. To initialize the EM algorithm, we use the majority estimate $\gamma_j^{(0)} = \frac{\sum_{i=1}^{n} \mathbf{1}[\mathcal{L}_{ij}=+1]}{n}$.

We implement the above algorithm in our experiments. Note that the model we consider in the theoretical analysis is the simpler "one-coin" model where every worker is characterized by only a single parameter μ_i - the probability that she labels an assigned task correctly. The EM algorithm for that case can be derived in a similar manner to the one described above; see the proof of Lemma 13 above.

KOS algorithms. We implemented the iterative algorithm presented in Karger et al. (2014) which we replicate below in our notation.

Algorithm 4 KOS algorithm

1: **Input:** $\mathcal{L}$,$\mathcal{B} = (W, \mathcal{T}, E)$, $k_{\max}$.
2: For all $(w_i, t_j) \in E$, initialize $m_{i \to j}^{(0)}$ with random $Z_{ij} \sim \mathcal{N}(1,1)$
3: For $k = 1, 2, \ldots, k_{\max}$,

- For all $(w_i, t_j) \in E$, update $m_{j \to i}^{(k)} = \sum_{i' \neq i} \mathcal{L}_{ij} m_{i \to j}^{(k-1)}$
- For all $(w_i, t_j) \in E$, update $m_{i \to j}^{(k)} = \sum_{j' \neq j} \mathcal{L}_{ij} m_{j \to i}^{(k)}$

4: For all t_j, compute $m_j = \sum_{i=1}^{n} \mathcal{L}_{ij} m_{i \to j}^{(k_{\max}-1)}$
5: **Output:** label for task t_j as $\hat{y}_j = \text{sign}(\text{m}_\text{j})$

This algorithm was proposed for random regular graphs in the paper and we modified it in the following way for use in non-regular graphs:

Algorithm 5 KOS(NORM) algorithm

1: **Input:** $\mathcal{L}$,$\mathcal{B} = (W, \mathcal{T}, E)$, $k_{\max}$.
2: For all $(w_i, t_j) \in E$, initialize $m_{i \to j}^{(0)}$ with random $Z_{ij} \sim \mathcal{N}(1,1)$
3: For $k = 1, 2, \ldots, k_{\max}$,

- For all $(w_i, t_j) \in E$, update $m_{j \to i}^{(k)} = \frac{1}{deg_{\mathcal{B}}(t_j)} \sum_{i' \neq i} \mathcal{L}_{ij} m_{i \to j}^{(k-1)}$
- For all $(w_i, t_j) \in E$, update $m_{i \to j}^{(k)} = \frac{1}{deg_{\mathcal{B}}(w_i)} \sum_{j' \neq j} \mathcal{L}_{ij} m_{j \to i}^{(k)}$

4: For all t_j, compute $m_j = \sum_{i=1}^{n} \mathcal{L}_{ij} m_{i \to j}^{(k_{\max}-1)}$
5: **Output:** label for task t_j as $\hat{y}_j = \text{sign}(\text{m}_\text{j})$

We chose $k_{\max} = 100$ in our experiments.

Simulation Details. Here we discuss how we imposed the degree bias on adversaries in our simulation study. Given a worker-task assignment graph, let d_w denote the degree of worker w and $d_{\min}, d_{\text{avg}}, d_{\max}$ denote resp. the minimum, average and maximum worker degrees.

- *Adversaries have high degrees*. For each worker w, define $q_w = q \cdot \frac{d_{\max} - d_w}{d_{\max} - d_{\text{avg}}}$. Then, each worker w is an adversary with probability $1 - q_w$. First, note that the expected number of honest workers is given by

$$\sum_w q_w = \frac{q}{d_{\max} - d_{\text{avg}}} \sum_w (d_{\max} - d_w) = q \cdot n$$

  Next, we can see that workers with higher degrees have a smaller q_w, which implies that they have a greater chance of being an adversary. In an analogous manner, we deal with the case of low degrees.

- *Adversaries have low degrees*. For each worker w, define $q_w = q \cdot \frac{d_w - d_{\min}}{d_{\text{avg}} - d_{\min}}$. Then, each worker w is an adversary with probability $1 - q_w$. Again, we have that the expected number of honest workers is given by

$$\sum_w q_w = \frac{q}{d_{\text{avg}} - d_{\min}} \sum_w (d_w - d_{\min}) = q \cdot n$$

  In this case, lower the degree d_w, higher the chance $(1 - q_w)$ that a worker is chosen as an adversary.

Abstract

Many applications, such as human action recognition and object detection, can be formulated as a multiclass classification problem. One-vs-rest (OVR) is one of the most widely used approaches for multiclass classification due to its simplicity and excellent performance. However, many confusing classes in such applications will degrade its results. For example, *hand clap* and *boxing* are two confusing actions. *Hand clap* is easily misclassified as *boxing*, and vice versa. Therefore, precisely classifying confusing classes remains a challenging task. To obtain better performance for multiclass classifications that have confusing classes, we first develop a classifier chain model for multiclass classification (CCMC) to transfer class information between classifiers. Then, based on an analysis of our proposed model, we propose an easy-to-hard learning paradigm for multiclass classification to automatically identify easy and hard classes and then use the predictions from simpler classes to help solve harder classes. Similar to CCMC, the classifier chain (CC) model is also proposed by Read et al. (2009) to capture the label dependency for multi-label classification. However, CC does not consider the order of difficulty of the labels and achieves degenerated performance when there are many confusing labels. Therefore, it is non-trivial to learn the appropriate label order for CC. Motivated by our analysis for CCMC, we also propose the easy-to-hard learning paradigm for multi-label classification to automatically identify easy and hard labels, and then use the predictions from simpler labels to help solve harder labels. We also demonstrate that our proposed strategy can be successfully applied to a wide range of applications, such as ordinal classification and relationship prediction. Extensive empirical studies validate our analysis and the effectiveness of our proposed easy-to-hard learning strategies.

Keywords: Multiclass Classification, Multi-label Classification, Classifier Chain, Easy-to-hard Learning Paradigm

1. Introduction

Many applications can be formulated as a multiclass classification problem. For example, human action recognition aims to classify videos into different categories of human action. In the KTH data set (Schüldt et al., 2004), for example, there are six types of human action: *walk*, *jog*, *run*, *hand wave*, *hand clap* and *boxing*. These actions can be classified into two main categories: leg movements (*walk*, *jog* and *run*) and hand movements (*hand wave*, *hand clap* and *boxing*). It is easy to differentiate between leg and hand movements, such as *walk* and *hand wave*, but actions within leg or hand movements, such as hand clap and boxing, are easily confused. *Hand clap* is easily misclassified as *boxing*, and vice versa. Confusing classes are ubiquitous in real world applications, especially for data sets with many classes. For example, there are many confusing classes in the ALOI data set from the LIBSVM website[1], which contains 1,000 classes. Therefore, precisely classifying multiclass data sets with confusing classes is a challenging task.

From the confusion matrix of one-vs-rest (OVR) on the KTH data set shown in Figure 1, we observe that *walk* is the easiest action to classify and *hand clap* is the hardest action to classify, as the *walk* action can be correctly identified by OVR whereas the percentage of *hand clap* images that are misclassified as *boxing* is 22.5%. To achieve accurate prediction performance, according to Figure 1, we should classify *walk* first, followed by *run*, *jog* and *hand wave*. *Boxing* and *hand clap* are the last two actions to classify. The motivation behind this paper is to solve classification tasks from easy to hard, and to use the predictions from simpler tasks to help solve the harder tasks.

To achieve our goal, a classifier chain model for multiclass classification (CCMC) is proposed to transfer class information between classifiers. Furthermore, we generalize CCMC over a random class order and provide a theoretical analysis of the generalization error for the proposed generalized model. Our results show that the upper bound of the generalization error depends on the sum of the reciprocal of the square of the margin over the classes. Therefore, we conclude that class order does affect the performance of CCMC, and a globally optimal class order exists only when the minimization of the upper bound is achieved over this CCMC. Lastly, based on our results, we propose the easy-to-hard learning paradigm for multiclass classification to automatically identify easy and hard classes and then use the predictions from simpler classes to help solve harder classes.

Multi-label classification, where each instance can belong to multiple labels simultaneously, has garnered significant attention from researchers as a result of its various applica-

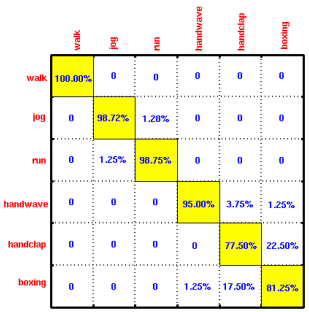

Figure 1: Confusion Matrix of OVR on the KTH Data Set. In the confusion matrix, the entry in the i-th row and j-th column is the percentage of images from action i that are misclassified as action j. Average classification accuracy rates for individual actions are listed along the diagonal, which is colored yellow.

tions, which range from document classification and gene function prediction, to automatic image annotation. For example, a document can be associated with a range of topics, such as *Sports*, *Finance* and *Education* (Schapire and Singer, 2000); a gene belongs to the functions of *protein synthesis*, *metabolism* and *transcription* (Barutcuoglu et al., 2006); an image may have both *beach* and *tree* tags (Boutell et al., 2004).

Similar to CCMC, a classifier chain (CC) model is also proposed by Read et al. (2009) to capture the label dependency for multi-label classification. It also tries to use information from previous labels to help train the classifier for the next label. However, CC's performance degenerates when there are many confusing labels, because the main drawback of CC is that it does not consider the order of difficulty of the labels. Therefore, it is non-trivial to learn the appropriate label order for CC.

Motivated by our analysis for CCMC, we first generalize CC over a random label order and provide the generalization error bound for the proposed generalized model. Then we propose the easy-to-hard learning paradigm for multi-label classification to automatically identify easy and hard labels. Lastly, we use the predictions from simpler labels to help solve harder labels. To learn the objective of our proposed easy-to-hard learning paradigms, it is very expensive to search over $q!$ different class or label orders[2], where q denotes the number of classes or labels, which is computationally infeasible for a large q. We thus propose a set of easy-to-hard learning algorithms to simplify the search process of the optimal learning sequence.

Experiments on a wide spectrum of data sets show that our proposed methods excel in all data sets for multi-label and multiclass classification problems. The results validate our analysis and the effectiveness of our proposed easy-to-hard learning algorithms. Lastly, we demonstrate that our proposed easy-to-hard learning strategies can be successfully applied

2. ! represents the factorial notation.

to a wide range of applications, such as ordinal classification (Chu and Ghahramani, 2005) and relationship prediction (Massa and Avesani, 2006).

We organize this paper as follows. Section 2 summarizes existing related works and problems. The easy-to-hard learning paradigm for multi-label and multiclass classification are proposed in Sections 3 and 4. Learning algorithms and time complexity analysis are described in Section 5. We present two applications in Section 6. Section 7 shows the comprehensive experimental results. The last section provides concluding remarks.

Notations: Assume $\mathbf{x}_t \in \mathbb{R}^d$ is a real vector representing an input or instance (feature) for $t \in \{1, \cdots, n\}$. n denotes the number of training instances. $\mathcal{Y}_t \subseteq \{\lambda_1, \lambda_2, \cdots, \lambda_q\}$ is the corresponding output (class or label). $\mathbf{y}_t \in \{0,1\}^q$ is used to represent the set $\mathcal{Y}_t$, where $\mathbf{y}_t(j) = 1$ if and only if $\lambda_j \in \mathcal{Y}_t$. Note that, there is only one element in $\mathcal{Y}_t$ for the multiclass problem.

2. Related Work and Problems

2.1 Multiclass Classification

2.1.1 OVR and OVO

One-vs-rest (OVR) and one-vs-one (OVO) are two famous strategies for decomposing multiclass classification problems into multiple binary classification problems. Hsu and Lin (2002), Rifkin and Klautau (2004), Demirkesen and Cherifi (2008) and Lapin et al. (2015, 2016) have already shown that OVR and OVO are successful schemes that are as accurate as more complicated approaches, such as error-correcting output coding (ECOC) (Dietterich and Bakiri, 1995), the tree-based method (Beygelzimer et al., 2009a,b; Bengio et al., 2010; Yang and Tsang, 2011; Liu and Tsang, 2016) and multi-class SVM (Weston and Watkins, 1999; Lapin et al., 2015, 2016).

OVR works as follows: a binary classifier is trained for each class λ_j, with all of the instances in the j-th class having positive labels, and all other instances having negative labels. q binary classifiers are then trained on $\{\mathbf{x}_t, \mathbf{y}_t(1)\}_{t=1}^n, \cdots, \{\mathbf{x}_t, \mathbf{y}_t(q)\}_{t=1}^n$. The final output of OVR for each testing instance is the class that corresponds to the classifier with the highest output value. OVR ignores correlations between classes and each classifier is trained independently. OVO trains all possible $q(q-1)/2$ binary classifiers from a training set of q classes, where each classifier is trained on only two out of q classes.

The main differences between OVR and OVO relate to computational issues and applications: 1) Computational issues: OVO requires $\mathcal{O}(q^2)$ classifiers, while OVR trains $\mathcal{O}(q)$ classifiers. If q is very large, then the cost of OVO will be prohibitive. 2) Applications: many real world data sets are partially labelled, as a result of the heavy burden of labelling data. We call this kind of data "background data" (See also (Niu et al., 2016)). It arises in many applications, for example, multiclass image segmentation (Guillaumin et al., 2010; Pham et al., 2015), object detection (Torralba et al., 2004; Huo et al., 2016) and multi-class video segmentation (Budvytis et al., 2010). OVR can be used both in supervised and semi-supervised settings, while OVO can not be used in semi-supervised settings. Thus, OVR can be used to tackle this kind of background data, but OVO cannot. Milgram et al. (2006) have already shown that OVR appears to be significantly more accurate than OVO for handwriting recognition.

2.1.2 Rifkin and Klautau's conjecture

OVR is a lower cost approach with many more applications than OVO. However, Rifkin and Klautau (2004), who conduct a thorough study on OVR, point out that the condition of OVR working as well as any other clever schemes is that the classes are independent - we do not necessarily expect instances from class "A" to be closer to those in class "B" than those in class "C". They also speculate that an algorithm that exploits the relationship between classes could offer superior performance, and that this would remains an open problem. To the best of our knowledge, this problem has still not been well-addressed, which is why the present paper studies this problem to provide an answer.

2.2 Multi-label Classification

One popular strategy for multi-label classification is to reduce the original problem into many binary classification problems. Many works have followed this strategy. For example, binary relevance (BR) (Tsoumakas et al., 2010) is a simple approach for multi-label learning which independently trains a binary classifier for each label. Recently, Chen and Lin (2012); Liu and Tsang (2015a,b); Zhang and Zhou (2014); Gong et al. (2017); Liu and Tsang (2017) have shown that multi-label learning methods that explicitly capture label dependency will usually achieve better prediction performance. Therefore, modeling label dependency is one of the major challenges in multi-label classification problems.

To capture label dependency, Hsu et al. (2009) first use the compressed sensing technique to handle multi-label classification problems. They project the original label space into a low dimensional label space. A regression model is then trained on each transformed label. Lastly, multi-labels are recovered from the regression output, which usually involves solving a quadratic programming problem (Hsu et al., 2009). Many works have been developed in this way (Zhang and Schneider, 2011, 2012; Tai and Lin, 2012). Such methods mainly aim to use different projection methods to transform the original label space into another effective label space. However, an expensive encoding and decoding procedure prevents these methods from being practical.

Another important approach attempts to exploit the different orders (first-order, second-order and high-order) of label correlations (Zhang and Zhang, 2010; Zhang and Zhou, 2014). Following this way, some works try to provide a probabilistic interpretation for label correlations. For example, Guo and Gu (2011) model the label correlations using a conditional dependency network; PCC (Dembczynski et al., 2010) exploits a high-order Markov Chain model to capture the correlations between the labels and provide an accurate probabilistic interpretation of classifier chain (CC) (Read et al., 2009). Some other works (Kang et al., 2006; Read et al., 2009; Huang and Zhou, 2012) focus on modeling the label correlations in a deterministic way. Among them, the CC model is one of the most popular methods due to its simplicity and promising experimental results (Read et al., 2009).

CC works as follows: one classifier is trained for each label. For the $(i+1)$th label, each instance is augmented with the 1st, 2nd, $\cdots$, ith label as the input to train the $(i+1)$th classifier. Given a new instance to be classified, CC firstly predicts the value of the first label, then takes this instance together with the predicted value as the input to predict the value of the next label. CC proceeds in this way until the last label is predicted. However, here the question is: *Does the label order affect the performance of CC?* Apparently yes,

because different classifier chains involve different classifiers trained on different training sets. Thus, to reduce the influence of the label order, Read et al. (2009) propose the ensemble of classifier chains (ECC) to average the multi-label predictions of CC over a set of random ordering chains. Since the performance of CC is sensitive to the choice of label, there is another important question: *Is there any globally optimal classifier chain which can achieve the optimal prediction performance for CC?* If yes, *how can the globally optimal classifier chain be found?* This paper studies this problem and provides an answer.

2.3 Curriculum Learning

Curriculum learning (Bengio et al., 2009) can be seen as a sequence of training criteria. Each training criterion in the sequence is associated with a different set of weights in the training examples, or more generally, in a re-weighting of the training distribution. Initially, the weights favor easier examples that can be learned most easily. The next training criterion involves a slight change in the weighting of examples that increases the probability of sampling slightly more difficult examples. Overall, curriculum learning aims to find easier examples. However, up to now, curriculum learning has not defined what easy examples mean, or equivalently, how to sort the examples into a sequence that illustrates the simpler concepts first.

Inspired by curriculum learning, this paper clearly defines easy and hard tasks and provides the strategy to learn easy and hard tasks. Our empirical studies verify that our method is able to automatically identify easy and hard tasks, and use the predictions of classifiers from easier tasks to train the classifier for harder tasks.

3. The Easy-to-hard Learning Paradigm for Multiclass Classification

3.1 Classifier Chain for Multiclass Classification

In multi-label classification, each instance can belong to multiple labels simultaneously, while multiclass classification classifies instances into one of more than two classes. Therefore, multiclass classification (Hsu and Lin, 2002) is a quite different learning task compared to multi-label classification (Zhang and Zhou, 2014). Many applications, such as human action recognition and object detection, can be formulated as a multiclass classification problem. However, many confusing classes in such applications will degrade the existing solver's performance. For example, *hand clap* and *boxing* are two confusing actions. *Hand clap* is easily misclassified as boxing, and vice versa. Therefore, it is non-trivial to precisely classify confusing classes for multiclass classification.

To solve these issues, motivated by CC for multi-label classification, we propose a classifier chain model for multiclass classification (CCMC) which aims to transfer class information between classifiers. CCMC trains q binary classifiers h_j ($j \in \{1, \cdots, q\}$), with all of the instances in the j-th class having positive labels, and all other instances having negative labels. Similar to CC, classifiers of CCMC are linked along a chain. CCMC works as follows: binary classifier h_1 is first trained for class λ_1, then the augmented vector $\{\mathbf{x}_t, h_1(\mathbf{x}_t)\}_{t=1}^n$ is used as the input to train classifier h_2 for class λ_2. Similarly, $\mathbf{x}_t$ augments all previous prediction values of $h_1, \cdots, h_j$ as the input to train classifier h_{j+1} for class λ_{j+1}. CCMC proceeds in this way until the last classifier h_q for class λ_q has been trained.

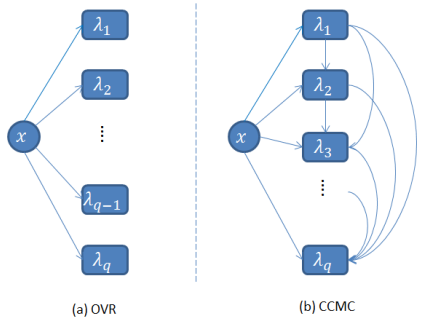

Figure 2: Schematic illustration of OVR and CCMC. A circle represents the input $\mathbf{x}$. A rectangle represents class $\lambda_i (t \in \{1, \cdots, q\})$. The starting point of the arrow denotes the input to train the classifier for the class to which the arrow points.

Given a new testing instance $\mathbf{x}$, classifier h_1 in the chain is responsible for predicting the value for λ_1 using input $\mathbf{x}$. h_2 predicts the value for λ_2 taking $\mathbf{x}$ plus the predicted value of $h_1(\mathbf{x})$ as an input. Similarly, h_{j+1} predicts the value for λ_{j+1} using $\mathbf{x}$ plus all previous prediction results from $h_1, \cdots, h_j$ as the input. CCMC proceeds in this way until the value of the last class λ_q has been predicted. Similar to OVR, the final output of CCMC for $\mathbf{x}$ is the class that corresponds to the classifier with the highest output value. CCMC exploits the class dependence by passing class information between classifiers. Figure 2 illustrates the working scheme between OVR and CCMC.

3.2 Generalized Classifier Chain for Multiclass Classification

We generalize the CCMC model over a random class order, called *generalized classifier chain for multiclass classification* (GCCMC). Assume that classes $\{\lambda_1, \lambda_2, \cdots, \lambda_q\}$ are randomly reordered as $\{\zeta_1, \zeta_2, \cdots, \zeta_q\}$, where $\zeta_j = \lambda_k$ means class λ_k moves to position j from k. In the GCCMC model, classifiers are also linked along a chain where each classifier h_j deals with the binary classification problem for class ζ_j (λ_k). GCCMC follows the same training and testing procedures as CCMC, the only difference being the class order.

3.3 Analysis

In this subsection, we analyze the generalization error bound of the multiclass classification problem using GCCMC based on some techniques, such as fat shattering dimension (Kearns and Schapire, 1990) and the upper bound theorem of covering numbers (Shawe-Taylor et al., 1998).

Let $\mathbf{X}$ represent the input space. Both $\mathbf{s}$ and $\bar{\mathbf{s}}$ are m multiclass examples drawn independently according to an unknown distribution D. We denote logarithms to base 2 by log. If $\mathcal{S}$ is a set, $|\mathcal{S}|$ denotes its cardinality. $\|\cdot\|$ means the l_2 norm.

We begin with the definition of the fat shattering dimension.

Definition 1 (Kearns and Schapire (1990)) *Let $\mathcal{H}$ be a set of real valued functions. We say that a set of points P is γ-shattered by $\mathcal{H}$ relative to $r = (r_p)_{p \in P}$ if there are real numbers r_p indexed by $p \in P$ such that for all binary vectors b indexed by P, there is a function $f_b \in \mathcal{H}$ satisfying*

$$f_b(p) = \begin{cases} \geq r_p + \gamma & \text{if } b_p = 1 \\ \leq r_p - \gamma & \text{otherwise} \end{cases}$$

The fat shattering dimension $fat(\gamma)$ of the set $\mathcal{H}$ is a function from the positive real numbers to the integers which maps a value γ to the size of the largest γ-shattered set, if this is finite, or infinity otherwise.

Assume that $\mathcal{H}$ is the real valued function class and $h \in \mathcal{H}$. $l(y, h(x))$ denotes the loss function. The expected error of h is defined as $er_D[h] = E_{(x,y)\sim D}[l(y, h(x))]$, where (x, y) drawn from the unknown distribution D. Here we select 0-1 loss function. So, $er_D[h] = P_{(x,y)\sim D}(h(x) \neq y)$. The empirical risk $er_{\mathbf{s}}[h]$ is defined as $er_{\mathbf{s}}[h] = \frac{1}{n}\sum_{t=1}^{n} \mathbf{I}\big(y_t \neq h(x_t)\big)$.[3]

Suppose that $\mathcal{N}(\epsilon, \mathcal{H}, \mathbf{s})$ is the ϵ-covering number of $\mathcal{H}$ with respect to the l_∞ pseudo-metric measuring the maximum discrepancy on the example $\mathbf{s}$. The notion of the covering number can be referred to Appendix A. We introduce the following general corollary regarding the bound of the covering number:

Corollary 2 (Shawe-Taylor et al. (1998)) *Let $\mathcal{H}$ be a class of functions $X \to [a, b]$ and D a distribution over X. Choose $0 < \epsilon < 1$ and let $d = fat(\epsilon/4) \leq em$. Then*

$$E(\mathcal{N}(\epsilon, \mathcal{H}, \boldsymbol{s})) \leq 2\Big(\frac{4m(b-a)^2}{\epsilon^2}\Big)^{d\log(2em(b-a)/(d\epsilon))} \tag{1}$$

where the expectation E is over examples $\boldsymbol{s} \in X^m$ drawn according to D^m.

We study the generalization error bound of the specified GCCMC with the specified number of classes and margins. Let G be the set of classifiers of GCCMC, $G = \{h_1, h_2, \cdots, h_q\}$. $er_{\mathbf{s}}[G]$ denotes the fraction of the number of errors that GCCMC makes on $\mathbf{s}$. Define $\hat{\mathbf{x}} \in \mathbf{X} \times \{0, 1\}$, $\hat{h}_j(\hat{\mathbf{x}}) = h_j(\mathbf{x})(1 - \mathbf{y}(j)) - h_j(\mathbf{x})\mathbf{y}(j)$.

We introduce the following proposition:

Proposition 3 *If an instance $\boldsymbol{x} \in \boldsymbol{X}$ is misclassified by a GCCMC model, then $\exists h_j \in G, \hat{h}_j(\hat{\mathbf{x}}) \geq 0$.*

Proof For multiclass problem, assume that an instance $\mathbf{x}$ belongs to class ζ_i: $\mathbf{y}(i) = 1$, $\mathbf{y}(g) = 0 (\forall g \in \{1, 2, \cdots, q\}, g \neq i)$, and that it is misclassified as ζ_j. Suppose that classifier $h_j \in G$ reports the highest confidence score for this instance: $h_j(\mathbf{x})$.

3. The expression $\mathbf{I}\big(y_t \neq h(x_t)\big)$ evaluates to 1 if $y_t \neq h(x_t)$ is true and to 0 otherwise.

Case 1: $h_j(\mathbf{x}) \geq 0$. In this case, $\hat{h}_j(\hat{\mathbf{x}}) = h_j(\mathbf{x})(1-\mathbf{y}(j)) - h_j(\mathbf{x})\mathbf{y}(j) = h_j(\mathbf{x}) \geq 0$.

Case 2: $h_j(\mathbf{x}_t) < 0$. In this case, all classifiers will output negative real numbers as the result of h_j reporting the highest confidence score. Thus, $\hat{h}_i(\hat{\mathbf{x}}) = h_i(\mathbf{x})(1-\mathbf{y}(i)) - h_i(\mathbf{x})\mathbf{y}(i) = -h_i(\mathbf{x}) \geq 0$. ■

Lemma 4 *Given a specified GCCMC model with q classes and with margins $\gamma^1, \gamma^2, \cdots, \gamma^q$ for each class satisfying $k_i = fat(\gamma^i/8)$, where fat is continuous from the right. If GCCMC has correctly classified m multiclass examples $\boldsymbol{s}$ generated independently according to the unknown (but fixed) distribution D and $\bar{\boldsymbol{s}}$ is a set of another m multiclass examples, then we can bound the following probability to be less than δ: $P^{2m}\{\boldsymbol{s}\bar{\boldsymbol{s}} : \exists$ a GCCMC model, it correctly classifies $\boldsymbol{s}$, fraction of $\bar{\boldsymbol{s}}$ misclassified $> \epsilon(m,q,\delta)\} < \delta$, where $\epsilon(m,q,\delta) = \frac{1}{m}(Q\log(32m) + \log\frac{2^q}{\delta})$ and $Q = \sum_{i=1}^{q} k_i \log(\frac{8em}{k_i})$.*

Proof (of Lemma 4). Suppose that G is a GCCMC model with q classes and with margins $\gamma^1, \gamma^2, \cdots, \gamma^q$, the probability event in Lemma 4 can be described as

$$A = \{\mathbf{s}\bar{\mathbf{s}} : \exists G, k_i = fat(\gamma^i/8), er_{\mathbf{s}}[G] = 0, er_{\bar{\mathbf{s}}}[G] > \epsilon\}.$$

Let $\hat{\mathbf{s}}$ and $\hat{\bar{\mathbf{s}}}$ denote two different set of m multiclass examples, which are drawn i.i.d. from the distribution $D \times \{0,1\}$. Applying the definition of $\hat{\mathbf{x}}$, $\hat{h}$ and Proposition 3, the event can also be written as $A = \{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}} : \exists G, \hat{\gamma}^i = \gamma^i/2, k_i = fat(\hat{\gamma}^i/4), er_{\mathbf{s}}[G] = 0, r_i = max_t \hat{h}_i(\hat{\mathbf{x}}_t), 2\hat{\gamma}^i = -r_i, |\{\hat{\mathbf{y}} \in \hat{\bar{\mathbf{s}}} : \exists h_i \in G, \hat{h}_i(\hat{\mathbf{y}}) \geq 2\hat{\gamma}^i + r_i\}| > m\epsilon\}$. Here, $-max_t \hat{h}_i(\hat{\mathbf{x}}_t)$ means the minimal value of $|h_i(\mathbf{x})|$ which represents the margin for class ζ_i, so $2\hat{\gamma}^i = -r_i$. Let $\gamma_{k_i} = min\{\gamma' : fat(\gamma'/4) \leq k_i\}$, so $\gamma_{k_i} \leq \hat{\gamma}^i$, we define the following function:

$$\pi(\hat{h}) = \begin{cases} 0 & \text{if } \hat{h} \geq 0 \\ -2\gamma_{k_i} & \text{if } \hat{h} \leq -2\gamma_{k_i} \\ \hat{h} & \text{otherwise} \end{cases}$$

so $\pi(\hat{h}) \in [-2\gamma_{k_i}, 0]$. Let $\pi(\hat{G}) = \{\pi(\hat{h}) : h \in G\}$.

Let $B^{k_i}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}$ represent the minimal γ_{k_i}-cover set of $\pi(\hat{G})$ in the pseudo-metric $d_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}$. We have that for any $h_i \in G$, there exists $\tilde{f} \in B^{k_i}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}$, $|\pi(\hat{h}_i(\hat{\mathbf{z}})) - \pi(\tilde{f}(\hat{\mathbf{z}}))| < \gamma_{k_i}$, for all $\hat{\mathbf{z}} \in \hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}$. For all $\hat{\mathbf{x}} \in \hat{\mathbf{s}}$, by the definition of r_i, $\hat{h}_i(\hat{\mathbf{x}}) \leq r_i = -2\hat{\gamma}^i$, and $\gamma_{k_i} \leq \hat{\gamma}^i$, $\hat{h}_i(\hat{\mathbf{x}}) \leq -2\gamma_{k_i}$, $\pi(\hat{h}_i(\hat{\mathbf{x}})) = -2\gamma_{k_i}$, so $\pi(\tilde{f}(\hat{\mathbf{x}})) < -2\gamma_{k_i} + \gamma_{k_i} = -\gamma_{k_i}$. However, there are at least $m\epsilon$ points $\hat{\mathbf{y}} \in \hat{\bar{\mathbf{s}}}$ such that $\hat{h}_i(\hat{\mathbf{y}}) \geq 0$, so $\pi(\tilde{f}(\hat{\mathbf{y}})) > -\gamma_{k_i} > max_t \pi(\tilde{f}(\hat{\mathbf{x}}_t))$. Since π only reduces the separation between output values, we conclude that the inequality $\tilde{f}(\hat{\mathbf{y}}) > max_t \tilde{f}(\hat{\mathbf{x}}_t)$ holds. Moreover, the $m\epsilon$ points in $\hat{\bar{\mathbf{s}}}$ with the largest $\tilde{f}$ values must remain for the inequality to hold. By the permutation argument, at most $2^{-m\epsilon}$ of the sequences obtained by swapping corresponding points satisfy the conditions for fixed $\tilde{f}$.

As for any $h_i \in G$, there exists $\tilde{f} \in B^{k_i}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}$, so there are $|B^{k_i}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|$ possibilities of $\tilde{f}$ that satisfy the inequality for k_i. Note that $|B^{k_i}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|$ is a positive integer which is usually bigger than 1, and by the union bound, we obtain the following inequality:

$$P(A) \leq (E(|B^{k_1}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|) + \cdots + E(|B^{k_q}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|))2^{-m\epsilon} \leq (E(|B^{k_1}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|) \times \cdots \times E(|B^{k_q}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|))2^{-m\epsilon}$$

Since every set of points γ-shattered by $\pi(\hat{G})$ can be γ-shattered by $\hat{G}$, so $fat_{\pi(\hat{G})}(\gamma) \leq fat_{\hat{G}}(\gamma)$, where $\hat{G} = \{\hat{h} : h \in G\}$. Hence, by Corollary 2 (setting $[a,b]$ to $[-2\gamma_{k_i}, 0]$, ϵ to γ_{k_i} and m to $2m$),

$$E(|B^{k_i}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|) = E(\mathcal{N}(\gamma_{k_i}, \pi(\hat{G}), \hat{\mathbf{s}}\hat{\bar{\mathbf{s}}})) \leq 2(32m)^{d\log(\frac{8em}{d})}$$

where $d = fat_{\pi(\hat{G})}(\gamma_{k_i}/4) \leq fat_{\hat{G}}(\gamma_{k_i}/4) \leq k_i$. Thus $E(|B^{k_i}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|) \leq 2(32m)^{k_i \log(\frac{8em}{k_i})}$, and we obtain

$$P(A) \leq (E(|B^{k_1}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|) \times \cdots \times E(|B^{k_q}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|))2^{-m\epsilon} \leq \prod_{i=1}^{q} 2(32m)^{k_i \log(\frac{8em}{k_i})} = 2^q(32m)^Q$$

where $Q = \sum_{i=1}^{q} k_i \log(\frac{8em}{k_i})$. And so $(E(|B^{k_1}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|) \times \cdots \times E(|B^{k_q}_{\hat{\mathbf{s}}\hat{\bar{\mathbf{s}}}}|))2^{-m\epsilon} < \delta$ provided

$$\epsilon(m,q,\delta) \geq \frac{1}{m}\Big(Q\log(32m) + \log\frac{2^q}{\delta}\Big)$$

as required. ■

Lemma 4 applies to a particular GCCMC model with a specified number of classes and a specified margin for each class. In practice, we will observe the margins after running the GCCMC model. Thus, we must bound the probabilities uniformly over all of the possible margins to obtain a practical bound. The generalization error bound of the multiclass classification problem using GCCMC is shown as follows:

Theorem 5 *Suppose that random m multiclass examples can be correctly classified using a GCCMC model, and suppose this GCCMC model contains q classifiers with margins $\gamma^1, \gamma^2, \cdots, \gamma^q$ for each class. Then we can bound the generalization error with probability greater than $1-\delta$ to be less than*

$$\frac{130R^2}{m}\Big(Q'\log(8em)\log(32m) + \log\frac{2(2m)^q}{\delta}\Big)$$

where $Q' = \sum_{i=1}^{q} \frac{1}{(\gamma^i)^2}$ and R is the radius of a ball containing the support of the distribution.

Before proving Theorem 5, we state one key symmetrization lemma and Theorem 7.

Lemma 6 (Symmetrization) *Let $\mathcal{H}$ be the real valued function class. $\boldsymbol{s}$ and $\bar{\boldsymbol{s}}$ are m examples both drawn independently according to the unknown distribution D. If $m\epsilon^2 \geq 2$, then*

$$P_{\boldsymbol{s}}(\sup_{h\in\mathcal{H}} |er_D[h] - er_{\boldsymbol{s}}[h]| \geq \epsilon) \;\leq\; 2P_{\boldsymbol{s}\bar{\boldsymbol{s}}}(\sup_{h\in\mathcal{H}} |er_{\bar{\boldsymbol{s}}}[h] - er_{\boldsymbol{s}}[h]| \geq \epsilon/2) \tag{2}$$

The proof of this lemma can be found in Appendix B.

Theorem 7 (Bartlett and Shawe-Taylor (1998)) *Let $\mathcal{H}$ be restricted to points in a ball of $\boldsymbol{M}$ dimensions of radius R about the origin, then*

$$fat_{\mathcal{H}}(\gamma) \leq \min\Big\{\frac{R^2}{\gamma^2}, \boldsymbol{M}+1\Big\} \tag{3}$$

Proof (of Theorem 5). We must bound the probabilities over different margins. We first use Lemma 6 to bound the probability of error in terms of the probability of the discrepancy between the performance on two halves of a double example. Then we combine this result with Lemma 4. We must consider all possible patterns of k_i's for ζ_i. The largest value of k_i is m. Thus, for fixed q, we can bound the number of possibilities by m^q. Hence, there are m^q of applications of Lemma 4.

Let $c_i = \{\gamma^1, \gamma^2, \cdots, \gamma^q\}$ denote the i-th combination of margins varied in $\{1, \cdots, m\}^q$. $\mathcal{G}$ denotes a set of GCCMC models. The generalization error of G can be represented as $er_D[G]$ and $er_{\mathbf{s}}[G]$ is 0, where $G \in \mathcal{G}$. The uniform convergence bound of the generalization error is

$$P_{\mathbf{s}}(\sup_{G\in\mathcal{G}} |er_D[G] - er_{\mathbf{s}}[G]| \geq \epsilon)$$

Applying Lemma 6,

$$P_{\mathbf{s}}(\sup_{G\in\mathcal{G}} |er_D[G] - er_{\mathbf{s}}[G]| \geq \epsilon) \leq 2P_{\mathbf{s}\bar{\mathbf{s}}}(\sup_{G\in\mathcal{G}} |er_{\bar{\mathbf{s}}}[G] - er_{\mathbf{s}}[G]| \geq \epsilon/2)$$

Let $J_{c_i} = \{\mathbf{s}\bar{\mathbf{s}} : \exists$ a GCCMC model G with q classes and with margins $c_i : k_i = fat(\gamma^i/8), er_{\mathbf{s}}[G] = 0, er_{\bar{\mathbf{s}}}[G] \geq \epsilon/2\}$. Clearly,

$$P_{\mathbf{s}\bar{\mathbf{s}}}(\sup_{G\in\mathcal{G}} |er_{\bar{\mathbf{s}}}[G] - er_{\mathbf{s}}[G]| \geq \epsilon/2) \leq P^{m^q}\Big(\bigcup_{i=1}^{m^q} J_{c_i}\Big)$$

As k_i still satisfies $k_i = fat(\gamma^i/8)$, Lemma 4 can still be applied to each case of $P^{m^q}(J_{c_i})$. Let $\delta_k = \delta/m^q$. Applying Lemma 4 (replacing δ by $\delta_k/2$), we get:

$$P^{m^q}(J_{c_i}) < \delta_k/2$$

where $\epsilon(m, k, \delta_k/2) \geq 2/m(Q\log(32m) + \log\frac{2\times 2^q}{\delta_k})$ and $Q = \sum_{i=1}^q k_i \log(\frac{4em}{k_i})$. It suffices to show by the union bound that $P^{m^q}(\bigcup_{i=1}^{m^q} J_{c_i}) \leq \sum_{i=1}^{m^q} P^{m^q}(J_{c_i}) < \delta_k/2 \times m^q = \delta/2$. Applying Lemma 6,

$$\begin{aligned} P_{\mathbf{s}}(\sup_{G\in\mathcal{G}} |er_D[G] - er_{\mathbf{s}}[G]| \geq \epsilon) &\leq 2P_{\mathbf{s}\bar{\mathbf{s}}}(\sup_{G\in\mathcal{G}} |er_{\bar{\mathbf{s}}}[G] - er_{\mathbf{s}}[G]| \geq \epsilon/2) \\ &\leq 2P^{m^q}\Big(\bigcup_{i=1}^{m^q} J_{c_i}\Big) < \delta \end{aligned}$$

Thus, $P_{\mathbf{s}}(\sup_{G\in\mathcal{G}} |er_D[G] - er_{\mathbf{s}}[G]| \leq \epsilon) \geq 1 - \delta$. Let R be the radius of a ball containing the support of the distribution. Applying Theorem 7, we get $k_i = fat(\gamma^i/8) \leq 65R^2/(\gamma^i)^2$. Note that we have replaced the constant $8^2 = 64$ by 65 in order to ensure the continuity from the right required for the application of Lemma 4. We have upperbounded $\log(8em/k_i)$ by $\log(8em)$. Thus,

$$\begin{aligned} er_D[G] &\leq 2/m\Big(Q\log(32m) + \log\frac{2(2m)^q}{\delta}\Big) \\ &\leq \frac{130R^2}{m}\Big(Q'\log(8em)\log(32m) + \log\frac{2(2m)^q}{\delta}\Big) \end{aligned}$$

where $Q' = \sum_{i=1}^q \frac{1}{(\gamma^i)^2}$. ■

Given the training data size and the number of classes, Theorem 5 reveals an important factor in reducing the generalization error bound for the GCCMC model: the minimization of the sum of the reciprocal of the square of the margin over the classes. Thus, we obtain the following Corollary:

Corollary 8 (Globally Optimal Classifier Chain for Multiclass Classification) *Suppose that random m multiclass examples with q classes can be correctly classified using a GCCMC model, this GCCMC model is the globally optimal classifier chain if and only if the minimization of Q' in Theorem 5 is achieved over this classifier chain.*

Based on Corollary 8, we propose the following easy-to-hard learning paradigm for multiclass classification problems.

Definition 9 (Easy-to-hard Learning Paradigm for Multiclass Classification) *The easy-to-hard learning paradigm for multiclass classification problem is to minimize Q' in Theorem 5. By minimizing Q', we can automatically identify easy and hard classes.*

Remark. Classes with a larger margin are easier to identify than those with a smaller margin. Thus, the intuitive idea of the easy-to-hard learning paradigm is to identify the class with a larger margin first, followed by ones with a smaller margin.

Discussion of Rifkin and Klautau's Conjecture. Rifkin and Klautau (2004) speculate that an algorithm which exploits the relationship between classes can offer superior performance, and this remains an open problem. Theoretically, Corollary 10 provides an affirmative answer to Rifkin and Klautau (2004)'s conjecture based on Theorem 5:

Corollary 10 *By exploiting the relationship between classes, our proposed GCCMC model is able to achieve a lower generalization error bound. Furthermore, our proposed easy-to-hard learning paradigm can optimize the performance of GCCMC.*

Motivated by the above analysis, we derive the following easy-to-hard learning paradigm for multi-label classification.

4. The Easy-to-hard Learning Paradigm for Multi-label Classification

4.1 Classifier Chain for Multi-label Classification

Similar to CCMC, the *classifier chain* (CC) model (Read et al., 2009) is proposed to train q binary classifiers h_j ($j \in \{1, \cdots, q\}$) for multi-label problems. Classifiers are linked along a chain where each classifier h_j deals with the binary classification problem for label λ_j. The augmented vector $\{\mathbf{x}_t, \mathbf{y}_t(1), \cdots, \mathbf{y}_t(j)\}_{t=1}^n$ is used as the input for training classifier h_{j+1}. Given a new testing instance $\mathbf{x}$, classifier h_1 in the chain is responsible for predicting the value of $\mathbf{y}(1)$ using input $\mathbf{x}$. Then, h_2 predicts the value of $\mathbf{y}(2)$ taking $\mathbf{x}$ plus the predicted value of $\mathbf{y}(1)$ as an input. Following in this way, h_{j+1} predicts $\mathbf{y}(j+1)$ using the predicted value of $\mathbf{y}(1), \cdots, \mathbf{y}(j)$ as additional input information. CC passes label information between classifiers, allowing CC to exploit the label dependence and thus overcome the label independence problem of BR.

Different classifier chains involve different classifiers learned on different training sets and thus the order of the chain itself clearly affects the prediction performance. To solve the issue of selecting a chain order for CC, Read et al. (2009) propose the extension of CC, called *ensembled classifier chain* (ECC), to average the multi-label predictions of CC over a set of random chain ordering. ECC first randomly reorders the labels $\{\lambda_1, \lambda_2, \cdots, \lambda_q\}$ many times. Then, CC is applied to the reordered labels for each time and the performance of CC is averaged over those times to obtain the final prediction performance.

4.2 Generalized Classifier Chain for Multi-label Classification

We generalize the CC model over a random label order, called *generalized classifier chain* (GCC) model. Assume the labels $\{\lambda_1, \lambda_2, \cdots, \lambda_q\}$ are randomly reordered as $\{\zeta_1, \zeta_2, \cdots, \zeta_q\}$, where $\zeta_j = \lambda_k$ means label λ_k moves to position j from k. In the GCC model, classifiers are also linked along a chain where each classifier h_j deals with the binary classification problem for label ζ_j (λ_k). GCC follows the same training and testing procedures as CC, while the only difference is the label order. In the GCC model, for input $\mathbf{x}_t$, $\mathbf{y}_t(j) = 1$ if and only if $\zeta_j \in \mathcal{Y}_t$.

4.3 Analysis

Motivated by our analysis in Section 3, we analyze the generalization error bound of the multi-label classification problem using GCC.

Let $\mathbf{X}$ represent the input space. Both $\mathbf{s}$ and $\bar{\mathbf{s}}$ are m multi-label examples drawn independently according to an unknown distribution D.

We first study the generalization error bound of the specified GCC with the specified number of labels and margins. Let G be the set of classifiers of GCC, $G = \{h_1, h_2, \cdots, h_q\}$. $er_{\mathbf{s}}[G]$ denotes the fraction of the number of errors that GCC makes on $\mathbf{s}$. Define $\hat{\mathbf{x}} \in \mathbf{X} \times \{0, 1\}$, $\hat{h}_j(\hat{\mathbf{x}}) = h_j(\mathbf{x})(1 - \mathbf{y}(j)) - h_j(\mathbf{x})\mathbf{y}(j)$.

We introduce the following proposition:

Proposition 11 *If an instance $\boldsymbol{x} \in \boldsymbol{X}$ is misclassified by a GCC model, then $\exists h_j \in G, \hat{h}_j(\hat{\mathbf{x}}) \geq 0$.*

Proof For multi-label problem, it is easy to verify that if an instance $\mathbf{x} \in \mathbf{X}$ is correctly classified by h_j, then $\hat{h}_j(\hat{\mathbf{x}}) < 0$, otherwise, $\hat{h}_j(\hat{\mathbf{x}}) \geq 0$. ■

Lemma 12 *Given a specified GCC model with q labels and with margins $\gamma^1, \gamma^2, \cdots, \gamma^q$ for each label satisfying $k_i = fat(\gamma^i/8)$, where fat is continuous from the right. If GCC has correctly classified m multi-labeled examples $\boldsymbol{s}$ generated independently according to the unknown (but fixed) distribution D and $\bar{\boldsymbol{s}}$ is a set of another m multi-labeled examples, then we can bound the following probability to be less than δ: $P^{2m}\{\boldsymbol{s}\bar{\boldsymbol{s}} : \exists$ a GCC model, it correctly classifies $\boldsymbol{s}$, fraction of $\bar{\boldsymbol{s}}$ misclassified $> \epsilon(m, q, \delta)\} < \delta$, where $\epsilon(m, q, \delta) = \frac{1}{m}(Q \log(32m) + \log \frac{2^q}{\delta})$ and $Q = \sum_{i=1}^{q} k_i \log(\frac{8em}{k_i})$.*

The proof can be adapted from the proof for Lemma 4.

Based on Lemma 12, we can bound the probabilities uniformly over all of the possible margins to obtain a practical bound. The generalization error bound of the multi-label classification problem using GCC is shown as follows:

Theorem 13 *Suppose that random m multi-labeled examples can be correctly classified using a GCC model, and suppose this GCC model contains q classifiers with margins $\gamma^1, \gamma^2, \cdots, \gamma^q$ for each label. Then we can bound the generalization error with probability greater than $1 - \delta$ to be less than*

$$\frac{130R^2}{m}\Big(Q' \log(8em) \log(32m) + \log \frac{2(2m)^q}{\delta}\Big)$$

where $Q' = \sum_{i=1}^{q} \frac{1}{(\gamma^i)^2}$ and R is the radius of a ball containing the support of the distribution.

The proof can be adapted from the proof for Theorem 5.

Theorem 13 reveals an important factor in reducing the generalization error bound for the GCC model: the minimization of the sum of the reciprocal of the square of the margin over the labels, given the training data size and the number of labels. Thus, we obtain the following Corollary:

Corollary 14 (Globally Optimal Classifier Chain for Multi-label Classification) *Suppose that random m multi-labeled examples with q labels can be correctly classified using a GCC model, this GCC model is the globally optimal classifier chain if and only if the minimization of Q' in Theorem 13 is achieved over this classifier chain.*

Based on Corollary 14, we propose the following easy-to-hard learning paradigm for multi-label classification.

Definition 15 (Easy-to-hard Learning Paradigm for Multi-label Classification) *The easy-to-hard learning paradigm for multi-label classification problem is to minimize Q' in Theorem 13. By minimizing Q', we can automatically identify easy and hard labels.*

Discussion of Label's Relationship. Recently, many works, such as Read et al. (2009) and Guo and Schuurmans (2011), have conducted extensive experiments to show that multi-label learning methods which explicitly capture the label's relationship will usually achieve better prediction performance. However, to the best of our knowledge, very few works study the reasons behind these promising empirical results. Based on Theorem 13, Corollary 16 provides theoretical support for this problem:

Corollary 16 *By exploiting the relationship between labels, our proposed GCC model is able to achieve a lower generalization error bound. Furthermore, our proposed easy-to-hard learning paradigm can optimize the performance of GCC.*

Given the number of classes or labels q, there are $q!$ different class or label orders. It is very expensive to find the globally optimal CCMC or CC, which can minimize Q', by searching over all of the class or label orders. Next, we discuss some simple easy-to-hard learning algorithms.

5. Easy-to-hard Learning Algorithm

In this section, we propose some simple easy-to-hard learning algorithms. To clearly state the algorithms, we redefine the margins with class or label order information. Given class or label set $\mathcal{M} = \{\lambda_1, \lambda_2, \cdots, \lambda_q\}$. Let $o_i (1 \leq o_i \leq q)$ denote the order of λ_i in the GCCMC or GCC model, $\gamma_i^{o_i}$ represents the margin for λ_i, with previous $o_i - 1$ classes or labels as the augmented input. If $o_i = 1$, then γ_i^1 represents the margin for λ_i, without augmented input. Then Q' is redefined as $Q' = \sum_{i=1}^{q} \frac{1}{(\gamma_i^{o_i})^2}$.

5.1 Dynamic Programming Algorithm

To simplify the search algorithm mentioned before, we propose the CCMC-DP and CC-DP algorithm to find the globally optimal CCMC and CC, respectively. Note that $Q' = \sum_{i=1}^{q} \frac{1}{(\gamma_i^{o_i})^2} = \frac{1}{(\gamma_q^{o_q})^2} + \cdots + \left[\frac{1}{(\gamma_{k+1}^{o_{k+1}})^2} + \sum_{j=1}^{k} \frac{1}{(\gamma_j^{o_j})^2}\right]$, we explore the idea of dynamic programming (DP) to iteratively optimize Q' over a subset of $\mathcal{M}$ with the length of $1, 2, \cdots, q$. Lastly, we obtain the optimal Q' over $\mathcal{M}$. Assume $i \in \{1, \cdots, q\}$. Let $V(i, \eta)$ be the optimal Q' over a subset of $\mathcal{M}$ with the length of $\eta (1 \leq \eta \leq q)$, where the class or label order ends by λ_i. M_i^η represents the corresponding class or label set for $V(i, \eta)$. When $\eta = q$, $V(i, q)$ is the optimal Q' over $\mathcal{M}$, where the class or label order ends by λ_i. The DP equation is written as:

$$V(i, \eta + 1) = \min_{j \neq i, \lambda_i \notin M_j^\eta} \left\{ \frac{1}{(\gamma_i^{\eta+1})^2} + V(j, \eta) \right\} \tag{4}$$

where $\gamma_i^{\eta+1}$ is the margin for λ_i, with M_j^η as the augmented input. The initial condition of DP is: $V(i, 1) = \frac{1}{(\gamma_i^1)^2}$ and $M_i^1 = \{\lambda_i\}$. The optimal Q' over $\mathcal{M}$ can be obtained by solving $\min_{i \in \{1, \cdots, q\}} V(i, q)$. Assume that the training time of linear SVM takes $\mathcal{O}(nd)$. The CCMC-DP or CC-DP algorithm is shown as the following bottom-up procedure: from the bottom, we first compute $V(i, 1) = \frac{1}{(\gamma_i^1)^2}$, which takes $\mathcal{O}(nd)$. Then we compute $V(i, 2) = \min_{j \neq i, \lambda_i \notin M_j^1} \{\frac{1}{(\gamma_i^2)^2} + V(j, 1)\}$, which requires at most $\mathcal{O}(qnd)$, and set $M_i^2 = M_j^1 \cup \{\lambda_i\}$. Similarly, it takes at most $\mathcal{O}(q^2 nd)$ time complexity to calculate $V(i, q)$. Lastly, we iteratively solve this DP equation, and use $\min_{i \in \{1, \cdots, q\}} V(i, q)$ to obtain the optimal solution, which requires at most $\mathcal{O}(q^3 nd)$ time complexity.

Theorem 17 (Correctness of DP) *Q' can be minimized by CCMC-DP or CC-DP, which means this Algorithm can find the globally optimal CCMC or CC.*

The proof can be found in Appendix C.

5.2 Greedy Algorithm

We propose the CCMC-Greedy and CC-Greedy algorithm to find a locally optimal CCMC and CC, respectively. To save time, we construct only one classifier chain with the locally optimal class or label order. If the maximum margin can be achieved over this class or label, without augmented input, we select this class or label from $\{\lambda_1, \lambda_2, \cdots, \lambda_q\}$ as the first class or label. The first class or label is denoted by ζ_1. We then select the class or label from the remaining classes or labels as the second class or label, if the maximum margin can be achieved over this class or label with ζ_1 as the augmented input. We continue in this way until the last class or label has been selected. CCMC-Greedy and CC-Greedy take $\mathcal{O}(q^2 nd)$ time, respectively. We show the details of the CC-Greedy algorithm in Appendix D.

5.3 Fast Greedy Algorithm

In multiclass problems, CCMC-DP and CCMC-Greedy are intractable for data sets with a large number of classes. To further speed up the CCMC-Greedy algorithm, we propose fast greedy algorithm (CCMC-FG), which scales linearly with q, to greedily optimize the order of the top ω classes. Similar to CCMC-Greedy, if the maximum margin can be achieved over this class without augmented input, we select this class from $\{\lambda_1, \lambda_2, \cdots, \lambda_q\}$ as the first class. The first class is denoted by ζ_1. Then we select the class from the remaining classes as the second class, if the maximum margin can be achieved over this class with prediction values of the classifier trained for class ζ_1 as the augmented input. We continue in this way until the ω class has been selected. Lastly, we use the remaining $q - \omega$ classes to form the classifier chain. CCMC-FG takes $\mathcal{O}(q\omega nd)$ time.

Remark. CCMC-Greedy converges to the locally optimal CCMC, while CCMC-FG finds the top ω locally optimal class order.

5.4 Tree-Based Algorithm

For multi-label problem, CC-DP and CC-Greedy are very time-consuming for data sets with many labels. We propose Tree-DP and Tree-Greedy algorithms to further speed up CC-DP and CC-Greedy, respectively, which scale linearly with q. We create a tree recursively in a top-down manner.

Assume that $\{\mathbf{x}_t, \mathbf{y}_t\}_{t=1}^n$ is the input data for the root node. Suppose that the label set $\{\lambda_1, \lambda_2, \cdots, \lambda_q\}$ in the root node is randomly split into two subsets with about the same size for left and right child nodes: $leftset = \{\lambda_1, \cdots, \lambda_{q/2}\}$ and $rightset = \{\lambda_{q/2+1}, \cdots, \lambda_q\}$. A training example can be considered annotated with $leftset$ and $rightset$ if it is annotated with at least one of the labels in $leftset$ and $rightset$, respectively. In this way, $leftset$ and $rightset$ can be seen as two labels. Then, in the root node, we train the CC with $leftset$ and $rightset$ as two labels using CC-DP or CC-Greedy. After that, left and right child nodes only keep the examples that are annotated with $leftset$ and $rightset$, respectively. This approach recurses into each child node that contains more than a single label.

Starting from the root node, we use the trained CC classifier on this node for prediction and we follow the recursive process. Finally, this process may lead to the prediction of some labels corresponding to some leaves. We provide the following corollary pertaining to the Tree-DP.

Corollary 18 *After building a tree using the Tree-DP algorithm, we can find the globally optimal CC in each decision node of the tree.*

Proof Given the structure of the tree, according to Theorem 17, we can find the globally optimal label order in each decision node using the CC-DP algorithm. ■

For each internal node, we only deal with two labels, thus the training time of Tree-DP and Tree-Greedy only take $\mathcal{O}(8nd)$ and $\mathcal{O}(4nd)$, respectively. The number of internal nodes in such a tree is equal to $q-1$. In total, Tree-DP and Tree-Greedy take $\mathcal{O}(8(q-1)nd)$ and $\mathcal{O}(4(q-1)nd)$ training time, respectively. Assume that the testing instance goes along ι paths in our tree during the testing procedure and the depth of the tree is $\log(q)$. In each decision node, we take $\mathcal{O}(d)$ time for testing. Totally, the testing time for Tree-DP and Tree-Greedy is $\mathcal{O}(\iota \log(q)d)$.

6. Applications

This section shows that our framework can be used for various applications, such as ordinal classification and relationship prediction.

6.1 Ordinal Classification

Many practical applications involve situations exhibiting an order among the different categories. For example, a user rates movies by giving them grades based on quality. These grades represent the ranking information. For example, grade classes are ordered as $D < C < B < A$. This is a learning task for predicting ordinal classes, referred to as ordinal classification (Seah et al., 2012).

Several algorithms and methods have been developed to deal with ordinal classification, such as SVM techniques (Shashua and Levin, 2002), binary decomposition (Destercke and Yang, 2014), Gaussian processes (Chu and Ghahramani, 2005) and monotone functions (Tehrani et al., 2012). However, all these methods do not capture and use correlated information between ordinal classes. To achieve this goal, we transform ordinal classification into multiclass classification and then apply CCMC for ordinal classification.

Consider an ordinal classification problem with q ordered categories. We denote these categories as $\mathcal{Y}_t \subseteq \{\lambda_1, \lambda_2, \cdots, \lambda_q\}$ to keep the known ordering information. $\mathbf{y}_t \in \{0,1\}^q$ is used to represent the set $\mathcal{Y}_t$, where $\mathbf{y}_t(j) = 1$ if and only if $\lambda_j \in \mathcal{Y}_t$, and there is only one element in $\mathcal{Y}_t$ for the ordinal classification problem. So, we transform ordinal classification into a multiclass classification problems. Then, we apply CCMC for ordinal classification as follows: the binary classifier h_1 is first trained for the ordinal class λ_1, then the augmented vector $\{\mathbf{x}_t, h_1(\mathbf{x}_t)\}_{t=1}^n$ is used as the input to train classifier h_2 for ordinal class λ_2. Similarly, $\mathbf{x}_t$ augments all previous prediction values of $h_1, \cdots, h_j$ as the input to train classifier h_{j+1} for ordinal class λ_{j+1}. CCMC proceeds in this way until the last classifier h_q for ordinal class λ_q has been trained.

6.2 Relationship Prediction

Relationship prediction problems in the online review website Epinions (Massa and Avesani, 2006) attempt to predict whether people trust or distrust others based on their reviews. Such social networks can be modeled as a signed network where trust/distrust are modeled as positive/negative edges between entities (Leskovec et al., 2010). The problem then becomes predicting unknown relationship between any two users given the network.

Many approaches, such as Hsieh et al. (2012) and Chiang et al. (2014), perform matrix completion on an adjacency matrix and then use the sign of the completed matrix

for relationship prediction. Recently, Chiang et al. (2015) achieve state-of-the-art performance by incorporating the feature information of users. Based on feature information, we provide new insight into the design of relationship prediction algorithms. Specifically, we first transform relationship prediction into a multi-label classification problem by considering trust/distrust as positive/negative labels. Then, we apply our proposed easy-to-hard learning strategy to solve relationship prediction tasks.

Relationship prediction is represented as a graph with the adjacency matrix $R \in \{0,1\}^{n \times n}$, which denotes relationships between users as follows:

$$R_{ij} = \begin{cases} 1, & \text{if user } i \text{ and user } j \text{ have positive relationship;} \\ 0, & \text{if user } i \text{ and user } j \text{ have negative relationship} \end{cases}$$

We assume that user i and user i have a positive relationship. The attribute information of user i can be extracted as the input or instance (feature) $\mathbf{x}_i$, and the i-th row vector of R can be used as label $\mathbf{y}_i$. So, we transform relationship prediction into a multi-label classification problem. Then, CC model can be used to deal with the transformed problems, and we can apply our proposed easy-to-hard learning strategy to solve relationship prediction tasks.

7. Experiment

In this section, we perform experimental studies on a number of real world data sets to evaluate the performance of our proposed algorithms for multiclass and multi-label classification problems. To perform a fair comparison, we use the same linear classification/regression package LIBLINEAR (Fan et al., 2008) with L2-regularized square hinge loss (primal) to train the classifiers for all methods and use the default parameter settings in LIBLINEAR. All experiments are conducted on a workstation with a 3.4GHZ Intel CPU and 32GB main memory running on a Linux platform.

7.1 Experiment on Multiclass Classification

In this subsection, we first demonstrate our motivation on the recognition of human action (Schüldt et al., 2004). We then consider a variety of benchmark multiclass data sets without background from the LIBSVM website[4] to evaluate the performance of the proposed algorithms for multiclass classification. Lastly, we conduct experiments on two multiclass data sets with background collected from Silberman et al. (2012) and He et al. (2004). The training/testing partition is either predefined or the data is randomly split into 80% training and 20% testing. The statistics of each data set are reported in Table 1. We compare our algorithms with some baseline methods: OVO, OVR, ECOC (Dietterich and Bakiri, 1995) and Top-k SVM (Lapin et al., 2015, 2016). The library for ECOC is from Pedregosa et al. (2011) and the size of code for ECOC is selected using 5-fold cross validation over the range $\{2, 10, 30, 50\}$. Top-k SVM (Lapin et al., 2015, 2016) is one of the state-of-the-art generalized multiclass SVM for top-k error optimization. The code is provided by their authors. Following the similar parameter settings in Lapin et al. (2015, 2016) for Top-k SVM, k is selected using 5-fold cross validation over the range $\{1, 3, 5, 10\}$.

OVO	OVR	ECOC	Top-k SVM	CCMC	CCMC-Greedy	CCMC-DP
8.81	8.18	7.73	8.13	7.34	6.29	5.66

7.1.1 Human action recognition

We first validate our methods by recognizing complex human actions on the KTH data set Schüldt et al. (2004). KTH contains six types of human action: *walk*, *jog*, *run*, *hand wave*, *hand clap* and *boxing*. The confusion matrix of OVR on the KTH data set is shown in Figure 1. From Figure 1, we can see that it is easy to identify *walk* from other actions, whereas it is difficult to distinguish between *boxing* and *hand clap*. This observation is consistent with commonsense. Our model aims to classify classes from simple to hard; the classifier of the hard actions will benefit significantly from the prediction of the simple actions.

The testing error rates of the different methods are shown in Table 2. The order of actions identified by CCMC-Greedy is: *run*, *hand wave*, *walk*, *jog*, *boxing* and *hand clap*. CCMC-DP finds the action order: *walk*, *run*, *jog*, *hand wave*, *boxing* and *hand clap*. From these results, we observe that:

- For the KTH data set, our methods achieve a better prediction performance than OVO, OVR, ECOC and Top-k SVM, which verifies that our model effectively uses the predictions of previous classifiers to improve the performance of OVR.

- CCMC-Greedy and CCMC-DP improve CCMC, which also verifies our motivation: we should classify the classes from easy to hard. The order of actions (from easy to hard) found by CCMC-Greedy and CCMC-DP are consistent with the confusion matrix, which demonstrates that our model can automatically identify easy and hard classes, and use the predictions of classifiers from easier classes to train the classifier for harder classes.

Figure 3 shows the confusion matrix of CCMC-DP on the KTH data set. By comparing Figure 1 with Figure 3, we observe that our method significantly improves OVR in terms of the classification accuracy rate for each action. For example, we achieve 100% accuracy for *run* and improve the accuracy for *hand clap* from 77.50% to 81.25%.

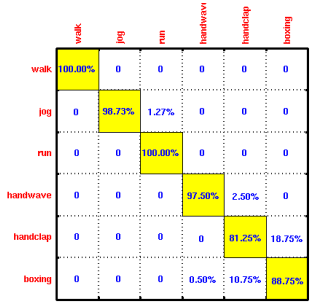

Figure 3: Confusion Matrix of CCMC-DP on the KTH Data Set.

7.1.2 Results without background data

We compare OVO, OVR and ECOC with our algorithms on the benchmark data sets without background. The classification results for our methods and baseline approaches on the IRIS, SEGMENT, SEISMIC and RCV1 data sets are reported in Table 3. Based on these results, we make the following observations.

- Our results show that OVR and OVO perform as accurate as ECOC and Top-k SVM, which is consistent with the empirical results in Rifkin and Klautau (2004), Demirkesen and Cherifi (2008) and Lapin et al. (2015, 2016).

- CCMC consistently improves the prediction performance of OVR and other baselines on all data sets. The results verify Rifkin and Klautau (2004)'s conjecture: an algorithm which exploits the relationship between classes can offer superior performance.

- When OVO outperforms OVR on certain data sets such as SEISMIC and SEGMENT, our methods are able to achieve superior prediction performance to OVO on these data sets.

- CCMC-Greedy is better than CCMC, and CCMC-DP outperforms CCMC-Greedy and CCMC. The results validate our theoretical analysis: i) Class order affects the performance of CCMC. ii) CCMC-DP is able to find the globally optimal CCMC which achieves the best prediction performance compared to CCMC-Greedy and CCMC. iii) The CCMC-Greedy algorithm achieves comparable prediction performance with CCMC-DP.

We also evaluate the performance of our fast greedy algorithm on the ALOI data set, which contains 1,000 classes. Here, ω is set to 10, 30, 50 and 100. The classification results and training time are reported in Table 4, from which we can see that CCMC-FG outperforms CCMC and improves the prediction performance of OVR, ECOC and Top-k SVM by about 9%, 6% and 5%, respectively. The prediction performance of CCMC-FG improves with the increased value of ω.

Table 3: Testing error rate (in %) on data sets without background.

Data set	OVO	OVR	ECOC	Top-k SVM	CCMC	CCMC-Greedy	CCMC-DP

Top-k SVM	9.4	65s
CCMC	5.46	12,715s
CCMC-FG($\omega = 10$)	5.27	16,327s
CCMC-FG($\omega = 30$)	5.08	31,886s
CCMC-FG($\omega = 50$)	4.94	67,582s
CCMC-FG($\omega = 100$)	4.78	163,891s

7.1.3 Results with background data

The OVO, ECOC and Top-k SVM approaches cannot be directly applied to background data. Table 5 shows the classification results for our methods and OVR on the NYU and SOWERBY data sets. From the results of Table 5, we can see that:

- CCMC consistently outperforms OVR.
- CCMC-Greedy achieves better prediction performance than CCMC and is comparable to CCMC-DP.
- CCMC-DP improves the prediction performance of OVR on the data sets with background by 3%.

7.1.4 Training time

This section studies the training time of the proposed methods and baselines on all data sets. The results are shown in Tables 4 and 6. From these results, we can see that:

- Top-k SVM is much faster than other methods on the ALOI data set with 1000 classes.
- Compared to OVR, CCMC maintains the training time over an acceptable threshold, while CCMC consistently improves OVR.

Table 5: Testing error rate (in %) on data sets with background.

- CCMC-Greedy is much faster than CCMC-DP.
- With the increasing value of ω, the training time of CCMC-FG rises, but the prediction performance of CCMC-FG becomes better. ω can be set according to the time and accuracy requirements of applications.

The testing time of the proposed methods is similar to OVR. Although the training time of the proposed approaches is slower than OVR, the time required to test is of more importance than the time required to train for many applications.

7.1.5 Comparisons with deep learning methods

ADIOS (Cissé et al., 2016) is a state-of-the-art deep learning architecture for solving multiple class and label tasks. Unlike traditional deep learning methods that use a flat output layer, ADIOS aims to capture the complex dependency between labels/classes to improve deep learning methods. Their approach is to split the label/class set into two subsets, G_1 and G_2, such that given G_1, the labels/classes in G_2 are independent. Our strategy to leverage label/class dependency is very different from that of ADIOS, as shown in Figure 2, we use a classifier chain model for multi-class classification and find the optimal class ordering. After that, we use the predictions of classifiers from easier classes to train the classifiers for harder classes. As such, the assumptions and constraints used in ADOIS are not applicable in our model.

This subsection conducts the experiments on the ILSVRC2012 data set[5]. It contains 1,000 object categories (Liu et al., 2017). Due to the limit of computational resources, we randomly sample 58,700 training instances and 31,300 testing instances from the ILSVRC2012 data set. We use the source code provided by the authors of ADIOS with default parameters. According to Cissé et al. (2016), we use one hidden layer with 1024 rectified linear units (ReLUs) (Glorot et al., 2011) between inputs and G_1, and another 512-dimensional ReLUs between the hidden layer before G_1 and G_2 as well as direct connections between G_1 and G_2. We also compare with VGG (Simonyan and Zisserman, 2014) and residual nets (ResNet) (He et al., 2016). Both VGG and ResNet use a flat output layer, in which do not model the dependency between the classes(Cissé et al., 2016), so the rich structure information among classes is missing in VGG and ResNet. We use the source code provided by the respective authors with default parameters. Following He et al. (2016), we use the 34-layer residual nets due to the limit of computational resources, and also extract

5. http://www.image-net.org/challenges/LSVRC/2012/

Table 7: Testing error rate (in %) of VGG, ResNet-34, ADIOS and CCMC-FG on the ILSVRC2012 data set.

Method	VGG	ResNet-34	ADIOS	CCMC-FG+VGG features	CCMC-FG+ResNet features
Testing Error	23.95	21.51	21.28	23.98 ($\omega = 10$)	21.85 ($\omega = 10$)
				22.67 ($\omega = 30$)	20.11 ($\omega = 30$)
				20.73 ($\omega = 50$)	19.84 ($\omega = 50$)

2048-dimensional features by the ResNet-34. According to Simonyan and Zisserman (2014), we extract 4096-dimensional features from the 16-layer of the VGG. Here, ω is set to 10, 30 and 50 for our method.

The classification results are reported in Table 7. From this table, we can observe that

- ADIOS outperforms VGG and ResNet-34, which verifies ADIOS's claim: existing deep learning approaches do not take into account the often unknown but nevertheless rich relationships between classes, this knowledge about the rich class structure (and other deep structure in data) is sometime referred to as dark knowledge (e.g. by Hinton et al. (2015) and Ba and Caruana (2014)).
- Without the restriction of the assumptions and constraints used in ADOIS, our method achieves better performance than ADIOS with the increasing value of ω.
- CCMC-FG with ResNet features obtains better performance than CCMC-FG with VGG features, which demonstrates that our proposed method can be further improved based on better features.
- Based on the deep learning features, CCMC-FG consistently improves VGG and ResNet-34 with the increasing value of ω. The results validate our analysis and the better ordering of classes obtains the better performance. Note that the above mentioned results were obtained using 58,700 training data points. We conclude that with limited data, the usage of structure information is helpful. We conjecture that this advantage may ultimately vanish as more and more data becomes available for training.

7.2 Experiment on Multi-label Classification

We conduct experiments on ten real-world multi-label data sets with various domains from three websites.[6][7][8] The EURLEX_SM and EURLEX_ED data sets are preprocessed according to the experimental settings in Dembczynski et al. (2010) and Zhang and Schneider (2012). The statistics of data sets are presented in Table 8. We compare our algorithms with some baseline methods: BR, CC, ECC, CCA (Zhang and Schneider, 2011) and MMOC (Zhang and Schneider, 2012). ECC is averaged over several CC predictions with random

Table 8: Multi-label data sets used in the experiments.

Data	# inst.	# attr.	# labels	Domain
YEAST	2,417	103	14	biology
IMAGE	2,000	294	5	image
SLASHDOT	3,782	1,079	22	text
ENRON	1,702	1,001	53	text
LLOG	799	1,004	10	linguistics
ART	6,849	23,146	10	art
EURLEX_SM_10	11,454	5,000	10	text
EURLEX_ED_10	6,540	5,000	10	text
EURLEX_SM	19,348	5,000	201	text
EURLEX_ED	19,348	5,000	3,993	text

order and the ensemble size in ECC is set to 10 according to Dembczynski et al. (2010); Read et al. (2009). In our experiment, the running time of PCC and EPCC (Dembczynski et al., 2010) on most data sets, like SLASHDOT and ART, takes more than one week. From the results in Dembczynski et al. (2010), ECC is comparable with EPCC and outperforms PCC, so we do not consider PCC and EPCC here. CCA and MMOC are two state-of-the-art encoding-decoding (Hsu et al., 2009) methods. We cannot get the results of CCA and MMOC on ART , EURLEX_SM_10 and EURLEX_ED_10 data sets in one week.

We consider the following evaluation measurements Mao et al. (2013) to measure the prediction performance of all methods fairly:

- Example-F1: computes the F-1 score for all the labels of each testing example and then takes the average of the F-1 score.
- Macro-F1: calculates the F-1 score for each label and then takes the average of the F-1 score.
- Micro-F1: computes true positives, true negatives, false positives and false negatives over all labels, and then calculates an overall F-1 score.

The larger the value of those measurements, the better the performance. We perform 5-fold cross-validation on each data set and report the mean and standard error of each evaluation measurement.

7.2.1 Small-scale results

Three measurement results for CC-Greedy, CC-DP and baseline approaches in respect to the different small-scale data sets are reported in Tables 9, 10 and 11. We conduct the pairwise t-test at a 5% significance level to show that our methods perform significantly better than the compared methods. From the results, we can see that:

- BR generally underperforms in terms of Macro-F1 and Micro-F1 and it is much inferior to other methods in terms of Example-F1. Our experiment provides empirical evidence that the label correlations exist in many real word data sets and because BR ignores the information about the correlations between the labels, BR achieves poor performance on most data sets.

Table 9: Results of Example-F1 on the various small-scale data sets (mean ± standard deviation). The best results are in bold. Numbers in square brackets indicate the rank. "-" denotes the training time is more than one week.

- CC improves on the performance of BR, however, it underperforms compared to ECC. This result verifies the answer to our first question stated in Section 2.2: the label order does affect the performance of CC; ECC, which averages over several CC predictions with random order, improves the performance of CC.

Table 11: Results of Micro-F1 on the various small-scale data sets (mean ± standard deviation). The best results are in bold. Numbers in square brackets indicate the rank. "-" denotes the training time is more than one week.

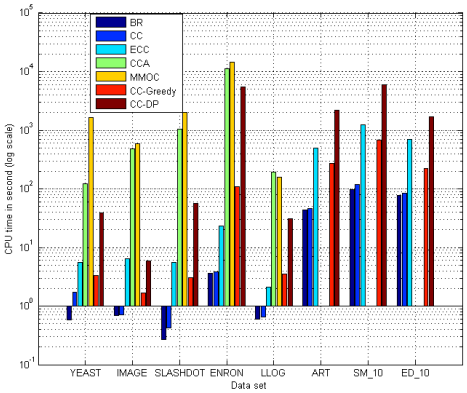

Figure 4: Training time (in second) of all methods on the small-scale data sets. EURLEX_SM_10 and EURLEX_ED_10 are abbreviated to SM_10 and ED_10.

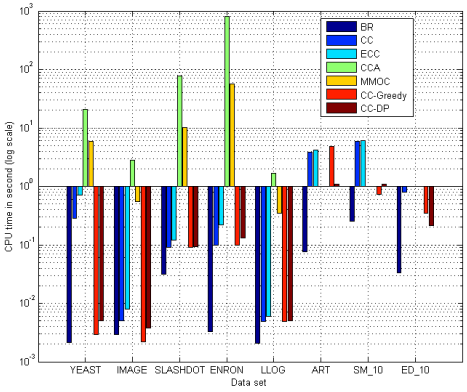

Figure 5: Testing time (in second) of all methods on the small-scale data sets. EURLEX_SM_10 and EURLEX_ED_10 are abbreviated to SM_10 and ED_10.

- Our algorithms outperform CCA and MMOC. This study verifies that optimal CC achieves competitive results compared with state-of-the-art encoding-decoding approaches.

- Our proposed CC-DP and CC-Greedy algorithms are successful on most data sets. This empirical result verifies the effectiveness of our easy-to-hard learning strategies, and we provide an answer to the last two questions stated in Section 2.2: a globally optimal CC exists and CC-DP is able to find the globally optimal CC that achieves the best prediction performance. The CC-Greedy algorithm achieves comparable prediction performance with CC-DP.

Figures 4 and 5 show the training and testing time of CC-Greedy, CC-DP and the baseline methods on the small-scale data sets, respectively. According to these two figures, we can see that:

- Our proposed algorithms are much faster than CCA and MMOC in terms of both training and testing time.
- CC-Greedy and CC-DP achieve comparable testing time with BR, CC and ECC. Though the training time of our algorithms are slower than BR, CC and ECC, our extensive empirical studies show that our algorithms achieve superior prediction performance than those baselines.
- The CC-Greedy algorithm is much faster than CC-DP in terms of training time, and it achieves comparable prediction performance with CC-DP.

7.2.2 Large-scale results

This subsection studies the performance of Tree-Greedy, Tree-DP and other baselines on the EURLEX_SM and EURLEX_ED data sets with many labels. We cannot get the results of CCA and MMOC on EURLEX_SM and EURLEX_ED data sets in one week. And we also cannot get the results of ECC on EURLEX_ED data set in one week. The prediction performance of Tree-Greedy, Tree-DP and the baselines are reported in Tables 12, 13 and 14. We conduct the pairwise t-test at a 5% significance level to show that our methods perform significantly better than the compared methods. From the results, we can see that: our proposed Tree-Greedy and Tree-DP algorithms consistently outperform BR, CC and ECC on the data sets with many labels.

The training and testing time of Tree-Greedy, Tree-DP and the baselines on the EURLEX_SM and EURLEX_ED data sets are shown in Figure 6. According to this figure, we can observe that compared to BR, CC and ECC, our algorithms maintain the testing time over an acceptable threshold, while our methods are much faster than the baselines in terms of training time.

7.3 Experiment on Ordinal Classification

This subsection conducts experiments on four ordinal data sets with various domains from website[9]. The statistics of these data sets are presented in Table 15. We compare our algorithm with some baseline methods: SVM (Shashua and Levin, 2002), MAP (Chu and Ghahramani, 2005), EP (Chu and Ghahramani, 2005) and BD (Destercke and Yang, 2014).

9. http://www.gatsby.ucl.ac.uk/ chuwei/ordinalregression.html

Table 12: Results of Example-F1 on EURLEX_SM and EURLEX_ED data sets (mean ± standard deviation). The best results are in bold. Numbers in square brackets indicate the rank. "-" denotes the training time is more than one week.

Data set	BR	CC	ECC	Tree-Greedy	Tree-DP
EURLEX_SM	0.6970±0.02[5]	0.7233±0.01[4]	0.7263±0.01[3]	0.7292±0.01[2]	**0.7301**±0.01[1]
EURLEX_ED	0.4345±0.03[4]	0.4528±0.02[3]	-	0.4550±0.01[2]	**0.4563**±0.01[1]
Average Rank	4.5	3.5	3	2	1

Table 13: Results of Macro-F1 on EURLEX_SM and EURLEX_ED data sets (mean ± standard deviation). The best results are in bold. Numbers in square brackets indicate the rank. "-" denotes the training time is more than one week.

Data set	BR	CC	ECC	Tree-Greedy	Tree-DP
EURLEX_SM	0.4777±0.02[5]	0.4785±0.02[4]	0.4800±0.02[3]	0.4817±0.01[2]	**0.4834**±0.01[1]
EURLEX_ED	0.1660±0.01[4]	0.1812±0.00[3]	-	0.1844±0.00[2]	**0.1848**±0.00[1]
Average Rank	4.5	3.5	3	2	1

The results are shown in Table 16. From this table, we can see that our proposed CCMC-DP outperforms the other baselines on all data sets, which verifies that our method is able to capture and use the correlated information between ordinal classes, and boost the performance of ordinal classification problems.

7.4 Experiment on Relationship Prediction

This subsection conducts experiments on the Epinions data set (Massa and Avesani, 2006). According to Chiang et al. (2015), we collect 10,000 users and 41 features in this data set. We compare our proposed Tree-DP algorithm with some popular methods: IMC (Jain and Dhillon, 2013), MF-ALS (Hsieh et al., 2012), HOC-3 (Chiang et al., 2014), HOC-5 (Chiang et al., 2014) and DirtyIMC (Chiang et al., 2015). We perform 5-fold cross-validation on this data set and report the mean and standard error of Example-F1. The results are shown in Table 17. From this table, we can see that 1) DirtyIMC outperforms the other baselines, which verifies the effectiveness of using feature information and is consistent with the empirical results in Chiang et al. (2015). 2) Our proposed Tree-DP algorithm is able to achieve the best accuracy among all baselines, which demonstrates the superior performance of the easy-to-hard learning strategy.

8. Conclusion

To precisely classify multiclass data sets with confusing classes, this paper aims to solve classification tasks from easy to hard, and then use the predictions from simpler tasks to help solve the harder tasks. To achieve our goal, we first build the classifier chain model for

Table 14: Results of Micro-F1 on EURLEX_SM and EURLEX_ED data sets (mean ± standard deviation). The best results are in bold. Numbers in square brackets indicate the rank. "-" denotes the training time is more than one week.

EURLEX_ED	0.4200±0.01[4]	0.4477±0.01[3]	-	0.4527±0.00[2]	**0.4549**±0.00[1]
Average Rank	4.5	3	4	2	1

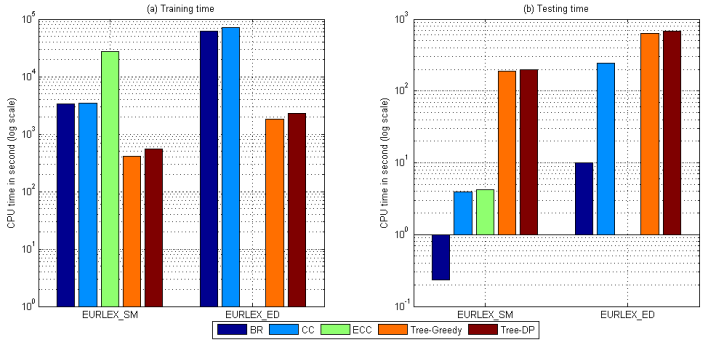

Figure 6: Training and testing time (in second) of BR, CC, ECC, Tree-Greedy and Tree-DP on EURLEX_SM and EURLEX_ED data sets.

multiclass classification (CCMC) to transfer class information between classifiers. Then, we generalize the CCMC model over a random class order and provide a theoretical analysis of the generalization error for the proposed generalized model. Our results show that the upper bound of the generalization error depends on the sum of the reciprocal of the square of the margin over the classes. Based on our results, we propose the easy-to-hard learning paradigm for multiclass classification to automatically identify easy and hard classes and then use the predictions from simpler classes to help solve harder classes.

Similar to CCMC, a CC model is also proposed by Read et al. (2009) to capture the label dependency for multi-label classification. However, confusing labels decrease the generalization performance of CC, especially when there are many confusing labels, because it ignores the label's order of difficulty. Thus, it is imperative to learn the appropriate label order for CC. Motivated by our analysis of CCMC, we first generalize the CC over a random label order and provide the generalization error bound for the proposed generalized model, and then we also propose the easy-to-hard learning paradigm for multi-label classification

Table 15: Ordinal data sets used in the experiments.

Boston Housing	26.72	26.04	25.85	25.86	23.50

to automatically identify easy and hard labels. Lastly, we use the predictions from simpler labels to help solve harder labels.

It is very expensive to search over $q!$ different class or label orders for learning the objective of our proposed easy-to-hard learning paradigms, which is computationally infeasible for a large q. We thus propose the CCMC-DP and CC-DP algorithms to find the globally optimal solution, respectively, which requires $\mathcal{O}(q^3nd)$ complexity. To speed up the CCMC-DP and CC-DP algorithm, we propose the CCMC-Greedy and CC-Greedy algorithms to find a locally optimal CCMC and CC, respectively, which takes $\mathcal{O}(q^2nd)$ time. Fast greedy and tree-based algorithms are further developed to handle large data sets with many classes and labels, respectively, which scale linearly with q.

Comprehensive experiments on extensive multiclass data sets, without and with background, demonstrate that our proposed methods consistently improve the prediction performance of OVR and outperforms ECOC and Top-k multiclass SVM. Our human action recognition experiment results also validate our analysis and the success of our proposed easy-to-hard learning strategies: we can automatically identify easy and hard classes, and use the predictions of classifiers from easier classes to train the classifiers for harder classes. Furthermore, this paper also provide an affirmative answer to Rifkin and Klautau's conjecture.

Empirical results on ten real-world multi-label data sets from different domains verify the effectiveness of our easy-to-hard learning strategies, and we provide an answer to the last two questions stated in Section 2.2: a globally optimal CC exists, and CC-DP is able to find the globally optimal CC which achieves the best prediction performance. Moreover, we provide theoretical support for the argument: multi-label learning methods which explicitly capture the label's relationship will usually achieve better prediction performance.

Table 17: Results of Example-F1 on the Epinions data sets (mean ± standard deviation).

Data set	IMC	MF-ALS	HOC-3	HOC-5	DirtyIMC	Tree-DP
Epinions	0.910 ± 0.002	0.936 ± 0.001	0.926 ± 0.001	0.927 ± 0.002	0.939 ± 0.001	0.946 ± 0.001

Lastly, we demonstrate our proposed easy-to-hard learning strategies can be successfully applied to a wide range of applications, such as ordinal classification and relationship prediction. From a more philosophical point of view, our work has shown that the proper usage of structure information in multiclass and multi-label problems yields better modeling, in other words structuring output class information may be an attractive path to incorporate more dark knowledge into learning models.

Acknowledgments

We would like to thank the action editor and reviewers for their valuable comments and constructive suggestions on our paper. Appendix A. Covering Numbers

Definition 19 (Covering Numbers) *Let (X, d) be a (pseudo-) metric space, A be a subset of X and $\epsilon > 0$. A set $B \subseteq X$ is an ϵ-cover for A, if for every $a \in A$, there exists $b \in B$ such that $d(a, b) < \epsilon$. The ϵ-covering number of A, $\mathcal{N}_d(\epsilon, A)$, is the minimal cardinality of an ϵ-cover for A (if there is no such finite cover then it is defined to be ∞).*

In the main paper, let $\mathcal{N}(\epsilon, \mathcal{H}, \mathbf{s})$ be the ϵ-covering number of $\mathcal{H}$ with respect to the l_∞ pseudo-metric measuring the maximum discrepancy on the sample $\mathbf{s}$, that is, with respect to the distance $d(f, g) = \max_{1 \le t \le m} |f(x_t) - g(x_t)|$, for $f, g \in \mathcal{H}$.

Appendix B. Proof of Lemma 6

Proof (of Lemma 6). For each $\mathbf{s}$, let $\bar{h}_{\mathbf{s}}$ be a function for which $|er_D[\bar{h}_{\mathbf{s}}] - er_{\mathbf{s}}[\bar{h}_{\mathbf{s}}]| \ge \epsilon$ if such a function exists, and any fixed function in $\mathcal{H}$ otherwise. Then

$$\begin{aligned} P_{\mathbf{s}\bar{\mathbf{s}}}(\sup_{h\in\mathcal{H}} |er_{\bar{\mathbf{s}}}[h] - er_{\mathbf{s}}[h]| \ge \epsilon/2) \ge & P_{\mathbf{s}\bar{\mathbf{s}}}(|er_{\bar{\mathbf{s}}}[\bar{h}_{\mathbf{s}}] - er_{\mathbf{s}}[\bar{h}_{\mathbf{s}}]| \ge \epsilon/2) \\ \ge & P_{\mathbf{s}\bar{\mathbf{s}}}(\{|er_D[\bar{h}_{\mathbf{s}}] - er_{\mathbf{s}}[\bar{h}_{\mathbf{s}}]| \ge \epsilon\} \bigcap \{|er_{\bar{\mathbf{s}}}[\bar{h}_{\mathbf{s}}] - er_D[\bar{h}_{\mathbf{s}}]| \le \epsilon/2\}) \\ = & E_{\mathbf{s}}[\mathbf{I}(|er_D[\bar{h}_{\mathbf{s}}] - er_{\mathbf{s}}[\bar{h}_{\mathbf{s}}]| \ge \epsilon) P_{\bar{\mathbf{s}}}(|er_{\bar{\mathbf{s}}}[\bar{h}_{\mathbf{s}}] - er_D[\bar{h}_{\mathbf{s}}]| \le \epsilon/2)] \end{aligned} \tag{5}$$

Now the conditional probability inside can be bounded using Chebyshev's inequality:

$$P_{\bar{\mathbf{s}}}(|er_{\bar{\mathbf{s}}}[\bar{h}_{\mathbf{s}}] - er_D[\bar{h}_{\mathbf{s}}]| \le \epsilon/2) \ge 1 - \frac{\mathbf{Var}_{\bar{\mathbf{s}}}[er_{\bar{\mathbf{s}}}[\bar{h}_{\mathbf{s}}]]}{\epsilon^2/4} \tag{6}$$

Since $\bar{\mathbf{s}} \sim D^m$ and $er_{\bar{\mathbf{s}}}[\bar{h}_{\mathbf{s}}]$ is $1/m$ times a Binomial random variable with parameters $(m, er_D[\bar{h}_{\mathbf{s}}])$, we have $\mathbf{Var}_{\bar{\mathbf{s}}}[er_{\bar{\mathbf{s}}}[\bar{h}_{\mathbf{s}}]] = \frac{er_D[\bar{h}_{\mathbf{s}}](1-er_D[\bar{h}_{\mathbf{s}}])}{m} \le \frac{1}{4m}$. This gives

$$P_{\bar{\mathbf{s}}}(|er_{\bar{\mathbf{s}}}[\bar{h}_{\mathbf{s}}] - er_D[\bar{h}_{\mathbf{s}}]| \le \epsilon/2) \ge 1 - \frac{1}{m\epsilon^2} \ge \frac{1}{2} \tag{7}$$

whenever $m\epsilon^2 \ge 2$. Thus we get

$$\begin{aligned} P_{\mathbf{s}\bar{\mathbf{s}}}(\sup_{h\in\mathcal{H}} |er_{\bar{\mathbf{s}}}[h] - er_{\mathbf{s}}[h]| \ge \epsilon/2) \ge & \frac{1}{2} P_{\mathbf{s}}(|er_D[\bar{h}_{\mathbf{s}}] - er_{\mathbf{s}}[\bar{h}_{\mathbf{s}}]| \ge \epsilon) \\ = & \frac{1}{2} P_{\mathbf{s}}(\sup_{h\in\mathcal{H}} |er_D[h] - er_{\mathbf{s}}[h]| \ge \epsilon) \end{aligned} \tag{8}$$

where the last step of Eq. (8) is by definition of $\bar{h}_{\mathbf{s}}$. ■

Appendix C. Proof of Theorem 15

Proof (of Theorem 15). We proof the theorem using the mathematical induction. For $i \in \{1, \cdots, q\}$,

Case 1: $V(i,1) = \frac{1}{(\gamma_i^1)^2}$, where γ_i^1 is the margin for λ_i, without augmented input and $M_i^1 = \{\lambda_i\}$.

Case 2: $V(i,2) = \min_{j \neq i, \lambda_i \notin M_j^1}\{(\frac{1}{(\gamma_i^2)^2} + V(j,1)\}$, where γ_i^2 is the margin for λ_i, with M_j^1 as the augmented input. As in case 1, we already calculated $V(i,1)$, so we can easily find the solution of $V(i,2)$. Assume $V(j,1)$ is the optimal value for computing $V(i,2)$, then we can get $M_i^2 = M_j^1 \cup \{\lambda_i\}$.

Case 3: Assume $V(i,k-1), k \leq q$ is the optimal Q' over a subset of $\mathcal{M}$ with the length of $k-1$, where the class or label order ends by λ_i and M_i^{k-1} denote the corresponding class or label set for $V(i,k-1)$.

Case 4: $V(i,k) = \min_{j \neq i, \lambda_i \notin M_j^{k-1}}\{\frac{1}{(\gamma_i^k)^2} + V(j,k-1)\}$, where γ_i^k is the margin for λ_i, with M_j^{k-1} as the augmented input. Based on the assumption in case 3, we can obtain $V(i,k), i \in \{1, \cdots, q\}$. Thus, we can find the optimal Q' over $\mathcal{M}$ by using CCMC-DP or CC-DP algorithm. ■

Appendix D. Greedy Algorithm

This section presents the details of the CC-Greedy algorithm. Let $\{\mathbf{x}_t\}_{t=1}^n$ be the feature and $\{\mathbf{y}_t(\zeta_j)\}_{t=1}^n$ be the label, the output parameter of SVM is defined as $[\mathbf{w}_j, b] = SVM(\{\mathbf{x}_t, \mathbf{y}_t(\zeta_1), \cdots, \mathbf{y}_t(\zeta_{j-1})\}_{t=1}^n, \{\mathbf{y}_t(\zeta_j)\}_{t=1}^n)$.

Algorithm 1 CC-Greedy

Input: training data $\{\mathbf{x}_t, \mathbf{y}_t\}_{t=1}^n$ with size n and label set $\{\lambda_1, \lambda_2, \cdots, \lambda_q\}$.
Set $\mathcal{M} = \{\lambda_1, \lambda_2, \cdots, \lambda_q\}$.
for $\lambda_j \in \mathcal{M}$ **do**
  Calculate $[\mathbf{w}_j, b] = SVM(\{\mathbf{x}_t\}_{t=1}^n, \{\mathbf{y}_t(\lambda_j)\}_{t=1}^n)$.
  Calculate $\gamma_j^1 = \frac{1}{||\mathbf{w}_j||^2}$.
end for
Calculate $\nu = \arg_{\lambda_j \in \mathcal{M}} \min \frac{1}{(\gamma_j^1)^2}$.
Set $\mathcal{M} = \mathcal{M} - \{\lambda_\nu\}$
Set $C[1] = \lambda_\nu$.
for $s = 2$ **to** q **do**
  for $\lambda_k \in \mathcal{M}$ **do**
    Calculate $[\mathbf{w}_k, b] = SVM(\{\mathbf{x}_t, \mathbf{y}_t(C[1]), \cdots, \mathbf{y}_t(C[s-1])\}_{t=1}^n, \{\mathbf{y}_t(\lambda_k)\}_{t=1}^n)$.
    Calculate $\gamma_k^s = \frac{1}{||\mathbf{w}_k||^2}$.
  end for
  Calculate $\nu = \arg_{\lambda_k \in \mathcal{M}} \min \frac{1}{(\gamma_k^s)^2}$.
  Set $\mathcal{M} = \mathcal{M} - \{\lambda_\nu\}$.
  Set $C[s] = \lambda_\nu$.
end for
Output this locally optimal CC.

Fisher Consistency for Prior Probability Shift

Dirk Tasche* dirk.tasche@gmx.net

Editor: Charles Elkan

Abstract

We introduce Fisher consistency in the sense of unbiasedness as a desirable property for estimators of class prior probabilities. Lack of Fisher consistency could be used as a criterion to dismiss estimators that are unlikely to deliver precise estimates in test data sets under prior probability and more general data set shift. The usefulness of this unbiasedness concept is demonstrated with three examples of classifiers used for quantification: Adjusted Count, EM-algorithm and CDE-Iterate. We find that Adjusted Count and EM-algorithm are Fisher consistent. A counter-example shows that CDE-Iterate is not Fisher consistent and, therefore, cannot be trusted to deliver reliable estimates of class probabilities.

Keywords: Classification, quantification, class distribution estimation, Fisher consistency, data set shift

1. Introduction

The application of a classifier to a test data set often is based on the assumption that the data for training the classifier is representative of the test data. While this assumption might be true sometimes or even most of the time, there may be circumstances when the distributions of the classes or the features or both are genuinely different in the test set and the training set. Spam emails represent a familiar example of this situation: The typical contents of spam emails and their proportion of the total daily number of emails received may significantly vary over time. Spam email filters developed on the set of emails received last week may become less effective this week due to changes in the composition of the email traffic. In the machine learning community, this phenomenon is called *data set shift* or population drift. The area of research of how to learn a model appropriate for a test set on a differently composed training set is called domain adaptation.

The simplest type of data set shift occurs when the training set and the test set differ only in the distribution of the classes of the instances. In this case, only the prior (or unconditional) class probabilities (or *class prevalences*) change between the training set and the test set; this type of data set shift is called *prior probability shift*. In the context of supervised or semi-supervised learning, the class prevalences in the labelled portion of the training set are always known. In contrast, the class prevalences in the test set may be known or unknown at the time of the application of the classifier to the test set, depending on the cause of the data set shift. For example, in a binary classification exercise the class prevalence of the majority class in the training set might deliberately be reduced by removing instances of that class at random, in order to facilitate the training of the classifier. If the original training set were a random sample of the test set then the test set class prevalences would be equal to the original training set class prevalences and therefore known. The earlier mentioned spam email filter problem represents an example of the situation where the test set class prevalences are unknown due to possible data set shift.

In this paper, we primarily study the question of how to estimate the unknown class prevalences in a test data set when the training set and the test set are related by prior probability shift. This problem was coined *quantification* by Forman (2008). Solutions to the problem are known at least since the 1960s (Gart and Buck, 1966) but research for more and better solutions has been ongoing ever since. It seems, however, as if the criteria of what should be deemed a 'good' solution are not fully clear.

In the words of Cox and Hinkley (1974, p. 287) *Fisher consistency* is described as "Roughly this requires that if the whole 'population' of random variables is observed, then the method of estimation should give exactly the right answer". Obtaining the right answer when looking for the value of a parameter is an intuitive concept that exhibits similarity to the concept of unbiasedness. In particular, if a wrong decision based on the estimated value of a parameter can entail severe financial loss or cause damage to a person's health, getting the value of the parameter right is very important. Hofer and Krempl (2013) and Tasche (2014) present examples related to the estimation of credit losses. Nonetheless, requiring that the right answer be obtained also on finite samples from the population would be too harsh, given that by the nature of randomness the empirical distribution associated with a finite sample can be quite different from the population distribution.

For these reasons, we argue that as a minimum, it should be required that class prevalence estimators (or *quantifiers*) be Fisher consistent. Cox and Hinkley (1974, p. 287) comment that "Consistency, however, gives us no idea of the magnitude of the errors of estimation likely for any given n [the sample size]". Therefore, being Fisher consistent cannot be a sufficient criterion for a class prevalence estimator to be useful. Rather, by the logic of a necessary criterion, lack of Fisher consistency should be considered a reason to dismiss a candidate estimator. For even for very large sample sizes, with such an estimator there would not be any guarantee of obtaining an approximation of the true parameter value.

Accordingly, focussing on *binary* classification and quantification, with this paper we make three contributions to the literature on quantification of class prevalences:

- We formally introduce the concept of unbiasedness expressed as Fisher consistency, in a prior probability shift context and more generally for quantification of class prevalences in the presence of any data set shift.

- We illustrate the usefulness of the notion of Fisher consistency, by demonstrating with three popular quantification approaches that Fisher consistency may be used as a criterion to cull inapt quantifiers. In other words, Fisher consistency can serve as a filter to eliminate quantifiers that are unlikely to provide precise estimates.

- We show that Fisher consistency of an estimator is not a global concept that can be expected to hold for all types of data set shift. To demonstrate this fact, we suggest a new type of data set shift, called 'invariant density ratio'-type data set shift, which generalises prior probability shift. We also propose a method for generating non-trivial examples of this type of data set shift.

'Invariant density ratio'-type data set shift is interesting of its own for the following two reasons:

- It can be described as a covariate shift without the 'contamination' effect that can entail the test set class prevalences to be very similar to the training set class prevalences (Tasche, 2013, p. 83).
- Prior probability shift is a special case of 'invariant density ratio'-type data set shift (see Section 2.4 below). Therefore, estimators which are Fisher consistent with respect to 'Invariant density ratio'-type data set shift potentially have a wider scope of application than estimators that are Fisher consistent only with respect to prior probability shift.

In Section 2.4.3, this list is supplemented by a number of other interesting properties of 'invariant density ratio'-type data set shift. The plan for the paper is as follows:

- In Section 2, we recall the concepts from binary classification and quantification that are relevant for the subject of the paper. These concepts include Bayes classifiers and some types of data set shift, including prior probability shift. In addition, we motivate and define the notion of Fisher consistency.
- In Section 3, we describe three approaches to class prevalence estimation which serve to illustrate the role of Fisher consistency for this task. The three approaches are Adjusted Count (Forman, 2008), the EM-algorithm (Saerens et al., 2001) and CDE-Iterate (Xue and Weiss, 2009).
- In Section 4, we explore by numerical examples under which circumstances the three approaches discussed in Section 3 cease to be Fisher consistent for the estimation of class prevalences. The most important finding here is that CDE-Iterate is not Fisher consistent under prior probability shift. Hence there is no guarantee that CDE-Iterate will find the true class prevalences even in the presence of that quite benign type of data set shift.
- We conclude in Section 5 with some comments on the findings of the paper.
- Appendix A presents some tables with computation results for additional information while Appendix B provides a mathematically rigorous derivation of the equation that characterises the limit of CDE-Iterate.

Notation. Concepts and notation used in this paper are formally introduced where needed. For additional quick reference, here is a short list of the most important symbols:

- $\mathcal{X}$: Feature space.

- $\{0,1\}$: Two classes, 0 positive and 1 negative.
- (X,Y): X is the vector of the features of an instance, Y denotes the class of the instance.
- P: Probability distribution of the training set.
- Q: Probability distribution of the test set.
- $\mathrm{P}[Y=i\,|\,X]$: Feature-conditional probability of class i in the training set (analogous for Q).
- $\mathrm{P}[X\in S\,|\,Y=i]$: $\mathrm{P}[X\,|\,Y]$ denotes the class-conditional distribution of the features in the training set. $\mathrm{P}[X\in S\,|\,Y=i]$ stands for the probability that the realisation of X is an element of the set S, conditional on the class of the instance being i (analogous for Q).
- $g:\mathcal{X}\to\{0,1\}$: Classifier that assigns class $g(x)$ to a realisation x of the features of an instance.
- f_0, f_1: Class-conditional feature densities on the training set.
- h_0, h_1: Class-conditional feature densities on the test set.

2. Estimating Prior Probabilities

In this section, we recall some basic concepts from the theory of binary classification and quantification to build the basis for the discussion of prevalence estimation approaches in Section 3 and the numerical examples in Section 4. The concepts discussed include Bayes classifiers and different types of data set shift including prior probability shift and its extension called here 'invariant density ratio'-type data set shift. In addition, we introduce the notion of unbiasedness of prevalence estimators in the shape of Fisher consistency which is most appropriate in the quantification context central for this paper.

2.1 Binary Classification and Bayes Error at Population Level

The basic model we consider is a random vector (X,Y) with values in a product $\mathcal{X}\times\{0,1\}$ of sets. For example, in applications for credit scoring, we might have $\mathcal{X}=\mathbb{R}^d$ for some positive integer d. A realisation of $X\in\mathcal{X}$ is interpreted as the vector of features of an observed instance. $Y\in\{0,1\}$ is the class of the observed instance. For the purpose of this paper, 0 is the interesting (positive) class, as in Hernández-Orallo et al. (2012).

Classification problem. On the basis of the observed features X of an instance, make a guess (prediction) $g(X)\in\{0,1\}$ of the instance's class Y such that the probability of an error is minimal. In mathematical terms: Find $g^*:\mathcal{X}\to\{0,1\}$ such that

$$\mathrm{P}[g^*(X)\neq Y] \;=\; \min_g \mathrm{P}[g(X)\neq Y]. \tag{1a}$$

The functions g in (1a) used for predicting Y are called (crisp) classifiers. The value of the minimum in (1a) is called *Bayes error*. (1a) accounts for two possibilities to make

classification errors:

$$\text{'Predict 0 if the true class is 1'} = \{g(X) = 0, Y = 1\}, \qquad \text{and}$$
$$\text{'Predict 1 if the true class is 0'} = \{g(X) = 1, Y = 0\}.$$

Cost-sensitive errors. In practice, the consequences of these two erroneous predictions might have different severities. Say the cost related to 'predict 0 if the true class is 1' is $c_1 \geq 0$, and the cost related to 'predict 1 if the true class is 0' is $c_0 \geq 0$. To deal with the issue of different severities, a cost-sensitive version of (1a) can be studied:

$$c_1 \, \mathrm{P}[g^*(X) = 0, \, Y = 1] + c_0 \, \mathrm{P}[g^*(X) = 1, \, Y = 0] = \min_g c_1 \, \mathrm{P}[g(X) = 0, \, Y = 1] + c_0 \, \mathrm{P}[g(X) = 1, \, Y = 0]. \quad (1b)$$

To make this problem non-trivial, of course one has to assume that $c_0 + c_1 > 0$.

Bayes classifier. A solution g^* to (1b) and therefore also to (1a) (case of $c_0 = c_1 = 1$) exists and is well-known (see Section 2.2 of van Trees, 1968, or Section 1.3 of Elkan, 2001):

$$g^*(X) \;=\; \begin{cases} 0, & \text{if } \mathrm{P}[Y = 0 \,|\, X] > \frac{c_1}{c_0 + c_1}, \\ 1, & \text{if } \mathrm{P}[Y = 0 \,|\, X] \leq \frac{c_1}{c_0 + c_1}. \end{cases} \quad (2)$$

In this equation, $\mathrm{P}[Y = 0 \,|\, X]$ denotes the (non-elementary) conditional probability of the event $Y = 0$ given X, as defined in standard textbooks on statistical learning and probability theory (see Appendix A.7 of Devroye et al., 1996, and Section 4.1 of Durrett, 1996, respectively). Being a function of X, $\mathrm{P}[Y = 0 \,|\, X]$ is also a non-constant random variable whenever X and Y are not stochastically independent. In the following, we also call $\mathrm{P}[Y = 0 \,|\, X]$ *feature-conditional class probability*. The function $g^*(X)$ as defined in (2) is called a Bayes classifier.

A proof of (2) is also provided in Appendix B below (see Lemma 5). That proof shows, in particular, that the solution g^* to (1b) is unique in the sense of $\mathrm{P}[g^*(X) = \tilde{g}(X)] = 1$ for any other minimiser $\tilde{g}$ of (1b), as long as the distribution of the ratio of the class-conditional feature densities is continuous (see Section 2.4 for the definition of the density ratio).

2.2 Binary Classification and Bayes Error at Sample Level

In theory, the binary classification problem with cost-sensitive errors is completely solved in Section 2.1. In practice, however, there are issues that can make the Bayes classifier (2) unfeasible:

- Typically, the joint probability distribution of (X, Y) is not exactly known but has to be inferred from a finite sample (called 'training set') $(x_{1,tr}, y_{1,tr}), \ldots, (x_{m,tr}, y_{m,tr}) \in \mathcal{X} \times \{0, 1\}$. If $\mathcal{X}$ is high-dimensional this may be difficult and require a large sample size to reduce errors due to random variation.

- As the Bayes classifier is explicitly given by (2), one can try to avoid estimating the entire distribution of (X, Y) and, instead, only estimate the feature-conditional probability $\mathrm{P}[Y = 0 \,|\, X]$ (also called posterior probability). However, this task is not significantly simpler than estimating the distribution of (X, Y), as illustrated by the fact that methods for the estimation of non-elementary conditional probabilities constitute a major branch of applied statistics.

By structural assumptions on the nature of the classification problem (1b), the approach based on direct estimation of the feature-conditional probability can be rendered more accessible. Logistic regression provides the possibly most important example for this approach (see, e.g., Cramer, 2003). But the price of the underlying assumptions may be high and include significant deterioration of goodness of fit. That is why alternative approaches based on direct implementation of the optimisation of the right-hand side of (1b) are popular. Lessmann et al. (2015) give a survey of the variety of methods available, just for application to credit scoring.

As mentioned in the introduction, one of the topics of this paper is an investigation into the question of whether certain quantifiers are Fisher consistent. In Section 4 below, the demonstration of lack of Fisher consistency is based on counter-examples which are non-trivial but simple enough to allow for the exact computation of the feature-conditional class probabilities and hence also the Bayes classifiers.

2.3 Data Set Shift

Even if one has succeeded in estimating a Bayes classifier or at least a reasonably good approximate Bayes classifier, issues may arise that spoil its effective deployment. Quite often, it is assumed that any instance with known features vector x but unknown class y that is presented for classification has been drawn at random from the same population as the training set. However, for a number of reasons this assumption can be wrong (see, e.g., Quiñonero-Candela et al., 2009; Kull and Flach, 2014; Moreno-Torres et al., 2012; Dal Pozzolo et al., 2015). A lot of research has been undertaken and is ongoing on methods to deal with this problem of so-called data set shift. In this paper, we consider the following variant of the problem:

- There is a training data set $(x_{1,tr}, y_{1,tr}), \ldots, (x_{m,tr}, y_{m,tr}) \in \mathcal{X} \times \{0, 1\}$ which is assumed to be an independent and identically distributed sample from the population distribution $\mathrm{P}(X, Y)$ of the random vector (X, Y) as described in Section 2.1.

- There is another data set, the test data set, $(x_{1,te}, y_{1,te}), \ldots, (x_{n,te}, y_{n,te}) \in \mathcal{X} \times \{0, 1\}$ which is assumed to be an independent and identically distributed sample from a possibly different population distribution $\mathrm{Q}(X, Y)$. Moreover, training and test data have been independently generated.

- For the instances in the training data set, their class labels are visible and can be made use of for learning classifiers (i.e. solving optimisation problem (1b)).

- For the instances in the test data set, their class labels are invisible to us or become visible only with large delay.

This assumption is intended to describe a setting where the test instances arrive batch-wise, not as a stream. We also assume that the sizes m of the training set and n of the test set are reasonably large such that trying to infer properties of the respective population distributions makes sense.

As far as the theory for this paper is concerned, we will ignore the issues caused by the fact that we know the training data set distribution $\mathrm{P}(X, Y)$ and the test data set

distribution $\mathrm{Q}(X, Y)$ only by inference from finite samples. Instead we will assume that we can directly deal with the population distributions $\mathrm{P}(X, Y)$ and $\mathrm{Q}(X, Y)$. Throughout the whole paper, we make the assumption that there are both positive and negative instances in both of the populations, i.e. it holds that

$$0 < \mathrm{P}[Y = 0] < 1 \qquad \text{and} \qquad 0 < \mathrm{Q}[Y = 0] < 1. \tag{3}$$

The problem that $\mathrm{P}(X, Y)$ and $\mathrm{Q}(X, Y)$ may not be the same is treated under different names in the literature (Moreno-Torres et al., 2012): data set shift, domain adaptation, population drift and others. There are several facets of the problem:

- Classifiers may have to be adapted to the test set or re-trained.
- The feature-conditional probabilities may have to be adapted to the test set or re-estimated.
- The unconditional class probabilities (also called prior probabilities or prevalences) may have to be re-adjusted for the test set or re-estimated.

Quantification. In this paper, we focus on the estimation of the prevalences $\mathrm{Q}[Y = 0]$ and $\mathrm{Q}[Y = 1]$ in the test set, as parameters of distribution $\mathrm{Q}(X, Y)$. This problem is called quantification (Forman, 2008) and of its own interest beyond its auxiliary function for classification and estimation of the feature-conditional probabilities (González et al., 2016).

2.4 Quantification in the Presence of Prior Probability Shift

In technical terms, the quantification problem as presented in Section 2.3 can be described as follows:

- We know the joint distribution of features and class labels (X, Y) under the training set probability distribution P.
- We know the distribution of the features X under the test set probability distribution Q.
- How can we infer the prevalences of the classes under Q, i.e. the probabilities $\mathrm{Q}[Y = 0]$ and $\mathrm{Q}[Y = 1] = 1 - \mathrm{Q}[Y = 0]$, by making best possible use of our knowledge of $\mathrm{P}(X, Y)$ and $\mathrm{Q}(X)$?

This question cannot be answered without assuming that the test set probability distribution Q shares some properties with the training set probability distribution P. This means to make more specific assumptions about the structure of the data set shift between training set and test set. In the literature, a variety of different types of data set shift have been discussed. See Moreno-Torres et al. (2012), Kull and Flach (2014) or Hofer (2015) for a number of examples, including 'covariate shift' and 'prior probability shift' which possibly are the two most studied types of data set shift. This paper focusses on prior probability shift.

2.4.1 Prior Probability Shift

This type of data set shift also has been called 'global shift' (Hofer and Krempl, 2013). The assumption of prior probability shift is, in particular, appropriate for circumstances where the features of an instance are caused by the instance's class membership (Fawcett and Flach, 2005). Technically, prior probability shift can be described as 'the class-conditional feature distributions of the training and test sets are the same', i.e.

$$\mathrm{Q}[X \in S \,|\, Y = 0] = \mathrm{P}[X \in S \,|\, Y = 0] \quad \text{and} \quad \mathrm{Q}[X \in S \,|\, Y = 1] = \mathrm{P}[X \in S \,|\, Y = 1], \tag{4}$$

for all measurable sets $S \subset \mathcal{X}$. Note that (4) does *not* imply $\mathrm{Q}[X \in S] = \mathrm{P}[X \in S]$ for all measurable $S \subset \mathcal{X}$ because the training set class distribution $\mathrm{P}(Y)$ and the test set class distribution $\mathrm{Q}(Y)$ still can be different.

In this paper, we will revisit three approaches to the estimation of the prevalences in population Q in the presence of prior probability shift as defined by (4). Specifically, we will check both in theory and by simple examples if these three approaches satisfy the basic estimation quality criterion of Fisher consistency. For this purpose, a slight generalisation of prior probability shift called 'invariant density ratio'-type data set shift will prove useful. Before we introduce it, let us briefly recall some facts on conditional probabilities and probability densities.

2.4.2 Feature-Conditional Class Probabilities and Class-Conditional Feature Densities

Typically, the class-conditional feature distributions $\mathrm{P}(X \,|\, Y = i)$, $i = 0, 1$, of a data set have got densities f_0 and f_1 respectively with respect to some reference measure like the d-dimensional Lebesgue measure. Then also the unconditional feature distribution $\mathrm{P}(X)$ has a density f which can be represented as

$$f(x) \;=\; \mathrm{P}[Y = 0]\, f_0(x) + (1 - \mathrm{P}[Y = 0])\, f_1(x) \quad \text{for all } x \in \mathcal{X}. \tag{5a}$$

Moreover, the feature-conditional class probability $\mathrm{P}[Y = 0 \,|\, X]$ can be expressed in terms of the densities f_0 and f_1:

$$\mathrm{P}[Y = 0 \,|\, X](x) \;=\; \frac{\mathrm{P}[Y = 0]\, f_0(x)}{\mathrm{P}[Y = 0]\, f_0(x) + (1 - \mathrm{P}[Y = 0])\, f_1(x)}, \quad x \in \mathcal{X}. \tag{5b}$$

Conversely, assume that there is a density f of the unconditional feature distribution $\mathrm{P}(X)$ and the feature-conditional class probability $\mathrm{P}[Y = 0 \,|\, X]$ is known. Then the class-conditional feature densities f_0 and f_1 are determined as follows:

$$\begin{aligned} f_0(x) &= \frac{\mathrm{P}[Y = 0 \,|\, X](x)}{\mathrm{P}[Y = 0]}\, f(x), \quad x \in \mathcal{X}, \\ f_1(x) &= \frac{1 - \mathrm{P}[Y = 0 \,|\, X](x)}{1 - \mathrm{P}[Y = 0]}\, f(x), \quad x \in \mathcal{X}. \end{aligned} \tag{6}$$

2.4.3 Invariant Density Ratio

Assume that there are densities f_0 and f_1 for the class-conditional feature distributions $\mathrm{P}(X \,|\, Y = i)$, $i = 0, 1$, of the training set population. We then say that the data set shift

from population P to Q is of 'invariant density ratio'-type if there are also densities h_0 and h_1 respectively for the class-conditional distributions $\mathrm{Q}(X \mid Y = i)$, $i = 0, 1$, of the test set, and it holds that

$$\frac{f_0(x)}{f_1(x)} \;=\; \frac{h_0(x)}{h_1(x)} \quad \text{for all } x \in \mathcal{X}. \tag{7}$$

Note that by (6), the density ratio $\frac{f_0}{f_1}$ can be rewritten as

$$\frac{f_0(x)}{f_1(x)} \;=\; \frac{\mathrm{P}[Y = 0 \mid X](x)}{1 - \mathrm{P}[Y = 0 \mid X](x)} \, \frac{1 - \mathrm{P}[Y = 0]}{\mathrm{P}[Y = 0]}, \quad x \in \mathcal{X}, \tag{8}$$

as long as $\mathrm{P}[Y = 0 \mid X](x) < 1$. Hence the density ratio can be calculated without knowledge of the values of the densities if the feature-conditional class probabilities or reasonable approximations are known.

Obviously, 'invariant density ratio' is implied by prior probability shift if all involved class-conditional distributions have got densities. 'Invariant density ratio'-type data set shift was discussed in some detail by Tasche (2014). It is an interesting type of data set shift for several reasons:

1) 'Invariant density ratio' extends the concept of prior probability shift.

2) Conceptually, 'invariant density ratio' is similiar to covariate shift. To see this recall first that covariate shift is defined by the property that the feature-conditional class probabilities of the training and test sets are the same (Moreno-Torres et al., 2012, Section 4.1):

$$\mathrm{P}[Y = 0 \mid X] \;=\; \mathrm{Q}[Y = 0 \mid X]. \tag{9a}$$

   Then, if there are densities of the class-conditional feature distributions under P and Q like for (7), (9a) can be rewritten as

$$\frac{\mathrm{P}[Y = 0]}{1 - \mathrm{P}[Y = 0]} \, \frac{f_0(x)}{f_1(x)} \;=\; \frac{\mathrm{Q}[Y = 0]}{1 - \mathrm{Q}[Y = 0]} \, \frac{h_0(x)}{h_1(x)} \quad \text{for all } x \in \mathcal{X}. \tag{9b}$$

   Hence, covariate shift also can be described in terms of the ratio of the class-conditional densities, like 'invariant density ratio'. The two types of data set shift coincide if $\mathrm{P}[Y = 0] = \mathrm{Q}[Y = 0]$, i.e. if the class prevalences in the training and test sets are the same.

3) The maximum likelihood estimates of class prevalences under prior probability shift actually are maximum likelihood estimates under 'invariant density ratio', too (Tasche, 2014, p. 152 and Remark 1). Hence they can be calculated with the EM (expectation-maximisation) algorithm as described by Saerens et al. (2001).

4) In terms of the data set shift taxonomy of Moreno-Torres et al. (2012), 'invariant density ratio' is a non-trivial but manageable 'other' shift, i.e. it is neither a prior-probability shift, nor a covariate shift, nor a concept shift.

By properties 1) and 2), 'invariant density ratio' has got conceptual similarities with both prior probability shift and covariate shift. In Section 4 below, we will make use of its manageability property 4) to construct an example of data set shift that reveals the limitations of some common approaches to the estimation of class prevalences.

2.5 Fisher Consistency

In Section 1, Fisher consistency of an estimator has been described as the property that the true value of a parameter related to a probability distribution is recovered when the estimator is applied to the distribution on the whole population. In this section, we apply the notion of Fisher consistency to the quantification of binary class prevalences.

In practice, estimators are often Fisher consistent and asymptotically consistent (weakly or strongly, see Section 10.4 of van der Vaart, 1998, for the definitions) at the same time. Gerow (1989) discusses the questions of when this is the case and what concept Fisher (1922) originally defined. Our focus on Fisher consistency is not meant to imply that asymptotic consistency is a less important property. In the context of statistical learning, asymptotic consistency seems to have enjoyed quite a lot of attention, as shown for instance by the existence of books like Devroye et al. (1996). In addition, the convergence aspect of asymptotic consistency often can be checked empirically by observing the behaviour of large samples. However, in some cases it might be unclear if the limit of a seemingly asymptotically consistent large sample is actually the right one. This is why, thanks to its similarity to the concept of unbiasedness which also refers to getting the right value of a parameter, Fisher consistency becomes an important property.

Definition 1 (Fisher consistency) *In the data set shift setting of this paper as described in Section 2.3, we say that an estimator $T(\mathrm{Q})$, applied to the elements Q of a family $\mathcal{Q}$ of possible population distributions of the test set, is Fisher consistent in $\mathcal{Q}$ for the prevalence of class 0 if it holds that*

$$T(\mathrm{Q}) \;=\; \mathrm{Q}[Y = 0] \quad \textit{for all } \mathrm{Q} \in \mathcal{Q}. \tag{10}$$

This definition of Fisher consistency is more restrictive than the definition by Cox and Hinkley (1974) quoted in Section 1. For it requires the specification of a family of distributions to which the parameter 'recovery' property applies. The family $\mathcal{Q}$ of most interest for the purpose of this paper is the set of distributions Q that are related to one fixed training set distribution P by prior probability shift, i.e. by (4).

3. Three Approaches to Estimating Class Prevalences under Prior Probability Shift

In this section, we study three approaches to the estimation of binary class prevalences:

- Adjusted Count (AC) (Forman, 2008), called 'confusion matrix approach' by Saerens et al. (2001), but in use since long before (Gart and Buck, 1966),
- the EM (expectation maximisation) algorithm by Saerens et al. (2001), described before as maximum likelihood approach by Peters and Coberly (1976), and
- CDE-Iterate (CDE for class distribution estimation) by Xue and Weiss (2009).

A variety of other approaches have been and are being studied in the literature (see the discussion in Hofer, 2015, for a recent overview). The selection of approaches to be discussed in this paper was driven by findings of Xue and Weiss (2009) and more recently Karpov

et al. (2016). According to that research, for the estimation of binary class prevalences the CDE-Iterate approach seems to perform equally well or even stronger than AC which by itself was found to outperform the popular EM-algorithm. In this section, we recall the technical details of the approaches which are needed to implement the numerical examples of Section 4 below.

In addition, we check the three estimators on a theoretical basis for Fisher consistency. In particular with regard to CDE-Iterate, the theory is inconclusive with regard to its possible Fisher consistency. However, the example of Section 4.2 below shows that CDE-Iterate is not Fisher consistent for class 0 prevalence under prior probability shift, in contrast to both AC and the EM-algorithm.

3.1 Adjusted Count (AC)

Let $g : \mathcal{X} \to \{0, 1\}$ be any classifier. Under prior probability shift as described by (4), we then obtain

$$\begin{aligned} \mathrm{Q}[g(X) = 0] &= \mathrm{Q}[Y = 0]\,\mathrm{Q}[g(X) = 0 \,|\, Y = 0] + (1 - \mathrm{Q}[Y = 0])\,\mathrm{Q}[g(X) = 0 \,|\, Y = 1] \\ &= \mathrm{Q}[Y = 0]\,\mathrm{P}[g(X) = 0 \,|\, Y = 0] + (1 - \mathrm{Q}[Y = 0])\,\mathrm{P}[g(X) = 0 \,|\, Y = 1]. \quad (11) \end{aligned}$$

If $\mathrm{P}[g(X) = 0 \,|\, Y = 0] \neq \mathrm{P}[g(X) = 0 \,|\, Y = 1]$, i.e. if $g(X)$ and Y are not stochastically independent, (11) is equivalent to

$$\mathrm{Q}[Y = 0] \;=\; \frac{\mathrm{Q}[g(X) = 0] - \mathrm{P}[g(X) = 0 \,|\, Y = 1]}{\mathrm{P}[g(X) = 0 \,|\, Y = 0] - \mathrm{P}[g(X) = 0 \,|\, Y = 1]}. \quad (12)$$

Equation (12) is called the AC approach to the quantification of binary class prevalences. Let us recall some useful facts about AC:

- Equation (12) has been around for a long time, at least since the 1960s. In this paper, the quantification approach related to (12) is called 'Adjusted Count' as in Forman (2008) because this term nicely describes what is done.
- $\mathrm{Q}[g(X) = 0]$ is the proportion of instances in the test set (measured by counting) that are classified (predicted) positive by classifier $g(X)$.
- $\mathrm{P}[g(X) = 0 \,|\, Y = 1]$ is the 'false positive rate', as measured for classifier $g(X)$ on the training set.
- $\mathrm{P}[g(X) = 0 \,|\, Y = 0]$ is the 'true positive rate', as measured for classifier $g(X)$ on the training set.
- Forman (2008) discusses AC in detail and provides a number of variations of the theme in order to account for its deficiencies.
- Possibly, the main issue with AC is that in practice the result of the right-hand side of (12) can turn out to be negative or greater than 1. This can happen for one or more of the following reasons:
  1. The data set shift in question actually is no prior probability shift, i.e. (4) does not hold.
  2. The estimates of the true positive and true negative rates are inaccurate.
  3. The estimation of the scoring function underlying the classifier from limited training data may be inaccurate (both biased and subject to high variance).
- In theory, if the data set shift is indeed a prior probability shift, the result of the right-hand side of (12) should be the same, regardless of which admissible (i.e. such that the denominator is not zero) classifier is deployed for determining the proportion of instances in the test set classified positive. Hence, whenever in practice different classifiers give significantly different results, that could suggest that the assumption of prior probability shift is wrong.
- As long as $g(X)$ and Y are at least somewhat dependent, possible lack of power of the classifier g should not be an issue for the applicability of (12) because the denominator on the right-hand side of (12) is then different from zero.

For a training set distribution P denote by $\mathcal{Q}_{\mathrm{prior}} = \mathcal{Q}_{\mathrm{prior}}(\mathrm{P})$ the family of distributions Q that are related to P by prior probability shift in the sense of Definition 1, i.e.

$$\mathcal{Q}_{\mathrm{prior}} \;=\; \{\mathrm{Q} : \mathrm{Q} \text{ is probability measure satisfying (4)}\}. \quad (13)$$

Then, for fixed training set distribution P and fixed classifier $g(X)$ such that $g(X)$ and Y are not independent under P, the AC approach is Fisher consistent in $\mathcal{Q}_{\mathrm{prior}}$ for the prevalence of class 0 by construction: Define the operator $T = T_{g,\mathrm{P}}$ by

$$T(\mathrm{Q}) \;=\; \frac{\mathrm{Q}[g(X) = 0] - \mathrm{P}[g(X) = 0 \,|\, Y = 1]}{\mathrm{P}[g(X) = 0 \,|\, Y = 0] - \mathrm{P}[g(X) = 0 \,|\, Y = 1]}.$$

Then (12) implies (10) for $\mathrm{Q} \in \mathcal{Q}_{\mathrm{prior}}$. However, denote—again for some fixed training set distribution P—by $\mathcal{Q}_{\mathrm{invariant}} = \mathcal{Q}_{\mathrm{invariant}}(\mathrm{P})$ the family of distributions Q that are related to P by 'invariant density ratio'-type data set shift in the sense of (7), i.e.

$$\mathcal{Q}_{\mathrm{invariant}} \;=\; \{\mathrm{Q} : \mathrm{Q} \text{ is probability measure satisfying (7)}\}. \quad (14)$$

Then in general the AC approach is not Fisher consistent in $\mathcal{Q}_{\mathrm{invariant}}$. For it is shown in Section 4.3 below that there are a classifier g^*, a distribution P^* and a related distribution $\mathrm{Q}^* \in \mathcal{Q}_{\mathrm{invariant}}(\mathrm{P}^*)$ such that

$$T_{g^*,\mathrm{P}^*}(\mathrm{Q}^*) \neq \mathrm{Q}^*[Y = 0].$$

3.2 EM-Algorithm

Saerens et al. (2001) made the EM-algorithm popular for the estimation of class prevalences, as a necessary step for the re-adjustment of thresholds of soft classifiers. A closer inspection of the article by Peters and Coberly (1976) shows that they actually had studied the same algorithm and provided conditions for its convergence. In particular, this observation again draws attention to the fact that the EM-algorithm, deployed on data samples, should result in unique maximum likelihood estimates of the class prevalences.

As noticed by Du Plessis and Sugiyama (2014), the population level equivalent of sample level maximum likelihood estimation of the class prevalences under an assumption of prior

probability shift is minimisation of the Kullback-Leibler distance between the estimated test set feature distribution and the observed test set feature distribution. Moreover, Tasche (2014) observed that the EM-algorithm finds the true values of the class prevalences not only under prior probability shift but also under 'invariant density ratio'-type data set shift. In other words, the EM-algorithm is Fisher consistent both in $\mathcal{Q}_{\text{prior}}$ and $\mathcal{Q}_{\text{invariant}}$, as defined in (13) and (14) respectively, for the prevalence of class 0. See Proposition 2 below for a formal proof.

In the case of two classes, the maximum-likelihood version of the EM-algorithm in the sense of solving the likelihood equation is more efficient than the EM-algorithm itself. This statement applies even more to the population level calculations. In this paper, therefore, we describe the result of the EM-algorithm as the unique solution of a specific equation, as presented in Tasche (2014).

3.3 Calculating the Result of the EM-Algorithm.

In the population setting of Section 2.3 with training set distribution $\mathrm{P}(X, Y)$ and test set distribution $\mathrm{Q}(X, Y)$, assume that the class-conditional feature distributions $\mathrm{P}(X \,|\, Y = i)$, $i = 0, 1$, of the training set have got densities f_0 and f_1. Define the density ratio R by

$$R(x) \;=\; \frac{f_0(x)}{f_1(x)}, \quad \text{for } x \in \mathcal{X}. \tag{15}$$

We then define the estimation operator $T_R(\mathrm{Q})$ for the prevalence of class 0 as the unique solution $q \in (0, 1)$ of the equation (Tasche, 2014)

$$0 \;=\; \mathrm{E}_{\mathrm{Q}}\left[\frac{R(X) - 1}{1 + q\,(R(X) - 1)}\right], \tag{16a}$$

where E_{Q} denotes the expectation operator with respect to Q. Unfortunately, not always does a solution of (16a) exist in $(0, 1)$. There exists a solution in $(0, 1)$ if and only if

$$\mathrm{E}_{\mathrm{Q}}[R(X)] > 1 \quad \text{and} \quad \mathrm{E}_{\mathrm{Q}}\left[\frac{1}{R(X)}\right] > 1, \tag{16b}$$

and if there is a solution in $(0, 1)$ it is unique (Tasche, 2014, Remark 2(a)).

Proposition 2 *The operator $T_R(\mathrm{Q})$ (EM-algorithm), as defined by* (16a)*, is Fisher consistent in $\mathcal{Q}_{prior}$ and $\mathcal{Q}_{invariant}$ for the prevalence of class 0.*

Proof We only have to prove the claim for $\mathcal{Q}_{\text{invariant}}$ because $\mathcal{Q}_{\text{prior}}$ is a subset of $\mathcal{Q}_{\text{invariant}}$. Let any $\mathrm{Q} \in \mathcal{Q}_{\text{invariant}}$ be given and denote by h_i, $i = 0, 1$, its class-conditional feature densities. By (7) and (5b), it then follows that

$$\begin{aligned}
\mathrm{E}_{\mathrm{Q}}\left[\frac{R(X) - 1}{1 + \mathrm{Q}[Y = 0]\,(R(X) - 1)}\right] &= \mathrm{E}_{\mathrm{Q}}\left[\frac{h_0 - h_1}{h_1 + \mathrm{Q}[Y = 0]\,(h_0 - h_1)}\right] \\
&= \frac{\mathrm{E}_{\mathrm{Q}}\big[\mathrm{Q}[Y = 0 \,|\, X]\big]}{\mathrm{Q}[Y = 0]} - \frac{\mathrm{E}_{\mathrm{Q}}\big[\mathrm{Q}[Y = 1 \,|\, X]\big]}{\mathrm{Q}[Y = 1]} \\
&= 1 - 1 = 0.
\end{aligned}$$

Hence, the prevalence $\mathrm{Q}[Y = 0]$ of class 0 is a solution of (16a) and, therefore, the only solution. As a consequence, $T_R(\mathrm{Q})$ is well-defined and satisfies $T_R(\mathrm{Q}) = \mathrm{Q}[Y = 0]$. ■

In practice, for fixed q the right-hand side of (16a) could be estimated on a test set sample $(x_{1,te}, y_{1,te}), \ldots, (x_{n,te}, y_{n,te})$ as in Section 2.3 by the sample average

$$\frac{1}{n}\sum_{i=1}^{n} \frac{R(x_{i,te}) - 1}{1 + q\,(R(x_{i,te}) - 1)},$$

where R could be plugged in as a training set estimate of the density ratio by means of (8).

3.4 CDE-Iterate

In order to successfully apply the AC quantification approach as described in Section 3.1, we must get hold of reliable estimates of the training set true and false positive rates of the classifier deployed. If the positive class is the minority class, the estimation of the true positive rate can be subject to large uncertainties and hence may be hard to achieve with satisfactory accuracy. Similarly, if the negative class is the minority class, the estimation of the false positive rate can be rather difficult.

Application of the EM-algorithm as introduced by Saerens et al. (2001) or described in Section 3.2 requires reliable estimation of the feature-conditional class probabilities or the density ratio. Again, such estimates in general are hard to achieve. That is why alternative methods for quantification are always welcome. In particular, methods that are based exclusively on learning one or more crisp classifiers are promising. For learning classifiers is a well-investigated problem for which efficient solution approaches are available (see, for instance, Lessmann et al., 2015, for a survey related to credit scoring).

Xue and Weiss (2009) proposed 'CDE-Iterate' (CDE for class distribution estimation) which is appropriately summarised by Karpov et al. (2016) as follows: "The main idea of this method is to retrain a classifier at each iteration, where the iterations progressively improve the quantification accuracy of performing the 'classify and count' method via the generated cost-sensitive classifiers." Xue and Weiss motivated the CDE-Iterate algorithm as kind of an equivalent of the EM-algorithm, with the training set feature-conditional class probabilities replaced by Bayes classifiers (or approximations of the Bayes classifiers) learnt on the training set.

In this paper, we do not retrain a classifier but make use of the fact that we have got a closed-form representation of the optimal classifier resulting from the retraining, by (2). Taking this into account and using notation adapted for this paper, we obtain the following description of the CDE-Iterate procedure:

CDE-Iterate algorithm

1) Set initial parameters: $k = 0$, $c_0^{(0)} = 1$, $c_1^{(0)} = 1$.

2) Find Bayes classifier under training distribution $\mathrm{P}(X, Y)$:

$$g_k(X) \;=\; \begin{cases} 0, & \text{if } \mathrm{P}[Y = 0 \,|\, X] > \frac{c_1^{(k)}}{c_0^{(k)} + c_1^{(k)}}, \\ 1, & \text{if } \mathrm{P}[Y = 0 \,|\, X] \le \frac{c_1^{(k)}}{c_0^{(k)} + c_1^{(k)}}. \end{cases}$$

3) Under test feature distribution $\mathrm{Q}(X)$ compute $q_k = \mathrm{Q}[g_k(X) = 0]$.

4) Increment k by 1.

5) Reset cost parameters: $c_1^{(k)} = \frac{1-q_{k-1}}{1-\mathrm{P}[Y=0]}$, $c_0^{(k)} = \frac{q_{k-1}}{\mathrm{P}[Y=0]}$.

6) If convergence is reached or $k = k_{\max}$ then stop, and accept q_{k-1} as the CDE-Iterate estimate of $\mathrm{Q}[Y = 0]$. Else continue with step 2.

Xue and Weiss (2009) did not provide a proof of convergence or unbiasedness for CDE-Iterate. In Section 6 of their paper, they state that "one improvement would be to adapt the CDE-Iterative method to automatically terminate once the class distribution estimate converges. This might improve overall performance over any specific CDE-Iterate-n method and would eliminate the problem of identifying the appropriate number of iterations. It is possible that such a CDE-converge method would outperform CDE-AC." In this paper, we prove convergence of CDE-Iterate and also show that it does not outperform 'CDE-AC' (Adjusted Count in the notation of this paper) for class distribution estimation under prior probability shift, thus answering the quoted research questions of Xue and Weiss.

The proof of the convergence of CDE-Iterate as described above is provided in Proposition 6 in Appendix B below. There it is also shown that the limit $q^* = \lim_{k\to\infty} q_k$ solves the following equation[1]:

$$q^* \;=\; \begin{cases} \mathrm{Q}\left[R(X) \geq \frac{1-q^*}{q^*}\right], & \text{if } q_0 \geq q_1 \text{ and } q_k > q^* \text{ for all } k, \\ \mathrm{Q}\left[R(X) > \frac{1-q^*}{q^*}\right], & \text{otherwise,} \end{cases} \tag{17}$$

where $R(x)$ is defined by (15).

The limit result (17) is quite general in so far as it is not based on any assumption with regard to the type of data set shift between the training set distribution $\mathrm{P}(X, Y)$ and the test set distribution $\mathrm{Q}(X, Y)$. If we restrict the type of data set shift to prior probability shift or 'invariant density ratio'-type data set shift as defined in Section 2.4, does (17) then imply Fisher consistency for the prevalence of class 0 in either of these two families of distributions? As we show by example in the following section, the answer to this question is 'no'.

4. Numerical Examples

In Section 3, we have found that AC as an estimator of class prevalences is Fisher consistent for prior probability shift while the EM-algorithm is even Fisher consistent for the more general 'invariant density ratio'-type data set shift. We have not yet answered the question if CDE-Iterate is Fisher consistent for either of these two data set shift types.

The property of an estimator to be Fisher consistent is something that has to be proved. In contrast, lack of Fisher consistency of an estimator is conveniently shown by providing a counter-example. This is the purpose of the following subsections: We show by examples that

1. Subject to the technical condition that $\mathrm{P}(X)$ has a density f such that $\mathrm{Q}[f(X) > 0] = 1$.

- CDE-Iterate is not Fisher consistent for prior probability shift (and hence for 'invariant density ratio'-type data set shift neither),
- AC is not Fisher consistent for 'invariant density ratio'-type data set shift, and
- the EM-algorithm is no longer Fisher consistent if the 'invariant density ratio'-type data set shift is slightly modified.

We present the counter-examples as a simulation and estimation experiment that is executed for each of the three following example models:

- Section 4.2: Binormal model with equal variances for both training and test set (prior probability shift).
- Section 4.3: Binormal model with equal variances for training set and model with non-normal class-conditional densities but identical density ratio for test set ('invariant density ratio'-type data set shift).
- Section 4.4: Binormal model with equal variances for training set and model with non-normal class-conditional densities and a different density ratio for test set (neither prior probability shift nor 'invariant density ratio'-type data set shift).

The experimental design is described in Section 4.1 below. The classical binormal model with equal variances has been selected as the training set model for the following reasons:

- Logistic regression finds the correct feature-conditional class probabilities.
- Needed algorithms are available in common software packages like R.
- The ratio of the class-conditional feature densities has a particularly simple shape, see (21b) below.
- The binormal model with equal variances has been found useful before for a similar experiment (Tasche, 2016).

Thresholds for Bayes classifier under data set shift. We deploy the logistic regression as coded by R Core Team (2014). Therefore, it is convenient to always use the feature-conditional class-probability $\mathrm{P}[Y = 0 \,|\, X]$ as the Bayes classifier, both for the training set and for the test set after a possible data set shift (then with a modified threshold). In order to be able to do so, we observe that, under prior probability shift or even 'invariant density ratio'-type data set shift, the test set Bayes classifier $g_{\mathrm{test}}(X)$ for the cost-sensitive error criterion (1b) can be represented both as

$$g_{\mathrm{test}}(X) \overset{(2)}{=} \begin{cases} 0, & \text{if } \mathrm{Q}[Y = 0 \,|\, X] > \frac{c_1}{c_0+c_1}, \\ 1, & \text{if } \mathrm{Q}[Y = 0 \,|\, X] \leq \frac{c_1}{c_0+c_1}, \end{cases}$$

and as (see Saerens et al., 2001, Section 2.2)

$$g_{\text{test}}(X) \;=\; \begin{cases} 0, & \text{if } \mathrm{P}[Y=0\,|\,X] > \dfrac{c_1 \frac{1-\mathrm{Q}[Y=0]}{1-\mathrm{P}[Y=0]}}{c_1 \frac{1-\mathrm{Q}[Y=0]}{1-\mathrm{P}[Y=0]} + c_0 \frac{\mathrm{Q}[Y=0]}{\mathrm{P}[Y=0]}}, \\ 1, & \text{if } \mathrm{P}[Y=0\,|\,X] \leq \dfrac{c_1 \frac{1-\mathrm{Q}[Y=0]}{1-\mathrm{P}[Y=0]}}{c_1 \frac{1-\mathrm{Q}[Y=0]}{1-\mathrm{P}[Y=0]} + c_0 \frac{\mathrm{Q}[Y=0]}{\mathrm{P}[Y=0]}}. \end{cases} \tag{18}$$

4.1 Design of the Experiment

In the subsequent sections 4.2, 4.3 and 4.4, we conduct the following experiment and report its results[2]:

- For a given training set (sample and population) represented by distribution $\mathrm{P}(X,Y)$, we determine the Bayes classifier that is optimal for minimising the Bayes error (1a). We represent the Bayes classifier by a decision threshold applied to the feature-conditional probability of class 0 as in (2), with $c_0 = 1 = c_1$.
- We create test sets (by simulation or as population distribution), represented by distributions $\mathrm{Q}(X,Y)$, which are related to the training set by certain types of data set shift, including prior probability shift and 'invariant density ratio'-type data set shift.
- On the test sets, we deploy three different quantification methods for the estimation of the prevalence of class 0 (see also Definition 3 below): CDE-Iterate (defined in Section 3.4), Adjusted Count (defined in Section 3.1), and EM-algorithm (defined in Section 3.2).
- Based on the estimated class 0 prevalences, we adapt the threshold of the Bayes classifier according to (18) such that it would be optimal for minimising the Bayes error (equivalently for maximising the classification accuracy) if the estimated prevalence were equal to the true test set class 0 prevalence and the test set were related to the training set by prior probability shift or by 'invariant density ratio'-type data set shift.
- We report the following results for samples and populations:
  - Classification accuracy and F-measure (see (23a) and (23b) for the definitions) of the adapted Bayes classifier when applied to the test set, because these measures were used by Xue and Weiss (2009).
  - Estimated prevalences of class 0, for direct comparison of estimation results and true values.
  - Relative error: If q is the true probability and $\tilde{q}$ the estimated probability, then we tabulate

$$\max\left(\frac{|\tilde{q}-q|}{q}, \frac{|1-\tilde{q}-(1-q)|}{1-q}\right) \;=\; \frac{|\tilde{q}-q|}{\min(q,1-q)}. \tag{19}$$

2. The R-scripts used for creating the tables and figures of this paper can be received upon request from the author.

Relative error behaves similar to Kullback-Leibler distance used by Karpov et al. (2016), but is defined also for $\tilde{q} = 0$ and $\tilde{q} = 1$ and, moreover, has a more intuitive interpretation.

Modelled class prevalences. The setting is broadly the same as for the artificial data set in Karpov et al. (2016). For each model, we consider a training set with class probabilities 50%, combined with test sets with class 0 probabilities 1%, 5%, 10%, 30%, 50%, 70%, 90%, 95% and 99%. For the samples as well as for the population distributions, we deploy the estimation approaches whose acronyms are given in the following definition to estimate the test set class 0 prevalences.

Definition 3 (Acronyms for estimation approaches)
The following estimation approaches are used in this section:

- *CDE-Iterate in three variants:*
  - *CDE1: First iteration of the algorithm described in Section 3.4. Identical with Classify & Count of Forman (2008).*
  - *CDE2: Second iteration of the algorithm described in Section 3.4.*
  - *CDE∞: CDE-Iterate converged, as described in Section 3.4.*
- *AC: Adjusted Count as described in Section 3.1.*
- *EM: EM-algorithm as described in Section 3.2.*

4.2 Training Set: Binormal; Test Set: Binormal

We consider the classical binormal model with equal variances as an example that fits well into the prior probability shift setting of Section 2.4. We specify the binormal model by defining the class-conditional feature distributions.

- *Training set:* Both class-conditional feature distributions are normal, with equal variances, i.e.

$$\mathrm{P}(X\,|\,Y=0) = \mathcal{N}(\mu,\sigma^2), \qquad \mathrm{P}(X\,|\,Y=1) = \mathcal{N}(\nu,\sigma^2), \tag{20a}$$

  with $\mu < \nu$ and $\sigma > 0$.
- *Test set:* Same as training set.
- For this section's numerical experiment, the following parameter values have been chosen:

$$\mu = 0, \qquad \nu = 2, \qquad \sigma = 1. \tag{20b}$$

For the sake of brevity, in the following we sometimes refer to the setting of this section as 'double' binormal. The feature-conditional class probability $\mathrm{P}[Y=0\,|\,X]$ in the training set is given by

$$\mathrm{P}[Y=0\,|\,X](x) \;=\; \frac{1}{1+\exp(a\,x+b)}, \quad x \in \mathbb{R}, \tag{21a}$$

with $a = \frac{\nu-\mu}{\sigma^2} > 0$ and $b = \frac{\mu^2-\nu^2}{2\,\sigma^2} + \log\left(\frac{1-\mathrm{P}[Y=0]}{\mathrm{P}[Y=0]}\right)$. For the density ratio R according to (15), we obtain

$$R(x) \;=\; \exp\left(x\,\tfrac{\mu-\nu}{\sigma^2} + \tfrac{\nu^2-\mu^2}{2\,\sigma^2}\right), \quad x \in \mathbb{R}. \tag{21b}$$

For the sample version of the example in this section, we create by Monte-Carlo simulation a training sample $\big((x_{1,tr}, y_{1,tr}), \ldots, (x_{m,tr}, y_{m,tr})\big) \in (\mathbb{R} \times \{0,1\})^m$ and test samples $\big((x_{1,te}, y_{1,te}),\, \ldots,\, (x_{n,te}, y_{n,te})\big) \in (\mathbb{R} \times \{0,1\})^n$ with class-conditional feature distributions given by (20a) that approximate the training set population distribution P and the test set population distributions Q as described in general terms in Section 2.4 and more specifically here by (20a), (20b) and the respective class 0 prevalences.

- In principle, $(x_{1,tr}, y_{1,tr}), \ldots, (x_{m,tr}, y_{m,tr})$ is an independent and identically distributed (iid) sample from P as specified by (20a), (20b) and 'training' class 0 prevalence $\mathrm{P}[Y=0] = 0.5$.

- In principle, $(x_{1,te}, y_{1,te}), \ldots,\, (x_{n,te}, y_{n,te})$ is an iid sample from Q as specified by (20a), (20b) and 'test' class 0 prevalences $\mathrm{Q}[Y=0] \in \{0.01, 0.05, 0.1, 0.3, 0.5, 0.7, 0.9, 0.95, 0.99\}$.

- However, following the precedent of Xue and Weiss (2009), for both data sets we have used stratified sampling such that the proportion of $(x_{i,tr}, y_{i,tr})$ with $y_{i,tr} = 0$ in the training set is exactly $\mathrm{P}[Y=0]$, and the proportion of $(x_{i,te}, y_{i,te})$ with $y_{i,te} = 0$ in the test set is exactly $\mathrm{Q}[Y=0]$.

The sample sizes for both the training and the test set samples have been chosen to be 10,000, i.e.

$$m \;=\; n \;=\; 10,000. \tag{22}$$

In our experimental design, the sampling is conducted mainly for illustration purposes because at the same time we also calculate the results at population (i.e. sample size ∞) level such that we know the theoretical outcomes. Therefore, for each parametrisation of each model, there is no repeated sampling, i.e. only one sample is created.

Table 1 shows the class 0 prevalence estimates made in the double binormal setting of this section. Note that in the lower panel of the table, the population estimates by AC and EM are exact—as they should be since in Sections 3.1 and 3.2 we have proved that both estimators are Fisher consistent for the prevalence of class 0 in the family of prior probability shifted distributions. The numbers from the lower panel also show that, in general, neither of the three CDE-Iterate[3] variants CDE1, CDE2 and CDE∞ are Fisher consistent for class 0 prevalence under prior probability shift, except for the case of identical training and test set distributions.

As mentioned in Section 2.1, in the setting of the binormal model with equal variances, the Bayes classifier is unique, irrespective of its specific representation. Hence, in this example, there is no chance to work-around the lack of Fisher consistency for CDE-Iterate by trying to find alternative Bayes classifiers.

3. Note that in any case the tabulated estimates by CDE1, CDE2 and CDE∞ confirm the monotonicity statement in Proposition 6 of Appendix B for the convergence of CDE-Iterate.

Table 1: Class 0 prevalence estimates on the test sets. Training set: Binormal with equal variances. Test sets: Binormal with equal variances. 'Q[Y=0]' is the true test set prevalence of class 0. See Definition 3 for the other acronyms.

However, from the sample estimation numbers in the upper panel of Table 1, we can conclude that in practice CDE2 may provide estimates of the class 0 prevalence that are better or at least not much worse than the AC and EM estimates. Table 4 in Appendix A with the relative errors of the estimates confirms this observation. Such incidences could explain the favourable performance of CDE-Iterate observed by Xue and Weiss (2009) and Karpov et al. (2016).

For the sake of completeness, in Tables 5 and 6 in Appendix A, we report the classification accuracies and F-measures respectively, for the training set Bayes classifier with adapted thresholds according to (18), computed on the different test sets. The metrics classification accuracy and F-measure here are of interest because Xue and Weiss (2009) used them for measuring the performance of the classifiers discussed in their study. For any classifier $g : \mathcal{X} \to \{0,1\}$, we make use of the following population level formulae for classification accuracy and F-measure:

$$\text{Classification accuracy} \;=\; 1 - \text{Classification Error} \;=\; \mathrm{Q}[g(X) = Y], \tag{23a}$$

$$\begin{aligned}\text{F-measure} \;&=\; \frac{2 \times \text{Recall} \times \text{Precision}}{\text{Recall} + \text{Precision}} \\ &=\; \frac{2\,\mathrm{Q}[g(X)=0\,|\,Y=0]\,\mathrm{Q}[Y=0\,|\,g(X)=0]}{\mathrm{Q}[g(X)=0\,|\,Y=0] + \mathrm{Q}[Y=0\,|\,g(X)=0]}.\end{aligned} \tag{23b}$$

In these formulae, Q is used to indicate the test set probability distribution in accordance with the general assumption of this paper.

Basically, Tables 5 and 6 in Appendix A demonstrate that it is hard to draw conclusions on quantification performance by looking at classification accuracy or F-measure as

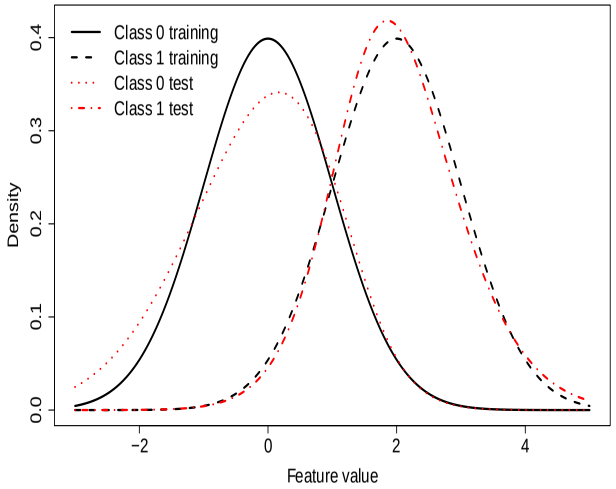

Figure 1: Training set and test set class-conditional densities for Section 4.3. The ratio of the training set densities and the ratio of the test set densities are equal.

performance metrics. Both at sample and at population level, the tabulated classification accuracy values of CDE∞, AC and EM are almost indistinguishable. While the slightly better accuracy values for EM-algorithm and AC compared to CDE∞ at population level are indeed sure evidence of better performance, the better values at sample level might just be random effects. A similar statement applies to the F-measure values of CDE2, AC and EM. The NaNs in Table 6 are caused by zero and negative estimates of the class 0 prevalence.

4.3 Training Set: Binormal; Test Set: Non-normal Densities, Binormal Density Ratio

The combination of a binormal model with equal variances for the training set and a model with the same density ratio but non-normal class-conditional feature distributions provides an example that fits conveniently into the 'invariant density ratio'-type data set shift setting of Section 2.4. We again specify the two models by their class-conditional feature densities.

Training set. Both class-conditional feature distributions are normal, with equal variances, as specified in (20a) and (20b).

Test set. We specify the test set distribution by class-conditional feature densities h_0 and h_1 chosen in such a way that their ratio $\frac{h_0(x)}{h_1(x)}$, $x \in \mathbb{R}$, is given by (21b). Then it equals the feature density ratio in the double binormal model from Section 4.2. In addition, we

require that the resulting model is easy to handle numerically but still not too close to the double binormal model. To achieve this, we apply the following steps:

- We start with a normal density h^* characterised by the parameters

$$\text{Mean} \;=\; \vartheta, \qquad \text{variance} \;=\; \tau^2 \;>\; 0. \tag{24a}$$

  For the purpose of this paper, we have chosen

$$\vartheta \;=\; 0.5, \qquad \tau \;=\; 1.4. \tag{24b}$$

- Then we apply Theorem 3 of Tasche (2014) to decompose h^* into a mixture $q^*\, h_0 + (1-q^*)\, h_1$ of h_0 and h_1, subject to the condition $\frac{h_0(x)}{h_1(x)} = \exp\left(x\,\frac{\mu-\nu}{\sigma^2} + \frac{\nu^2-\mu^2}{2\,\sigma^2}\right)$, $x \in \mathbb{R}$, with μ, ν and σ given by (20b). The important step for the decomposition is to determine q^*. This can be done as suggested in Section 3.2, by solving a version of Equation (16a) for the variable q:

$$0 \;=\; \int_{-\infty}^{\infty} \frac{R(x)-1}{1+q\,(R(x)-1)}\, h^*(x)\, dx, \tag{25a}$$

  where $R(x)$ is given by (21b). There is a unique solution $0 < q = q^* < 1$ if and only if

$$\int R(x)\, h^*(x)\, dx > 1 \quad \text{and} \quad \int R(x)^{-1}\, h^*(x)\, dx > 1.$$

  With parameters set as in (20b) and (24b), the solution for q is

$$q^* \;=\; 0.7239184.$$

- If q^* denotes the solution of (25a) the resulting class conditional feature densities are determined as

$$h_0(x) \;=\; \frac{R(x)\, h^*(x)}{1+q^*\,(R(x)-1)} \quad \text{and} \quad h_1(x) \;=\; \frac{h^*(x)}{1+q^*\,(R(x)-1)}, \qquad x \in \mathbb{R}. \tag{25b}$$

Once the densities h_0 and h_1 have been made available by (25b), the test set class-conditional feature distributions $\mathrm{Q}(X \,|\, Y = 0)$ and $\mathrm{Q}(X \,|\, Y = 1)$ can be defined as the distributions determined by these densities. Figure 1 shows the test set class-conditional densities from (25b) and the normal densities related to the training set.

For the population-related calculations and the sample simulations, we use the sample sizes as specified in (22), training set class 0 prevalence $\mathrm{P}[Y = 0] = 0.5$ and test set class 0 prevalences $\mathrm{Q}[Y = 0] \in \{0.01, 0.05, 0.1, 0.3, 0.5, 0.7, 0.9, 0.95, 0.99\}$ as in the double binormal case of Section 4.2. Again, the samples are stratified with separate sampling from classes 0 and 1. This is straightforward for the binormal model of the training set, but less straightforward for the test set distributions given by the class-conditional densities (25b). For this sampling we have applied the simple accept-reject algorithm described in Robert and Casella (2004, Corollary 2.17).

Table 2: Class 0 prevalence estimates on the test sets. Training set: Binormal with equal variances. Test sets: Non-normal densities, binormal density ratio. 'Q[Y=0]' is the true test set prevalence of class 0. See Definition 3 for the other acronyms.

Table 2 shows the class 0 prevalence estimates made in the 'binormal – non-binormal with binormal density ratio' setting of this section. In the lower panel of the table, the population estimates by EM are exact—as they should be since in Section 3.2 we have proved that the EM-algorithm is Fisher consistent for the prevalence of class 0 in the family of test set distributions subject to 'invariant density ratio'-type data set shift. The numbers from the lower panel also show that, in general, neither AC nor any of the three CDE-Iterate variants CDE1, CDE2 and CDE∞ are Fisher consistent for class 0 prevalence under 'invariant density ratio'-type data set shift, not even in the case of training and test sets with equal class 0 prevalences. However, while the performance of CDE∞ and CDE1 is really poor, CDE2 at least is not worse than AC in this setting.

This observation is confirmed by looking at the relative error table 7 in Appendix A and the upper 'sample' panel of Table 2. Hence, outside of the prior probability setting, CDE2 may well outperform AC. The 'sample' error figures also demonstrate that while in theory the EM-algorithm should deliver unbiased estimates of the class 0 test set prevalence under 'invariant density ratio'-type data set shift, in practice for extreme prevalences like 1% or 99% the estimation error may be significant also for the EM-algorithm.

Since we have already seen in Section 4.2 that measurements of accuracy and F-measure are not very helpful for assessing quantification accuracy, we do not present them for the model of this section.

4.4 Training Set: Binormal; Test Set: Non-normal Densities, Non-binormal Density Ratio

The setting of this section for the training and test set distributions is exactly the same as in Section 4.3, with the exception that the ratio $\frac{h_0}{h_1}$ of the class-conditional feature densities

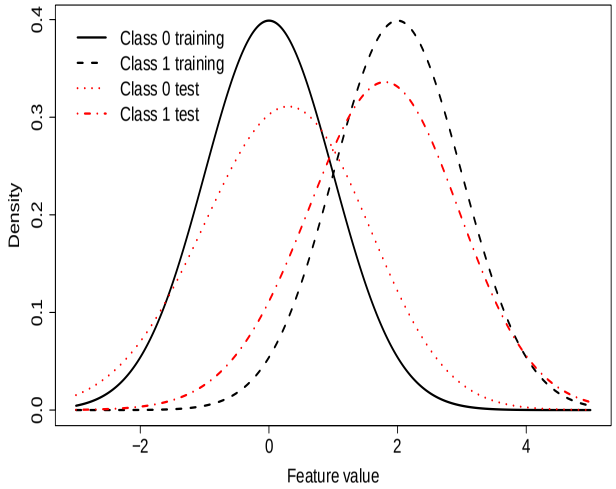

Figure 2: Training set and test set class-conditional densities for Section 4.4. The ratio of the test set densities is equal to the square root of the ratio of the training set densities.

is not equal to the test set density as given by (21b) but to its square root:

$$\frac{h_0(x)}{h_1(x)} \;=\; \sqrt{R(X)} \;=\; \exp\left(\frac{2\,x\,(\mu-\nu)+\nu^2-\mu^2}{4\,\sigma^2}\right). \tag{26}$$

Otherwise, the class-conditional feature densities h_0 and h_1 are again determined by the solution of (25a) and (25b) (with $R(x)$ replaced by $\sqrt{R(X)}$). This time, the solution for q is

$$q^* \;=\; 0.8152434.$$

Figure 2 shows the test set class-conditional densities from (25b) and the normal densities related to the training set in this case. Also the sample simulations are conducted in the same way as in Section 4.3, again with an accept-reject algorithm deployed for the test set simulations.

Table 3 and Table 8 in Appendix A show that the EM-algorithm is no longer Fisher consistent for the prevalence of class 0 when the test set distribution under consideration has not been generated from the training set distribution by 'invariant density ratio'-type data set shift. Unsurprisingly, given that AC is not Fisher consistent on test sets which are not generated by prior probability shift, it is not Fisher consistent in the family of test set distributions generated by this modified 'invariant density ratio'-type data set shift

either. While both CDE1 and CDE2 perform really poorly in this section's model setting, CDE∞ performs better, both at sample and at population level. At sample level, even the CDE∞-estimates of the small class 0 prevalences look sensible.

5. Conclusions

In this paper, we have discussed the notion of Fisher consistency as a basic unbiasedness requirement for class prevalence quantifiers in the presence of data set shift. The usefulness of Fisher consistency has been demonstrated with three examples of classifiers serving as quantifiers: Adjusted Count, EM-algorithm, and CDE-Iterate. We have shown by example that CDE-Iterate is not Fisher consistent even for simple prior probability shift. Adjusted Count and EM-algorithm are Fisher consistent for prior probability shift but lose this property under data set shifts deviating not much from prior probability shift. Hence before relying on prevalence estimates by Adjusted Count or EM-algorithm, users should carefully check what kind of data set shift they are confronted with. As a further contribution to quantification-related research, we have suggested a method, based on the concept of 'invariant density ratio'-type data set shift, for conveniently generating non-trivial data set shift beyond prior probability shift and covariate shift but conceptually close to both of these types of data set shift.

Appendix B. Proof of the Convergence of CDE-Iterate

In order to provide a fully rigorous proof of Equation (17) that characterises the limit of CDE-Iterate, we adopt measure-theoretic notation in this section. See standard textbooks on probability theory like Billingsley (1995) or Durrett (1996) for reference.

We discuss the problem in a 'mixture model' probabilitistic context specified by the following assumption.

Assumption 4 *P_0 and P_1 are probability measures on some measurable space $(\Omega, \mathcal{H})$. Both P_0 and P_1 are absolutely continuous with respect to some measure μ on $(\Omega, \mathcal{H})$. The density of P_i with respect to μ is f_i, $i = 0, 1$.*

Note that in the setting of Sections 2 and 3.4, Assumption 4 is satisfied when the training set class-conditional feature distributions have got densities. Choose in that case $\Omega = \mathcal{X}$, $\mathrm{P}_0[H] = \mathrm{P}[X \in H \,|\, Y = 0]$ and $\mathrm{P}_1[H] = \mathrm{P}[X \in H \,|\, Y = 1]$. The σ-field $\mathcal{H}$ is any appropriate σ-field on $\mathcal{X}$, for instance the Borel-σ-field in case $\mathcal{X} = \mathbb{R}^d$.

For events $H \in \mathcal{H}$ we denote the complement of H in Ω by H^c, i.e. we have $H^c = \Omega \backslash H$. Then, in the setting of this section, crisp classifiers $g(X)$ with values 0 or 1 are described as events by the relations $\{g(X) = 0\} = H$ and $\{g(X) = 1\} = H^c$.

The following lemma translates the optimisation problem (1b) and its solution (2) into this section's notation and enhances them with a statement on the uniqueness of the solution.

Lemma 5 *Let $a_0, a_1 \geq 0$. Under Assumption 4, then for all $H \in \mathcal{H}$, it holds that*

$$a_0\,\mathrm{P}_0[H^c] + a_1\,\mathrm{P}_1[H] \;\geq\; a_0\,\mathrm{P}_0[a_1\,f_1 \geq a_0\,f_0] + a_1\,\mathrm{P}_1[a_1\,f_1 < a_0\,f_0]. \tag{27}$$

Equality in (27) *holds if and only if* $0 = \mu\big(H \cap \{a_1\, f_1 > a_0\, f_0\}\big)$ *and* $0 = \mu\big(H^c \cap \{a_1\, f_1 < a_0\, f_0\}\big)$.

Proof We inspect the following chain of equations and inequalities:

$$\begin{aligned}
a_0\,\mathrm{P}_0[H^c] + a_1\,\mathrm{P}_1[H] &= a_0 + a_1\,\mathrm{P}_1[H] - a_0\,\mathrm{P}_0[H] \\
&= a_0 + \int_H a_1\, f_1 - a_0\, f_0\, d\mu \\
&= a_0 + \int_{H\cap\{a_1\, f_1 < a_0\, f_0\}} a_1\, f_1 - a_0\, f_0\, d\mu + \int_{H\cap\{a_1\, f_1 > a_0\, f_0\}} a_1\, f_1 - a_0\, f_0\, d\mu \\
&\overset{\text{a)}}{\geq} a_0 + \int_{H\cap\{a_1\, f_1 < a_0\, f_0\}} a_1\, f_1 - a_0\, f_0\, d\mu \\
&\overset{\text{b)}}{\geq} a_0 + \int_{\{a_1\, f_1 < a_0\, f_0\}} a_1\, f_1 - a_0\, f_0\, d\mu \\
&= a_0\,\mathrm{P}_0[a_1\, f_1 \geq a_0\, f_0] + a_1\,\mathrm{P}_1[a_1\, f_1 < a_0\, f_0].
\end{aligned}$$

This proves (27). By inequality a), equality in (27) implies $0 = \int_{H\cap\{a_1\, f_1 > a_0\, f_0\}} a_1\, f_1 - a_0\, f_0\, d\mu$ and, therefore, $0 = \mu\big(H \cap \{a_1\, f_1 > a_0\, f_0\}\big)$. Similarly, equality in (27) implies $0 = \mu\big(H^c \cap \{a_1\, f_1 < a_0\, f_0\}\big)$ because of inequality b). ■

Lemma 5 characterises the solutions H^* of the optimisation problem

$$a_0\,\mathrm{P}_0[(H^*)^c] + a_1\,\mathrm{P}_1[H^*] \;=\; \min_{H\in\mathcal{H}} a_0\,\mathrm{P}_0[H^c] + a_1\,\mathrm{P}_1[H]. \tag{28}$$

One solution is the event $\{a_1\, f_1 < a_0\, f_0\} \in \mathcal{H}$. However, the solution is not unique. For instance, $\{a_1\, f_1 \leq a_0\, f_0\} \in \mathcal{H}$ is another solution as it easily can be checked that the two conditions for equality in (27) are satisfied. If we have $\mu(a_1\, f_1 = a_0\, f_0) = 0$, then the minimising event $\{a_1\, f_1 < a_0\, f_0\}$ from Lemma 5 is unique in the following sense: If $H^* \in \mathcal{H}$ is another minimising event then it follows that[4]

$$\begin{aligned}
0 \;&=\; \mu\big(\Delta(H^*, \{a_1\, f_1 < a_0\, f_0\})\big) \\
&=\; \mu\big((H^*)^c \cap \{a_1\, f_1 < a_0\, f_0\}\big) + \mu\big(H^* \cap \{a_1\, f_1 < a_0\, f_0\}^c\big).
\end{aligned}$$

Hence H^* and $\{a_1\, f_1 < a_0\, f_0\}$ are almost everywhere equal.

Assume, similarly to Section 2.3, that there is another probability measure Q on $(\Omega, \mathcal{H})$. Q is interpreted as the unconditional distribution of the features on a test set whose class distribution is (not yet) known. In the notation of this section, then the CDE-Iterate algorithm of Xue and Weiss (2009) can be described as follows:

CDE-Iterate algorithm

1) Set initial parameters: $k = 0$, $a_0^{(0)} > 0$, $a_1^{(0)} > 0$.

2) Find optimal classifier under Assumption 4: $H_k = \{a_1^{(k)}\, f_1 < a_0^{(k)}\, f_0\}$.

4. For two sets A and B, the term $\Delta(A, B)$ denotes the set difference $\Delta(A, B) = ((A \cap B^c) \cup (A^c \cap B)$.

3) Under probability Q compute $q_k = \mathrm{Q}[H_k]$.

4) Increment k by 1.

5) Reset cost parameters: $a_0^{(k)} = q_{k-1}$, $a_1^{(k)} = 1 - q_{k-1}$.

6) If convergence is reached or $k = k_{\max}$ then stop, else continue with step 2).

Convergence of the CDE-algorithm as given above or in the paper by Xue and Weiss (2009) is not obvious. However, we can state the following result.

Proposition 6 *Under Assumption 4, the sequence* $(q_k)_{k\geq 0}$ *determined by the CDE-algorithm as described in this section converges for any probability measure* Q *on* $(\Omega, \mathcal{H})$ *and any choice of the intial parameters* $a_0^{(0)} > 0$ *and* $a_1^{(0)} > 0$. *The limit* $q^* = \lim_{k\to\infty} q_k$ *satisfies the equation*

$$q^* \;=\; \begin{cases} \mathrm{Q}\big[(1-q^*)\, f_1 \leq q^*\, f_0,\; f_0 + f_1 > 0\big], & \text{if } q_0 \geq q_1 \text{ and } q_n > q^* \text{ for all } k. \\ \mathrm{Q}\big[(1-q^*)\, f_1 < q^*\, f_0\big], & \text{otherwise.} \end{cases} \tag{29}$$

Proof Suppose that $q_k \leq q_{k+1}$ for some k. Then it follows that

$$\begin{aligned}
q_{k+2} &= \mathrm{Q}\big[(1-q_{k+1})\, f_1 < q_{k+1}\, f_0\big] \\
&= \mathrm{Q}\big[f_1 < q_{k+1}\,(f_0 + f_1)\big] \\
&\geq \mathrm{Q}\big[(1-q_k)\, f_1 < q_k\, f_0\big] \\
&= q_{k+1}.
\end{aligned}$$

Hence $(q_k)_{k\geq 0}$ is non-decreasing if $q_0 \leq q_1$. Similarly, it can be shown that $(q_k)_{k\geq 0}$ is non-increasing if $q_0 \geq q_1$. It follows that $q^* = \lim_{k\to\infty} q_k$ exists.

Note that $\mathrm{Q}\big[f_1 < x\,(f_0 + f_1)\big] = \mathrm{Q}[f_0 + f_1 > 0]\,\mathrm{Q}\big[\frac{f_1}{f_0+f_1} < x \,|\, f_0 + f_1 > 0\big]$ is the left-continuous version of a distribution function. Therefore, it follows that

$$\begin{aligned}
\lim_{y\uparrow x} \mathrm{Q}\big[f_1 < y\,(f_0 + f_1)\big] &= \mathrm{Q}\big[f_1 < x\,(f_0 + f_1)\big], \\
\lim_{y\downarrow x} \mathrm{Q}\big[f_1 < y\,(f_0 + f_1)\big] &= \mathrm{Q}\big[f_1 \leq x\,(f_0 + f_1),\; f_0 + f_1 > 0\big]
\end{aligned}$$

By definition of q_k, this implies (29). ■

Editor: Geoff Holmes

Abstract

We introduce openXBOW, an open-source toolkit for the generation of bag-of-words (BoW) representations from multimodal input. In the BoW principle, word histograms were first used as features in document classification, but the idea was and can easily be adapted to, e. g., acoustic or visual descriptors, introducing a prior step of vector quantisation. The openXBOW toolkit supports arbitrary numeric input features and text input and concatenates computed sub-bags to a final bag. It provides a variety of extensions and options. To our knowledge, openXBOW is the first publicly available toolkit for the generation of crossmodal bags-of-words. The capabilities of the tool have been exemplified in different scenarios: sentiment analysis in tweets, classification of snore sounds, and time-dependent emotion recognition based on acoustic, linguistic, and visual information, where improved results over other feature representations were observed.

Keywords: bag-of-words, multimodal signal processing, histogram feature representations, feature learning

1. Introduction

The bag-of-words (BoW) principle is a common practice in *natural language processing* (NLP) (Weninger et al., 2013). In this method, *word histograms* are generated, i. e., within a text document, the frequencies of each word from a dictionary are counted. The resulting *term frequency* (TF) vector is then input to a classifier, such as a *support vector machine* (SVM), i. e., a machine learning scheme which is known to cope well with possibly irrelevant features and large, yet sparse feature vectors.

BoW has been adopted by the visual computing community, where it is known under the name bag-of-visual-words (BoVW) (Wu et al., 2011). Instead of lexical words, local image features are extracted from an image and their general distribution is modelled by a histogram. In recent years, the principle has also been employed successfully in the field of audio classification, where it is known under the term bag-of-audio-words (BoAW). Acoustic *low-level descriptors* (LLDs), such as *mel-frequency cepstral coefficients*, are extracted from the audio signal; then, the LLD vectors from single frames are quantised according to a codebook (Pancoast and Akbacak, 2014). This codebook can be the result of, e. g., a k-means clustering (Pokorny et al., 2015) or a random sampling of LLDs (Rawat et al., 2013). A histogram finally describes the distribution of the codebook vectors over the whole audio segment. Major applications of BoAW are acoustic and multimedia event detection (Rawat et al., 2013; Pancoast and Akbacak, 2013; Lim et al., 2015), but they have also been successfully employed for music information retrieval (Riley et al., 2008), emotion recognition (Schmitt et al., 2016b), and medical diagnosis (Schmitt et al., 2016a).

In this contribution, we introduce the first open-source toolkit for the generation of BoW representations across modalities, thus named openXBOW ("open crossbow" – 'X' stands for CROSSmodal). The motivation behind openXBOW is to ease the generation of a fused BoW-based representation from different modalities. These modalities can be the acoustic or the visual domain, providing numeric LLDs, and written documents or transcriptions of speech, providing text or *symbolic* input. However, arbitrary modalities, such as, e. g., stemming from physiological measurement or feature streams as used in brain computing, can be processed. In case of multimodal or 'crossmodal' usage, the output of the toolkit is a concatenated feature vector consisting of histogram representations per modality or combinations of these. Crossmodal BoW have already been employed, e. g., for depression monitoring (Joshi et al., 2013), exploiting both the audio and the video domain.

openXBOW provides a multitude of options, e. g., different modes of vector quantisation, codebook generation, TF weighting, and methods known from natural language processing to process the textual features. To the knowledge of the authors, such a toolkit has not been published, so far, whereas there are already some libraries implementing BoVW, such as *DBoW2* (Gálvez-López and Tardos, 2012).

In the next section, we give an overview of the openXBOW tool, its structure and its options. In Section 3, we give results from an exemplary application of the tool. We conclude and give an outlook on future developments in openXBOW in Section 4.

2. Overview

openXBOW is implemented in Java and can thus be used on any common platform. It has been published on GitHub as a public repository[1], including both the source code and a compiled jar file for users who do not have a Java Development Kit installed. The software and the source code are published under GPLv3. openXBOW supports three formats for input and output: *CSV* (comma separated values), *ARFF* (attribute-relation file format), used in the broadly applied machine learning software *Weka* (Hall et al., 2009), and *LIBSVM* file format (only for output), used in LIBSVM (Chang and Lin, 2011) and LIBLINEAR (Fan et al., 2008). All options, which are configured through the command line call, are displayed when calling openXBOW ('java -jar openXBOW.jar').

The input is processed in the way shown in Figure 1. First, the input features can be pre-processed, particularly, (min-max)-normalisation or standardisation can be applied to the numeric descriptors, which is meaningful in case feature types with (significantly) different ranges of values are combined. The corresponding parameters are stored in the *codebook file*, in order to be applied also to a given test file (online approach).

For codebook generation, there are four different methods; *random sampling*, which means that the codebook vectors are picked randomly from the input, whereas *random sampling++* favours far-off vectors as proposed by Arthur and Vassilvitskii (2007). This implements basically the initialisation step of *k-means++ clustering*, which is also available besides the classical *k-means clustering*. The codebook generation can also be done in a *supervised* manner, learning a codebook from the input descriptors of one class separately,

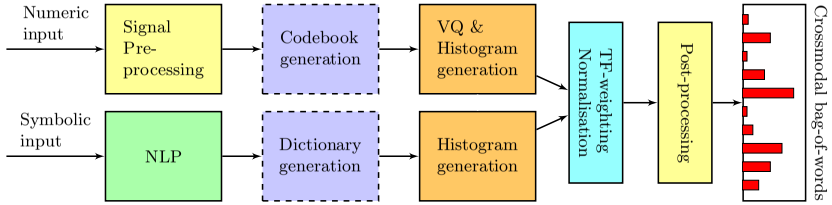

Figure 1: Overview of the basic workflow of openXBOW.

first, and then concatenating these codebooks to form a *super-codebook* (Grzeszick et al., 2015). Besides, it is also possible to split the input into well-defined sub-vectors in order to generate different sub-codebooks for different feature types. The vector quantisation (VQ) of the input is based on the minimum *Euclidean distance* between an input vector and all words in the codebook, sometimes referred to as *templates*. The bag-of-words are then generated from the term frequencies, i. e., the number of occurrences of each template, within the whole document. In the input file, all feature vectors belonging to the same instance need to have the same unique name as an attribute. The input can also be subject to *multiple assignments*, where not only the word with the closest distance is considered but a specified number of close templates. A way of doing *soft* vector quantisation is applying *Gaussian encoding* (Pancoast and Akbacak, 2014), where in each word assignment step, the increment is weighted with the distance to the templates.

For the text domain, standard processing techniques known from NLP are available, such as *stopping*, *n-grams*, and *n-character-grams*. The numeric codebook and the symbolic dictionary are stored in a file to be used for independent test data.

The BoW representations of different domains are fused into a single feature vector (early fusion). Logarithmic TF-weighting and inverse document-frequency (IDF) weighting can be applied (Riley et al., 2008). The bags can then be normalised, a step which might be meaningful if the input instances have different lengths. Finally, post-processing in terms of (min-max-)normalisation and standardisation is available for the resulting BoW.

3. Experiments

The usage of openXBOW is now shortly exemplified in one scenario: *crossmodal emotion recognition*. The above mentioned GitHub repository includes a *tutorial* which allows the user to reproduce results for different scenarios and several features types, including *sentiment analysis* of *tweets* in a data set of more than 1 million instances.

Emotion recognition in speech has been conducted on the SEWA[2] (Automatic Sentiment Analysis in the Wild) corpus, more specifically, on video chat recordings of 64 German subjects. The overall length of this audio-visual data is approximately 89 minutes, the data was split into subject-independent training, development (devel), and test partitions (34/14/16 subjects). Emotion has been annotated continuously in terms of the two emotional dimensions *arousal* and *valence* (Schmitt et al., 2016b). Results are presented in terms of the *concordance correlation coefficient* (CCC) between the prediction and the annotation. For

Modality	Arousal (devel)	Arousal (test)	Valence (devel)	Valence (test)
Acoustic	.535	.470	.402	.426
Visual	.434	.314	.385	.344
Linguistic	.364	.293	.328	.320
Crossmodal (early fusion)	.560	.432	.536	.509
Crossmodal (late fusion)	.588	.499	.495	.523

Table 1: Performance (in terms of CCC) of emotion recognition on the SEWA German video chats using crossmodal BoW. The codebook size for numeric features is 1 000, the number of assignments is 10. The dictionary consists of 346 words.

the acoustic domain, the 65 LLDs from the ComParE feature set have been extracted using the toolkit openSMILE (Eyben et al., 2013). For the visual domain, we used 49 *facial landmarks* extracted with the Chehra Face Tracker (Asthana et al., 2014). Manual transcriptions of the speech were used as linguistic input. As the target of the prediction is time-dependent, the input was segmented into overlapping blocks of 8 *s* width and 0.1 *s* hop size, as described by Schmitt et al. (2016b). For decoding of the BoW, LIBLINEAR was used; the complexity parameter was optimised on the development set. The results reported in Table 1 show that, both early and late fusion—by training another SVM based on the predictions from single modalities—are suitable for the prediction of emotional speaker states. Further results with BoAW on well-established databases with comparison to other approaches have been reported by Schmitt et al. (2016a,b).

The performance of openXBOW is quite decent. On a system with an *Intel Core i7-4770 (3.4 GHz)* CPU, *16 GB RAM*, *Windows 10* operating system, and *Java Version 8, Update 121*, the computation of the aforementioned crossmodal BoW (with early fusion) took 263 *s* for training and 67 *s* for prediction. Calling openXBOW for a short video segment of 8 *s* duration takes 0.57 *s*. Thus, the toolkit is suitable for real-time applications ($< 10\,\%$ real-time factor for crossmodal input). For the sentiment analysis task mentioned in the *tutorial*, the generation of the BoW representation for 1 million tweets took 118 *s*.

4. Conclusions and Outlook

We introduced our novel openXBOW toolkit—a first of its kind—for the generation of BoW representations from crossmodal symbolic (including text), but also numeric (such as audio or video feature streams) information representations. We showed the potential of the toolkit and the underlying BoW principle in a crossmodal emotion recognition task on a state-of-the-art database.

Future work on openXBOW will include further codebook generation techniques such as *EM clustering* or *non-negative matrix factorisation* and alternative methods of soft vector quantisation.

Acknowledgments

The research leading to these results has received funding from the European Union's Horizon 2020 and 7th Framework Programmes under GA No. 645094 (H2020 IA SEWA) and No. 338164 (ERC StG iHEARu).

Editor: Leon Bottou

Abstract

We analyze the learning properties of the stochastic gradient method when multiple passes over the data and mini-batches are allowed. We study how regularization properties are controlled by the step-size, the number of passes and the mini-batch size. In particular, we consider the square loss and show that for a universal step-size choice, the number of passes acts as a regularization parameter, and optimal finite sample bounds can be achieved by early-stopping. Moreover, we show that larger step-sizes are allowed when considering mini-batches. Our analysis is based on a unifying approach, encompassing both batch and stochastic gradient methods as special cases. As a byproduct, we derive optimal convergence results for batch gradient methods (even in the non-attainable cases).

1. Introduction

Modern machine learning applications require computational approaches that are at the same time statistically accurate and numerically efficient (Bousquet and Bottou, 2008). This has motivated a recent interest in stochastic gradient methods (SGM), since on the one hand they enjoy good practical performances, especially in large scale scenarios, and on the other hand they are amenable to theoretical studies. In particular, unlike other learning approaches, such as empirical risk minimization or Tikhonov regularization, theoretical results on SGM naturally integrate statistical and computational aspects.

Most generalization studies on SGM consider the case where only one pass over the data is allowed and the step-size is appropriately chosen, see (Cesa-Bianchi et al., 2004; Nemirovski et al., 2009; Ying and Pontil, 2008; Tarres and Yao, 2014; Dieuleveut and Bach, 2016; Orabona, 2014) and references therein, possibly considering averaging (Poljak, 1987). In particular, recent works show how the step-size can be seen to play the role of a regularization parameter whose choice controls the bias and variance properties of the obtained solution (Ying and Pontil, 2008; Tarres and Yao, 2014; Dieuleveut and Bach, 2016; Lin et al., 2016a). These latter works show that balancing these contributions, it is possible to derive a step-size choice leading to optimal learning bounds. Such a choice typically depends on some unknown properties of the data generating distributions and it can be chosen by cross-validation in practice.

While processing each data point only once is natural in streaming/online scenarios, in practice SGM is often used to process large data-sets and multiple passes over the data are typically considered. In this case, the number of passes over the data, as well as the step-size, need then to be determined. While the role of multiple passes is well understood if the goal is empirical risk minimization (see e.g., Boyd and Mutapcic, 2007), its effect with respect to generalization is less clear. A few recent works have recently started to tackle this question. In particular, results in this direction have been derived in (Hardt et al., 2016) and (Lin et al., 2016a). The former work considers a general stochastic optimization setting and studies stability properties of SGM allowing to derive convergence results as well as finite sample bounds. The latter work, restricted to supervised learning, further develops these results to compare the respective roles of step-size and number of passes, and show how different parameter settings can lead to optimal error bounds. In particular, it shows that there are two extreme cases: while one between the step-size or the number of passes is fixed a priori, while the other one acts as a regularization parameter and needs to be chosen adaptively. The main shortcoming of these latter results is that they are for the worst case, in the sense that they do not consider the possible effect of benign assumptions on the problem (Zhang, 2005; Caponnetto and De Vito, 2007) that can lead to faster rates for other learning approaches such as Tikhonov regularization. Further, these results do not consider the possible effect on generalization of mini-batches, rather than a single point in each gradient step (Shalev-Shwartz et al., 2011; Dekel et al., 2012; Sra et al., 2012; Ng, 2016). This latter strategy is often considered especially for parallel implementation of SGM.

The study in this paper fills in these gaps in the case where the loss function is the least squares loss. We consider a variant of SGM for least squares, where gradients are sampled uniformly at random and mini-batches are allowed. The number of passes, the step-size and the mini-batch size are then parameters to be determined. Our main results highlight the respective roles of these parameters and show how can they be chosen so that the corresponding solutions achieve optimal learning errors in a variety of settings. In particular, we show for the first time that multi-pass SGM with early stopping and a universal step-size choice can achieve optimal convergence rates, matching those of ridge regression (Smale and Zhou, 2007; Caponnetto and De Vito, 2007). Further, our analysis shows how the mini-batch size and the step-size choice are tightly related. Indeed, larger mini-batch sizes allow considering larger step-sizes while keeping the optimal learning bounds. This result gives insights on how to exploit mini-batches for parallel computations while preserving optimal statistical accuracy. Finally, we note that a recent work (Rosasco and Villa, 2015) is related to the analysis in the paper. The generalization properties of a multi-pass incremental gradient are analyzed in (Rosasco and Villa, 2015), for a cyclic, rather than a stochastic, choice of the gradients and with no mini-batches. The analysis in this latter case appears to be harder and results in (Rosasco and Villa, 2015) give good learning bounds only in restricted setting and considering iterates rather than the excess risk. Compared to (Rosasco and Villa, 2015) our results show how stochasticity can be exploited to get fast rates and analyze the role of mini-batches. The basic idea of our proof is to approximate the SGM learning sequence in terms of the batch gradient descent sequence, see Subsection 3.7 for further details. This allows to study batch and stochastic gradient methods simultaneously, and may be also useful for analyzing other learning algorithms.

This paper is an extended version of a prior conference paper (Lin and Rosasco, 2016). In (Lin and Rosasco, 2016), we give convergence results with optimal rates for the attainable case

(i.e., assuming the existence of at least one minimizer of the expected risk over the hypothesis space) in a fixed step-size setting. In this new version, we give convergence results with optimal rates, for both the attainable and non-attainable cases, and consider more general step-size choices. The extension from the attainable case to the non-attainable case is non-trivial. As will be seen from the proof, in contrast to the attainable case, a different and refined estimation is needed for the non-attainable case. Interestingly, as a byproduct of this paper, we also derived optimal rates for the batch gradient descent methods in the non-attainable case. To the best of our knowledge, such a result may be the first kind for batch gradient methods, without requiring any extra unlabeled data as that in (Caponnetto and Yao, 2010). Finally, we also add novel convergence results for the iterates showing that they converge to the minimal norm solution of the expected risk with optimal rates.

The rest of this paper is organized as follows. Section 2 introduces the learning setting and the SGM algorithm. Main results with discussions and proof sketches are presented in Section 3. Preliminary lemmas necessary for the proofs will be given in Section 4 while detailed proofs will be conducted in Sections 5 to 8. Finally, simple numerical simulations are given in Section 9 to complement our theoretical results.

Notation For any $a, b \in \mathbb{R}$, $a \vee b$ denotes the maximum of a and b. $\mathbb{N}$ is the set of all positive integers. For any $T \in \mathbb{N}$, $[T]$ denotes the set $\{1, \cdots, T\}$. For any two positive sequences $\{a_t\}_{t\in[T]}$ and $\{b_t\}_{t\in[T]}$, the notation $a_t \lesssim b_t$ for all $t \in [T]$ means that there exists a positive constant $C \geq 0$ such that C is independent of t and that $a_t \leq Cb_t$ for all $t \in [T]$.

2. Learning with SGM

We begin by introducing the learning setting we consider, and then describe the SGM learning algorithm. Following (Rosasco and Villa, 2015), the formulation we consider is close to the setting of functional regression, and covers the reproducing kernel Hilbert space (RKHS) setting as a special case, see Appendix A. In particular, it reduces to standard linear regression for finite dimensions.

2.1 Learning Problems

Let H be a separable Hilbert space, with inner product and induced norm denoted by $\langle\cdot,\cdot\rangle_H$ and $\|\cdot\|_H$, respectively. Let the input space $X \subseteq H$ and the output space $Y \subseteq \mathbb{R}$. Let ρ be an unknown probability measure on $Z = X \times Y$, $\rho_X(\cdot)$ the induced marginal measure on X, and $\rho(\cdot|x)$ the conditional probability measure on Y with respect to $x \in X$ and ρ.

Considering the square loss function, the problem under study is the minimization of the *risk*,

$$\inf_{\omega\in H} \mathcal{E}(\omega), \quad \mathcal{E}(\omega) = \int_{X\times Y} (\langle\omega, x\rangle_H - y)^2 d\rho(x, y), \tag{1}$$

when the measure ρ is known only through a sample $\mathbf{z} = \{z_i = (x_i, y_i)\}_{i=1}^m$ of size $m \in \mathbb{N}$, independently and identically distributed (i.i.d.) according to ρ. In the following, we measure the quality of an approximate solution $\hat{\omega} \in H$ (an estimator) considering *the excess risk*, i.e.,

$$\mathcal{E}(\hat{\omega}) - \inf_{\omega\in H} \mathcal{E}(\omega). \tag{2}$$

Throughout this paper, we assume that there exists a constant $\kappa \in [1, \infty[$, such that

$$\langle x, x'\rangle_H \leq \kappa^2, \quad \forall x, x' \in X. \tag{3}$$

2.2 Stochastic Gradient Method

We study the following variant of SGM, possibly with mini-batches. Unlike some of the variants studied in the literature, the algorithm we consider in this paper does not involve any explicit penalty term or any projection step, in which case one does not need to tune the penalty/projection parameter.

Algorithm 1 *Let $b \in [m]$. Given any sample $\mathbf{z}$, the b-minibatch stochastic gradient method is defined by $\omega_1 = 0$ and*

$$\omega_{t+1} = \omega_t - \eta_t \frac{1}{b} \sum_{i=b(t-1)+1}^{bt} (\langle\omega_t, x_{j_i}\rangle_H - y_{j_i}) x_{j_i}, \qquad t = 1, \ldots, T, \tag{4}$$

where $\{\eta_t > 0\}$ is a step-size sequence. Here, $j_1, j_2, \cdots, j_{bT}$ are i.i.d. random variables from the uniform distribution on $[m]$ [1].

We add some comments on the above algorithm. First, different choices for the mini-batch size b can lead to different algorithms. In particular, for $b = 1$, the above algorithm corresponds to a simple SGM, while for $b = m$, it is a stochastic version of the batch gradient descent. In this paper, we are particularly interested in the cases of $b = 1$ and $b = \sqrt{m}$. Second, other choices on the initial value, rather than $\omega_1 = 0$, is possible. In fact, following from our proofs in this paper, the interested readers can see that the convergence results stated in the next subsections still hold for other choices of initial values. Finally, the number of total iterations T can be bigger than the number of sample points m. This indicates that we can use the sample more than once, or in another words, we can run the algorithm with multiple passes over the data. Here and in what follows, the number of 'passes' over the data is referred to $\lceil \frac{bt}{m} \rceil$ at t iterations of the algorithm.

The aim of this paper is to derive excess risk bounds for Algorithm 1. Throughout this paper, we assume that $\{\eta_t\}_t$ is non-increasing, and $T \in \mathbb{N}$ with $T \geq 3$. We denote by $\mathbf{J}_t$ the set $\{j_l : l = b(t-1)+1, \cdots, bt\}$ and by $\mathbf{J}$ the set $\{j_l : l = 1, \cdots, bT\}$.

3. Main Results with Discussions

In this section, we first state some basic assumptions. Then, we present and discuss our main results.

3.1 Assumptions

The following assumption is related to a moment assumption on $|y|^2$. It is weaker than the often considered bounded output assumption, such as the binary classification problems where $Y = \{-1, 1\}$.

Assumption 1 *There exists constants $M \in]0, \infty[$ and $v \in]1, \infty[$ such that*

$$\int_Y y^{2l} d\rho(y|x) \leq l! M^l v, \quad \forall l \in \mathbb{N}, \tag{5}$$

ρ_X-almost surely.

1. Note that, the random variables $j_1, \cdots, j_{bT}$ are conditionally independent given the sample $\mathbf{z}$.

To present our next assumption, we introduce the operator $\mathcal{L}_\rho : L^2(H,\rho_X) \to L^2(H,\rho_X)$, defined by $\mathcal{L}_\rho(f) = \int_X \langle x,\cdot\rangle_H f(x)\rho_X(x)$. Here, $L^2(H,\rho_X)$ is the Hilbert space of square integral functions from H to $\mathbb{R}$ with respect to ρ_X, with norm,

$$\|f\|_\rho = \left(\int_X |f(x)|^2 d\rho_X(x)\right)^{1/2}.$$

Under Assumption (3), $\mathcal{L}_\rho$ can be proved to be positive trace class operators (Cucker and Zhou, 2007), and hence $\mathcal{L}_\rho^\zeta$ with $\zeta \in \mathbb{R}$ can be defined by using the spectral theory.

It is well known (see e.g., Cucker and Zhou, 2007) that the function minimizing $\int_Z (f(x)-y)^2 d\rho(z)$ over all measurable functions $f : H \to \mathbb{R}$ is the regression function, given by

$$f_\rho(x) = \int_Y y d\rho(y|x), \qquad x \in X. \tag{6}$$

Define another Hilbert space $H_\rho = \{f : X \to \mathbb{R} | \exists \omega \in H \text{ with } f(x) = \langle \omega, x\rangle_H, \rho_X\text{-almost surely}\}$. Under Assumption (3), it is easy to see that H_ρ is a subspace of $L^2(H,\rho_X)$. Let $f_\mathcal{H}$ be the projection of the regression function f_ρ onto the closure of H_ρ in $L^2(H,\rho_X)$. It is easy to see that the search for a solution of Problem (1) is equivalent to the search of a linear function in H_ρ to approximate $f_\mathcal{H}$. From this point of view, bounds on the excess risk of a learning algorithm on H_ρ or H, naturally depend on the following assumption, which quantifies how well, the target function $f_\mathcal{H}$ can be approximated by H_ρ.

Assumption 2 *There exist $\zeta > 0$ and $R > 0$, such that $\|\mathcal{L}_\rho^{-\zeta} f_\mathcal{H}\|_\rho \le R$.*

The above assumption is fairly standard in non-parametric regression (Cucker and Zhou, 2007; Rosasco and Villa, 2015). The bigger ζ is, the more stringent the assumption is, since

$$\mathcal{L}_\rho^{\zeta_1}(L^2(H,\rho_X)) \subseteq \mathcal{L}_\rho^{\zeta_2}(L^2(H,\rho_X)) \quad \text{when } \zeta_1 \ge \zeta_2.$$

In particular, for $\zeta = 0$, we are making no assumption, while for $\zeta = 1/2$, we are requiring $f_\mathcal{H} \in H_\rho$, since (Rosasco and Villa, 2015)

$$H_\rho = \mathcal{L}_\rho^{1/2}(L^2(H,\rho_X)). \tag{7}$$

In the case of $\zeta \ge 1/2$, $f_\mathcal{H} \in H_\rho$, which implies Problem (1) has at least one solution in the space H. In this case, we denote $\omega^\dagger$ as the solution with the minimal H-norm.

Finally, the last assumption relates to the capacity of the hypothesis space.

Assumption 3 *For some $\gamma \in]0,1]$ and $c_\gamma > 0$, $\mathcal{L}_\rho$ satisfies*

$$\mathrm{tr}(\mathcal{L}_\rho(\mathcal{L}_\rho + \lambda I)^{-1}) \le c_\gamma \lambda^{-\gamma}, \quad \text{for all } \lambda > 0. \tag{8}$$

The left hand-side of of (8) is called as the effective dimension (Caponnetto and De Vito, 2007), or the degrees of freedom (Zhang, 2005). It can be related to covering/entropy number conditions, see (Steinwart and Christmann, 2008) for further details. Assumption 3 is always true for $\gamma = 1$ and $c_\gamma = \kappa^2$, since $\mathcal{L}_\rho$ is a trace class operator which implies the eigenvalues of $\mathcal{L}_\rho$, denoted as σ_i, satisfy $\mathrm{tr}(\mathcal{L}_\rho) = \sum_i \sigma_i \le \kappa^2$. This is referred to as the capacity independent setting. Assumption 3 with $\gamma \in]0,1]$ allows to derive better error rates. It is satisfied, e.g., if the eigenvalues of $\mathcal{L}_\rho$ satisfy a polynomial decaying condition $\sigma_i \sim i^{-1/\gamma}$, or with $\gamma = 0$ if $\mathcal{L}_\rho$ is finite rank.

3.2 Optimal Rates for SGM and Batch GM: Simplified Versions

We start with the following corollaries, which are the simplified versions of our main results stated in the next subsections.

Corollary 1 (Optimal Rate for SGM) *Under Assumptions 2 and 3, let $|y| \le M$ almost surely for some $M > 0$. Let $p_* = \lceil m^{\frac{1}{2\zeta+\gamma}} \rceil$ if $2\zeta+\gamma > 1$, or $p_* = \lceil m^{1-\epsilon} \rceil$ with $\epsilon \in]0,1[$ otherwise. Consider the SGM with*
1) $b = 1$, $\eta_t \simeq \frac{1}{m}$ for all $t \in [(p_* m)]$, and $\tilde\omega_{p_*} = \omega_{p_* m+1}$.
If $\delta \in]0,1]$ and $m \ge m_\delta$, then with probability[2] at least $1-\delta$, it holds

$$\mathbb{E}_\mathbf{J}[\mathcal{E}(\tilde\omega_{p_*})] - \inf_H \mathcal{E} \le C \begin{cases} m^{-\frac{2\zeta}{2\zeta+\gamma}} & \text{when } 2\zeta+\gamma > 1; \\ m^{-2\zeta(1-\epsilon)} & \text{otherwise.} \end{cases} \tag{9}$$

Furthermore, the above also holds for the SGM with[3]
2) $b = \sqrt{m}$, $\eta_t \simeq \frac{1}{\sqrt{m}}$ for all $t \in [(p_*\sqrt{m})]$, and $\tilde\omega_{p_*} = \omega_{p_*\sqrt{m}+1}$.
In the above, m_δ and C are positive constants depending on $\kappa^2, \|\mathcal{T}_\rho\|, M, \zeta, R, c_\gamma, \gamma$, a polynomial of $\log m$ and $\log(1/\delta)$, and m_δ also on δ (and also on $\|f_\mathcal{H}\|_\infty$ in the case that $\zeta < 1/2$).

We add some comments on the above result. First, the above result asserts that, at p_* passes over the data, the SGM with two different fixed step-size and fixed mini-batch size choices, achieves optimal learning error bounds, matching (or improving) those of ridge regression (Smale and Zhou, 2007; Caponnetto and De Vito, 2007). Second, according to the above result, using mini-batch allows to use a larger step-size while achieving the same optimal error bounds. Finally, the above result can be further simplified in some special cases. For example, if we consider the capacity independent case, i.e., $\gamma = 1$, and assuming that $f_\mathcal{H} \in H_\rho$, which is equivalent to making Assumption 2 with $\zeta = 1/2$ as mentioned before, the error bound is $O(m^{-1/2})$, while the number of passes $p_* = \lceil \sqrt{m} \rceil$.

Remark 1 (Finite Dimensional Case) *With a simple modification of our proofs, we can derive similar results for the finite dimensional case, i.e., $H = \mathbb{R}^d$, where in this case, $\gamma = 0$. In particular, letting $\zeta = 1/2$, under the same assumptions of Corollary 1, if one considers the SGM with $b = 1$ and $\eta_t \simeq \frac{1}{m}$ for all $t \in [m^2]$, then with high probability, $\mathbb{E}_\mathbf{J}[\mathcal{E}(\omega_{m^2+1})] - \inf_H \mathcal{E} \lesssim d/m$, provided that $m \gtrsim d \log d$.*

Remark 2 *From the proofs, one can easily see that if $f_\mathcal{H}$ and $\mathcal{E}(\tilde\omega_{p_*}) - \inf_H \mathcal{E}$ are replaced respectively by $f_* \in L^2(H,\rho_X)$ and $\|\langle\cdot,\tilde\omega_{p_*}\rangle_H - f_*\|_\rho^2$, in both the assumptions and the error bounds, then all theorems and their corollaries of this paper are still true, as long as f_* satisfies $\int_X (f_* - f_\rho)(x) K_x d\rho_X = 0$. As a result, if we assume that f_ρ satisfies Assumption 2 (with $f_\mathcal{H}$ replaced by f_ρ), as typically done in (Smale and Zhou, 2007; Caponnetto and De Vito, 2007; Steinwart et al., 2009; Caponnetto and Yao, 2010) for the RKHS setting, we have that with high probability,*

$$\mathbb{E}_\mathbf{J}\|\langle\cdot,\tilde\omega_{p_*}\rangle_H - f_\rho\|_\rho^2 \le C \begin{cases} m^{-\frac{2\zeta}{2\zeta+\gamma}} & \text{when } 2\zeta+\gamma > 1; \\ m^{-2\zeta(1-\epsilon)} & \text{otherwise.} \end{cases}$$

In this case, the factor $\|f_\mathcal{H}\|_\infty$ from the upper bounds for the case $\zeta < 1/2$ is exactly $\|f_\rho\|_\infty$ and can be controlled by the condition $|y| \le M$ (and more generally, by Assumption 1). Since

2. Here, 'high probability' refers to the sample $\mathbf{z}$.
3. Here, we assume that $\sqrt{m}$ is an integer.

many common RKHSs are universally consistent (Steinwart and Christmann, 2008), making Assumption 2 on f_ρ is natural and moreover, deriving error bounds with respect to f_ρ seems to be more interesting in this case.

As a byproduct of our proofs in this paper, we derive the following optimal results for batch gradient methods (GM), defined by $\nu_1 = 0$ and

$$\nu_{t+1} = \nu_t - \eta_t \frac{1}{m}\sum_{i=1}^{m}(\langle \nu_t, x_i\rangle_H - y_i)x_i, \qquad t = 1, \dots, T. \tag{10}$$

Corollary 2 (Optimal Rate for Batch GM) *Under the assumptions and notations of Corollary 1, consider batch GM (10) with $\eta_t \simeq 1$. If m is large enough, then with high probability, (9) holds for $\tilde{\omega}_{p_*} = \nu_{p_*+1}$.*

In the above corollary, the convergence rates are optimal for $2\zeta + \gamma > 1$. To the best of our knowledge, these results are the first ones with minimax rates (Caponnetto and De Vito, 2007; Blanchard and Mücke, 2016) for the batch GM in the non-attainable case. Particularly, they improve the results in the previous literature, see Subsection 3.6 for more discussions.

Corollaries 1 and 2 cover the main contributions of this paper. In the following subsections, we will present the main theorems of this paper, following with several corollaries and simple discussions, from which one can derive the simplified versions stated in this subsection. In the next subsection, we present results for SGM in the attainable case while results in the non-attainable case will be given in Subsection 3.4, as the bounds for these two cases are different and particularly their proofs require different estimations. At last, results with more specific convergence rates for batch GM will be presented in Subsection 3.5.

3.3 Main Results for SGM: Attainable Case

In this subsection, we present convergence results in the attainable case, i.e., $\zeta \geq 1/2$, following with simple discussions. One of our main theorems in the attainable case is stated next, and provides error bounds for the studied algorithm. For the sake of readability, we only present results in a fixed step-size setting in this section. Results in a general setting ($\eta_t = \eta_1 t^{-\theta}$ with $0 \leq \theta < 1$ can be found in Section 7.

Theorem 1 *Under Assumptions 1, 2 and 3, let $\zeta \geq 1/2$, $\delta \in]0,1[$, $\eta_t = \eta\kappa^{-2}$ for all $t \in [T]$, with $\eta \leq \frac{1}{8(\log T+1)}$. If $m \geq m_\delta$, then the following holds with probability at least $1-\delta$: for all $t \in [T]$,*

$$\begin{aligned}\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{t+1})] - \inf_H \mathcal{E} \leq q_1(\eta t)^{-2\zeta} + q_2 m^{-\frac{2\zeta}{2\zeta+\gamma}}(1 + m^{-\frac{1}{2\zeta+\gamma}}\eta t)^2 \log^2 T \log^2\frac{1}{\delta} \\ + q_3 \eta b^{-1}(1 \vee m^{-\frac{1}{2\zeta+\gamma}}\eta t)\log T.\end{aligned} \tag{11}$$

Here, m_δ, q_1, q_2 and q_3 are positive constants depending on $\kappa^2, \|\mathcal{T}_\rho\|, M, v, \zeta, R, c_\gamma, \gamma$, and m_δ also on δ (which will be given explicitly in the proof).

There are three terms in the upper bounds of (11). The first term depends on the regularity of the target function and it arises from bounding the bias, while the last two terms result from estimating the sample variance and the computational variance (due to the random choices of the points), respectively. To derive optimal rates, it is necessary to balance these three terms.

Solving this trade-off problem leads to different choices on η, T, and b, corresponding to different regularization strategies, as shown in subsequent corollaries.

The first corollary gives generalization error bounds for simple SGM, with a universal step-size depending on the number of sample points.

Corollary 3 *Under Assumptions 1, 2 and 3, let $\zeta \geq 1/2$, $\delta \in]0,1[$, $b = 1$ and $\eta_t \simeq \frac{1}{m}$ for all $t \in [m^2]$. If $m \geq m_\delta$, then with probability at least $1-\delta$, there holds*

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{t+1})] - \inf_H \mathcal{E} \lesssim \left\{\left(\frac{m}{t}\right)^{2\zeta} + m^{-\frac{2\zeta+2}{2\zeta+\gamma}}\left(\frac{t}{m}\right)^2\right\} \cdot \log^2 m \log^2\frac{1}{\delta}, \quad \forall t \in [m^2], \tag{12}$$

and in particular,

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{T^*+1})] - \inf_H \mathcal{E} \lesssim m^{-\frac{2\zeta}{2\zeta+\gamma}} \log^2 m \log^2\frac{1}{\delta}, \tag{13}$$

where $T^* = \lceil m^{\frac{2\zeta+\gamma+1}{2\zeta+\gamma}} \rceil$. Here, m_δ is exactly the same as in Theorem 1.

Remark 3 *Ignoring the logarithmic term and letting $t = pm$, Eq. (12) becomes*

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{pm+1})] - \inf_H \mathcal{E} \lesssim p^{-2\zeta} + m^{-\frac{2\zeta+2}{2\zeta+\gamma}} p^2.$$

A smaller p may lead to a larger bias, while a larger p may lead to a larger sample error. From this point of view, p has a regularization effect.

The second corollary provides error bounds for SGM with a fixed mini-batch size and a fixed step-size (which depend on the number of sample points).

Corollary 4 *Under Assumptions 1, 2 and 3, let $\zeta \geq 1/2$, $\delta \in]0,1[$, $b = \lceil \sqrt{m} \rceil$ and $\eta_t \simeq \frac{1}{\sqrt{m}}$ for all $t \in [m^2]$. If $m \geq m_\delta$, then with probability at least $1-\delta$, there holds*

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{t+1})] - \inf_H \mathcal{E} \lesssim \left\{\left(\frac{\sqrt{m}}{t}\right)^{2\zeta} + m^{-\frac{2\zeta+2}{2\zeta+\gamma}}\left(\frac{t}{\sqrt{m}}\right)^2\right\} \log^2 m \log^2\frac{1}{\delta}, \quad \forall t \in [m^2], \tag{14}$$

and particularly,

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{T^*+1})] - \inf_H \mathcal{E} \lesssim m^{-\frac{2\zeta}{2\zeta+\gamma}} \log^2 m \log^2\frac{1}{\delta}, \tag{15}$$

where $T^* = \lceil m^{\frac{1}{2\zeta+\gamma}+\frac{1}{2}} \rceil$.

The above two corollaries follow from Theorem 1 with the simple observation that the dominating terms in (11) are the terms related to the bias and the sample variance, when a small step-size is chosen. The only free parameter in (12) and (14) is the number of iterations/passes. The ideal stopping rule is achieved by balancing the two terms related to the bias and the sample variance, showing the regularization effect of the number of passes. Since the ideal stopping rule depends on the unknown parameters ζ and γ, a hold-out cross-validation procedure is often used to tune the stopping rule in practice. Using an argument similar to that in Chapter 6 from (Steinwart and Christmann, 2008), it is possible to show that this procedure can achieve the same convergence rate.

We give some further remarks. First, the upper bound in (13) is optimal up to a logarithmic factor, in the sense that it matches the minimax lower rate in (Caponnetto and De Vito, 2007; Blanchard and Mücke, 2016). Second, according to Corollaries 3 and 4, $\frac{bT^*}{m} \simeq m^{\frac{1}{2\zeta+\gamma}}$ passes

over the data are needed to obtain optimal rates in both cases. Finally, in comparing the simple SGM and the mini-batch SGM, Corollaries 3 and 4 show that a larger step-size is allowed to use for the latter.

In the next result, both the step-size and the stopping rule are tuned to obtain optimal rates for simple SGM with multiple passes. In this case, the step-size and the number of iterations are the regularization parameters.

Corollary 5 *Under Assumptions 1, 2 and 3, let $\zeta \geq 1/2$, $\delta \in]0,1[$, $b = 1$ and $\eta_t \simeq m^{-\frac{2\zeta}{2\zeta+\gamma}}$ for all $t \in [m^2]$. If $m \geq m_\delta$, and $T^* = \lceil m^{\frac{2\zeta+1}{2\zeta+\gamma}} \rceil$, then (13) holds with probability at least $1-\delta$.*

The next corollary shows that for some suitable mini-batch sizes, optimal rates can be achieved with a constant step-size (which is nearly independent of the number of sample points) by early stopping.

Corollary 6 *Under Assumptions 1, 2 and 3, let $\zeta \geq 1/2$, $\delta \in]0,1[$, $b = \lceil m^{\frac{2\zeta}{2\zeta+\gamma}} \rceil$ and $\eta_t \simeq \frac{1}{\log m}$ for all $t \in [m]$. If $m \geq m_\delta$, and $T^* = \lceil m^{\frac{1}{2\zeta+\gamma}} \rceil$, then (13) holds with probability at least $1-\delta$.*

According to Corollaries 5 and 6, around $m^{\frac{1-\gamma}{2\zeta+\gamma}}$ passes over the data are needed to achieve the best performance in the above two strategies. In comparisons with Corollaries 3 and 4 where around $m^{\frac{\zeta+1}{2\zeta+\gamma}}$ passes are required, the latter seems to require fewer passes over the data. However, in this case, one might have to run the algorithms multiple times to tune the step-size, or the mini-batch size.

Remark 4 *1) If we make no assumption on the capacity, i.e., $\gamma = 1$, Corollary 5 recovers the result in (Ying and Pontil, 2008) for one pass SGM.*
2) If we make no assumption on the capacity and assume that $f_{\mathcal{H}} \in H_\rho$, from Corollaries 5 and 6, we see that the optimal convergence rate $O(m^{-1/2})$ can be achieved after one pass over the data in both of these two strategies. In this special case, Corollaries 5 and 6 recover the results for one pass SGM in, e.g., (Shamir and Zhang, 2013; Dekel et al., 2012).

The next result gives generalization error bounds for 'batch' SGM with a constant step-size (nearly independent of the number of sample points).

Corollary 7 *Under Assumptions 1, 2 and 3, let $\zeta \geq 1/2$, $\delta \in]0,1[$, $b = m$ and $\eta_t \simeq \frac{1}{\log m}$ for all $t \in [m]$. If $m \geq m_\delta$, and $T^* = \lceil m^{\frac{1}{2\zeta+\gamma}} \rceil$, then (13) holds with probability at least $1-\delta$.*

Theorem 1 and its corollaries give convergence results with respect to the target function values. In the next theorem and corollary, we will present convergence results in H-norm.

Theorem 2 *Under the assumptions of Theorem 1, the following holds with probability at least $1-\delta$: for all $t \in [T]$*

$$\mathbb{E}_{\mathbf{J}}[\|\omega_t - \omega^\dagger\|_H^2] \leq q_1(\eta t)^{1-2\zeta} + q_2 m^{-\frac{2\zeta-1}{2\zeta+\gamma}}(1 + m^{-\frac{1}{2\zeta+\gamma}}\eta t)^2 \log^2 T \log^2 \frac{1}{\delta} + q_3 \eta^2 t b^{-1}. \tag{16}$$

Here, q_1, q_2 and q_3 are positive constants depending on $\kappa^2, \|\mathcal{T}_\rho\|, M, v, \zeta, R, c_\gamma$, and γ (which can be given explicitly in the proof).

The proof of the above theorem is similar as that for Theorem 1, and will be given in Subsection 8. Again, the upper bound in (16) is composed of three terms related to bias, sample variance, and computational variance. Balancing these three terms leads to different choices on η, T, and b, as shown in the following corollary.

Corollary 8 *With the same assumptions and notations from any one of Corollaries 3 to 7, the following holds with probability at least $1-\delta$:*

$$\mathbb{E}_{\mathbf{J}}[\|\omega_{T^*+1} - \omega^\dagger\|_H^2] \lesssim m^{-\frac{2\zeta-1}{2\zeta+\gamma}} \log^2 m \log^2 \frac{1}{\delta}.$$

The convergence rate in the above corollary is optimal up to a logarithmic factor, as it matches the minimax rate shown in (Blanchard and Mücke, 2016).

In the next subsection, we will present convergence results in the non-attainable case, i.e., $\zeta < 1/2$.

3.4 Main Results for SGM: Non-attainable Case

Our main theorem in the non-attainable case is stated next, and provides error bounds for the studied algorithm. Here, we present results with a fixed step-size, whereas general results with a decaying step-size will be given in Section 7.

Theorem 3 *Under Assumptions 1, 2 and 3, let $\zeta \leq 1/2$, $\delta \in]0,1[$, $\eta_t = \eta\kappa^{-2}$ for all $t \in [T]$, with $0 < \eta \leq \frac{1}{8(\log T+1)}$. Then the following holds for all $t \in [T]$ with probability at least $1-\delta$:*
1) if $2\zeta + \gamma > 1$ and $m \geq m_\delta$, then

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{t+1})] - \inf_H \mathcal{E} \leq \left(q_1(\eta t)^{-2\zeta} + q_2 m^{-\frac{2\zeta}{2\zeta+\gamma}}\right)(1 \vee m^{-\frac{1}{2\zeta+\gamma}}\eta t)^3 \log^4 T \log^2 \frac{1}{\delta} + q_3 \eta b^{-1}(1 \vee m^{-\frac{1}{2\zeta+\gamma}}\eta t) \log T; \tag{17}$$

2) if $2\zeta + \gamma \leq 1$ and for some $\epsilon \in]0,1[$, $m \geq m_{\delta,\epsilon}$, then

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{t+1})] - \inf_H \mathcal{E} \leq \left(q_1(\eta t)^{-2\zeta} + q_2 m^{\gamma(1-\epsilon)-1}\right)(1 \vee \eta m^{\epsilon-1} t)^3 \log^4 T \log^2 \frac{1}{\delta} + q_3 \eta b^{-1}(1 \vee m^{\epsilon-1}\eta t) \log T.$$

Here, m_δ (or $m_{\delta,\epsilon}$), q_1, q_2 and q_3 are positive constants depending only on $\kappa^2, \|\mathcal{T}_\rho\|, M, v, \zeta, R, c_\gamma, \gamma$, $\|f_{\mathcal{H}}\|_\infty$, and m_δ (or $m_{\delta,\epsilon}$) also on δ (and ϵ).

The upper bounds in (11) (for the attainable case) and (17) (for the non-attainable case) are similar, whereas the latter has an extra logarithmic factor. Consequently, in the subsequent corollaries, we derive $O(m^{-\frac{2\zeta}{2\zeta+\gamma}} \log^4 m)$ for the non-attainable case. In comparison with that for the attainable case, the convergence rate for the non-attainable case has an extra $\log^2 m$ factor.

Similar to Corollaries 3 and 4, and as direct consequences of the above theorem, we have the following generalization error bounds for the studied algorithm with different choices of parameters in the non-attainable case.

Corollary 9 *Under Assumptions 1, 2 and 3, let $\zeta \leq 1/2$, $\delta \in]0,1[$, $b = 1$ and $\eta_t \simeq \frac{1}{m}$ for all $t \in [m^2]$. With probability at least $1-\delta$, the following holds:*
1) if $2\zeta + \gamma > 1$, $m \geq m_\delta$ and $T^* = \lceil m^{\frac{1+2\zeta+\gamma}{2\zeta+\gamma}} \rceil$, then

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{T^*+1})] - \inf_H \mathcal{E} \lesssim m^{-\frac{2\zeta}{2\zeta+\gamma}} \log^4 m \log^2 \frac{1}{\delta}; \tag{18}$$

2) if $2\zeta+\gamma \leq 1$, *and for some* $\epsilon \in]0,1[$, $m \geq m_{\delta,\epsilon}$, *and* $T^* = \lceil m^{2-\epsilon} \rceil$, *then*

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{T^*+1})] - \inf_{H} \mathcal{E} \lesssim m^{-2\zeta(1-\epsilon)} \log^4 m \log^2 \frac{1}{\delta}. \tag{19}$$

Here, m_δ *and* $m_{\delta,\epsilon}$ *are given by Theorem 3.*

Corollary 10 *Under Assumptions 1, 2 and 3, let* $\zeta \leq 1/2$, $\delta \in]0,1[$, $b \simeq \sqrt{m}$ *and* $\eta_t \simeq \frac{1}{\sqrt{m}}$ *for all* $t \in [m^2]$. *With probability at least* $1-\delta$, *there holds*
1) if $2\zeta+\gamma > 1$, $m \geq m_\delta$ *and* $T^* = \lceil m^{\frac{1}{2\zeta+\gamma}+\frac{1}{2}} \rceil$, *then (18) holds;*
2) if $2\zeta+\gamma \leq 1$, *for some* $\epsilon \in]0,1[$, $m \geq m_{\delta,\epsilon}$, *and* $T^* = \lceil m^{\frac{3}{2}-\epsilon} \rceil$, *then (19) holds.*

The convergence rates in the above corollaries, i.e., $m^{-\frac{2\zeta}{2\zeta+\gamma}}$ if $2\zeta+\gamma > 1$ or $m^{-2\zeta(1-\epsilon)}$ otherwise, match those in (Dieuleveut and Bach, 2016) for one pass SGM with averaging, up to a logarithmic factor. Also, in the capacity independent case, i.e., $\gamma = 1$, the convergence rates in the above corollary read as $m^{-\frac{2\zeta}{2\zeta+1}}$ (since $2\zeta+\gamma$ is always bigger than 1), which are exactly the same as those in (Ying and Pontil, 2008) for one pass SGM.

Similar results to Corollaries 5–7 can be also derived for the non-attainable case by applying Theorem 3. Refer to Appendix B for more details.

3.5 Main Results for Batch GM

In this subsection, we present convergence results for batch GM. As a byproduct of our proofs in this paper, we have the following convergence rates for batch GM.

Theorem 4 *Under Assumptions 1, 2 and 3, set* $\eta_t \simeq 1$, *for all* $t \in [m]$. *Let* $T^* = \lceil m^{\frac{1}{2\zeta+\gamma}} \rceil$ *if* $2\zeta+\gamma > 1$, *or* $T^* = \lceil m^{1-\epsilon} \rceil$ *with* $\epsilon \in]0,1[$ *otherwise. Then with probability at least* $1-\delta$ *(*$0 < \delta < 1$*), the following holds for the learning sequence generated by (10):*
1) if $\zeta > 1/2$ *and* $m \geq m_\delta$, *then*

$$\mathcal{E}(\nu_{T_*+1}) - \inf_{H} \mathcal{E} \lesssim m^{-\frac{2\zeta}{2\zeta+\gamma}} \log^2 m \log^2 \frac{1}{\delta};$$

2) if $\zeta \leq 1/2$, $2\zeta+\gamma > 1$ *and* $m \geq m_\delta$, *then*

$$\mathcal{E}(\nu_{T_*+1}) - \inf_{H} \mathcal{E} \lesssim m^{-\frac{2\zeta}{2\zeta+\gamma}} \log^4 m \log^2 \frac{1}{\delta};$$

3) if $2\zeta+\gamma \leq 1$ *and* $m \geq m_{\delta,\epsilon}$, *then*

$$\mathcal{E}(\nu_{T_*+1}) - \inf_{H} \mathcal{E} \lesssim m^{-2\zeta(1-\epsilon)} \log^4 m \log^2 \frac{1}{\delta}.$$

Here, m_δ *(or* $m_{\delta,\epsilon}$*), and all the constants in the upper bounds are positive and depend only on* $\kappa^2, \|\mathcal{T}_\rho\|, M, v, \zeta, R, c_\gamma, \gamma, \|f_{\mathcal{H}}\|_\infty$, *and* m_δ *(or* $m_{\delta,\epsilon}$*) also on* δ *(and* ϵ*).*

3.6 Discussions

We must compare our results with previous works. For non-parametric regression with the square loss, one pass SGM has been studied in, e.g., (Ying and Pontil, 2008; Shamir and Zhang, 2013; Tarres and Yao, 2014; Dieuleveut and Bach, 2016). In particular, Ying and Pontil (2008) proved

capacity independent rate of order $O(m^{-\frac{2\zeta}{2\zeta+1}} \log m)$ with a fixed step-size $\eta \simeq m^{-\frac{2\zeta}{2\zeta+1}}$, and Dieuleveut and Bach (2016) derived capacity dependent error bounds of order $O(m^{-\frac{2\min(\zeta,1)}{2\min(\zeta,1)+\gamma}})$ (when $2\zeta+\gamma > 1$) for the average. Note also that a regularized version of SGM has been studied in (Tarres and Yao, 2014), where the derived convergence rate is of order $O(m^{-\frac{2\zeta}{2\zeta+1}})$ assuming that $\zeta \in [\frac{1}{2}, 1]$. In comparison with these existing convergence rates, our rates from (13) are comparable, either involving the capacity condition, or allowing a broader regularity parameter ζ (which thus improves the rates). For finite dimensional cases, it has been shown in (Bach and Moulines, 2013) that one pass SGM with averaging with a constant step-size achieves the optimal convergence rate of $O(d/m)$. In comparisons, our results for multi-pass SGM with a smaller step-size seems to be suboptimal in the computational complexity, as we need m passes over the data to achieve the same rate. The reason for this may arise from "the computational error" that will be introduced later, or the fact that we do not consider an averaging step as done in (Bach and Moulines, 2013). We hope that in the future by considering a larger step-size and averaging, one can reduce the computational complexity of multi-pass SGM while achieving the same rate.

More recently, Rosasco and Villa (2015) studied multiple passes SGM with a fixed ordering at each pass, also called incremental gradient method. Making no assumption on the capacity, rates of order $O(m^{-\frac{\zeta}{\zeta+1}})$ (in $L^2(H, \rho_X)$-norm) with a universal step-size $\eta \simeq 1/m$ are derived. In comparisons, Corollary 3 achieves better rates, while considering the capacity assumption. Note also that Rosasco and Villa (2015) proved sharp rate in H-norm for $\zeta \geq 1/2$ in the capacity independent case. In comparisons, we derive optimal capacity-dependent rate, considering mini-batches.

The idea of using mini-batches (and parallel implements) to speed up SGM in a general stochastic optimization setting can be found, e.g., in (Shalev-Shwartz et al., 2011; Dekel et al., 2012; Sra et al., 2012; Ng, 2016). Our theoretical findings, especially the interplay between the mini-batch size and the step-size, can give further insights on parallelization learning. Besides, it has been shown in (Cotter et al., 2011; Dekel et al., 2012) that for one pass mini-batch SGM with a fixed step-size $\eta \simeq b/\sqrt{m}$ and a smooth loss function, assuming the existence of at least one solution in the hypothesis space for the expected risk minimization, the convergence rate is of order $O(\sqrt{1/m} + b/m)$ by considering an averaging scheme. When adapting to the learning setting we consider, this reads as that if $f_{\mathcal{H}} \in H_\rho$, i.e., $\zeta = 1/2$, the convergence rate for the average is $O(\sqrt{1/m} + b/m)$. Note that, $f_{\mathcal{H}}$ does not necessarily belong to H_ρ in general. Also, our derived convergence rate from Corollary 4 is better, when the regularity parameter ζ is greater than $1/2$, or γ is smaller than 1.

For batch GM in the attainable case, convergent results with optimal rates have been derived in, e.g, (Bauer et al., 2007; Caponnetto and Yao, 2010; Blanchard and Mücke, 2016; Dicker et al., 2017). In particular, Bauer et al. (2007) proved convergence rates $O(m^{-\frac{2\zeta}{2\zeta+1}})$ without considering Assumption 3, and Caponnetto and Yao (2010) derived convergence rates $O(m^{-\frac{2\zeta}{2\zeta+\gamma}})$. For the non-attainable case, convergent results with suboptimal rates $O(m^{\frac{-2\zeta}{2\zeta+2}})$ can be found in (Yao et al., 2007), and to the best of our knowledge, the only result with optimal rate $O(m^{\frac{-2\zeta}{2\zeta+\gamma}})$ is the one derived by Caponnetto and Yao (2010), but the result requires extra unlabeled data. In contrast, Theorem 4 of this paper does not require any extra unlabeled data, while achieving the same optimal rates (up to a logarithmic factor). To the best of our knowledge, Theorem 4 may be the first optimal result in the non-attainable case for batch GM.

We end this discussion with some further comments on batch GM and simple SGM. First, according to Corollaries 1 and 2, it seems that both simple SGM (with step-size $\eta_t \simeq m^{-1}$) and batch GM (with step-size $\eta_t \simeq 1$) have the same computational complexities (which are related to the number of passes) and the same orders of upper bounds. However, there is a subtle difference between these two algorithms. As we see from (22) in the coming subsection, every m iterations of simple SGM (with step-size $\eta_t \simeq m^{-1}$) corresponds to one iteration of batch GM (with step-size $\eta_t \simeq 1$). In this sense, SGM discretizes and refines the regularization path of batch GM, which thus may lead to smaller generalization errors. This phenomenon can be further understood by comparing our derived bounds, (11) and (73), for these two algorithms. Indeed, if one can ignore the computational error, one can easily show that the minimization (over t) of right hand-side of (11) with $\eta \simeq m^{-1}$ is always smaller than that of (73) with $\eta \simeq 1$. At last, by Corollary 6, using a larger step-size for SGM allows one to stop earlier (while sharing the same optimal rates), which thus reduces the computational complexity. This suggests that SGM may have some computational advantage over batch GM.

3.7 Proof Sketch (Error Decomposition)

The key to our proof is a novel error decomposition, which may be also used in analysing other learning algorithms. One may also use the approach in (Bousquet and Bottou, 2008; Lin et al., 2016b,a) which is based on the following error decomposition,

$$\mathbb{E}\mathcal{E}(\omega_t) - \inf_H \mathcal{E} = [\mathbb{E}(\mathcal{E}(\omega_t) - \mathcal{E}_{\mathbf{z}}(\omega_t)) + \mathbb{E}\mathcal{E}_{\mathbf{z}}(\tilde{\omega}) - \mathcal{E}(\tilde{\omega})] + \mathbb{E}(\mathcal{E}_{\mathbf{z}}(\omega_t) - \mathcal{E}_{\mathbf{z}}(\tilde{\omega})) + \mathcal{E}(\tilde{\omega}) - \inf_H \mathcal{E},$$

where $\tilde{\omega} \in H$ is some suitably intermediate element and $\mathcal{E}_{\mathbf{z}}$ denotes the empirical risk over $\mathbf{z}$, i.e.,

$$\mathcal{E}_{\mathbf{z}}(\cdot) = \frac{1}{m}\sum_{i=1}^{m} (\langle \cdot, x_i\rangle - y_i)^2 . \tag{20}$$

However, one can only derive a sub-optimal convergence rate, since the proof procedure involves upper bounding the learning sequence to estimate the sample error (the first term of right-hand side). Also, in this case, the 'regularity' of the regression function can not be fully utilized for estimating the bias (the last term). Thanks to the property of squares loss, we can exploit a different error decomposition leading to better results.

To describe the decomposition, we need to introduce two sequences. The *population iteration* is defined by $\mu_1 = 0$ and

$$\mu_{t+1} = \mu_t - \eta_t \int_X (\langle \mu_t, x\rangle_H - f_\rho(x))x d\rho_X(x), \qquad t = 1, \ldots, T. \tag{21}$$

The above iterated procedure is ideal and can not be implemented in practice, since the distribution ρ_X is unknown in general. Replacing ρ_X by the empirical measure and $f_\rho(x_i)$ by y_i, we derive the *sample iteration* (associated with the sample $\mathbf{z}$), i.e., (10). Clearly, μ_t is deterministic and ν_t is a H-valued random variable depending on $\mathbf{z}$. Given the sample $\mathbf{z}$, the sequence $\{\nu_t\}_t$ has a natural relationship with the learning sequence $\{\omega_t\}_t$, since

$$\mathbb{E}_{\mathbf{J}}[\omega_t] = \nu_t. \tag{22}$$

Indeed, taking the expectation with respect to $\mathbf{J}_t$ on both sides of (4), and noting that ω_t depends only on $\mathbf{J}_1, \cdots, \mathbf{J}_{t-1}$ (given any $\mathbf{z}$), one has

$$\mathbb{E}_{\mathbf{J}_t}[\omega_{t+1}] = \omega_t - \eta_t \frac{1}{m}\sum_{i=1}^{m} (\langle \omega_t, x_i\rangle_H - y_i)x_i,$$

and thus,

$$\mathbb{E}_{\mathbf{J}}[\omega_{t+1}] = \mathbb{E}_{\mathbf{J}}[\omega_t] - \eta_t \frac{1}{m}\sum_{i=1}^{m} (\langle \mathbb{E}_{\mathbf{J}}[\omega_t], x_i\rangle_H - y_i)x_i, \quad t = 1, \ldots, T,$$

which satisfies the iterative relationship given in (10). By an induction argument, (22) can then be proved.

Let $\mathcal{S}_\rho : H \to L^2(H, \rho_X)$ be the linear map defined by $(\mathcal{S}_\rho \omega)(x) = \langle \omega, x\rangle_H, \forall \omega, x \in H$. We have the following error decomposition.

Proposition 1 *We have*

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_t)] - \inf_H \mathcal{E} \le 2\|\mathcal{S}_\rho \mu_t - f_{\mathcal{H}}\|_\rho^2 + 2\|\mathcal{S}_\rho \nu_t - \mathcal{S}_\rho \mu_t\|_\rho^2 + \mathbb{E}_{\mathbf{J}}[\|\mathcal{S}_\rho \omega_t - \mathcal{S}_\rho \nu_t\|_\rho^2]. \tag{23}$$

Proof For any $\omega \in H$, we have (Rosasco and Villa, 2015)

$$\mathcal{E}(\omega) - \inf_{\omega \in H} \mathcal{E}(\omega) = \|\mathcal{S}_\rho \omega - f_{\mathcal{H}}\|_\rho^2.$$

Thus, $\mathcal{E}(\omega_t) - \inf_H \mathcal{E} = \|\mathcal{S}_\rho \omega_t - f_{\mathcal{H}}\|_\rho^2$, and

$$\begin{aligned}\mathbb{E}_{\mathbf{J}}[\|\mathcal{S}_\rho \omega_t - f_{\mathcal{H}}\|_\rho^2] &= \mathbb{E}_{\mathbf{J}}[\|\mathcal{S}_\rho \omega_t - \mathcal{S}_\rho \nu_t + \mathcal{S}_\rho \nu_t - f_{\mathcal{H}}\|_\rho^2] \\ &= \mathbb{E}_{\mathbf{J}}[\|\mathcal{S}_\rho \omega_t - \mathcal{S}_\rho \nu_t\|_\rho^2 + \|\mathcal{S}_\rho \nu_t - f_{\mathcal{H}}\|_\rho^2] + 2\mathbb{E}_{\mathbf{J}}\langle \mathcal{S}_\rho \omega_t - \mathcal{S}_\rho \nu_t, \mathcal{S}_\rho \nu_t - f_{\mathcal{H}}\rangle_\rho.\end{aligned}$$

Using (22) in the above equality, we get,

$$\mathbb{E}_{\mathbf{J}}[\|\mathcal{S}_\rho \omega_t - f_{\mathcal{H}}\|_\rho^2] = \mathbb{E}_{\mathbf{J}}[\|\mathcal{S}_\rho \omega_t - \mathcal{S}_\rho \nu_t\|_\rho^2 + \|\mathcal{S}_\rho \nu_t - f_{\mathcal{H}}\|_\rho^2].$$

The proof is finished by considering,

$$\|\mathcal{S}_\rho \nu_t - f_{\mathcal{H}}\|_\rho^2 = \|\mathcal{S}_\rho \nu_t - \mathcal{S}_\rho \mu_t + \mathcal{S}_\rho \mu_t - f_{\mathcal{H}}\|_\rho^2 \le 2\|\mathcal{S}_\rho \nu_t - \mathcal{S}_\rho \mu_t\|_\rho^2 + 2\|\mathcal{S}_\rho \mu_t - \mathcal{S}_\rho f_{\mathcal{H}}\|_\rho^2.$$

■

There are three terms in the upper bound of the error decomposition (23). We refer to the deterministic term $\|\mathcal{S}_\rho \mu_t - f_{\mathcal{H}}\|_\rho^2$ as the *bias*, the term $\|\mathcal{S}_\rho \nu_t - \mathcal{S}_\rho \mu_t\|_\rho^2$ depending on $\mathbf{z}$ as the *sample variance*, and $\mathbb{E}_{\mathbf{J}}[\|\mathcal{S}_\rho \omega_t - \mathcal{S}_\rho \nu_t\|_\rho^2]$ as the *computational variance*. The bias term, which is deterministic, has been well studied in the literature, see e.g., (Yao et al., 2007) and also (Rosasco and Villa, 2015). The main novelties of this paper are the estimate of the sample and computational variances and the difficult part is the estimate of the computational variances. The proof of these results is quite lengthy and makes use of some ideas from (Yao et al., 2007; Smale and Zhou, 2007; Bauer et al., 2007; Ying and Pontil, 2008; Tarres and Yao, 2014; Rudi et al., 2015). These three error terms will be estimated in Sections 5 and 6. The bounds in Theorems 1 and 3 thus follow plugging these estimations in the error decomposition, see Section 7 for more details. The proof for Theorem 2 is similar, see Section 8 for the details.

4. Preliminary Analysis

In this section, we introduce some notation and preliminary lemmas that are necessary to our proofs.

4.1 Notation

We first introduce some notations. For $t \in \mathbb{N}$, $\Pi_{t+1}^{T}(L) = \prod_{k=t+1}^{T}(I - \eta_k L)$ for $t \in [T-1]$ and $\Pi_{T+1}^{T}(L) = I$, for any operator $L : \mathcal{H} \to \mathcal{H}$, where $\mathcal{H}$ is a Hilbert space and I denotes the identity operator on $\mathcal{H}$. $\mathbb{E}[\xi]$ denotes the expectation of a random variable ξ. For a given bounded operator $L : L^2(H, \rho_X) \to H$, $\|L\|$ denotes the operator norm of L, i.e., $\|L\| = \sup_{f \in L^2(H,\rho_X), \|f\|_\rho = 1} \|Lf\|_H$. We will use the conventional notations on summation and production: $\prod_{i=t+1}^{t} = 1$ and $\sum_{i=t+1}^{t} = 0$.

We next introduce some auxiliary operators. Let $\mathcal{S}_\rho : H \to L^2(H, \rho_X)$ be the linear map $\omega \to \langle \omega, \cdot \rangle_H$, which is bounded by κ under Assumption (3). Furthermore, we consider the adjoint operator $\mathcal{S}_\rho^* : L^2(H, \rho_X) \to H$, the covariance operator $\mathcal{T}_\rho : H \to H$ given by $\mathcal{T}_\rho = \mathcal{S}_\rho^* \mathcal{S}_\rho$, and the operator $\mathcal{L}_\rho : L^2(H, \rho_X) \to L^2(H, \rho_X)$ given by $\mathcal{S}_\rho \mathcal{S}_\rho^*$. It can be easily proved that $\mathcal{S}_\rho^* g = \int_X x g(x) d\rho_X(x)$ and $\mathcal{T}_\rho = \int_X \langle \cdot, x \rangle_H x d\rho_X(x)$. The operators $\mathcal{T}_\rho$ and $\mathcal{L}_\rho$ can be proved to be positive trace class operators (and hence compact). For any $\omega \in H$, it is easy to prove the following isometry property (Steinwart and Christmann, 2008)

$$\|\mathcal{S}_\rho \omega\|_\rho = \|\sqrt{\mathcal{T}_\rho}\omega\|_H. \tag{24}$$

We define the sampling operator $\mathcal{S}_{\mathbf{x}} : H \to \mathbb{R}^m$ by $(\mathcal{S}_{\mathbf{x}}\omega)_i = \langle \omega, x_i \rangle_H$, $i \in [m]$, where the norm $\|\cdot\|_{\mathbb{R}^m}$ in $\mathbb{R}^m$ is the Euclidean norm times $1/\sqrt{m}$. Its adjoint operator $\mathcal{S}_{\mathbf{x}}^* : \mathbb{R}^m \to H$, defined by $\langle \mathcal{S}_{\mathbf{x}}^* \mathbf{y}, \omega \rangle_H = \langle \mathbf{y}, \mathcal{S}_{\mathbf{x}} \omega \rangle_{\mathbb{R}^m}$ for $\mathbf{y} \in \mathbb{R}^m$ is thus given by $\mathcal{S}_{\mathbf{x}}^* \mathbf{y} = \frac{1}{m} \sum_{i=1}^m y_i x_i$. Moreover, we can define the empirical covariance operator $\mathcal{T}_{\mathbf{x}} : H \to H$ such that $\mathcal{T}_{\mathbf{x}} = \mathcal{S}_{\mathbf{x}}^* \mathcal{S}_{\mathbf{x}}$. Obviously,

$$\mathcal{T}_{\mathbf{x}} = \frac{1}{m} \sum_{i=1}^{m} \langle \cdot, x_i \rangle_H x_i.$$

With these notations, (21) and (10) can be rewritten as

$$\mu_{t+1} = \mu_t - \eta_t (\mathcal{T}_\rho \mu_t - \mathcal{S}_\rho^* f_\rho), \qquad t = 1, \ldots, T, \tag{25}$$

and

$$\nu_{t+1} = \nu_t - \eta_t (\mathcal{T}_{\mathbf{x}} \nu_t - \mathcal{S}_{\mathbf{x}}^* \mathbf{y}), \qquad t = 1, \ldots, T, \tag{26}$$

respectively.

Using the projection theorem, one can prove that

$$\mathcal{S}_\rho^* f_\rho = \mathcal{S}_\rho^* f_{\mathcal{H}}. \tag{27}$$

Indeed, since $f_{\mathcal{H}}$ is the projection of the regression function f_ρ onto the closure of H_ρ in $L^2(H, \rho_X)$, according to the projection theorem, one has

$$\langle f_{\mathcal{H}} - f_\rho, \mathcal{S}_\rho \omega \rangle_\rho = 0, \qquad \forall \omega \in H,$$

which can be written as

$$\langle \mathcal{S}_\rho^* f_{\mathcal{H}} - \mathcal{S}_\rho^* f_\rho, \omega \rangle_H = 0, \qquad \forall \omega \in H,$$

and thus leading to (27).

4.2 Concentration Inequality

We need the following concentration result for Hilbert space valued random variable used in (Caponnetto and De Vito, 2007) and based on the results in (Pinelis and Sakhanenko, 1986).

Lemma 11 *Let $w_1, \cdots, w_m$ be i.i.d random variables in a Hilbert space with norm $\|\cdot\|$. Suppose that there are two positive constants B and σ^2 such that*

$$\mathbb{E}[\|w_1 - \mathbb{E}[w_1]\|^l] \leq \frac{1}{2} l! B^{l-2} \sigma^2, \quad \forall l \geq 2. \tag{28}$$

Then for any $0 < \delta < 1$, the following holds with probability at least $1 - \delta$,

$$\left\| \frac{1}{m} \sum_{k=1}^{m} w_m - \mathbb{E}[w_1] \right\| \leq 2 \left(\frac{B}{m} + \frac{\sigma}{\sqrt{m}} \right) \log \frac{2}{\delta}.$$

In particular, (28) holds if

$$\|w_1\| \leq B/2 \quad a.s., \quad \text{and} \quad \mathbb{E}[\|w_1\|^2] \leq \sigma^2. \tag{29}$$

4.3 Basic Estimates

Finally, we introduce the following three basic estimates, whose proofs can be found in Appendix C.

Lemma 12 *Let $\theta \in [0, 1[$, and $t \in \mathbb{N}$. Then*

$$\frac{t^{1-\theta}}{2} \leq \sum_{k=1}^{t} k^{-\theta} \leq \frac{t^{1-\theta}}{1-\theta}.$$

Lemma 13 *Let $\theta \in \mathbb{R}$ and $t \in \mathbb{N}$. Then*

$$\sum_{k=1}^{t} k^{-\theta} \leq t^{\max(1-\theta, 0)} (1 + \log t).$$

Lemma 14 *Let $q \in \mathbb{R}$ and $t \in \mathbb{N}$ with $t \geq 3$. Then*

$$\sum_{k=1}^{t-1} \frac{1}{t-k} k^{-q} \leq 2 t^{-\min(q,1)} (1 + \log t).$$

In the next sections, we begin prooving the main results. The proofs are quite lengthy and they are divided into several steps. For the ease of readability, we list some of the notations and definitions in Appendix D. We also remark that we are particularly interested in developing error bounds in terms of the stepsize η_t ($= \eta_1 t^{-\theta}$), the number of iterations t or T, the 'regularization' parameter $\lambda > 0$, the sample size m, the minibatch size b, and the failing profitability δ. Other parameters such as $\kappa^2, \|\mathcal{T}_\rho\|, M, v, R, c_\gamma$ and $\|f_{\mathcal{H}}\|_\infty$ can be always viewed as some constants, which are less important in our error bounds.

5. Estimating Bias and Sample Variance

In this section, we estimate the bias and the sample variance.

5.1 Bias

In this subsection, we develop upper bounds for the bias, i.e., $\|\mathcal{S}_\rho \mu_t - f_{\mathcal{H}}\|_\rho^2$. Towards this end, we introduce the following lemma, whose proof borrows idea from (Ying and Pontil, 2008; Tarres and Yao, 2014).

Lemma 15 *Let L be a compact, positive operator on a separable Hilbert space H. Assume that $\eta_1\|L\| \leq 1$. Then for $t \in \mathbb{N}$ and any non-negative integer $k \leq t-1$,*

$$\|\Pi_{k+1}^t(L)L^\zeta\| \leq \left(\frac{\zeta}{\mathrm{e}\sum_{j=k+1}^t \eta_j}\right)^\zeta. \tag{30}$$

Proof Let $\{\sigma_i\}$ be the sequence of eigenvalues of L. We have

$$\|\Pi_{k+1}^t(L)L^\zeta\| = \sup_i \prod_{l=k+1}^t (1-\eta_l\sigma_i)\sigma_i^\zeta.$$

Using the basic inequality

$$1 + x \leq \mathrm{e}^x \qquad \text{for all } x \geq -1, \tag{31}$$

with $\eta_l\|L\| \leq 1$, we get

$$\begin{aligned}\|\Pi_{k+1}^t(L)L^\zeta\| &\leq \sup_i \exp\left\{-\sigma_i \sum_{l=k+1}^t \eta_l\right\}\sigma_i^\zeta \\ &\leq \sup_{x\geq 0}\exp\left\{-x\sum_{l=k+1}^t \eta_l\right\}x^\zeta.\end{aligned}$$

The maximum of the function $g(x) = \mathrm{e}^{-cx}x^\zeta$(with $c>0$) over $\mathbb{R}_+$ is achieved at $x_{\max} = \zeta/c$, and thus

$$\sup_{x\geq 0}\mathrm{e}^{-cx}x^\zeta = \left(\frac{\zeta}{\mathrm{e}c}\right)^\zeta. \tag{32}$$

Using this inequality, one can get the desired result (30). ∎

With the above lemma and Lemma 12, we can derive the following result for the bias.

Proposition 2 *Under Assumption 2, let $\eta_1\kappa^2 \leq 1$. Then, for any $t \in \mathbb{N}$,*

$$\|\mathcal{S}_\rho\mu_{t+1} - f_{\mathcal{H}}\|_\rho \leq R\left(\frac{\zeta}{2\sum_{j=1}^t \eta_j}\right)^\zeta. \tag{33}$$

In particular, if $\eta_t = \eta t^{-\theta}$ for all $t \in \mathbb{N}$, with $\eta \in]0, \kappa^{-2}]$ and $\theta \in [0,1[$, then

$$\|\mathcal{S}_\rho\mu_{t+1} - f_{\mathcal{H}}\|_\rho \leq R\zeta^\zeta\eta^{-\zeta}t^{(\theta-1)\zeta}. \tag{34}$$

The above result is essentially proved in (Yao et al., 2007), see also (Rosasco and Villa, 2015) when step-size is fixed. For the sake of completeness, we provide a proof in Appendix C. The following lemma gives upper bounds for the sequence $\{\mu_t\}_{t\in\mathbb{N}}$ in H-norm. It will be used for the estimation on the sample variance in the next section.

Lemma 16 *Under Assumption 2, let $\eta_1\kappa^2 \leq 1$. The following holds for all $t \in \mathbb{N}$:*
1) If $\zeta \geq 1/2$,

$$\|\mu_{t+1}\|_H \leq R\kappa^{2\zeta-1}. \tag{35}$$

2) If $\zeta \in]0, 1/2]$,

$$\|\mu_{t+1}\|_H \leq R\left\{\kappa^{2\zeta-1} \vee \left(\sum_{k=1}^t \eta_k\right)^{\frac{1}{2}-\zeta}\right\}. \tag{36}$$

Proof The proof can be found in Appendix C. The proof for a fixed step-size (i.e., $\eta_t = \eta$ for all t) can be also found in (Rosasco and Villa, 2015). For a general step-size, the proof is similar. Note also that our proof for the non-attainable case is simpler than that in (Rosasco and Villa, 2015). ∎

5.2 Sample Variance

In this subsection, we estimate the sample variance, i.e., $\mathbb{E}[\|\mathcal{S}_\rho\mu_t - \mathcal{S}_\rho\nu_t\|_\rho^2]$. Towards this end, we need some preliminary analysis. We first introduce the following key inequality, which also provides the basic idea on estimating $\mathbb{E}[\|\mathcal{S}_\rho\mu_t - \mathcal{S}_\rho\nu_t\|_\rho^2]$.

Lemma 17 *For all $t \in [T]$, we have*

$$\|\mathcal{S}_\rho\nu_{t+1} - \mathcal{S}_\rho\mu_{t+1}\|_\rho \leq \sum_{k=1}^t \eta_k \left\|\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k\right\|_H, \tag{37}$$

where

$$N_k = (\mathcal{T}_\rho\mu_k - \mathcal{S}_\rho^* f_\rho) - (\mathcal{T}_{\mathbf{x}}\mu_k - \mathcal{S}_{\mathbf{x}}^*\mathbf{y}), \qquad \forall k \in [T]. \tag{38}$$

Proof Since ν_{t+1} and μ_{t+1} are given by (26) and (25), respectively,

$$\begin{aligned}\nu_{t+1} - \mu_{t+1} &= \nu_t - \mu_t + \eta_t\left\{(\mathcal{T}_\rho\mu_t - \mathcal{S}_\rho^* f_\rho) - (\mathcal{T}_{\mathbf{x}}\nu_t - \mathcal{S}_{\mathbf{x}}^*\mathbf{y})\right\} \\ &= (I - \eta_t\mathcal{T}_{\mathbf{x}})(\nu_t - \mu_t) + \eta_t\left\{(\mathcal{T}_\rho\mu_t - \mathcal{S}_\rho^* f_\rho) - (\mathcal{T}_{\mathbf{x}}\mu_t - \mathcal{S}_{\mathbf{x}}^*\mathbf{y})\right\},\end{aligned}$$

which is exactly

$$\nu_{t+1} - \mu_{t+1} = (I - \eta_t\mathcal{T}_{\mathbf{x}})(\nu_t - \mu_t) + \eta_t N_t.$$

Applying this relationship iteratively, with $\nu_1 = \mu_1 = 0$,

$$\nu_{t+1} - \mu_{t+1} = \Pi_1^t(\mathcal{T}_{\mathbf{x}})(\nu_1 - \mu_1) + \sum_{k=1}^t \eta_k\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k = \sum_{k=1}^t \eta_k\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k. \tag{39}$$

By (24), we have

$$\|\mathcal{S}_\rho\nu_{t+1} - \mathcal{S}_\rho\mu_{t+1}\|_\rho = \left\|\sum_{k=1}^t \eta_k\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k\right\|_H,$$

which leads to the desired result (37). ∎

The above lemma shows that in order to upper bound $\mathbb{E}[\|\mathcal{S}_\rho\mu_t - \mathcal{S}_\rho\nu_t\|_\rho^2]$, one may only need to

bound $\left\| \mathcal{T}_\rho^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}}) N_k \right\|_H$. A detailed look at this latter term indicates that one may analyze the terms $\mathcal{T}_\rho^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})$ and N_k separately, since $\mathbb{E}_{\mathbf{z}}[N_k] = 0$ and the properties of the deterministic sequence $\{\mu_k\}_k$ have been derived in Section 5.1. Moreover, to exploit the capacity condition from Assumption 3, we estimate $\|(\mathcal{T}_\rho + \lambda)^{-\frac{1}{2}} N_k\|_H$ (with $\lambda > 0$ properly chosen later), rather than $\|N_k\|_H$, as follows.

Lemma 18 *Under Assumptions 1, 2 and 3, let $\{N_t\}_t$ be as in (38). Then for any fixed $\lambda > 0$, and $T \geq 2$,*
1) if $\zeta \geq 1/2$, with probability at least $1 - \delta_1$, the following holds for all $k \in \mathbb{N}$:

$$\|(\mathcal{T}_\rho + \lambda)^{-\frac{1}{2}} N_k\|_H \leq 4(R\kappa^{2\zeta} + \sqrt{M}) \left(\frac{\kappa}{m\sqrt{\lambda}} + \frac{\sqrt{2\sqrt{v}c_\gamma}}{\sqrt{m\lambda^\gamma}} \right) \log \frac{4}{\delta_1}. \tag{40}$$

2) if $\zeta \in]0, 1/2[$, with probability at least $1 - \delta_1$, the following holds for all $k \in [T]$:

$$\|(\mathcal{T}_\rho + \lambda)^{-\frac{1}{2}} N_k\|_H \leq 2 \left(3\|f_{\mathcal{H}}\|_\infty + 2\sqrt{M} + \kappa R \right) \left(\frac{\kappa}{m\sqrt{\lambda}} + \frac{\sqrt{2\sqrt{v}c_\gamma}}{\sqrt{m\lambda^\gamma}} \right) \log \frac{3T}{\delta_1} + \frac{2\kappa^2 R \left(\sum_{i=1}^k \eta_i \right)^{\frac{1}{2}-\zeta}}{m\sqrt{\lambda}} \log \frac{3T}{\delta_1} + \frac{2\kappa R}{\sqrt{m\lambda}} \left(\frac{1}{\sum_{i=1}^k \eta_i} \right)^\zeta \log \frac{3T}{\delta_1}. \tag{41}$$

Proof We will apply Bernstein inequality from Lemma 11 to prove the result.
Attainable Case: $\zeta \geq 1/2$. See Appendix C for the proof.
Non-attainable case: $0 < \zeta < 1/2$.
Let $w_i = (f_{\mathcal{H}}(x_i) - y_i)(\mathcal{T}_\rho + \lambda)^{-1/2} x_i$, for all $i \in [m]$. Noting that by (27), and taking the expectation with respect to the random variable (x, y) (from the distribution ρ),

$$\mathbb{E}[\omega] = \mathbb{E}[(f_{\mathcal{H}}(x) - f_\rho(x))(\mathcal{T}_\rho + \lambda)^{-1/2} x] = 0.$$

Applying Hölder's inequality, for any $l \geq 2$,

$$\mathbb{E}[\|w - \mathbb{E}[w]\|_H^l] = \mathbb{E}[\|w\|_H^l] \leq 2^{l-1} \mathbb{E}[(|f_{\mathcal{H}}(x)|^l + |y|^l)\|(\mathcal{T}_\rho + \lambda)^{-1/2} x\|_H^l]$$
$$\leq 2^{l-1} \int_X (\|f_{\mathcal{H}}\|_\infty^l + \int_Y |y|^l d\rho(y|x)) \|(\mathcal{T}_\rho + \lambda)^{-1/2} x\|_H^l d\rho_X(x).$$

Using Cauchy-Schwarz's inequality and Assumption 1 which implies,

$$\int_Y y^l d\rho(y|x) \leq \left(\int_Y |y|^{2l} d\rho(y|x) \right)^{\frac{1}{2}} \leq \sqrt{l! M^l v} \leq l! (\sqrt{M})^l \sqrt{v}, \tag{42}$$

we get

$$\mathbb{E}[\|w - \mathbb{E}[w]\|_H^l] \leq 2^{l-1} (\|f_{\mathcal{H}}\|_\infty^l + l! (\sqrt{M})^l \sqrt{v}) \int_X \|(\mathcal{T}_\rho + \lambda)^{-1/2} x\|_H^l d\rho_X(x). \tag{43}$$

By Assumption (3),

$$\|(\mathcal{T}_\rho + \lambda I)^{-\frac{1}{2}} x\|_H \leq \frac{\|x\|_H}{\sqrt{\lambda}} \leq \frac{\kappa}{\sqrt{\lambda}}. \tag{44}$$

Besides, using the fact that $\mathbb{E}[\|\xi\|_H^2] = \mathbb{E}[\mathrm{tr}(\xi \otimes \xi)] = \mathrm{tr}(\mathbb{E}[\xi \otimes \xi])$ and $\mathbb{E}[x \otimes x] = \mathcal{T}_\rho$, we know that

$$\int_X \|(\mathcal{T}_\rho + \lambda I)^{-\frac{1}{2}} x\|_H^2 d\rho_X(x) = \mathrm{tr}((\mathcal{T}_\rho + \lambda I)^{-\frac{1}{2}} \mathcal{T}_\rho (\mathcal{T}_\rho + \lambda I)^{-\frac{1}{2}}) = \mathrm{tr}((\mathcal{T}_\rho + \lambda I)^{-1} \mathcal{T}_\rho),$$

and as a result of the above and Assumption 3,

$$\int_X \|(\mathcal{T}_\rho + \lambda I)^{-\frac{1}{2}} x\|_H^2 d\rho_X(x) \leq c_\gamma \lambda^{-\gamma}.$$

It thus follows that

$$\int_X \|(\mathcal{T}_\rho + \lambda)^{-1/2} x\|_H^l d\rho_X(x) \leq \left(\frac{\kappa}{\sqrt{\lambda}} \right)^{l-2} \int_X \|(\mathcal{T}_\rho + \lambda)^{-1/2} x\|_H^2 d\rho_X(x) \leq \left(\frac{\kappa}{\sqrt{\lambda}} \right)^{l-2} c_\gamma \lambda^{-\gamma}. \tag{45}$$

Plugging the above inequality into (43),

$$\begin{aligned} \mathbb{E}[\|w - \mathbb{E}[w]\|_H^l] &\leq 2^{l-1} (\|f_{\mathcal{H}}\|_\infty^l + l! (\sqrt{M})^l \sqrt{v}) \left(\frac{\kappa}{\sqrt{\lambda}} \right)^{l-2} c_\gamma \lambda^{-\gamma} \\ &\leq \frac{1}{2} l! \left(\frac{2\kappa(\|f_{\mathcal{H}}\|_\infty + \sqrt{M})}{\sqrt{\lambda}} \right)^{l-2} 4 c_\gamma \sqrt{v} (\|f_{\mathcal{H}}\|_\infty + \sqrt{M})^2 \lambda^{-\gamma}. \end{aligned}$$

Therefore, using Lemma 11, we get that with probability at least $1 - \delta$,

$$\left\| (\mathcal{T}_\rho + \lambda)^{-\frac{1}{2}} \frac{1}{m} \sum_{i=1}^m (f_{\mathcal{H}}(x_i) - y_i) x_i \right\|_H = \left\| \frac{1}{m} \sum_{i=1}^m (\mathbb{E}[w_i] - w_i) \right\|_H$$
$$\leq 4(\sqrt{M} + \|f_{\mathcal{H}}\|_\infty) \left(\frac{\kappa}{m\sqrt{\lambda}} + \frac{\sqrt{\sqrt{v}c_\gamma}}{\sqrt{m\lambda^\gamma}} \right) \log \frac{2}{\delta}. \tag{46}$$

We next let $\xi_i = (\mathcal{T}_\rho + \lambda)^{-1/2} (\langle \mu_k, x_i \rangle - f_{\mathcal{H}}(x_i)) x_i$, for all $i \in [m]$. We assume that $k \geq 2$. (The proof for the case $k = 1$ is simpler as $\mu_1 = 0$.) It is easy to see that the expectation of each ξ_i with respect to the random variable (x_i, y_i) is

$$\mathbb{E}[\xi] = (\mathcal{T}_\rho + \lambda)^{-1/2} (\mathcal{T}_\rho \mu_k - \mathcal{S}_\rho^* f_{\mathcal{H}}) = (\mathcal{T}_\rho + \lambda)^{-1/2} (\mathcal{T}_\rho \mu_k - \mathcal{S}_\rho^* f_\rho),$$

and

$$\|\xi\|_H \leq (\|\mathcal{S}_\rho \mu_k\|_\infty + \|f_{\mathcal{H}}\|_\infty) \|(\mathcal{T}_\rho + \lambda)^{-1/2} x\|_H.$$

By Assumption (3), $\|\mathcal{S}_\rho \mu_k\|_\infty \leq \kappa \|\mu_k\|_H$. It thus follows from the above and (44) that

$$\|\xi\|_H \leq (\kappa \|\mu_k\|_H + \|f_{\mathcal{H}}\|_\infty) \frac{\kappa}{\sqrt{\lambda}}.$$

Besides,

$$\mathbb{E}\|\xi\|_H^2 \leq \frac{\kappa^2}{\lambda} \mathbb{E}(\mu_k(x) - f_{\mathcal{H}}(x))^2 = \frac{\kappa^2}{\lambda} \|\mathcal{S}_\rho \mu_k - f_{\mathcal{H}}\|_\rho^2 \leq \frac{\kappa^2 R^2}{\lambda} \left(\frac{\zeta}{2 \sum_{i=1}^{k-1} \eta_i} \right)^{2\zeta} \leq \frac{\kappa^2 R^2}{\lambda} \left(\frac{1}{\sum_{i=1}^k \eta_i} \right)^{2\zeta},$$

where for the last inequality, we used (33). Applying Lemma 11 and (36), we get that with probability at least $1-\delta$,

$$\begin{aligned}
&\left\|(\mathcal{T}_\rho+\lambda)^{-1/2}[\frac{1}{m}\sum_{i=1}^m(\mu_k(x_i)-f_{\mathcal{H}}(x_i))x_i-(\mathcal{T}_\rho\mu_k-\mathcal{S}_\rho^*f_\rho)]\right\|_H\\
\leq\ & 2\kappa\left(\frac{\kappa\|\mu_k\|_H+\|f_{\mathcal{H}}\|_\infty}{m\sqrt{\lambda}}+\frac{R}{\sqrt{m\lambda}}\left(\frac{1}{\sum_{i=1}^k\eta_i}\right)^\zeta\right)\log\frac{2}{\delta}\\
\leq\ & 2\kappa\left(\frac{\kappa R+\|f_{\mathcal{H}}\|_\infty}{m\sqrt{\lambda}}+\frac{\kappa R\left(\sum_{i=1}^k\eta_i\right)^{\frac{1}{2}-\zeta}}{m\sqrt{\lambda}}+\frac{R}{\sqrt{m\lambda}}\left(\frac{1}{\sum_{i=1}^k\eta_i}\right)^\zeta\right)\log\frac{2}{\delta}.
\end{aligned}$$

Introducing the above estimate and (46) into the following inequality

$$\begin{aligned}
\|(\mathcal{T}_\rho+\lambda)^{-1/2}N_k\|_H\leq&\left\|(\mathcal{T}_\rho+\lambda)^{-\frac{1}{2}}\frac{1}{m}\sum_{i=1}^m\left(f_{\mathcal{H}}(x_i)-y_i\right)x_i\right\|_H\\
&+\left\|(\mathcal{T}_\rho+\lambda)^{-1/2}[\frac{1}{m}\sum_{i=1}^m(\mu_k(x_i)-f_{\mathcal{H}}(x_i))x_i-(\mathcal{T}_\rho\mu_k-\mathcal{S}_\rho^*f_\rho)]\right\|_H,
\end{aligned}$$

and then substituting with (36), by a simple calculation, one can prove the desired result by scaling δ. ∎

The next lemma is from Rudi et al. (2015), and is derived applying a recent Bernstein inequality from (Tropp, 2012; Minsker, 2011) for a sum of random operators.

Lemma 19 *Let $\delta_2\in(0,1)$ and $\frac{9\kappa^2}{m}\log\frac{m}{\delta_2}\leq\lambda\leq\|\mathcal{T}_\rho\|$. Then the following holds with probability at least $1-\delta_2$,*

$$\|(\mathcal{T}_{\mathbf{x}}+\lambda I)^{-\frac{1}{2}}\mathcal{T}_\rho^{\frac{1}{2}}\|\leq\|(\mathcal{T}_{\mathbf{x}}+\lambda I)^{-\frac{1}{2}}(\mathcal{T}_\rho+\lambda I)^{\frac{1}{2}}\|\leq 2. \tag{47}$$

Now we are in a position to estimate the sample variance.

Proposition 3 *Under Assumptions 1, 2 and 3, let $\eta_1\kappa^2\leq 1$ and $0<\lambda\leq\|\mathcal{T}_\rho\|$. Assume that (47) holds. Then for all $t\in[T]$:*
1) if $\zeta\geq 1/2$, and (40) hold, then for $t\in\mathbb{N}$,

$$\begin{aligned}
&\|\mathcal{S}_\rho\nu_{t+1}-\mathcal{S}_\rho\mu_{t+1}\|_\rho\\
\leq&4(R\kappa^{2\zeta}+\sqrt{M})\left(\frac{\kappa}{m\sqrt{\lambda}}+\frac{\sqrt{2\sqrt{v}c_\gamma}}{\sqrt{m\lambda^\gamma}}\right)\left(\sum_{k=1}^{t-1}\frac{2\eta_k}{\sum_{i=k+1}^t\eta_i}+4\lambda\sum_{k=1}^{t-1}\eta_k+\sqrt{2}\kappa^2\eta_t\right)\log\frac{4}{\delta_1}.
\end{aligned}\tag{48}$$

2) if $\zeta<1/2$, and (41) hold for any $t\in[T]$, then for $t\in[T]$:

$$\begin{aligned}
\|\mathcal{S}_\rho\nu_{t+1}-\mathcal{S}_\rho\mu_{t+1}\|_\rho\leq&\left(\sum_{k=1}^{t-1}\frac{2\eta_k}{\sum_{i=k+1}^t\eta_i}+4\lambda\sum_{k=1}^{t-1}\eta_k+\sqrt{2}\kappa^2\eta_t\right)\\
&\times\left(2\left(3\|f_{\mathcal{H}}\|_\infty+3\sqrt{M}+\kappa R\right)\left(\frac{\kappa}{m\sqrt{\lambda}}+\frac{\sqrt{2\sqrt{v}c_\gamma}}{\sqrt{m\lambda^\gamma}}\right)+\frac{2\kappa^2R\left(\sum_{i=1}^t\eta_i\right)^{\frac{1}{2}-\zeta}}{m\sqrt{\lambda}}\right)\log\frac{3T}{\delta_1}\\
&+\frac{2\kappa R}{\sqrt{m\lambda}}\log\frac{3T}{\delta_1}\left(\sum_{k=1}^{t-1}\frac{2\eta_k}{\left(\sum_{i=1}^k\eta_i\right)^\zeta\sum_{i=k+1}^t\eta_i}+4\lambda\sum_{k=1}^{t-1}\frac{\eta_k}{\left(\sum_{i=1}^k\eta_i\right)^\zeta}+\frac{\sqrt{2}\kappa^2\eta_t}{\left(\sum_{i=1}^t\eta_i\right)^\zeta}\right).
\end{aligned}\tag{49}$$

Proof For notational simplicity, we let $\mathcal{T}_{\rho,\lambda}=\mathcal{T}_\rho+\lambda I$ and $\mathcal{T}_{\mathbf{x},\lambda}=\mathcal{T}_{\mathbf{x}}+\lambda I$. Note that by Lemma 17, we have (37). When $k\in[t-1]$, by rewriting $\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k$ as

$$\mathcal{T}_\rho^{\frac{1}{2}}\mathcal{T}_{\mathbf{x},\lambda}^{-\frac{1}{2}}\mathcal{T}_{\mathbf{x},\lambda}^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\mathcal{T}_{\mathbf{x},\lambda}^{\frac{1}{2}}\mathcal{T}_{\mathbf{x},\lambda}^{-\frac{1}{2}}\mathcal{T}_{\rho,\lambda}^{\frac{1}{2}}\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}N_k,$$

we can upper bound $\|\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k\|_H$ as

$$\|\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k\|_H\leq\|\mathcal{T}_\rho^{\frac{1}{2}}\mathcal{T}_{\mathbf{x},\lambda}^{-\frac{1}{2}}\|\|\mathcal{T}_{\mathbf{x},\lambda}^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\mathcal{T}_{\mathbf{x},\lambda}^{\frac{1}{2}}\|\|\mathcal{T}_{\mathbf{x},\lambda}^{-\frac{1}{2}}\mathcal{T}_{\rho,\lambda}^{\frac{1}{2}}\|\|\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}N_k\|_H.$$

Applying (47), the above can be relaxed as

$$\|\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k\|_H\leq 4\|\mathcal{T}_{\mathbf{x},\lambda}^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\mathcal{T}_{\mathbf{x},\lambda}^{\frac{1}{2}}\|\|\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}N_k\|_H,$$

which is equivalent to

$$\|\mathcal{T}_{\rho,\lambda}^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k\|_H\leq 4\|\mathcal{T}_{\mathbf{x},\lambda}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\|\|\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}N_k\|_H.$$

Thus, following from $\eta_k\kappa^2\leq 1$ which implies $\eta_k\|\mathcal{T}_{\mathbf{x}}\|\leq 1$,

$$\begin{aligned}
\|\mathcal{T}_{\mathbf{x},\lambda}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\|&\leq\|\mathcal{T}_{\mathbf{x}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\|+\|\lambda\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\|\\
&\leq\|\mathcal{T}_{\mathbf{x}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\|+\lambda.
\end{aligned}$$

Applying Lemma 15 with $\zeta=1$ to bound $\|\mathcal{T}_{\mathbf{x}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\|$, we get

$$\|\mathcal{T}_{\mathbf{x},\lambda}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\|\leq\frac{1}{\mathrm{e}\sum_{j=k+1}^t\eta_j}+\lambda.$$

When $k=t$,

$$\begin{aligned}
\|\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k\|_H=\|\mathcal{T}_\rho^{\frac{1}{2}}N_t\|_H&\leq\|\mathcal{T}_\rho^{\frac{1}{2}}\|\|\mathcal{T}_{\rho,\lambda}^{\frac{1}{2}}\|\|\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}N_t\|_H\\
&\leq\|\mathcal{T}_\rho\|^{\frac{1}{2}}(\|\mathcal{T}_\rho\|+\lambda)^{\frac{1}{2}}\|\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}N_t\|_H.
\end{aligned}$$

Since $\lambda\leq\|\mathcal{T}_\rho\|\leq\mathrm{tr}(\mathcal{T}_\rho)\leq\kappa^2$, we derive

$$\|\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_t\|_H\leq\sqrt{2}\kappa^2\|\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}N_t\|_H.$$

From the above analysis, we see that $\sum_{k=1}^{t}\eta_k\left\|\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^{t}(\mathcal{T}_{\mathbf{x}})N_k\right\|_H$ can be upper bounded by

$$\leq\left(\sum_{k=1}^{t-1}\frac{\eta_k/2\|\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}N_k\|_H}{\sum_{i=k+1}^{t}\eta_i}+\lambda\sum_{k=1}^{t-1}\eta_k\|\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}N_k\|_H+\sqrt{2}\kappa^2\eta_t\|\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}N_t\|_H\right).$$

Plugging (40) (or (41)) into the above, and then combining with (37), we get the desired bound (48) (or (49)). The proof is complete. ■

Setting $\eta_t=\eta_1 t^{-\theta}$ in the above proposition, with the basic estimates from Section 4, we get the following explicit bounds for the sample variance.

Proposition 4 *Under Assumptions 1, 2 and 3, let $\eta_t=\eta_1 t^{-\theta}$ with $\eta_1\in]0,\kappa^{-2}]$ and $\theta\in[0,1[$. Assume that (47) holds. Then the following holds for all $t\in[T]$ and any $0<\lambda\leq\|\mathcal{T}_\rho\|$:*
1) If $\zeta\geq 1/2$, and (40) holds for all $t\in[T]$,

$$\begin{aligned}&\|\mathcal{S}_\rho\nu_{t+1}-\mathcal{S}_\rho\mu_{t+1}\|_\rho\\ \leq&4(R\kappa^{2\zeta}+\sqrt{M})\left(\frac{8\lambda\eta_1 t^{1-\theta}}{1-\theta}+4\log t+4+\sqrt{2}\eta_1\kappa^2\right)\left(\frac{\kappa}{m\sqrt{\lambda}}+\frac{\sqrt{2\sqrt{v}c_\gamma}}{\sqrt{m\lambda^\gamma}}\right)\log\frac{4}{\delta_1}.\end{aligned}\tag{50}$$

2) If $\zeta<1/2$, and (41) holds for all $t\in[T]$,

$$\begin{aligned}&\|\mathcal{S}_\rho\nu_{t+1}-\mathcal{S}_\rho\mu_{t+1}\|_\rho\leq\left(\frac{8\lambda\eta_1 t^{1-\theta}}{1-\theta}+4\log t+4+\sqrt{2}\eta_1\kappa^2\right)\log\frac{3T}{\delta_1}\\ \times&\left(2\left(3\|f_{\mathcal{H}}\|_\infty+3\sqrt{M}+\kappa R\right)\left(\frac{\kappa}{m\sqrt{\lambda}}+\frac{\sqrt{2\sqrt{v}c_\gamma}}{\sqrt{m\lambda^\gamma}}\right)+\left(\frac{\kappa}{1-\theta}\sqrt{\frac{\eta_1 t^{1-\theta}}{m}}+1\right)\frac{4\kappa R}{\sqrt{m\lambda}}\frac{1}{(\eta_1 t^{1-\theta})^\zeta}\right).\end{aligned}\tag{51}$$

Proof By Proposition 3, we have (48) or (49). Note that

$$\sum_{k=1}^{t-1}\frac{\eta_k}{\sum_{i=k+1}^{t}\eta_i}=\sum_{k=1}^{t-1}\frac{k^{-\theta}}{\sum_{i=k+1}^{t}i^{-\theta}}\leq\sum_{k=1}^{t-1}\frac{k^{-\theta}}{(t-k)t^{-\theta}}.$$

Applying Lemma 14, we get

$$\sum_{k=1}^{t-1}\frac{\eta_k}{\sum_{i=k+1}^{t}\eta_i}\leq 2+2\log t,$$

and by Lemma 12,

$$\sum_{k=1}^{t-1}\eta_k=\eta_1\sum_{k=1}^{t-1}k^{-\theta}\leq\frac{2\eta_1 t^{1-\theta}}{1-\theta}.$$

Introducing the last two estimates into (48) and (49), one can get (50) and that

$$\begin{aligned}&\|\mathcal{S}_\rho\nu_{t+1}-\mathcal{S}_\rho\mu_{t+1}\|_\rho\leq\left(\frac{8\lambda\eta_1 t^{1-\theta}}{1-\theta}+4\log t+4+\sqrt{2}\eta_1\kappa^2\right)\\ &\times\left(2\left(3\|f_{\mathcal{H}}\|_\infty+3\sqrt{M}+\kappa R\right)\left(\frac{\kappa}{m\sqrt{\lambda}}+\frac{\sqrt{2\sqrt{v}c_\gamma}}{\sqrt{m\lambda^\gamma}}\right)+\frac{4\kappa^2 R\left(\eta_1 t^{1-\theta}\right)^{\frac{1}{2}-\zeta}}{(1-\theta)m\sqrt{\lambda}}\right)\log\frac{3T}{\delta_1}\\ &+\frac{2\kappa R}{\sqrt{m\lambda}}\log\frac{3T}{\delta_1}\left(\sum_{k=1}^{t-1}\frac{2\eta_k}{\left(\sum_{i=1}^{k}\eta_i\right)^\zeta\sum_{i=k+1}^{t}\eta_i}+4\lambda\sum_{k=1}^{t-1}\frac{\eta_k}{\left(\sum_{i=1}^{k}\eta_i\right)^\zeta}+\frac{\sqrt{2}\kappa^2\eta_t}{\left(\sum_{i=1}^{t}\eta_i\right)^\zeta}\right).\end{aligned}$$

To prove (51), it remains to estimate the last term of the above. Again, using Lemmas 12, 13 and 14, we get

$$\begin{aligned}\sum_{k=1}^{t-1}\frac{\eta_k}{\left(\sum_{i=1}^{k}\eta_i\right)^\zeta\sum_{i=k+1}^{t}\eta_i}&=\frac{1}{\eta_1^\zeta}\sum_{k=1}^{t-1}\frac{k^{-\theta}}{\left(\sum_{i=1}^{k}i^{-\theta}\right)^\zeta\sum_{i=k+1}^{t}i^{-\theta}}\\ \leq&\frac{1}{\eta_1^\zeta}\sum_{k=1}^{t-1}\frac{k^{-\theta}}{(k^{1-\theta}/2)^\zeta(t-k)t^{-\theta}}=\frac{2^\zeta}{\eta_1^\zeta}t^\theta\sum_{k=1}^{t-1}\frac{k^{-(\theta+\zeta(1-\theta))}}{t-k}\\ \leq&\frac{2^\zeta}{\eta_1^\zeta}t^\theta 2t^{-(\theta+\zeta(1-\theta))}(1+\log t)\leq\frac{4(1+\log t)}{(\eta_1 t^{1-\theta})^\zeta},\end{aligned}$$

$$\sum_{k=1}^{t-1}\frac{\eta_k}{\left(\sum_{i=1}^{k}\eta_i\right)^\zeta}=\eta_1^{1-\zeta}\sum_{k=1}^{t-1}\frac{k^{-\theta}}{\left(\sum_{i=1}^{k}i^{-\theta}\right)^\zeta}\leq 2^\zeta\eta_1^{1-\zeta}\sum_{k=1}^{t-1}k^{-(\theta+\zeta(1-\theta))}\leq\frac{2(\eta_1 t^{1-\theta})^{1-\zeta}}{(1-\theta)},\quad\text{and}$$

$$\frac{\eta_t}{\left(\sum_{i=1}^{t}\eta_i\right)^\zeta}=\frac{\eta_1 t^{-\theta}}{\left(\sum_{i=1}^{t}\eta_1 i^{-\theta}\right)^\zeta}\leq 2^\zeta\frac{\eta_1 t^{-\theta}}{(\eta_1 t^{1-\theta})^\zeta}\leq\frac{\sqrt{2}\eta_1}{(\eta_1 t^{1-\theta})^\zeta}.$$

Therefore,

$$\begin{aligned}&\|\mathcal{S}_\rho\nu_{t+1}-\mathcal{S}_\rho\mu_{t+1}\|_\rho\leq\left(\frac{8\lambda\eta_1 t^{1-\theta}}{1-\theta}+4\log t+4+\sqrt{2}\eta_1\kappa^2\right)\\ &\times\left(2\left(3\|f_{\mathcal{H}}\|_\infty+3\sqrt{M}+\kappa R\right)\left(\frac{\kappa}{m\sqrt{\lambda}}+\frac{\sqrt{2\sqrt{v}c_\gamma}}{\sqrt{m\lambda^\gamma}}\right)+\frac{4\kappa^2 R\left(\eta_1 t^{1-\theta}\right)^{\frac{1}{2}-\zeta}}{(1-\theta)m\sqrt{\lambda}}\right)\log\frac{3T}{\delta_1}\\ &+\frac{2\kappa R}{\sqrt{m\lambda}}\log\frac{3T}{\delta_1}\left(8+8\log t+\frac{8\lambda\eta_1 t^{1-\theta}}{1-\theta}+2\kappa^2\eta_1\right)\frac{1}{(\eta_1 t^{1-\theta})^\zeta}.\end{aligned}$$

Rearranging terms, we can prove the second part. ■

In conclusion, we get the following result for the sample variance.

Theorem 5 *Under Assumptions 1, 2 and 3, let $\delta_1,\delta_2\in]0,1[$ and $\frac{9\kappa^2}{m}\log\frac{m}{\delta_2}\leq\lambda\leq\|\mathcal{T}_\rho\|$. Let $\eta_t=\eta_1 t^{-\theta}$ for all $t\in[T]$, with $\eta_1\in]0,\kappa^{-2}]$ and $\theta\in[0,1[$. Then with probability at least $1-\delta_1-\delta_2$, the following holds for all $t\in[T]$:*
1) if $\zeta\geq 1/2$, we have (50).
2) if $\zeta<1/2$, we have (51).

6. Estimating Computational Variance

In this section, we estimate the computational variance, $\mathbb{E}[\|\mathcal{S}_\rho\omega_t - \mathcal{S}_\rho\nu_t\|_\rho^2]$. For this, a series of lemmas is introduced.

6.1 Cumulative Error

We have the following lemma, which shows that the computational variance can be controlled by a sum of weighted empirical risks.

Lemma 20 *We have*

$$\mathbb{E}_{\mathbf{J}}\|\mathcal{S}_\rho\omega_{t+1} - \mathcal{S}_\rho\nu_{t+1}\|_\rho^2 \leq \frac{\kappa^2}{b}\sum_{k=1}^{t}\eta_k^2\left\|\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\right\|^2\mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_k)]. \tag{52}$$

Proof Since ω_{t+1} and ν_{t+1} are given by (4) and (26), respectively,

$$\begin{aligned}\omega_{t+1} - \nu_{t+1} &= (\omega_t - \nu_t) + \eta_t\left\{(\mathcal{T}_{\mathbf{x}}\nu_t - \mathcal{S}_{\mathbf{x}}^*\mathbf{y}) - \frac{1}{b}\sum_{i=b(t-1)+1}^{bt}(\langle\omega_t, x_{j_i}\rangle_H - y_{j_i})x_{j_i}\right\}\\ &= (I - \eta_t\mathcal{T}_{\mathbf{x}})(\omega_t - \nu_t) + \frac{\eta_t}{b}\sum_{i=b(t-1)+1}^{bt}\{(\mathcal{T}_{\mathbf{x}}\omega_t - \mathcal{S}_{\mathbf{x}}^*\mathbf{y}) - (\langle\omega_t, x_{j_i}\rangle_H - y_{j_i})x_{j_i}\}.\end{aligned}$$

Applying this relationship iteratively,

$$\omega_{t+1} - \nu_{t+1} = \Pi_1^t(\mathcal{T}_{\mathbf{x}})(\omega_1 - \nu_1) + \frac{1}{b}\sum_{k=1}^{t}\sum_{i=b(k-1)+1}^{bk}\eta_k\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})M_{k,i},$$

where we denote

$$M_{k,i} = (\mathcal{T}_{\mathbf{x}}\omega_k - \mathcal{S}_{\mathbf{x}}^*\mathbf{y}) - (\langle\omega_k, x_{j_i}\rangle_H - y_{j_i})x_{j_i}. \tag{53}$$

Since $\omega_1 = \nu_1 = 0$, then

$$\omega_{t+1} - \nu_{t+1} = \frac{1}{b}\sum_{k=1}^{t}\sum_{i=b(k-1)+1}^{bk}\eta_k\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})M_{k,i}.$$

Therefore,

$$\begin{aligned}\mathbb{E}_{\mathbf{J}}\|\mathcal{S}_\rho\omega_{t+1} - \mathcal{S}_\rho\nu_{t+1}\|_\rho^2 &= \frac{1}{b^2}\mathbb{E}_{\mathbf{J}}\left\|\sum_{k=1}^{t}\sum_{i=b(k-1)+1}^{bk}\eta_k\mathcal{S}_\rho\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})M_{k,i}\right\|_\rho^2\\ &= \frac{1}{b^2}\sum_{k=1}^{t}\sum_{i=b(k-1)+1}^{bk}\eta_k^2\mathbb{E}_{\mathbf{J}}\left\|\mathcal{S}_\rho\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})M_{k,i}\right\|_\rho^2,\end{aligned} \tag{54}$$

where for the last equality, we use the fact that if $k \neq k'$, or $k = k'$ but $i \neq i'$[4], then

$$\mathbb{E}_{\mathbf{J}}\langle\mathcal{S}_\rho\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})M_{k,i}, \mathcal{S}_\rho\Pi_{k'+1}^t(\mathcal{T}_{\mathbf{x}})M_{k',i'}\rangle_\rho = 0.$$

4. This is possible only when $b \geq 2$.

Indeed, if $k \neq k'$, without loss of generality, we consider the case $k < k'$. Recalling that $M_{k,i}$ is given by (53) and that given any $\mathbf{z}$, ω_k is depending only on $\mathbf{J}_1, \cdots, \mathbf{J}_{k-1}$, we thus have

$$\begin{aligned}&\mathbb{E}_{\mathbf{J}}\langle\mathcal{S}_\rho\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})M_{k,i}, \mathcal{S}_\rho\Pi_{k'+1}^t(\mathcal{T}_{\mathbf{x}})M_{k',i'}\rangle_\rho\\ &= \mathbb{E}_{\mathbf{J}_1,\cdots,\mathbf{J}_{k'-1}}\langle\mathcal{S}_\rho\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})M_{k,i}, \mathcal{S}_\rho\Pi_{k'+1}^t(\mathcal{T}_{\mathbf{x}})\mathbb{E}_{\mathbf{J}_{k'}}[M_{k',i'}]\rangle_\rho = 0.\end{aligned}$$

If $k = k'$ but $i \neq i'$, without loss of generality, we assume $i < i'$. By noting that ω_k is depending only on $\mathbf{J}_1, \cdots, \mathbf{J}_{k-1}$ and $M_{k,i}$ is depending only on ω_k and z_{j_i} (given any sample $\mathbf{z}$),

$$\begin{aligned}&\mathbb{E}_{\mathbf{J}}\langle\mathcal{S}_\rho\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})M_{k,i}, \mathcal{S}_\rho\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})M_{k,i'}\rangle_\rho\\ &= \mathbb{E}_{\mathbf{J}_1,\cdots,\mathbf{J}_{k-1}}\langle\mathcal{S}_\rho\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\mathbb{E}_{j_i}[M_{k,i}], \mathcal{S}_\rho\Pi_{k'+1}^t(\mathcal{T}_{\mathbf{x}})\mathbb{E}_{j_{i'}}[M_{k,i'}]\rangle_\rho = 0.\end{aligned}$$

Using the isometry property (24) to (54),

$$\mathbb{E}_{\mathbf{J}}\left\|\mathcal{S}_\rho\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})M_{k,i}\right\|_\rho^2 = \mathbb{E}_{\mathbf{J}}\left\|\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})M_{k,i}\right\|_H^2 \leq \left\|\mathcal{T}_\rho^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})\right\|^2\mathbb{E}_{\mathbf{J}}\left\|M_{k,i}\right\|_H^2,$$

and by applying the inequality $\mathbb{E}[\|\xi - \mathbb{E}[\xi]\|_H^2] \leq \mathbb{E}[\|\xi\|_H^2]$,

$$\mathbb{E}_{\mathbf{J}}\left\|M_{k,i}\right\|_H^2 \leq \mathbb{E}_{\mathbf{J}}\left\|(\langle\omega_k, x_{j_i}\rangle_H - y_{j_i})x_{j_i}\right\|_H^2 \leq \kappa^2\mathbb{E}_{\mathbf{J}}[(\langle\omega_k, x_{j_i}\rangle_H - y_{j_i})^2] = \kappa^2\mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_k)],$$

where for the last inequality we use (3). Therefore, we can get the desired result. ■

To estimate the computational variance from (52), we need to further develop upper bounds for the empirical risks and the weighted factors, which will be given in the following two subsections.

6.2 Bounding the Empirical Risk

This subsection is devoted to upper bounding $\mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_l)]$. The process relies on some tools from convex analysis and a decomposition related to the weighted averages and the last iterates from (Shamir and Zhang, 2013; Lin et al., 2016b). We begin by introducing the following lemma, a fact based on the square loss' special properties.

Lemma 21 *Given any sample* $\mathbf{z}$*, and* $l \in \mathbb{N}$*, let* $\omega \in H$ *be independent from* $\mathbf{J}_l$*, then*

$$\eta_l\left(\mathcal{E}_{\mathbf{z}}(\omega_l) - \mathcal{E}_{\mathbf{z}}(\omega)\right) \leq \|\omega_l - \omega\|_H^2 - \mathbb{E}_{\mathbf{J}_l}\|\omega_{l+1} - \omega\|_H^2 + \eta_l^2\kappa^2\mathcal{E}_{\mathbf{z}}(\omega_l). \tag{55}$$

Proof Since ω_{t+1} is given be (4), subtracting both sides of (4) by ω, taking the square H-norm, and expanding the inner product,

$$\begin{aligned}\|\omega_{l+1} - \omega\|_H^2 = \|\omega_l - \omega\|_H^2 &+ \frac{\eta_l^2}{b^2}\left\|\sum_{i=b(l-1)+1}^{bl}(\langle\omega_l, x_{j_i}\rangle_H - y_{j_i})x_{j_i}\right\|_H^2\\ &+\frac{2\eta_l}{b}\sum_{i=b(l-1)+1}^{bl}(\langle\omega_l, x_{j_i}\rangle_H - y_{j_i})\langle\omega - \omega_l, x_{j_i}\rangle_H.\end{aligned}$$

By Assumption (3), $\|x_{j_i}\|_H \leq \kappa$, and thus

$$\left\| \sum_{i=b(l-1)+1}^{bl} (\langle \omega_l, x_{j_i}\rangle_H - y_{j_i}) x_{j_i} \right\|_H^2 \leq \left(\sum_{i=b(l-1)+1}^{bl} |\langle \omega_l, x_{j_i}\rangle_H - y_{j_i}| \kappa \right)^2 \leq \kappa^2 b \sum_{i=b(l-1)+1}^{bl} (\langle \omega_l, x_{j_i}\rangle_H - y_{j_i})^2,$$

where for the last inequality, we used Cauchy-Schwarz inequality. Thus,

$$\|\omega_{l+1} - \omega\|_H^2 \leq \|\omega_l - \omega\|_H^2 + \frac{\eta_l^2 \kappa^2}{b} \sum_{i=b(l-1)+1}^{bl} (\langle \omega_l, x_{j_i}\rangle_H - y_{j_i})^2 + \frac{2\eta_l}{b} \sum_{i=b(l-1)+1}^{bl} (\langle \omega_l, x_{j_i}\rangle_H - y_{j_i})(\langle \omega, x_{j_i}\rangle_H - \langle \omega_l, x_{j_i}\rangle_H).$$

Using the basic inequality $a(b-a) \leq (b^2 - a^2)/2, \forall a, b \in \mathbb{R}$,

$$\|\omega_{l+1} - \omega\|_H^2 \leq \|\omega_l - \omega\|_H^2 + \frac{\eta_l^2 \kappa^2}{b} \sum_{i=b(l-1)+1}^{bl} (\langle \omega_l, x_{j_i}\rangle_H - y_{j_i})^2 + \frac{\eta_l}{b} \sum_{i=b(l-1)+1}^{bl} \left((\langle \omega, x_{j_i}\rangle_H - y_{j_i})^2 - (\langle \omega_l, x_{j_i}\rangle_H - y_{j_i})^2 \right).$$

Noting that ω_l and ω are independent from $\mathbf{J}_l$, and taking the expectation on both sides with respect to $\mathbf{J}_l$,

$$\mathbb{E}_{\mathbf{J}_l} \|\omega_{l+1} - \omega\|_H^2 \leq \|\omega_l - \omega\|_H^2 + \eta_l^2 \kappa^2 \mathcal{E}_{\mathbf{z}}(\omega_l) + \eta_l \left(\mathcal{E}_{\mathbf{z}}(\omega) - \mathcal{E}_{\mathbf{z}}(\omega_l) \right),$$

which leads to the desired result by rearranging terms. The proof is complete. ■

Using the above lemma and a decomposition related to the weighted averages and the last iterates from (Shamir and Zhang, 2013; Lin et al., 2016b), we can prove the following relationship.

Lemma 22 *Let $\eta_1 \kappa^2 \leq 1/2$ for all $t \in \mathbb{N}$. Then*

$$\eta_t \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_t)] \leq 4\mathcal{E}_{\mathbf{z}}(0) \frac{1}{t} \sum_{l=1}^{t} \eta_l + 2\kappa^2 \sum_{k=1}^{t-1} \frac{1}{k(k+1)} \sum_{i=t-k}^{t-1} \eta_i^2 \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)]. \tag{56}$$

Proof For $k = 1, \cdots, t-1$,

$$\begin{aligned} & \frac{1}{k} \sum_{i=t-k+1}^{t} \eta_i \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] - \frac{1}{k+1} \sum_{i=t-k}^{t} \eta_i \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] \\ = & \frac{1}{k(k+1)} \left\{ (k+1) \sum_{i=t-k+1}^{t} \eta_i \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] - k \sum_{i=t-k}^{t} \eta_i \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] \right\} \\ = & \frac{1}{k(k+1)} \sum_{i=t-k+1}^{t} (\eta_i \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] - \eta_{t-k} \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_{t-k})]). \end{aligned}$$

Summing over $k = 1, \cdots, t-1$, and rearranging terms, we get (Lin et al., 2016b)

$$\eta_t \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_t)] = \frac{1}{t} \sum_{i=1}^{t} \eta_i \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] + \sum_{k=1}^{t-1} \frac{1}{k(k+1)} \sum_{i=t-k+1}^{t} (\eta_i \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] - \eta_{t-k} \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_{t-k})]).$$

Since $\{\eta_t\}_t$ is decreasing and $\mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_{t-k})]$ is non-negative, the above can be relaxed as

$$\eta_t \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_t)] \leq \frac{1}{t} \sum_{i=1}^{t} \eta_i \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] + \sum_{k=1}^{t-1} \frac{1}{k(k+1)} \sum_{i=t-k+1}^{t} \eta_i \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i) - \mathcal{E}_{\mathbf{z}}(\omega_{t-k})]. \tag{57}$$

In the rest of the proof, we will upper bound the last two terms of the above.

To bound the first term of the right side of (57), we apply Lemma 21 with $\omega = 0$ to get

$$\eta_l \mathbb{E}_{\mathbf{J}} \left(\mathcal{E}_{\mathbf{z}}(\omega_l) - \mathcal{E}_{\mathbf{z}}(0) \right) \leq \mathbb{E}_{\mathbf{J}}[\|\omega_l\|_H^2 - \|\omega_{l+1}\|_H^2] + \eta_l^2 \kappa^2 \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_l)].$$

Rearranging terms,

$$\eta_l (1 - \eta_l \kappa^2) \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_l)] \leq \mathbb{E}_{\mathbf{J}}[\|\omega_l\|_H^2 - \|\omega_{l+1}\|_H^2] + \eta_l \mathcal{E}_{\mathbf{z}}(0).$$

It thus follows from the above and $\eta_l \kappa^2 \leq 1/2$ that

$$\eta_l \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_l)]/2 \leq \mathbb{E}_{\mathbf{J}}[\|\omega_l\|_H^2 - \|\omega_{l+1}\|_H^2] + \eta_l \mathcal{E}_{\mathbf{z}}(0).$$

Summing up over $l = 1, \cdots, t$,

$$\sum_{l=1}^{t} \eta_l \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_l)]/2 \leq \mathbb{E}_{\mathbf{J}}[\|w_1\|_H^2 - \|\omega_{t+1}\|_H^2] + \mathcal{E}_{\mathbf{z}}(0) \sum_{l=1}^{t} \eta_l.$$

Introducing with $\omega_1 = 0, \|\omega_{t+1}\|_H^2 \geq 0$, and then multiplying both sides by $2/t$, we get

$$\frac{1}{t} \sum_{l=1}^{t} \eta_l \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_l)] \leq 2\mathcal{E}_{\mathbf{z}}(0) \frac{1}{t} \sum_{l=1}^{t} \eta_l. \tag{58}$$

It remains to bound the last term of (57). Let $k \in [t-1]$ and $i \in \{t-k, \cdots, t\}$. Note that given the sample $\mathbf{z}$, ω_i is depending only on $\mathbf{J}_1, \cdots, \mathbf{J}_{i-1}$ when $i > 1$ and $\omega_1 = 0$. Thus, we can apply Lemma 21 with $\omega = \omega_{t-k}$ to derive

$$\eta_i \left(\mathcal{E}_{\mathbf{z}}(\omega_i) - \mathcal{E}_{\mathbf{z}}(\omega_{t-k}) \right) \leq \|\omega_i - \omega_{t-k}\|_H^2 - \mathbb{E}_{\mathbf{J}_i} \|\omega_{i+1} - \omega_{t-k}\|_H^2 + \eta_i^2 \kappa^2 \mathcal{E}_{\mathbf{z}}(\omega_i).$$

Therefore,

$$\eta_i \mathbb{E}_{\mathbf{J}} \left[\mathcal{E}_{\mathbf{z}}(\omega_i) - \mathcal{E}_{\mathbf{z}}(\omega_{t-k}) \right] \leq \mathbb{E}_{\mathbf{J}}[\|\omega_i - \omega_{t-k}\|_H^2 - \|\omega_{i+1} - \omega_{t-k}\|_H^2] + \eta_i^2 \kappa^2 \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)].$$

Summing up over $i = t-k, \cdots, t$,

$$\sum_{i=t-k}^{t} \eta_i \mathbb{E}_{\mathbf{J}} \left[\mathcal{E}_{\mathbf{z}}(\omega_i) - \mathcal{E}_{\mathbf{z}}(\omega_{t-k}) \right] \leq \kappa^2 \sum_{i=t-k}^{t} \eta_i^2 \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)].$$

Note that the left hand side is exactly $\sum_{i=t-k+1}^{t} \eta_i \mathbb{E}_{\mathbf{J}} \left[\mathcal{E}_{\mathbf{z}}(\omega_i) - \mathcal{E}_{\mathbf{z}}(\omega_{t-k})\right]$. We thus know that the last term of (57) can be upper bounded by

$$\begin{aligned} & \kappa^2 \sum_{k=1}^{t-1} \frac{1}{k(k+1)} \sum_{i=t-k}^{t} \eta_i^2 \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] \\ = \quad & \kappa^2 \sum_{k=1}^{t-1} \frac{1}{k(k+1)} \sum_{i=t-k}^{t-1} \eta_i^2 \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] + \kappa^2 \eta_t^2 \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_t)] \sum_{k=1}^{t-1} \frac{1}{k(k+1)}. \end{aligned}$$

Using the fact that

$$\sum_{k=1}^{t-1} \frac{1}{k(k+1)} = \sum_{k=1}^{t-1} \left(\frac{1}{k} - \frac{1}{k+1} \right) = 1 - \frac{1}{t} \leq 1,$$

and $\kappa^2 \eta_t \leq 1/2$, we get that the last term of (57) can be bounded as

$$\begin{aligned} & \sum_{k=1}^{t-1} \frac{1}{k(k+1)} \sum_{i=t-k+1}^{t} \eta_i (\mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] - \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_{t-k})]) \\ \leq \quad & \kappa^2 \sum_{k=1}^{t-1} \frac{1}{k(k+1)} \sum_{i=t-k}^{t-1} \eta_i^2 \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)] + \eta_t \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_t)]/2. \end{aligned}$$

Plugging the above and (58) into the decomposition (57), and rearranging terms

$$\eta_t \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_t)]/2 \leq 2\mathcal{E}_{\mathbf{z}}(0) \frac{1}{t} \sum_{l=1}^{t} \eta_l + \kappa^2 \sum_{k=1}^{t-1} \frac{1}{k(k+1)} \sum_{i=t-k}^{t-1} \eta_i^2 \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)],$$

which leads to the desired result by multiplying both sides by 2. The proof is complete. ■

We also need the following lemma, whose proof can be done using an induction argument.

Lemma 23 *Let $\{u_t\}_{t=1}^T$, $\{A_t\}_{t=1}^T$ and $\{B_t\}_{t=1}^T$ be three sequences of non-negative numbers such that $u_1 \leq A_1$ and*

$$u_t \leq A_t + B_t \sup_{i \in [t-1]} u_i, \qquad \forall t \in \{2, 3, \cdots, T\}. \tag{59}$$

Let $\sup_{t \in [T]} B_t \leq B < 1$. Then for all $t \in [T]$,

$$\sup_{k \in [t]} u_k \leq \frac{1}{1-B} \sup_{k \in [t]} A_k. \tag{60}$$

Proof When $t = 1$, (60) holds trivially since $u_1 \leq A_1$ and $B < 1$. Now assume for some $t \in \mathbb{N}$ with $2 \leq t \leq T$,

$$\sup_{i \in [t-1]} u_i \leq \frac{1}{1-B} \sup_{i \in [t-1]} A_i.$$

Then, by (59), the above hypothesis, and $B_t \leq B$, we have

$$u_t \leq A_t + B_t \sup_{i \in [t-1]} u_i \leq A_t + \frac{B_t}{1-B} \sup_{i \in [t-1]} A_i \leq \sup_{i \in [t]} A_i \left(1 + \frac{B_t}{1-B} \right) \leq \sup_{i \in [t]} A_i \frac{1}{1-B}.$$

Consequently,

$$\sup_{k \in [t]} u_k \leq \frac{1}{1-B} \sup_{k \in [t]} A_k,$$

thereby showing that indeed (60) holds for t. By mathematical induction, (60) holds for every $t \in [T]$. The proof is complete. ■

Now we can bound $\mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_k)]$ as follows.

Lemma 24 *Let $\eta_1 \kappa^2 \leq 1/2$ and for all $t \in [T]$ with $t \geq 2$,*

$$\frac{1}{\eta_t} \sum_{k=1}^{t-1} \frac{1}{k(k+1)} \sum_{i=t-k}^{t-1} \eta_i^2 \leq \frac{1}{4\kappa^2}. \tag{61}$$

Then for all $t \in [T]$,

$$\sup_{k \in [t]} \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_k)] \leq 8\mathcal{E}_{\mathbf{z}}(0) \sup_{k \in [t]} \left\{ \frac{1}{\eta_k k} \sum_{l=1}^{k} \eta_l \right\}. \tag{62}$$

Proof By Lemma 22, we have (56). Dividing both sides by η_t, we can relax the inequality as

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_t)] \leq 4\mathcal{E}_{\mathbf{z}}(0) \frac{1}{\eta_t t} \sum_{l=1}^{t} \eta_l + 2\kappa^2 \frac{1}{\eta_t} \sum_{k=1}^{t-1} \frac{1}{k(k+1)} \sum_{i=t-k}^{t-1} \eta_i^2 \sup_{i \in [t-1]} \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_i)].$$

In Lemma 23, we let $u_t = \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_t)]$, $A_t = 4\mathcal{E}_{\mathbf{z}}(0) \frac{1}{\eta_t t} \sum_{l=1}^{t} \eta_l$ and

$$B_t = 2\kappa^2 \frac{1}{\eta_t} \sum_{k=1}^{t-1} \frac{1}{k(k+1)} \sum_{i=t-k}^{t-1} \eta_i^2.$$

Condition (61) guarantees that $\sup_{t \in [T]} B_t \leq 1/2$. Thus, (60) holds, and the desired result follows by plugging with $B = 1/2$. The proof is complete. ■

Finally, we need the following lemma to bound $\mathcal{E}_{\mathbf{z}}(0)$, whose proof follows from applying the Bernstein inequality from Lemma 11.

Lemma 25 *Under Assumption 1, with probability at least $1 - \delta_3$ ($\delta_3 \in]0, 1[$), there holds*

$$\mathcal{E}_{\mathbf{z}}(0) \leq Mv + 2Mv \left(\frac{1}{m} + \frac{\sqrt{2}}{\sqrt{m}} \right) \log \frac{2}{\delta_3}.$$

In particular, if $m \geq 32 \log^2 \frac{2}{\delta_3}$, then

$$\mathcal{E}_{\mathbf{z}}(0) \leq 2Mv. \tag{63}$$

Proof Following from (5),

$$\int_Z y^{2l} d\rho \leq \frac{1}{2} l! M^{l-2} \cdot (2M^2 v), \qquad \forall l \in \mathbb{N},$$

and

$$\int_Z y^2 d\rho \leq Mv.$$

Therefore,

$$\begin{aligned}\int_Z |y^2 - \mathbb{E}y^2|^l d\rho &\leq \int_Z \max(|y|^{2l}, (\mathbb{E}y^2)^l) d\rho \\ &\leq \int_Z (|y|^{2l} + (\mathbb{E}y^2)^l) d\rho \\ &\leq \frac{1}{2} l! M^{l-2} \cdot (2M^2 v) + (Mv)^l \\ &\leq \frac{1}{2} l! (Mv)^{l-2} (2Mv)^2,\end{aligned}$$

where for the last inequality we used $v \geq 1$. Applying Lemma 11, with $\omega_i = y_i^2$ for all $i \in [m]$, $B = Mv$ and $\sigma = 2Mv$, we know that with probability at least $1 - \delta_3$, there holds

$$\frac{1}{n}\sum_{i=1}^n y_i^2 - \int_Z y^2 d\rho \leq 2Mv \left(\frac{1}{m} + \frac{2}{\sqrt{m}}\right) \log \frac{2}{\delta_3}.$$

The proof is complete. ∎

6.3 Bounding $\left\| \mathcal{T}_\rho^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x}) \right\|$

We bound the weighted factor $\left\| \mathcal{T}_\rho^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x}) \right\|$ as follows.

Lemma 26 *Assume (47) holds for some $\lambda > 0$ and $\eta_1 \kappa^2 \leq 1$. Then*

$$\|\mathcal{T}_\rho^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\|^2 \leq \frac{1}{\sum_{i=k+1}^t \eta_i} + 4\lambda.$$

Proof Note that we have

$$\|\mathcal{T}_\rho^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\| \leq \|\mathcal{T}_\rho^{\frac{1}{2}} (\mathcal{T}_\mathbf{x} + \lambda I)^{-\frac{1}{2}}\| \|(\mathcal{T}_\mathbf{x} + \lambda I)^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\|.$$

Using (47), we can relax the above as

$$\|\mathcal{T}_\rho^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\| \leq 2\|(\mathcal{T}_\mathbf{x} + \lambda I)^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\|,$$

which leads to

$$\|\mathcal{T}_\rho^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\|^2 \leq 4\|(\mathcal{T}_\mathbf{x} + \lambda I)^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\|^2.$$

Since

$$\begin{aligned}\|(\mathcal{T}_\mathbf{x} + \lambda I)^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\|^2 &= \|(\mathcal{T}_\mathbf{x} + \lambda I) \Pi_{k+1}^t(\mathcal{T}_\mathbf{x}) \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\| \\ &\leq \|\mathcal{T}_\mathbf{x} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x}) \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\| + \lambda \\ &= \|\mathcal{T}_\mathbf{x}^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\|^2 + \lambda,\end{aligned}$$

and with $\eta_t \kappa^2 \leq 1$, $\|\mathcal{T}_\mathbf{x}\| \leq \mathrm{tr}(\mathcal{T}_\mathbf{x}) \leq \kappa^2$, by Lemma 15,

$$\|\mathcal{T}_\mathbf{x}^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x})\|^2 \leq \frac{1}{2\mathrm{e}\sum_{i=k+1}^t \eta_i} \leq \frac{1}{4\sum_{i=k+1}^t \eta_i},$$

we thus derive the desired result. The proof is complete. ∎

6.4 Deriving Error Bounds

With Lemmas 20–26, we are ready to estimate the computational variance , $\mathbb{E}_\mathbf{J}\|\mathcal{S}_\rho \omega_{t+1} - \mathcal{S}_\rho \nu_{t+1}\|_\rho^2$, as follows.

Proposition 5 *Under Assumption 1, assume (47) holds for some $\lambda > 0$, $\eta_1 \kappa^2 \leq 1/2$, (61) and (63). Then, we have for all $t \in [T]$,*

$$\mathbb{E}_\mathbf{J}\|\mathcal{S}_\rho \omega_{t+1} - \mathcal{S}_\rho \nu_{t+1}\|_\rho^2 \leq \frac{16Mv\kappa^2}{b} \sup_{k\in[t]} \left\{ \frac{1}{\eta_k k} \sum_{l=1}^k \eta_l \right\} \left(\sum_{k=1}^{t-1} \frac{\eta_k^2}{\sum_{i=k+1}^t \eta_i} + 4\lambda \sum_{k=1}^{t-1} \eta_k^2 + \eta_t^2 \kappa^2 \right). \tag{64}$$

Proof According to Lemmas 20 and 24, we have (52) and (62). It thus follows that

$$\mathbb{E}_\mathbf{J}\|\mathcal{S}_\rho \omega_{t+1} - \mathcal{S}_\rho \nu_{t+1}\|_\rho^2 \leq \frac{8\mathcal{E}_\mathbf{z}(0)\kappa^2}{b} \sup_{k\in[t]} \left\{ \frac{1}{\eta_k k} \sum_{l=1}^k \eta_l \right\} \sum_{k=1}^t \eta_k^2 \left\| \mathcal{T}_\rho^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x}) \right\|^2.$$

Now the proof can be finished by applying Lemma 26 which tells us that

$$\begin{aligned}\sum_{k=1}^t \eta_k^2 \left\| \mathcal{T}_\rho^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x}) \right\|^2 &= \sum_{k=1}^{t-1} \eta_k^2 \left\| \mathcal{T}_\rho^{\frac{1}{2}} \Pi_{k+1}^t(\mathcal{T}_\mathbf{x}) \right\|^2 + \eta_t^2 \left\| \mathcal{T}_\rho^{\frac{1}{2}} \right\|^2 \\ &\leq \sum_{k=1}^{t-1} \frac{\eta_k^2}{\sum_{i=k+1}^t \eta_i} + 4\lambda \sum_{k=1}^{t-1} \eta_k^2 + \eta_t^2 \kappa^2,\end{aligned}$$

and (63) to the above inequality. The proof is complete. ∎

Setting $\eta_t = \eta_1 t^{-\theta}$ for some appropriate η_1 and θ in the above proposition, we get the following explicitly upper bounds for $\mathbb{E}_\mathbf{J}\|\mathcal{S}_\rho \omega_t - \mathcal{S}_\rho \omega_t\|_\rho^2$.

Proposition 6 *Under Assumption 1, assume (47) holds for some $\lambda > 0$ and (63). Let $\eta_t = \eta_1 t^{-\theta}$ for all $t \in [T]$, with $\theta \in [0, 1[$ and*

$$0 < \eta_1 \leq \frac{t^{\min(\theta, 1-\theta)}}{8\kappa^2(\log t + 1)}, \qquad \forall t \in [T]. \tag{65}$$

Then, for all $t \in [T]$,

$$\mathbb{E}_\mathbf{J}\|\omega_{t+1} - \nu_{t+1}\|_\rho^2 \leq \frac{16Mv\kappa^2}{b(1-\theta)} \left(5\eta_1 t^{-\min(\theta, 1-\theta)} + 8\lambda\eta_1^2 t^{(1-2\theta)_+} \right) (1 \vee \log t). \tag{66}$$

Proof We will use Proposition 5 to prove the result. Thus, we need to verify the condition (61). Note that

$$\sum_{k=1}^{t-1}\frac{1}{k(k+1)}\sum_{i=t-k}^{t-1}\eta_i^2=\sum_{i=1}^{t-1}\eta_i^2\sum_{k=t-i}^{t-1}\frac{1}{k(k+1)}=\sum_{i=1}^{t-1}\eta_i^2\left(\frac{1}{t-i}-\frac{1}{t}\right)\le\sum_{i=1}^{t-1}\frac{\eta_i^2}{t-i}.$$

Substituting with $\eta_i=\eta i^{-\theta}$, and by Lemma 14,

$$\sum_{k=1}^{t-1}\frac{1}{k(k+1)}\sum_{i=t-k}^{t-1}\eta_i^2\le\eta_1^2\sum_{i=1}^{t-1}\frac{i^{-2\theta}}{t-i}\le 2\eta_1^2 t^{-\min(2\theta,1)}(\log t+1).$$

Dividing both sides by $\eta_t\ (=\eta_1 t^{-\theta})$, and then using (65),

$$\frac{1}{\eta_t}\sum_{k=1}^{t-1}\frac{1}{k(k+1)}\sum_{i=t-k}^{t-1}\eta_i^2\le 2\eta_1 t^{-\min(\theta,1-\theta)}(\log t+1)\le\frac{1}{4\kappa^2}.$$

This verifies (61). Note also that by taking $t=1$ in (65), for all $t\in[T]$,

$$\eta_t\kappa^2\le\eta_1\kappa^2\le\frac{1}{8\kappa^2}\le\frac{1}{2}.$$

We thus can apply Proposition 5 to derive (64). What remains is to control the right hand side of (64). Since

$$\sum_{k=1}^{t-1}\frac{\eta_k^2}{\sum_{i=k+1}^{t}\eta_i}=\eta_1\sum_{k=1}^{t-1}\frac{k^{-2\theta}}{\sum_{i=k+1}^{t}i^{-\theta}}\le\eta_1\sum_{k=1}^{t-1}\frac{k^{-2\theta}}{(t-k)t^{-\theta}},$$

combining with Lemma 14,

$$\sum_{k=1}^{t-1}\frac{\eta_k^2}{\sum_{i=k+1}^{t}\eta_i}\le 2\eta_1 t^{-\min(\theta,1-\theta)}(\log t+1).$$

Also, by Lemma 12,

$$\frac{1}{\eta_k k}\sum_{l=1}^{k}\eta_l=\frac{1}{k^{1-\theta}}\sum_{l=1}^{k}l^{-\theta}\le\frac{1}{1-\theta},$$

and by Lemma 13,

$$\sum_{k=1}^{t-1}\eta_k^2=\eta_1^2\sum_{k=1}^{t-1}k^{-2\theta}\le\eta_1^2 t^{\max(1-2\theta,0)}(\log t+1).$$

Introducing the last three estimates into (64) and using that $\eta_t^2\kappa^2\le\eta_1 t^{-\theta}$ by (65), we get the desired result. The proof is complete. ■

Collect some of the above analysis, we get the following result for the computational variance.

Theorem 6 *Under Assumptions 1, let* $\delta_2\in]0,1[$, $\frac{9\kappa^2}{m}\log\frac{m}{\delta_2}\le\lambda\le\|\mathcal{T}_\rho\|$, $\delta_3\in]0,1[$, $m\ge 32\log^2\frac{2}{\delta_3}$, *and* $\eta_t=\eta_1 t^{-\theta}$ *for all* $t\in[T]$, *with* $\theta\in[0,1[$ *and* η_1 *such that (65). Then, with probability at least* $1-\delta_2-\delta_3$, *(66) holds for all* $t\in[T]$.

7. Deriving Total Error Bounds

The purpose of this section is to derive total error bounds.

7.1 Attainable Case

We have the following general theorem for $\zeta\ge 1/2$, with which we prove our main results stated in Section 3.

Theorem 7 *Under Assumptions 1, 2 and 3, let* $\zeta\ge 1/2$, $T\in\mathbb{N}$ *with* $T\ge 3$, $\delta\in]0,1[$, $\eta_t=\eta\kappa^{-2}t^{-\theta}$ *for all* $t\in[T]$, *with* $\theta\in[0,1[$ *and* η *such that*

$$0<\eta\le\frac{t^{\min(\theta,1-\theta)}}{8(\log t+1)},\qquad\forall t\in[T].\tag{67}$$

If for some $\epsilon\in]0,1]$,

$$m\ge\left(\frac{18\kappa^2}{\epsilon\|\mathcal{T}_\rho\|}\log\left(\frac{27\kappa^2}{\epsilon\|\mathcal{T}_\rho\|\delta}\right)\right)^{1/\epsilon},\tag{68}$$

then the following holds with probability at least $1-\delta$: *for all* $t\in[T]$,

$$\begin{aligned}\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{t+1})]-\inf_H\mathcal{E}\le{}& q_1(\eta t^{1-\theta})^{-2\zeta}+q_2 m^{\gamma(1-\epsilon)-1}(1\vee\eta^2 m^{2\epsilon-2}t^{2-2\theta})(\log T)^2\log^2\frac{12}{\delta}\\&+q_3\eta b^{-1}(t^{-\min(\theta,1-\theta)}\vee m^{\epsilon-1}\eta t^{(1-2\theta)_+})\log T.\end{aligned}\tag{69}$$

Here, $q_1=2R^2\zeta^{2\zeta}$, $q_2=\frac{10^4(R\kappa^{2\zeta}+\sqrt{M})^2(\kappa/\sqrt{\|\mathcal{T}_\rho\|}+\sqrt{2\sqrt{v}c_\gamma/\|\mathcal{T}_\rho\|^\gamma})^2}{(1-\theta)^2}$, *and* $q_3=\frac{208Mv}{1-\theta}$.

Proof Let $\lambda=\|\mathcal{T}_\rho\|m^{\epsilon-1}$. Clearly, $\lambda\le\|\mathcal{T}_\rho\|$. For any $A\ge 0$ and $B\ge 1$, by applying (32) with $\zeta=1, x=(Bm)^\epsilon$ and $c=\frac{\epsilon}{2AB^\epsilon}$,

$$A\log(Bm)=\frac{A}{\epsilon}\log((Bm)^\epsilon)\le\frac{A}{\epsilon}\log\left(\frac{2AB^\epsilon}{\mathrm{e}\epsilon}\right)+\frac{1}{2}m^\epsilon\le\frac{A}{\epsilon}\log\left(\frac{AB}{\epsilon}\right)+\frac{1}{2}m^\epsilon.\tag{70}$$

Using the above inequality with $A=\frac{9\kappa^2}{\|\mathcal{T}_\rho\|}$ and $B=\frac{1}{\delta_2}$, one can prove that the condition (68) ensures that $\frac{9\kappa^2}{m}\log\frac{m}{\delta_2}\le\lambda$ is satisfied with $\delta_2=\frac{\delta}{3}$, Therefore, by Lemma 19, (47) holds with probability at least $1-\delta_2$. Similarly the condition (68) implies that $m\ge 32\log^2\frac{2}{\delta_3}$ is satisfied with $\delta_3=\frac{\delta}{3}$, and thus by Lemma 25, (63) holds with probability at least $1-\delta_3$. Combining with Lemma 18, by taking the union bound, we know that with probability at least $1-\delta_1-\delta_2-\delta_3$, (47), (63) and (40) hold for all $k\in[T]$. Now, we can apply Propositions 4 and 6 to get (50) and (66). Noting that by (67), $\sqrt{2}\eta\le 1$, and by a simple calculation, we derive from (50) that

$$\begin{aligned}&\|\mathcal{S}_\rho\nu_{t+1}-\mathcal{S}_\rho\mu_{t+1}\|_\rho^2\\\le&\frac{4624(R\kappa^{2\zeta}+\sqrt{M})^2(\kappa/\sqrt{\|\mathcal{T}_\rho\|}+\sqrt{2\sqrt{v}c_\gamma/\|\mathcal{T}_\rho\|^\gamma})^2}{(1-\theta)^2}m^{\gamma(1-\epsilon)-1}(1\vee\lambda^2\eta^2\kappa^{-4}t^{2-2\theta}\vee\log^2 t)\log^2\frac{4}{\delta_1}\\\le&\frac{4624(R\kappa^{2\zeta}+\sqrt{M})^2(\kappa/\sqrt{\|\mathcal{T}_\rho\|}+\sqrt{2\sqrt{v}c_\gamma/\|\mathcal{T}_\rho\|^\gamma})^2}{(1-\theta)^2}m^{\gamma(1-\epsilon)-1}(1\vee\eta^2 m^{2\epsilon-2}t^{2-2\theta})(\log T)^2\log^2\frac{4}{\delta_1},\end{aligned}$$

where for the last inequality, we used $\|\mathcal{T}_\rho\|\le\kappa^2$. Similarly, by a simple calculation, we get from (66) that

$$\begin{aligned}\mathbb{E}_{\mathbf{J}}\|\mathcal{S}_\rho\omega_{t+1}-\mathcal{S}_\rho\nu_{t+1}\|_\rho^2&\le\frac{208Mv}{b(1-\theta)}(\eta t^{-\min(\theta,1-\theta)}\vee\lambda\eta^2\kappa^{-2}t^{(1-2\theta)_+})(1\vee\log t)\\&\le\frac{208Mv}{b(1-\theta)}(\eta t^{-\min(\theta,1-\theta)}\vee m^{\epsilon-1}\eta^2 t^{(1-2\theta)_+})\log T.\end{aligned}$$

Letting $\delta_1 = \frac{\delta}{3}$, and introducing the above estimates and (34) into (23), we get (69). The proof is complete. ■

Proof [of Theorem 1] By choosing $\epsilon = 1 - \frac{1}{2\zeta+\gamma}$ and $\theta = 0$ in Theorem 7, then the condition (68) reduces to $m \geq m_\delta$, where

$$m_\delta = \left(\frac{18\kappa^2 p}{\|\mathcal{T}_\rho\|}\log\left(\frac{27\kappa^2 p}{\|\mathcal{T}_\rho\|\delta}\right)\right)^p, \quad p = \frac{2\zeta+\gamma}{2\zeta+\gamma-1}. \tag{71}$$

The desired result thus follows by applying Theorem 7. ■

7.2 Non Attainable Case

For the non-attainable case, we have the following general results on generalization errors for SGM.

Theorem 8 *Under Assumptions 1, 2 and 3, let $\zeta \leq 1/2$, $T \in \mathbb{N}$ with $T \geq 3$, $\delta \in]0,1[$, $\eta_t = \eta\kappa^{-2}t^{-\theta}$ for all $t \in [T]$, with $\theta \in [0,1[$ and η such that (67) and for some $\epsilon \in]0,1]$, (68) holds. Then the following holds with probability at least $1-\delta$: for all $t \in [T]$,*

$$\begin{aligned}\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{t+1})] - \inf_H \mathcal{E} \lesssim &\left((\eta t^{1-\theta})^{-2\zeta} + m^{\gamma(1-\epsilon)-1}\right)(1 \vee \eta m^{\epsilon-1}t^{1-\theta})^3 \log^4 T \log^2\frac{1}{\delta} \\ &+\eta b^{-1}(t^{-\min(\theta,1-\theta)} \vee m^{\epsilon-1}\eta t^{(1-2\theta)_+})\log T.\end{aligned} \tag{72}$$

Here, the constant in the upper bounds is positive and depends only on $\kappa^2, \|\mathcal{T}_\rho\|, M, v, \zeta, R, c_\gamma$, γ and $\|f_{\mathcal{H}}\|_\infty$.

Proof The proof is similar to that for Theorem 7. We include the sketch only and omit the constants appeared. Similar to the proof of Theorem 7, with $\lambda = \|\mathcal{T}_\rho\|m^{\epsilon-1}$, one can prove that with probability at least $1-\delta_1-\delta_2-\delta_3$, (47), (63) and (41) hold for all $k \in [T]$. Now, we can apply Propositions 4 and 6 to get (51) and (66). Noting that by (65), $\sqrt{2}\eta \leq 1$, and by a simple calculation, we derive from (51) that

$$\begin{aligned}&\|\mathcal{S}_\rho\nu_{t+1} - \mathcal{S}_\rho\mu_{t+1}\|_\rho^2 \\ \lesssim& m^{\gamma(1-\epsilon)-1}(1 \vee \eta^2 m^{2\epsilon-2}t^{2-2\theta})\log^4 T\log^2\frac{1}{\delta} + (\eta t^{1-\theta})^{-2\zeta}(1 \vee \eta t^{1-\theta}m^{-1})(1 \vee \eta^2 m^{2\epsilon-2}t^{2-2\theta})\log^4 T\log^2\frac{1}{\delta} \\ \lesssim& m^{\gamma(1-\epsilon)-1}(1 \vee \eta^2 m^{2\epsilon-2}t^{2-2\theta})\log^4 T\log^2\frac{1}{\delta} + (\eta t^{1-\theta})^{-2\zeta}(1 \vee \eta m^{\epsilon-1}t^{1-\theta})^3\log^4 T\log^2\frac{1}{\delta}.\end{aligned}$$

The rest of the proof parallelizes to that for Theorem 7. ■

Now, we are in a position to prove Theorem 3.

Proof [of Theorem 3] The second part of the theorem follows directly from applying Theorem 8 with $\theta = 0$. The first part can be proved by applying Theorem 8 with $\theta = 0$ and $\epsilon = 1 - \frac{1}{2\zeta+\gamma}$, combining with the same argument from the proof of Theorem 1 to verify the condition (68). We omit the details. ■

7.3 Batch GM

Following the proof of Theorems 1 and 3, we know that the following results hold for batch GM, from which one can prove Theorem 4.

Theorem 9 *Under Assumptions 1, 2 and 3, set $\eta_t = \eta\kappa^{-2}$ with $\eta \leq 1$, for all $t \in [m]$. With probability at least $1-\delta$ $(0 < \delta < 1)$, the following holds for the learning sequence generated by (10):*
1) if $\zeta > 1/2$ and $m \geq m_\delta$ with m_δ given by (71), then

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{t+1})] - \inf_H \mathcal{E} \lesssim (\eta t)^{-2\zeta} + m^{-\frac{2\zeta}{2\zeta+\gamma}}(1 + m^{-\frac{1}{2\zeta+\gamma}}\eta t)^2\log^2 T\log^2\frac{1}{\delta}; \tag{73}$$

2) if $\zeta \leq 1/2$, $2\zeta+\gamma > 1$ and $m \geq m_\delta$ with m_δ given by (71), then

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{t+1})] - \inf_H \mathcal{E} \lesssim \left((\eta t)^{-2\zeta} + m^{-\frac{2\zeta}{2\zeta+\gamma}}\right)(1 \vee m^{-\frac{1}{2\zeta+\gamma}}\eta t)^3\log^4 T\log^2\frac{1}{\delta};$$

3) if $2\zeta+\gamma \leq 1$ and for some $\epsilon \in]0,1]$, (68) hold, then

$$\mathbb{E}_{\mathbf{J}}[\mathcal{E}(\omega_{t+1})] - \inf_H \mathcal{E} \lesssim \left((\eta t)^{-2\zeta} + m^{\gamma(1-\epsilon)-1}\right)(1 \vee \eta m^{\epsilon-1}t)^3\log^4 T\log^2\frac{1}{\delta}.$$

Here, all the constants in the upper bounds are positive and depend only on $\kappa^2, \|\mathcal{T}_\rho\|, M, v, \zeta, R, c_\gamma$ and γ (and also on $\|f_{\mathcal{H}}\|_\infty$ when $\zeta < 1/2$) .

8. Convergence in H-norm

In this section, we will give convergence results in H-norm for Algorithm 1 in the attainable case. For the sake of simplicity, we will only consider a fixed step-size sequence, i.e, $\eta_t = \eta$ for all t.

Using a similar procedure as that for (23), we can prove the following error decomposition,

$$\mathbb{E}_{\mathbf{J}}[\|\omega_t - \omega^\dagger\|_H^2] \lesssim \|\mu_t - \omega^\dagger\|_H^2 + \|\mu_t - \nu_t\|_H^2 + \mathbb{E}_{\mathbf{J}}[\|\omega_t - \nu_t\|_H^2]. \tag{74}$$

To estimate the bias term, $\|\mu_t - \omega^\dagger\|_H^2$, we introduce the following lemma from (Yao et al., 2007; Rosasco and Villa, 2015). Its proof is similar as that for (34) and will be given in Appendix C for the sake of completeness.

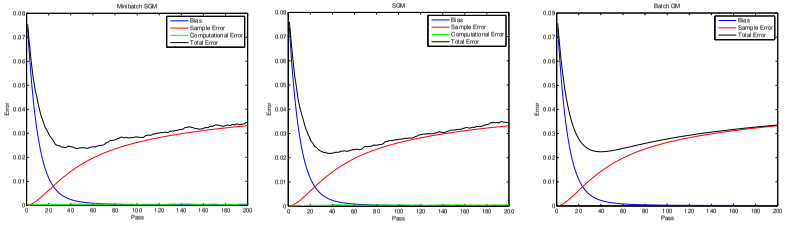
Lemma 27 *Under Assumption 2, let $\zeta \geq 1/2$ and $\eta_t = \eta$ for all $t \in \mathbb{N}$, with $\eta \in]0, \kappa^{-2}]$, then*

$$\|\mu_{t+1} - \omega^\dagger\|_H \leq R\left(\frac{\zeta-1/2}{\eta t}\right)^{\zeta-1/2}. \tag{75}$$

To estimate the sample variance term, $\|\mu_t - \nu_t\|_H^2$, we use (39) and get that

$$\begin{aligned}\|\nu_{t+1} - \mu_{t+1}\|_H &= \left\|\sum_{k=1}^t \eta_k \Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k\right\|_H \\ \leq \sum_{k=1}^t \eta_k \left\|\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}\right\| \left\|\mathcal{T}_{\rho,\lambda}^{-\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k\right\|_H &\leq \frac{1}{\sqrt{\lambda}}\sum_{k=1}^t \eta_k \left\|\mathcal{T}_{\rho,\lambda}^{\frac{1}{2}}\Pi_{k+1}^t(\mathcal{T}_{\mathbf{x}})N_k\right\|_H.\end{aligned}$$

From the proof of Theorem 5, we know that $\sum_{k=1}^{t} \eta_k \left\| \mathcal{T}_{\rho,\lambda}^{\frac{1}{2}} \Pi_{k+1}^{t}(\mathcal{T}_{\mathbf{x}}) N_k \right\|_H$ is upper bounded by the right-hand side of (50). With $\eta_t = \eta$ and $\lambda = \|\mathcal{T}_\rho\| m^{-\frac{1}{2\zeta+\gamma}}$, we thus have

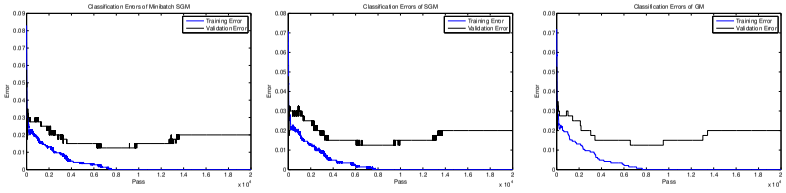


$$\|\nu_{t+1} - \mu_{t+1}\|_H \lesssim m^{-\frac{\zeta-1/2}{2\zeta+\gamma}} (1 + m^{-\frac{1}{2\zeta+\gamma}} \eta t) \log t \log \frac{1}{\delta}. \tag{76}$$

Finally, for the computational variance term, $\mathbb{E}_{\mathbf{J}}[\|\omega_t - \nu_t\|_H^2]$, we use a same procedure as that for (52) to get

$$\mathbb{E}_{\mathbf{J}} \|\omega_{t+1} - \nu_{t+1}\|_H^2 \leq \frac{\kappa^2}{b} \sum_{k=1}^{t} \eta^2 \left\| \Pi_{k+1}^{t}(\mathcal{T}_{\mathbf{x}}) \right\|^2 \mathbb{E}_{\mathbf{J}}[\mathcal{E}_{\mathbf{z}}(\omega_k)] \lesssim \frac{\eta^2 t}{b}, \tag{77}$$

where we used (62) and (63) in the last inequality. Introducing (75), (76) and (77) into the error decomposition (74), we can prove Theorem 2.



9. Numerical Simulations

(a) Minibatch SGM (b) SGM (c) Batch GM

Figure 1: Error decompositions for gradient-based learning algorithms on *synthesis data*, where $m = 100$.

In order to illustrate our theoretical results and the error decomposition, we first performed some simulations on a simple problem. We constructed $m = 100$ i.i.d. training examples of the form $y = f_\rho(x_i) + \omega_i$. Here, the regression function is $f_\rho(x) = |x - 1/2| - 1/2$, the input point x_i is

(a) Minibatch SGM (b) SGM (c) Batch GM

Figure 2: Misclassification Errors for gradient-based learning algorithms on *BreastCancer* dataset.

uniformly distributed in $[0, 1]$, and ω_i is a Gaussian noise with zero mean and standard deviation 1, for each $i \in [m]$. We perform three experiments with the same H, a RKHS associated with a Gaussian kernel $K(x, x') = \exp(-(x-x')^2/(2\sigma^2))$ where $\sigma = 0.2$. In the first experiment, we run mini-batch SGM, where the mini-batch size $b = \sqrt{m}$, and the step-size $\eta_t = 1/(8\sqrt{m})$. In the second experiment, we run simple SGM where the step-size is fixed as $\eta_t = 1/(8m)$, while in the third experiment, we run batch GM using the fixed step-size $\eta_t = 1/8$. For mini-batch SGM and SGM, the total error $\|\mathcal{S}_\rho \omega_t - f_\rho\|_{L^2_{\hat{\rho}}}^2$, the bias $\|\mathcal{S}_\rho \hat{\mu}_t - f_\rho\|_{L^2_{\hat{\rho}}}^2$, the sample variance $\|\mathcal{S}_\rho \nu_t - \mathcal{S}_\rho \hat{\mu}_t\|_{L^2_{\hat{\rho}}}^2$ and the computational variance $\|\mathcal{S}_\rho \omega_t - \mathcal{S}_\rho \nu_t\|_{L^2_{\hat{\rho}}}^2$, averaged over 50 trials, are depicted in Figures 1a and 1b, respectively. For batch GM, the total error $\|\mathcal{S}_\rho \nu_t - f_\rho\|_{L^2_{\hat{\rho}}}^2$, the bias $\|\mathcal{S}_\rho \hat{\mu}_t - f_\rho\|_{L^2_{\hat{\rho}}}^2$ and the sample variance $\|\mathcal{S}_\rho \nu_t - \hat{\mu}_t\|_{L^2_{\hat{\rho}}}^2$, averaged over 50 trials are depicted in Figure 1c. Here, we replace the unknown marginal distribution ρ_X by an empirical measure $\hat{\rho} = \frac{1}{2000} \sum_{i=1}^{2000} \delta_{\hat{x}_i}$, where each $\hat{x}_i$ is uniformly distributed in $[0, 1]$. From Figure 1a or 1b, we see that as the number of passes increases[5], the bias decreases, while the sample error increases. Furthermore, we see that in comparisons with the bias and the sample error, the computational error is negligible. In all these experiments, the minimal total error is achieved when the bias and the sample error are balanced. These empirical results show the effects of the three terms from the error decomposition, and complement the derived bound (11), as well as the regularization effect of the number of passes over the data. Finally, we tested the simple SGM, mini-batch SGM, and batch GM, using similar step-sizes as those in the first simulation, on the *BreastCancer* dataset[6]. The classification errors on the training set and the testing set of these three algorithms are depicted in Figure 2. We see that all of these algorithms perform similarly, which complement the bounds in Corollaries 3, 4 and 7.

Appendices

A. Learning with Kernel Methods

Let the input space Ξ be a closed subset of Euclidean space $\mathbb{R}^d$, the output space $Y \subseteq \mathbb{R}$. Let μ be an unknown but fixed Borel probability measure on $\Xi \times Y$. Assume that $\{(\xi_i, y_i)\}_{i=1}^m$ are i.i.d. from the distribution μ. A reproducing kernel K is a symmetric function $K : \Xi \times \Xi \to \mathbb{R}$ such that $(K(u_i, u_j))_{i,j=1}^\ell$ is positive semidefinite for any finite set of points $\{u_i\}_{i=1}^\ell$ in Ξ. The kernel K defines a reproducing kernel Hilbert space (RKHS) $(\mathcal{H}_K, \|\cdot\|_K)$ as the completion of the linear span of the set $\{K_\xi(\cdot) := K(\xi, \cdot) : \xi \in \Xi\}$ with respect to the inner product $\langle K_\xi, K_u \rangle_K := K(\xi, u)$. For any $f \in \mathcal{H}_K$, the reproducing property holds: $f(\xi) = \langle K_\xi, f \rangle_K$.

5. Note that the terminology 'running the algorithm with p passes' means 'running the algorithm with $\lceil mp/b \rceil$ iterations', where b is the mini-batch size.
6. `https://archive.ics.uci.edu/ml/datasets/`

Example 1 (Sobolev Spaces) *Let $X = [0, 1]$ and the kernel*

$$K(x, x') = \begin{cases} (1-y)x, & x \le y; \\ (1-x)y, & x \ge y. \end{cases}$$

Then the kernel induces a Sobolev Space $H = \{f : X \to \mathbb{R} | f$ is absolutely continuous , $f(0) = f(1) = 0, f \in L^2(X)\}$.

In learning with kernel methods, one considers the following minimization problem

$$\inf_{f \in \mathcal{H}_K} \int_{\Xi \times Y} (f(\xi) - y)^2 d\mu(\xi, y).$$

Since $f(\xi) = \langle K_\xi, f \rangle$ by the reproducing property, the above can be rewritten as

$$\inf_{f \in \mathcal{H}_K} \int_{\Xi \times Y} (\langle f, K_\xi \rangle - y)^2 d\mu(\xi, y).$$

Letting $X = \{K_\xi : \xi \in \Xi\}$ and defining another probability measure $\rho(K_\xi, y) = \mu(\xi, y)$, the above reduces to the learning setting in Section 2.

B. Further Corollaries for SGM in the non-attainable case

In this section, we state the convergence results for the SGM with different parameter choices similar as those in Corollaries 5–7, in the non-attainable case. These results are direct consequences of Theorem 3.

Corollary 28 *Under Assumptions 1, 2 and 3, let $\zeta \le 1/2$, $\delta \in]0, 1[$, $b = 1$, and $\eta_t \simeq m^{-\frac{2\zeta}{(2\zeta+\gamma)\vee 1}}$ for all $t \in [m^2]$. With probability at least $1 - \delta$, the following holds:*
1) if $2\zeta + \gamma > 1$, $m \ge m_\delta$ and $T^* = \lceil m^{\frac{2\zeta+1}{2\zeta+\gamma}} \rceil$, then we have (18);
2) if $2\zeta + \gamma \le 1$, and for some $\epsilon \in]0, 1[$, $m \ge m_{\delta,\epsilon}$, and $T^* = \lceil m^{1+2\zeta-\epsilon} \rceil$, then we have (19).

Corollary 29 *Under Assumptions 1, 2 and 3, let $\zeta \le 1/2$, $\delta \in]0, 1[$, $b \simeq m^{\frac{2\zeta}{(2\zeta+\gamma)\vee 1}}$, and $\eta_t \simeq \frac{1}{\log m}$ for all $t \in [m]$. With probability at least $1 - \delta$, the following holds:*
1) if $2\zeta + \gamma > 1$, $m \ge m_\delta$ and $T^* = \lceil m^{\frac{1}{2\zeta+\gamma}} \rceil$, then we have (18);
2) if $2\zeta + \gamma \le 1$, and for some $\epsilon \in]0, 1[$, $m \ge m_{\delta,\epsilon}$, and $T^* = \lceil m^{1-\epsilon} \rceil$, then we have (19).

Corollary 30 *Under Assumptions 1, 2 and 3, let $\zeta \le 1/2$, $\delta \in]0, 1[$, $b = m$ and $\eta_t \simeq \frac{1}{\log m}$ for all $t \in [m]$. With probability at least $1 - \delta$, the following holds:*
1) if $2\zeta + \gamma > 1$, $m \ge m_\delta$ and $T^* = \lceil m^{\frac{1}{2\zeta+\gamma}} \rceil$, then we have (18);
2) if $2\zeta + \gamma \le 1$, and for some $\epsilon \in]0, 1[$, $m \ge m_{\delta,\epsilon}$, and $T^* = \lceil m^{1-\epsilon} \rceil$, then we have (19).

C. Proofs for Lemmas

Proof [of Lemma 12] Note that

$$\sum_{k=1}^{t} k^{-\theta} \le 1 + \sum_{k=2}^{t} \int_{k-1}^{k} u^{-\theta} du = 1 + \int_1^t u^{-\theta} du = \frac{t^{1-\theta} - \theta}{1 - \theta},$$

which leads to the first part of the desired result. Similarly,

$$\sum_{k=1}^{t} k^{-\theta} \ge \sum_{k=1}^{t} \int_{k}^{k+1} u^{-\theta} du = \int_1^{t+1} u^{-\theta} du = \frac{(t+1)^{1-\theta} - 1}{1 - \theta},$$

and by mean value theorem, $(t+1)^{1-\theta} - 1 \ge (1-\theta)t(t+1)^{-\theta} \ge (1-\theta)t^{1-\theta}/2$. This proves the second part of the desired result. The proof is complete. ■

Proof [of Lemma 13] Note that

$$\sum_{k=1}^{t} k^{-\theta} = \sum_{k=1}^{t} k^{-1} k^{1-\theta} \le t^{\max(1-\theta, 0)} \sum_{k=1}^{t} k^{-1},$$

and

$$\sum_{k=1}^{t} k^{-1} \le 1 + \sum_{k=2}^{t} \int_{k-1}^{k} u^{-1} du = 1 + \log t.$$

■

Proof [of Lemma 14] Note that

$$\sum_{k=1}^{t-1} \frac{1}{t-k} k^{-q} = \sum_{k=1}^{t-1} \frac{k^{1-q}}{(t-k)k} \le t^{\max(1-q, 0)} \sum_{k=1}^{t-1} \frac{1}{(t-k)k},$$

and that by Lemma 13,

$$\sum_{k=1}^{t-1} \frac{1}{(t-k)k} = \frac{1}{t} \sum_{k=1}^{t-1} \left(\frac{1}{t-k} + \frac{1}{k} \right) = \frac{2}{t} \sum_{k=1}^{t-1} \frac{1}{k} \le \frac{2}{t}(1 + \log t).$$

■

Proof [of Proposition 2] Since μ_{t+1} is given by (25), introducing with (27),

$$\mu_{t+1} = \mu_t - \eta_t (\mathcal{T}_\rho \mu_t - \mathcal{S}_\rho^* f_\mathcal{H}). \tag{78}$$

Thus,

$$\mathcal{S}_\rho \mu_{t+1} = \mathcal{S}_\rho \mu_t - \eta_t \mathcal{S}_\rho (\mathcal{T}_\rho \mu_t - \mathcal{S}_\rho^* f_\mathcal{H}) = \mathcal{S}_\rho \mu_t - \eta_t \mathcal{L}_\rho (\mathcal{S}_\rho \mu_t - f_\mathcal{H}). \tag{79}$$

Subtracting both sides by $f_\mathcal{H}$,

$$\mathcal{S}_\rho \mu_{t+1} - f_\mathcal{H} = (I - \eta_t \mathcal{L}_\rho)(\mathcal{S}_\rho \mu_t - f_\mathcal{H}).$$

Using this equality iteratively, with $\mu_1 = 0$,

$$\mathcal{S}_\rho \mu_{t+1} - f_\mathcal{H} = -\Pi_1^t (\mathcal{L}_\rho) f_\mathcal{H}.$$

Taking the $L^2(H, \rho_X)$-norm, by Assumption 2,

$$\|\mathcal{S}_\rho \mu_{t+1} - f_\mathcal{H}\|_\rho = \|\Pi_1^t (\mathcal{L}_\rho) f_\mathcal{H}\|_\rho \le \|\Pi_1^t (\mathcal{L}_\rho) \mathcal{L}_\rho^\zeta\| R.$$

By applying Lemma 15, we get (33). Combining (33) with Lemma 12, we get (34). The proof is complete. ■

Proof [of Lemma 16] From (78), we have

$$\mu_{t+1} = (I - \eta_t \mathcal{T}_\rho)\mu_t + \eta_t \mathcal{S}_\rho^* f_{\mathcal{H}}.$$

Applying this relationship iteratively, and using $\mu_1 = 0$, we get

$$\mu_{t+1} = \sum_{k=1}^{t} \eta_k \Pi_{k+1}^t(\mathcal{T}_\rho)\mathcal{S}_\rho^* f_{\mathcal{H}} = \sum_{k=1}^{t} \eta_k \mathcal{S}_\rho^* \Pi_{k+1}^t(\mathcal{L}_\rho) f_{\mathcal{H}}.$$

Therefore, using Assumption 2 and spectral theory,

$$\|\mu_{t+1}\|_H \leq \left\| \sum_{k=1}^{t} \eta_k \mathcal{S}_\rho^* \Pi_{k+1}^t(\mathcal{L}_\rho)\mathcal{L}_\rho^\zeta \right\| R \leq R \max_{\sigma \in]0,\kappa^2]} \sigma^{1/2+\zeta} \sum_{k=1}^{t} \eta_k \Pi_{k+1}^t(\sigma).$$

Case $\zeta \geq 1/2$. For any $\sigma \in]0, \kappa^2]$,

$$\sigma^{1/2+\zeta} \sum_{k=1}^{t} \eta_k \Pi_{k+1}^t(\sigma) \leq \kappa^{2\zeta-1}\sigma \sum_{k=1}^{t} \eta_k \Pi_{k+1}^t(\sigma) \leq \kappa^{2\zeta-1},$$

where for the last inequality, we used

$$\sum_{k=1}^{t} \eta_k \sigma \Pi_{k+1}^t(\sigma) = \sum_{k=1}^{t} (1-(1-\eta_k\sigma))\Pi_{k+1}^t(\sigma) = \sum_{k=1}^{t} \Pi_{k+1}^t(\sigma) - \sum_{k=1}^{t} \Pi_k^t(\sigma) = 1 - \Pi_1^t(\sigma). \quad (80)$$

Thus,

$$\|\mu_{t+1}\|_H \leq R\kappa^{2\zeta-1}.$$

Case $\zeta < 1/2$. If $\sum_{k=1}^t \eta_k \leq \kappa^{-2}$, then for any $\sigma \leq \kappa^2$,

$$\sigma^{1/2+\zeta} \sum_{k=1}^{t} \eta_k \Pi_{k+1}^t(\sigma) \leq \sigma^{1/2+\zeta} \sum_{k=1}^{t} \eta_k \leq \kappa^{2\zeta-1}.$$

If $\sum_{k=1}^t \eta_k > \kappa^{-2}$, then for any $\sigma \leq (\sum_{k=1}^t \eta_k)^{-1}$,

$$\sigma^{1/2+\zeta} \sum_{k=1}^{t} \eta_k \Pi_{k+1}^t(\sigma) \leq \sigma^{1/2+\zeta} \sum_{k=1}^{t} \eta_k \leq \left(\sum_{k=1}^{t} \eta_k \right)^{1/2-\zeta},$$

while for $\kappa^2 \geq \sigma \geq (\sum_{k=1}^t \eta_k)^{-1}$, by (80),

$$\sigma^{1/2+\zeta} \sum_{k=1}^{t} \eta_k \Pi_{k+1}^t(\sigma) = \sigma^{\zeta-1/2} \sum_{k=1}^{t} \eta_k \sigma \Pi_{k+1}^t(\sigma) \leq \sigma^{\zeta-1/2} \leq \left(\sum_{k=1}^{t} \eta_k \right)^{1/2-\zeta}.$$

From the above analysis, we get that

$$\max_{\sigma \in]0,\kappa^2]} \sigma^{1/2+\zeta} \sum_{k=1}^{t} \eta_k \Pi_{k+1}^t(\sigma) \leq \kappa^{2\zeta-1} \vee \left(\sum_{k=1}^{t} \eta_k \right)^{1/2-\zeta},$$

and thus

$$\|\mu_{t+1}\|_H \leq R \left\{ \kappa^{2\zeta-1} \vee \left(\sum_{k=1}^{t} \eta_k \right)^{1/2-\zeta} \right\}.$$

The proof is complete. ■

Proof [of Lemma 18 (1)] *Bounding* $\left\| (\mathcal{T}_\rho + \lambda)^{-\frac{1}{2}} \left(\mathcal{S}_\rho^* f_\rho - \mathcal{S}_{\mathbf{x}}^* \mathbf{y} \right) \right\|_H$*:*
For all $i \in [m]$, let $w_i = y_i (\mathcal{T}_\rho + \lambda I)^{-\frac{1}{2}} x_i$. Obviously, from the definitions of f_ρ (see (6)) and $\mathcal{S}_\rho$,

$$\mathbb{E}[w_1] = \mathbb{E}_{x_1}[f_\rho(x_1)(\mathcal{T}_\rho + \lambda I)^{-\frac{1}{2}} x_1] = (\mathcal{T}_\rho + \lambda I)^{-\frac{1}{2}} \mathcal{S}_\rho^* f_\rho.$$

Thus,

$$(\mathcal{T}_\rho + \lambda)^{-\frac{1}{2}} \left(\mathcal{S}_\rho^* f_\rho - \mathcal{S}_{\mathbf{x}}^* \mathbf{y} \right) = \frac{1}{m} \sum_{i=1}^{m} (\mathbb{E}[w_i] - w_i).$$

We next estimate the constants B and $\sigma^2(w_1)$ in (28). Note that for any $l \geq 2$,

$$\mathbb{E}[\|w_1 - \mathbb{E}[w_1]\|_H^l] \leq \mathbb{E}[(\|w_1\|_H + \mathbb{E}[\|w_1\|_H])^l].$$

By using Hölder's inequality twice,

$$\mathbb{E}[\|w_1 - \mathbb{E}[w_1]\|_H^l] \leq 2^{l-1}\mathbb{E}[\|w_1\|_H^l + (\mathbb{E}[\|w_1\|_H])^l] \leq 2^{l-1}\mathbb{E}[\|w_1\|_H^l + \mathbb{E}[\|w_1\|_H^l]].$$

The right-hand side is exactly $2^l \mathbb{E}[\|w_1\|_H^l]$. Therefore, by recalling the definition of w_1 and expanding the integration,

$$\mathbb{E}[\|w_1 - \mathbb{E}[w_1]\|_H^l] \leq 2^l \int_X \|(\mathcal{T}_\rho + \lambda I)^{-\frac{1}{2}} x\|_H^l \int_Y y^l d\rho(y|x) d\rho_X(x). \quad (81)$$

Introducing (42) and (45) into the above inequality, we have

$$\mathbb{E}[\|w_1 - \mathbb{E}[w_1]\|_H^l] \leq l!(2\sqrt{M})^l \sqrt{v} \left(\frac{\kappa}{\sqrt{\lambda}} \right)^{l-2} c_\gamma \lambda^{-\gamma} = \frac{1}{2} l! \left(\frac{2\kappa\sqrt{M}}{\sqrt{\lambda}} \right)^{l-2} 8M\sqrt{v} c_\gamma \lambda^{-\gamma}.$$

Applying Bernstein inequality with $B = \frac{2\kappa\sqrt{M}}{\sqrt{\lambda}}$ and $\sigma = \sqrt{8M\sqrt{v}c_\gamma\lambda^{-\gamma}}$, we get that with probability at least $1 - \frac{\delta_1}{2}$, there holds

$$\left\| (\mathcal{T}_\rho + \lambda)^{-\frac{1}{2}} \left(\mathcal{S}_\rho^* f_\rho - \mathcal{S}_{\mathbf{x}}^* \mathbf{y} \right) \right\|_H = \left\| \frac{1}{m} \sum_{i=1}^{m} (\mathbb{E}[w_i] - w_i) \right\|_H \leq 4\sqrt{M} \left(\frac{\kappa}{m\sqrt{\lambda}} + \frac{\sqrt{2\sqrt{v}c_\gamma}}{\sqrt{m\lambda^\gamma}} \right) \log \frac{4}{\delta_1}. \quad (82)$$

Bounding $\|(\mathcal{T}_\rho + \lambda)^{-\frac{1}{2}}(\mathcal{T}_\rho - \mathcal{T}_{\mathbf{x}})\|$*:*
Let $\xi_i = (\mathcal{T}_\rho + \lambda)^{-\frac{1}{2}} x_i \otimes x_i$, for all $i \in [m]$. It is easy to see that $\mathbb{E}[\xi_i] = (\mathcal{T}_\rho + \lambda)^{-\frac{1}{2}} \mathcal{T}_\rho$, and that $(\mathcal{T}_\rho + \lambda)^{-\frac{1}{2}}(\mathcal{T}_\rho - \mathcal{T}_{\mathbf{x}}) = \frac{1}{m} \sum_{i=1}^m (\mathbb{E}[\xi_i] - \xi_i)$. Denote the Hilbert-Schmidt norm of a bounded operator from H to H by $\|\cdot\|_{HS}$. Note that

$$\|\xi_1\|_{HS}^2 = \|x_1\|_H^2 \mathrm{Trace}((\mathcal{T}_\rho + \lambda)^{-1/2} x_1 \otimes x_1 (\mathcal{T}_\rho + \lambda)^{-1/2}) = \|x_1\|_H^2 \mathrm{Trace}((\mathcal{T}_\rho + \lambda)^{-1} x_1 \otimes x_1).$$

By Assumption (3),

$$\|\xi_1\|_{HS} \leq \sqrt{\kappa^2 \mathrm{Trace}((\mathcal{T}_\rho+\lambda)^{-1}x_1\otimes x_1)} \leq \sqrt{\kappa^2 \mathrm{Trace}(x_1\otimes x_1)/\lambda} \leq \kappa^2/\sqrt{\lambda},$$

and furthermore, by Assumption 3,

$$\mathbb{E}[\|\xi_1\|_{HS}^2] \leq \kappa^2 \mathbb{E}\mathrm{Trace}((\mathcal{T}_\rho+\lambda)^{-1}x_1\otimes x_1) = \kappa^2 \mathrm{Trace}((\mathcal{T}_\rho+\lambda)^{-1}\mathcal{T}_\rho) \leq \kappa^2 c_\gamma \lambda^{-\gamma}.$$

According to Lemma 11, we get that with probability at least $1-\frac{\delta_1}{2}$, there holds

$$\|(\mathcal{T}_\rho+\lambda)^{-\frac{1}{2}}(\mathcal{T}_\rho-\mathcal{T}_{\mathbf{x}})\|_{HS} \leq 2\kappa\left(\frac{2\kappa}{m\sqrt{\lambda}}+\frac{\sqrt{c_\gamma}}{\sqrt{m\lambda^\gamma}}\right)\log\frac{4}{\delta_1}. \tag{83}$$

Finally, using the triangle inequality, we have,

$$\|(\mathcal{T}_\rho+\lambda)^{-\frac{1}{2}}N_k\|_H \leq \|(\mathcal{T}_\rho+\lambda)^{-\frac{1}{2}}(\mathcal{T}_\rho-\mathcal{T}_{\mathbf{x}})\|\|\mu_k\|_H + \left\|(\mathcal{T}_\rho+\lambda)^{-\frac{1}{2}}\left(\mathcal{S}_\rho^* f_\rho - \mathcal{S}_{\mathbf{x}}^*\mathbf{y}\right)\right\|_H.$$

Applying (35) to the above, introducing with (82) and (83), and then noting that $\kappa \geq 1$ and $v \geq 1$, one can prove the first part of the lemma.
■

Proof [of Lemma 27] Obviously, $f_{\mathcal{H}} = \mathcal{S}_\rho \omega^\dagger$ and thus $\mathcal{T}_\rho\omega^\dagger = \mathcal{S}_\rho^* f_{\mathcal{H}}$. Combining with Assumption 2, $\mathcal{T}_\rho\omega^\dagger = \mathcal{S}_\rho^*\mathcal{L}_\rho^\zeta\mathcal{L}_\rho^{-\zeta}f_{\mathcal{H}} = \mathcal{T}_\rho^\zeta\mathcal{S}_\rho^*\mathcal{L}_\rho^{-\zeta}f_{\mathcal{H}}$, and $\omega^\dagger = \mathcal{T}_\rho^\dagger\mathcal{T}_\rho^\zeta\mathcal{S}_\rho^*\mathcal{L}_\rho^{-\zeta}f_{\mathcal{H}}$. Subtracting $\omega^\dagger$ from both sides of (78), and using $\mathcal{S}_\rho^* f_{\mathcal{H}} = \mathcal{T}_\rho\omega^\dagger$, we know that

$$\mu_{t+1}-\omega^\dagger = (I-\eta_t\mathcal{T}_\rho)(\mu_t-\omega^\dagger).$$

Applying this relationship iteratively, with $\mu_1 = 0$,

$$\mu_{t+1}-\omega^\dagger = -\Pi_1^t(\mathcal{T}_\rho)\omega^\dagger = -\Pi_1^t(\mathcal{T}_\rho)\mathcal{T}_\rho^\dagger\mathcal{T}_\rho^\zeta\mathcal{S}_\rho^*\mathcal{L}_\rho^{-\zeta}f_{\mathcal{H}}.$$

Therefore,

$$\|\mu_{t+1}-\omega^\dagger\|_H \leq \|\Pi_1^t(\mathcal{T}_\rho)\mathcal{T}_\rho^\dagger\mathcal{T}_\rho^\zeta\mathcal{S}_\rho^*\|R \leq \|\Pi_1^t(\mathcal{T}_\rho)\mathcal{T}_\rho^{\zeta-1/2}\|R.$$

Applying Lemma 15, one can get the desired result. ■

D. List of Some Notations

Notation	Meaning
H	the hypothesis space
X, Y, Z	the input space, the output space and the sample space ($Z = X\times Y$)
ρ	the fixed probability measure on Z
ρ_X	the induced marginal measure of ρ on X
$\rho(\cdot\|x)$	the conditional probability measure on Y w.r.t. $x\in X$ and ρ
$\mathbf{z}$	the sample $\{z_i=(x_i,y_i)\}_{i=1}^m$ of size $m\in\mathbb{N}$, where each z_i is i.i.d. according to ρ.
m	the sample size of the sample $\mathbf{z}$
$\mathcal{E}$	the expected risk defined by (1)
$\mathcal{E}_{\mathbf{z}}$	the empirical risk w.r.t the sample $\mathbf{z}$ defined by (20)
κ^2	the constant from the bounded assumption (3) on the hypothesis space H
$\{\omega_t\}_t$	the sequence generated by the SGM
θ	the decaying rate on step-sizes
b	the minibatch size of the SGM
T	the maximal number of iterations for the SGM
j_i (j_t etc.)	the random index from the uniform distribution on $[m]$ for the SGM
$\mathbf{J}_t$	the set of random indices at t-th iteration of the SGM
$\mathbf{J}$	the set of all random indices for the SGM after T iterations
$\mathbb{E}_{\mathbf{J}}$	the expectation with respect to the random variables $\mathbf{J}$ (conditional on $\mathbf{z}$)
$\{\eta_t\}_t$	the sequence of step-sizes
M, v	the positive constants from the moment (bounded) assumption on the output
$L^2(H,\rho_X)$	the Hilbert space of square integral functions from H to $\mathbb{R}$ with respect to ρ_X
f_ρ	the regression function defined (6)
H_ρ	$\{f: X\to\mathbb{R}\|\exists\omega\in H$ with $f(x)=\langle\omega,x\rangle_H, \rho_X$-almost surely$\}$
ζ, R	the parameters related to the 'regularity' of $f_{\mathcal{H}}$ (see Assumption 2)
$\omega^\dagger$	the solution of Problem (1) with the minimal norm in the attainable case
γ, c_γ	the parameters related to the effective dimension (see Assumption 3)
$\{\sigma_i\}_i$	the sequence of eigenvalues of $\mathcal{L}_\rho$
$\{\nu_t\}_t$	the sequence generated by the batch GM (10)
$\{\mu_k\}_k$	the sequence defined by the population iteration (21)
$\mathcal{S}_\rho$	the linear map from $H\to L^2(H,\rho_X)$ defined by $\mathcal{S}_\rho\omega = \langle\omega,\cdot\rangle$
$\mathcal{S}_\rho^*$	the adjoint operator of $\mathcal{S}_\rho$, $\mathcal{S}_\rho^* f = \int_X f(x)x d\rho_X(x)$
$\mathcal{L}_\rho$	the operator from $L^2(H,\rho_X)$ to $L^2(H,\rho_X)$, $\mathcal{L}_\rho(f) = \mathcal{S}_\rho\mathcal{S}_\rho^* f = \int_X\langle x,\cdot\rangle_H f(x)\rho_X(x)$
$\mathcal{T}_\rho$	the covariance operator from H to H, $\mathcal{T}_\rho = \mathcal{S}_\rho^*\mathcal{S}_\rho = \int_X\langle\cdot,x\rangle x d\rho_X(x)$
$\mathcal{S}_{\mathbf{x}}$	the sampling operator from H to $\mathbb{R}^m$, $(\mathcal{S}_{\mathbf{x}}\omega)_i = \langle\omega,x_i\rangle_H, i\in[m]$
$\mathcal{S}_{\mathbf{x}}^*$	the adjoint operator of $\mathcal{S}_{\mathbf{x}}$, $\mathcal{S}_{\mathbf{x}}^*\mathbf{y} = \frac{1}{m}\sum_{i=1}^m y_i x_i$
$\mathcal{T}_{\mathbf{x}}$	the empirical covariance operator, $\mathcal{T}_{\mathbf{x}} = \mathcal{S}_{\mathbf{x}}^*\mathcal{S}_{\mathbf{x}} = \frac{1}{m}\sum_{i=1}^m\langle\cdot,x_i\rangle x_i$
$\Pi_{t+1}^T(L)$	$=\Pi_{k=t+1}(I-\eta_k L)$ when $t\in[T-1]$ and $\Pi_{T+1}^T = I$
$\sum_{i=t+1}^t\eta_i$	$=0$
λ	a 'regularization' parameter, $\lambda>0$
$\mathcal{T}_{\rho,\lambda}$,	$\mathcal{T}_{\rho,\lambda} = \mathcal{T}_\rho+\lambda$
$\mathcal{T}_{\mathbf{x},\lambda}$,	$\mathcal{T}_{\mathbf{x},\lambda} = \mathcal{T}_{\mathbf{x}}+\lambda$
$\{N_k\}_k$	the sequence defined by (38).
$M_{k,i}$	defined by (53)

Abstract

Recently, fundamental conditions on the sampling patterns have been obtained for finite completability of low-rank matrices or tensors given the corresponding ranks. In this paper, we consider the scenario where the rank is not given and we aim to approximate the unknown rank based on the location of sampled entries and some given completion. We consider a number of data models, including single-view matrix, multi-view matrix, CP tensor, tensor-train tensor and Tucker tensor. For each of these data models, we provide an upper bound on the rank when an arbitrary low-rank completion is given. We characterize these bounds both deterministically, i.e., with probability one given that the sampling pattern satisfies certain combinatorial properties, and probabilistically, i.e., with high probability given that the sampling probability is above some threshold. Moreover, for both single-view matrix and CP tensor, we are able to show that the obtained upper bound is exactly equal to the unknown rank if the lowest-rank completion is given. Furthermore, we provide numerical experiments for the case of single-view matrix, where we use nuclear norm minimization to find a low-rank completion of the sampled data and we observe that in most of the cases the proposed upper bound on the rank is equal to the true rank.

Keywords: Low-rank data completion, rank estimation, tensor, matrix, manifold, Tucker rank, tensor-train rank, CP rank, multi-view matrix.

1. Introduction

Developing methods and algorithms to study large high-dimensional data is becoming more indispensable as hyperspectral images and videos, product ranking datasets and other applications of big datasets are attracting more attention recently. Moreover, in order to guarantee the same level of efficiency in images or videos, a minor increment in dimensionality in the datasets entails a significant increment in the amount of the data, and this fact causes modeling and also computational challenges to analyze big high-dimensional datasets. Consequently, providing a statistically rigorous result requires a massive amount of data that grows exponentially with the dimension. The low-rank data completion problem is concerned with completing a matrix or tensor given a subset of its entries and some rank constraints. Various applications can be found in many fields including image and signal processing (Candès et al., 2013; Ji et al., 2010), data mining (Eldén, 2007), network coding (Harvey et al., 2005), compressed sensing (Lim and Comon, 2010; Sidiropoulos and Kyrillidis, 2012; Ashraphijuo et al., 2016c; Gandy et al., 2011; Ashraphijuo and Wang, 2017c; Ashraphijuo et al., 2015), reconstructing the visual data (Liu et al., 2013), bioinformatics and systems biology (Ogundijo et al., 2017; Ogundijo et al.), fingerprinting (Liu et al., 2016), etc. There is an extensive literature on developing various optimization methods to treat this problem including minimizing a convex relaxation of rank (Candès and Recht, 2009; Candès and Tao, 2010; Cai et al., 2010; Gandy et al., 2011; Ashraphijuo et al., 2016b; Ashraphijuo and Wang, 2017c), non-convex approaches (Recht and Ré, 2013), and alternating minimization (Jain et al., 2013; Ge et al., 2016), etc. More recently, deterministic conditions on the sampling patterns have been studied for subspace clustering in (Pimentel-Alarcón et al., 2016c, 2015, 2016a,b). Moreover, the fundamental conditions on the sampling pattern that lead to different numbers of completion (unique, finite, or infinite) for different data structures given the corresponding rank constraints have been investigated in (Pimentel-Alarcón et al., 2016d; Ashraphijuo et al., 2017c; Ashraphijuo and Wang, 2017b; Ashraphijuo et al., 2016a; Ashraphijuo and Wang, 2017a; Ashraphijuo et al., 2017d,a,b).

However, in many practical low-rank data completion problems, the rank may not be known *a priori*. In this paper, we investigate this problem and we aim to approximate the rank based on the given entries, where it is assumed that the original data is generically chosen from the manifold corresponding to the unknown rank. The only existing work that treats this problem for a single-view matrix data based on the sampling pattern is (Pimentel-Alarcón and Nowak, 2016), which requires some strong assumptions including the existence of a completion whose rank r is a lower bound on the unknown true rank r^*, i.e., $r^* \geq r$. We start by investigating the single-view matrix to provide a new analysis that does not require such assumption and also we can extend our approach to treat the CP rank tensor model. Moreover, we further generalize our approach to treat vector rank data models including the multi-view matrix, the Tucker rank tensor and the tensor-train (TT) rank tensor. For each of these data models, we obtain the upper bound on the scalar rank or component-wise upper bound on the unknown vector rank, deterministically based on the sampling pattern and the rank of a given completion. We also obtain such bound that holds with high probability based on the sampling probability. Moreover, for the single-view matrix, we provide some numerical results to show how tight our probabilistic bounds on the rank are (in terms of the sampling probability). In particular, we used nuclear norm minimization to find a completion and demonstrate our proposed method in obtaining a tight bound on the unknown rank.

In general, providing a completion requires much less samples than recovering the original sampled data. The goal of this paper is to solve the fundamental problem of rank determination for the original sampled data given an arbitrary low-rank data completion. One possible application scenario is to improve upon the low-rank completion obtained by the convex relaxation methods. Specifically, using convex optimization (minimization of nuclear and atomic norms or summation of nuclear norms of matricizations and unfoldings) or any other methods in the literature, we may be able to find a fairly low-rank "completion" of the original data, which is not necessarily equal (or even close) to the original sampled data. Then, under some circumstances, the rank of the obtained completion using any rank independent method can be an upper bound on the rank of the original sampled data (and sometimes the obtained rank can be exactly equal to the rank of the original sampled data).

We take advantage of the geometric analysis on the manifold of the corresponding data which leads to the fundamental conditions on the sampling pattern (independent of the value of entries) (Pimentel-Alarcón et al., 2016d; Ashraphijuo et al., 2017c; Ashraphijuo and Wang, 2017b; Ashraphi-

juo et al., 2016a; Ashraphijuo and Wang, 2017a) such that given an arbitrary low-rank completion we can provide a tight upper bound on the rank. To illustrate how such approximation is even possible consider the following example. Assume that an $n_1 \times n_2$ rank-2 matrix is chosen generically from the corresponding manifold. Hence, any 2×2 submatrix of this matrix is full-rank with probability one (due to the genericity assumption). Moreover, note that any 3×3 submatrix of this matrix is not full-rank. As a result, by observing the sampled entries we can find some bounds on the rank. Using the analysis in (Pimentel-Alarcón et al., 2016d; Ashraphijuo et al., 2017c; Ashraphijuo and Wang, 2017b; Ashraphijuo et al., 2016a; Ashraphijuo and Wang, 2017a) on finite completablity of the sampled data (finite number of completions) for different data models, we characterize both deterministic and probablistic bounds on the unknown rank.

The remained of the paper is organized as follows. In Section 2, we introduce the data models and problem statement. In Sections 3 and 4 we characterize our determintic and probablistic bounds for scalar-rank cases (single-view matrix and CP tensor) and vector-rank cases (multi-view matrix, Tucker tensor and TT tensor), respectively. Finally, Section 5 concludes the paper.

2. Data Models and Problem Statement

2.1 Matrix Models

2.1.1 SINGLE-VIEW MATRIX

Assume that the sampled matrix $\mathbf{U}$ is chosen generically from the manifold of the $n_1 \times n_2$ matrices of rank r^*, where r^* is unknown. The matrix $\mathbf{V} \in \mathbb{R}^{n_1 \times r^*}$ is called a basis for $\mathbf{U}$ if each column of $\mathbf{U}$ can be written as a linear combination of the columns of $\mathbf{V}$. Denote $\mathbf{\Omega}$ as the binary sampling pattern matrix that is of the same size as $\mathbf{U}$ and $\mathbf{\Omega}(\vec{x}) = 1$ if $\mathbf{U}(\vec{x})$ is observed and $\mathbf{\Omega}(\vec{x}) = 0$ otherwise, where $\vec{x} = (x_1, x_2)$ represents the entry corresponding to row number x_1 and column number x_2. Moreover, define $\mathbf{U}_{\mathbf{\Omega}}$ as the matrix obtained from sampling $\mathbf{U}$ according to $\mathbf{\Omega}$, i.e.,

$$\mathbf{U}_{\mathbf{\Omega}}(\vec{x}) = \begin{cases} \mathbf{U}(\vec{x}) & \text{if } \mathbf{\Omega}(\vec{x}) = 1, \\ 0 & \text{if } \mathbf{\Omega}(\vec{x}) = 0. \end{cases} \tag{1}$$

2.1.2 MULTI-VIEW MATRIX

The matrix $\mathbf{U} \in \mathbb{R}^{n \times (n_1+n_2)}$ is sampled. Denote a partition of $\mathbf{U}$ as $\mathbf{U} = [\mathbf{U}_1|\mathbf{U}_2]$ where $\mathbf{U}_1 \in \mathbb{R}^{n \times n_1}$ and $\mathbf{U}_2 \in \mathbb{R}^{n \times n_2}$ represent the first and second views of data, respectively. The sampling pattern is defined as $\mathbf{\Omega} = [\mathbf{\Omega}_1|\mathbf{\Omega}_2]$, where $\mathbf{\Omega}_1$ and $\mathbf{\Omega}_2$ represent the sampling patterns corresponding to the first and second views of data, respectively. Assume that $\text{rank}(\mathbf{U}_1) = r_1^*$, $\text{rank}(\mathbf{U}_2) = r_2^*$ and $\text{rank}(\mathbf{U}) = r^*$, and also $\mathbf{U}$ is chosen generically from the manifold structure with above parameters. Denote $\underline{r}^* = (r_1^*, r_2^*, r^*)$ which is assumed unknown.

2.2 Tensor Models

Assume that a d-way tensor $\mathcal{U} \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ is sampled. For the sake of simplicity in notation, define $N_i \triangleq \left(\Pi_{j=1}^{i}\, n_j\right)$, $\bar{N}_i \triangleq \left(\Pi_{j=i+1}^{d}\, n_j\right)$ and $N_{-i} \triangleq \frac{N_d}{n_i}$. Denote Ω as the binary sampling pattern tensor that is of the same size as $\mathcal{U}$ and $\Omega(\vec{x}) = 1$ if $\mathcal{U}(\vec{x})$ is observed and $\Omega(\vec{x}) = 0$ otherwise, where $\mathcal{U}(\vec{x})$ represents an entry of tensor $\mathcal{U}$ with coordinate $\vec{x} = (x_1, \ldots, x_d)$. Moreover, define $\mathcal{U}_\Omega$ as the tensor obtained from sampling $\mathcal{U}$ according to Ω, i.e.,

$$\mathcal{U}_\Omega(\vec{x}) = \begin{cases} \mathcal{U}(\vec{x}) & \text{if } \Omega(\vec{x}) = 1, \\ 0 & \text{if } \Omega(\vec{x}) = 0. \end{cases} \tag{2}$$

For each subtensor $\mathcal{U}'$ of the tensor $\mathcal{U}$, define $N_\Omega(\mathcal{U}')$ as the number of observed entries in $\mathcal{U}'$ according to the sampling pattern Ω.

Define the matrix $\widetilde{\mathbf{U}}_{(i)} \in \mathbb{R}^{N_i \times \bar{N}_i}$ as the i-th *unfolding* of the tensor $\mathcal{U}$, such that $\mathcal{U}(\vec{x}) = \widetilde{\mathbf{U}}_{(i)}(\widetilde{M}_i(x_1, \ldots, x_i), \widetilde{M}_{-i}(x_{i+1}, \ldots, x_d))$, where $\widetilde{M}_i : (x_1, \ldots, x_i) \to \{1, 2, \ldots, N_i\}$ and $\widetilde{M}_{-i} : (x_{i+1}, \ldots, x_d) \to \{1, 2, \ldots, \bar{N}_i\}$ are two bijective mappings.

Let $\mathbf{U}_{(i)} \in \mathbb{R}^{n_i \times N_{-i}}$ be the i-th *matricization* of the tensor $\mathcal{U}$, such that $\mathcal{U}(\vec{x}) = \mathbf{U}_{(i)}(x_i, M_i(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_d))$, where $M_i : (x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_d) \to \{1, 2, \ldots, N_{-i}\}$ is a bijective mapping. Observe that for any arbitrary tensor $\mathcal{A}$, the first matricization and the first unfolding are the same, i.e., $\mathbf{A}_{(1)} = \widetilde{\mathbf{A}}_{(1)}$.

In what follows, we introduce three different tensor ranks, i.e., the CP rank, Tucker rank and TT rank.

2.2.1 CP DECOMPOSITION

The CP rank of a tensor $\mathcal{U}$, $\text{rank}_{\text{CP}}(\mathcal{U}) = r$, is defined as the minimum number r such that there exist $\mathbf{a}_i^l \in \mathbb{R}^{n_i}$ for $1 \le i \le d$ and $1 \le l \le r$, such that

$$\mathcal{U} = \sum_{l=1}^{r} \mathbf{a}_1^l \otimes \mathbf{a}_2^l \otimes \ldots \otimes \mathbf{a}_d^l, \tag{3}$$

or equivalently,

$$\mathcal{U}(x_1, x_2, \ldots, x_d) = \sum_{l=1}^{r} \mathbf{a}_1^l(x_1)\mathbf{a}_2^l(x_2)\ldots\mathbf{a}_d^l(x_d), \tag{4}$$

where $\otimes$ denotes the tensor product (outer product) and $\mathbf{a}_i^l(x_i)$ denotes the x_i-th entry of vector $\mathbf{a}_i^l$. Note that $\mathbf{a}_1^l \otimes \mathbf{a}_2^l \otimes \ldots \otimes \mathbf{a}_d^l \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ is a rank-1 tensor, $l = 1, 2, \ldots, r$.

2.2.2 TUCKER DECOMPOSITION

Given $\mathcal{U} \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ and $\mathbf{X} \in \mathbb{R}^{n_i \times n_i'}$, the product $\mathcal{U}' \triangleq \mathcal{U} \times_i \mathbf{X} \in \mathbb{R}^{n_1 \times \cdots \times n_{i-1} \times n_i' \times n_{i+1} \times \cdots \times n_d}$ is defined as

$$\mathcal{U}'(x_1, \cdots, x_{i-1}, k_i, x_{i+1}, \cdots, x_d) \triangleq \sum_{x_i=1}^{n_i} \mathcal{U}(x_1, \cdots, x_{i-1}, x_i, x_{i+1}, \cdots, x_d)\mathbf{X}(x_i, k_i). \tag{5}$$

The Tucker rank of a tensor $\mathcal{U}$ is defined as $\text{rank}_{\text{Tucker}}(\mathcal{U}) = \underline{r} = (m_1, \ldots, m_d)$ where $m_i = \text{rank}(\mathbf{U}_{(i)})$, i.e., the rank of the i-th matricization, $i = 1, \ldots, d$. The Tucker decomposition of $\mathcal{U}$ is given by

$$\mathcal{U}(\vec{x}) = \sum_{k_1=1}^{m_1} \cdots \sum_{k_d=1}^{m_d} \mathcal{C}(k_1, \ldots, k_d)\mathbf{T}_1(k_1, x_1)\ldots\mathbf{T}_d(k_d, x_d), \tag{6}$$

or in short

$$\mathcal{U} = \mathcal{C} \times_{i=1}^{d} \mathbf{T}_i, \tag{7}$$

where $\mathcal{C} \in \mathbb{R}^{m_1 \times \cdots \times m_d}$ is the core tensor and $\mathbf{T}_i \in \mathbb{R}^{m_i \times n_i}$ are d orthogonal matrices.

2.2.3 TT DECOMPOSITION

The separation or TT rank of a tensor is defined as $\text{rank}_{\text{TT}}(\mathcal{U}) = \underline{r} = (u_1, \ldots, u_{d-1})$ where $u_i = \text{rank}(\widetilde{\mathbf{U}}_{(i)})$, i.e., the rank of the i-th unfolding, $i = 1, \ldots, d-1$. Note that $u_i \leq \max\{N_i, \bar{N}_i\}$ in general and also u_1 is simply the conventional matrix rank when $d = 2$. The TT decomposition of a tensor $\mathcal{U}$ is given by

$$\mathcal{U}(\vec{x}) = \sum_{k_1=1}^{u_1} \cdots \sum_{k_{d-1}=1}^{u_{d-1}} \mathcal{U}^{(1)}(x_1, k_1) \left(\prod_{i=2}^{d-1} \mathcal{U}^{(i)}(k_{i-1}, x_i, k_i) \right) \mathcal{U}^{(d)}(k_{d-1}, x_d), \tag{8}$$

or in short

$$\mathcal{U} = \mathcal{U}^{(1)} \ldots \mathcal{U}^{(d)}, \tag{9}$$

where the 3-way tensors $\mathcal{U}^{(i)} \in \mathbb{R}^{u_{i-1} \times n_i \times u_i}$ for $i = 2, \ldots, d-1$ and matrices $\mathcal{U}^{(1)} \in \mathbb{R}^{n_1 \times u_1}$ and $\mathcal{U}^{(d)} \in \mathbb{R}^{u_{d-1} \times n_d}$ are the components of this decomposition.

For each matrix or tensor model, we assume that the true rank of $\mathbf{U}$ or $\mathcal{U}$ is r^* or $\underline{r}^*$ which is unknown, and also $\mathbf{U}$ or $\mathcal{U}$ is chosen generically from the corresponding manifold. The table below represents the mentioned symbols in brief.

Data structure	Sampled data	Rank	Comments
Single-view matrix	$\mathbf{U} \in \mathbb{R}^{n_1 \times n_2}$	r^*	–
Multi-view matrix	$\mathbf{U} = [\mathbf{U}_1 \vert \mathbf{U}_2] \in \mathbb{R}^{n \times (n_1 + n_2)}$	$\underline{r}^* = (r_1^*, r_2^*, r^*)$	$r_i^* = \text{rank}(\mathbf{U}_i)$
CP tensor	$\mathcal{U} \in \mathbb{R}^{n_1 \times \cdots \times n_d}$	r^*	–
Tucker tensor	$\mathcal{U} \in \mathbb{R}^{n_1 \times \cdots \times n_d}$	$\underline{r}^* = (m_1^*, \ldots, m_d^*)$	$m_i^* = \text{rank}(\mathbf{U}_{(i)})$
TT tensor	$\mathcal{U} \in \mathbb{R}^{n_1 \times \cdots \times n_d}$	$\underline{r}^* = (u_1^*, \ldots, u_{d-1}^*)$	$u_i^* = \text{rank}(\widetilde{\mathbf{U}}_{(i)})$

2.3 Problem Statement

In this paper, we assume that there exists a full rank completion of the sampled data (i.e., the data is not over-sampled). For each one of the above data models, we are interested in obtaining the upper bound on the unknown scalar-rank r^* or component-wise upper bound on the unknown vector-rank $\underline{r}^*$, deterministically based on the sampling pattern $\mathbf{\Omega}$ or Ω and the rank of a given completion. Also, we aim to provide such bound that holds with high probability based only on the sampling probability of the entries and the rank of a given completion. Moreover, for the single-view matrix model and CP-rank tensor model, where the rank is a scalar, we provide both deterministic and probabilistic conditions such that the unknown rank can be exactly determined.

3. Scalar-Rank Cases

3.1 Single-View Matrix

Previously, this problem has been treated in (Pimentel-Alarcón and Nowak, 2016), where strong assumptions including the existence of a completion with rank $r \leq r^*$ have been used. In this section, we provide an analysis that does not require such assumption and moreover our analysis can be extended to multi-view data and tensors in the following sections. Furthermore, we show the tightness of our theoretical bounds via numerical examples.

Assume that $\mathbf{U} \in \mathbb{R}^{n_1 \times n_2}$ is the sampled matrix. Let $\mathbb{P}_1$ and $\mathbb{P}_2$ denote the Lebesgue measures on $\mathbb{R}^{n_1 \times r^*}$ and $\mathbb{R}^{r^* \times n_2}$, respectively. In this paper, we assume that the matrix $\mathbf{U}$ is chosen generically from the manifold of $n_1 \times n_2$ matrices of rank r^*, i.e., the entries of $\mathbf{U}$ are drawn independently with respect to Lebesgue measure on the corresponding manifold. Hence, the probability measures of all statements in this subsection are $\mathbb{P}_1 \times \mathbb{P}_2$.

3.1.1 DETERMINISTIC RANK ANALYSIS

The following condition will be used frequently in this subsection.

Condition A_r: Each column of the sampled matrix includes at least r sampled entries.

Consider an arbitrary column of the sampled matrix $\mathbf{U}(:, i)$, where $i \in \{1, \ldots, n_2\}$. Let $l_i = N_{\mathbf{\Omega}}(\mathbf{U}(:, i))$ denote the number of observed entries in the i-th column of $\mathbf{U}$. Condition A_r results that $l_i \geq r$.

We construct a binary valued matrix called **constraint matrix** $\breve{\mathbf{\Omega}}_r$ based on $\mathbf{\Omega}$ and a given number r. Specifically, we construct $l_i - r$ columns with binary entries based on the locations of the observed entries in $\mathbf{U}(:, i)$ such that each column has exactly $r+1$ entries equal to one. Assume that $x_1, \ldots, x_{l_i}$ are the row indices of all observed entries in this column. Let $\mathbf{\Omega}_r^i$ be the corresponding $n_1 \times (l_i - r)$ matrix to this column which is defined as the following: for any $j \in \{1, \ldots, l_i - r\}$, the j-th column has the value 1 in rows $\{x_1, \ldots, x_r, x_{r+j}\}$ and zeros elsewhere. Define the binary constraint matrix as $\breve{\mathbf{\Omega}}_r = \left[\mathbf{\Omega}_r^1 | \mathbf{\Omega}_r^2 \ldots | \mathbf{\Omega}_r^{n_2}\right] \in \mathbb{R}^{n_1 \times K_r}$ (Pimentel-Alarcón et al., 2016d), where $K_r = N_{\mathbf{\Omega}}(\mathbf{U}) - n_2 r$.

Condition B_r: There exists a submatrix[1] $\breve{\mathbf{\Omega}}_r' \in \mathbb{R}^{n_1 \times K}$ of $\breve{\mathbf{\Omega}}_r$ such that $K = n_1 r - r^2$ and for any $K' \in \{1, 2, \ldots, K\}$ and any submatrix $\breve{\mathbf{\Omega}}_r'' \in \mathbb{R}^{n_1 \times K'}$ of $\breve{\mathbf{\Omega}}_r'$ we have

$$r f(\breve{\mathbf{\Omega}}_r'') - r^2 \geq K', \tag{10}$$

where $f(\breve{\mathbf{\Omega}}_r'')$ denotes the number of nonzero rows of $\breve{\mathbf{\Omega}}_r''$.

Note that exhaustive enumeration is needed in order to check whether or not Condition B_r holds. Hence, the deterministic analysis cannot be used in practice for large-scale data. However, it serves as the basis of the subsequent probabilistic analysis that will lead to a simple lower bound on the sampling probability such that Condition B_r holds with high probability, which is of practical value.

In the following, we restate Theorem 1 in (Pimentel-Alarcón et al., 2016d) which will be used later.

Lemma 1 *With probability one, there are finitely many completions of the sampled matrix if and only if Conditions A_{r^*} and B_{r^*} hold.*

1. Specified by a subset of rows and a subset of columns (not necessarily consecutive).

Recall that the true rank r^* is assumed unknown.

Definition 2 *Let $\mathcal{S}_{\mathbf{\Omega}}$ denote the set of all natural numbers r such that both Conditions A_r and B_r hold.*

Lemma 3 *There exists a number $r_{\mathbf{\Omega}}$ such that $\mathcal{S}_{\mathbf{\Omega}} = \{1, 2, \ldots, r_{\mathbf{\Omega}}\}$.*

Proof Assume that $1 < r \leq \min\{n_1, n_2\}$ and $r \in \mathcal{S}_{\mathbf{\Omega}}$. It suffices to show $r - 1 \in \mathcal{S}_{\mathbf{\Omega}}$. By contradiction, assume that $r - 1 \notin \mathcal{S}_{\mathbf{\Omega}}$. Therefore, according to Lemma 1, there exist infinitely many completions of $\mathbf{U}$ of rank $r - 1$ and there exist at most finitely many completions of $\mathbf{U}$ of rank r.

Consider a rank $r - 1$ completion $\mathbf{U}_{r-1}$. Note that changing one single entry (a non-observed entry) of $\mathbf{U}_{r-1}$, for example $\mathbf{U}_{r-1}(1, 1) = x$, to a random number in $y \in \mathbb{R}$ changes the rank of this matrix by at most 1 and basically since we are changing to a random number, it can be easily seen that the rank does not decrease with probability one. Hence, the rank of the modified matrix $\mathbf{U}'_{r-1}$ would be either $r - 1$ or r. Assume that the rank has been increased to r. Then, we show there exist infinitely many completions of rank r, which contradicts the assumption. In fact, for any value of $\mathbf{U}_{r-1}(1, 1)$ except x, this matrix would be a rank r completion. To observe this more clearly, consider the $r \times r$ submatrix of $\mathbf{U}'_{r-1}$ whose determinant is not zero due to changing the value of $\mathbf{U}_{r-1}(1, 1)$. It is easily observed that this submatrix includes $\mathbf{U}'_{r-1}(1, 1)$ and let assume it is $\mathbf{U}'_{r-1}(1 : r, 1 : r)$, and therefore the determinant of $\mathbf{U}'_{r-1}(2 : r, 2 : r)$ is a nonzero number (otherwise the rank would not increase by changing the value of $\mathbf{U}_{r-1}(1, 1)$). Hence, it is easy to see that for any value of $\mathbf{U}_{r-1}(1, 1)$ except x, $\mathbf{U}'_{r-1}$ would be a rank r completion, and therefore there exist infinitely many completions of rank r and proof is complete in this scenario.

Now, assume that changing any of the non-observed entries does not increase the rank of $\mathbf{U}_{r-1}$. Then, this contradicts the assumption that there exists a full rank completion of the sampled data since there does not exist any completion of rank higher than $r - 1$. ■

The following theorem provides a relationship between the unknown rank r^* and $r_{\mathbf{\Omega}}$.

Theorem 4 *With probability one, exactly one of the following statements holds*
(i) $r^* \in \mathcal{S}_{\mathbf{\Omega}} = \{1, 2, \ldots, r_{\mathbf{\Omega}}\}$;
(ii) For any arbitrary completion of the sampled matrix $\mathbf{U}$ of rank r, we have $r \notin \mathcal{S}_{\mathbf{\Omega}}$.

Proof Suppose that there does not exist a completion of the sampled matrix $\mathbf{U}$ of rank r such that $r \in \mathcal{S}_{\mathbf{\Omega}}$. Therefore, it is easily verified that statement (ii) holds and statement (i) does not hold. On the other hand, assume that there exists a completion of the sampled matrix $\mathbf{U}$ of rank r, where $r \in \mathcal{S}_{\mathbf{\Omega}}$. Hence, statement (ii) does not hold and to complete the proof it suffices to show that with probability one, statement (i) holds.

Observe that $r_{\mathbf{\Omega}} \in \mathcal{S}_{\mathbf{\Omega}}$, and therefore Condition $A_{r_{\mathbf{\Omega}}}$ holds. Hence, each column of $\mathbf{U}$ includes at least $r_{\mathbf{\Omega}} + 1$ observed entries. On the other hand, the existence of a completion of the sampled matrix $\mathbf{U}$ of rank $r \in \mathcal{S}_{\mathbf{\Omega}}$ results in the existence of a basis $\mathbf{X} \in \mathbb{R}^{n_1 \times r}$ such that each column of $\mathbf{U}$ is a linear combination of the columns of $\mathbf{X}$, and thus there exists $\mathbf{Y} \in \mathbb{R}^{r \times n_2}$ such that $\mathbf{U}_{\mathbf{\Omega}} = (\mathbf{XY})_{\mathbf{\Omega}}$. Hence, given $\mathbf{X}$, each observed entry $\mathbf{U}(i, j)$ results in a degree-1 polynomial in

terms of the entries of $\mathbf{Y}$ as the following

$$\mathbf{U}(i, j) = \sum_{l=1}^{r} \mathbf{X}(i, l)\mathbf{Y}(l, j). \tag{11}$$

Consider the first column of $\mathbf{U}$ and recall that it includes at least $r_{\mathbf{\Omega}}+1 \geq r+1$ observed entries. The genericity of the coefficients of the above-mentioned polynomials results that using r of the observed entries the first column of $\mathbf{Y}$ can be determined uniquely. This is because there exists a unique solution for a system of r linear equations in r variables that are linearly independent. Then, there exists at least one more observed entry besides these r observed entries in the first column of $\mathbf{U}$ and it can be written as a linear combination of the r observed entries that have been used to obtain the first column of $\mathbf{Y}$. Let $\mathbf{U}(i_1, 1)$, $\ldots$, $\mathbf{U}(i_r, 1)$ denote the r observed entries that have been used to obtain the first column of $\mathbf{Y}$ and $\mathbf{U}(i_{r+1}, 1)$ denote the other observed entry. Hence, the existence of a completion of the sampled matrix $\mathbf{U}$ of rank $r \in \mathcal{S}_{\mathbf{\Omega}}$ results in an equation as the following

$$\mathbf{U}(i_{r+1}, 1) = \sum_{l=1}^{r} t_l \mathbf{U}(i_l, 1), \tag{12}$$

where t_l's are constant scalars, $l = 1, \ldots, r$. Assume that $r^* \notin \mathcal{S}_{\mathbf{\Omega}}$, i.e., statement (i) does not hold. Then, note that $r^* \geq r + 1$ and $\mathbf{U}$ is chosen generically from the manifold of $n_1 \times n_2$ rank-r^* matrices, and therefore an equation of the form of (12) holds with probability zero. Moreover, according to Lemma 1 there exist at most finitely many completions of the sampled matrix of rank r. Therefore, there exist a completion of $\mathbf{U}$ of rank r with probability zero, which contradicts the initial assumption that there exists a completion of the sampled matrix $\mathbf{U}$ of rank r, where $r \in \mathcal{S}_{\mathbf{\Omega}}$. ■

Note that the existing work that treats the similar problem for a single-view matrix data based on the sampling pattern is (Pimentel-Alarcón and Nowak, 2016), which requires some strong assumptions including the existence of a completion whose rank r is a lower bound on the unknown true rank r^*, i.e., $r^* \geq r$. We provide a new analysis that does not require such assumption and also based on our new analysis, we can extend our approach to treat other data structures.

Corollary 5 *Consider an arbitrary number $r' \in \mathcal{S}_{\mathbf{\Omega}}$. Similar to Theorem 4, it follows that with probability one, exactly one of the followings holds*
(i) $r^* \in \{1, 2, \ldots, r'\}$;
(ii) For any arbitrary completion of the sampled matrix $\mathbf{U}$ of rank r, we have $r \notin \{1, 2, \ldots, r'\}$.

As a result of Corollary 5, we have the following.

Corollary 6 *Assuming that there exists a rank-r completion of the sampled matrix $\mathbf{U}$ such that $r \in \mathcal{S}_{\mathbf{\Omega}}$, then with probability one $r^* \leq r$.*

Corollary 7 *Let $\mathbf{U}^*$ denote an optimal solution to the following NP-hard optimization problem*

$$\begin{array}{ll} \text{minimize}_{\mathbf{U}' \in \mathbb{R}^{n_1 \times n_2}} & \text{rank}(\mathbf{U}') \\ \text{subject to} & \mathbf{U}'_{\mathbf{\Omega}} = \mathbf{U}_{\mathbf{\Omega}}. \end{array} \tag{13}$$

Also, let $\hat{\mathbf{U}}$ denote a suboptimal solution to the above optimization problem. Then, Corollary 5 results the following statements:

(i) If $\text{rank}(\mathbf{U}^*) \in \mathcal{S}_{\mathbf{\Omega}}$, *then* $r^* = \text{rank}(\mathbf{U}^*)$ *with probability one.*

(ii) If $\text{rank}(\hat{\mathbf{U}}) \in \mathcal{S}_{\mathbf{\Omega}}$, *then* $r^* \leq \text{rank}(\hat{\mathbf{U}})$ *with probability one.*

Remark 8 *One challenge of applying Corollary 7 or any of the other obtained deterministic results is the computation of $\mathcal{S}_{\mathbf{\Omega}}$, which involves exhaustive enumeration to check Condition B_r. Next, for each number r, we provide a lower bound on the sampling probability in terms of r that ensures $r \in \mathcal{S}_{\mathbf{\Omega}}$ with high probability. Consequently, we do not need to compute $\mathcal{S}_{\mathbf{\Omega}}$ but instead we can certify the above results with high probability.*

3.1.2 PROBABILISTIC RANK ANALYSIS

The following lemma is a re-statement of Theorem 3 in (Pimentel-Alarcón et al., 2016d), which is the probabilistic version of Lemma 1.

Lemma 9 *Suppose $r \leq \frac{n_1}{6}$ and that each* **column** *of the sampled matrix is observed in at least l entries, uniformly at random and independently across entries, where*

$$l > \max\left\{12\ \log\left(\frac{n_1}{\epsilon}\right) + 12, 2r\right\}. \tag{14}$$

Also, assume that $r(n_1 - r) \leq n_2$. Then, with probability at least $1 - \epsilon$, $r \in \mathcal{S}_{\mathbf{\Omega}}$.

The following lemma is taken from (Ashraphijuo et al., 2016a) and will be used to derive a lower bound on the sampling probability that leads to the similar statement as Theorem 4 with high probability.

Lemma 10 *Consider a vector with n entries where each entry is observed with probability p independently from the other entries. If $p > p' = \frac{k}{n} + \frac{1}{\sqrt[4]{n}}$, then with probability at least $\left(1 - \exp(-\frac{\sqrt{n}}{2})\right)$, more than k entries are observed.*

The following proposition characterizes the probabilistic version of Theorem 4.

Proposition 11 *Suppose $r \leq \frac{n_1}{6}$, $r(n_1 - r) \leq n_2$ and that each entry of the sampled matrix is observed uniformly at random and independently across entries with probability p, where*

$$p > \frac{1}{n_1}\max\left\{12\ \log\left(\frac{n_1}{\epsilon}\right) + 12, 2r\right\} + \frac{1}{\sqrt[4]{n_1}}. \tag{15}$$

Then, with probability at least $(1-\epsilon)\left(1 - \exp(-\frac{\sqrt{n_1}}{2})\right)^{n_2}$, we have $r \in \mathcal{S}_{\mathbf{\Omega}}$.

Proof Consider an arbitrary column of $\mathbf{U}$ and note that resulting from Lemma 10 the number of observed entries at this column of $\mathbf{U}$ is greater than $\max\left\{12\ \log\left(\frac{n_1}{\epsilon}\right) + 12, 2r\right\}$ with probability at least $\left(1 - \exp(-\frac{\sqrt{n_1}}{2})\right)$. Therefore, the number of sampled entries at each column satisfies

$$l > \max\left\{12\ \log\left(\frac{n_1}{\epsilon}\right) + 12, 2r\right\}, \tag{16}$$

with probability at least $\left(1 - \exp(-\frac{\sqrt{n_1}}{2})\right)^{n_2}$. Thus, resulting from Lemma 9 with probability at least $(1-\epsilon)\left(1 - \exp(-\frac{\sqrt{n_1}}{2})\right)^{n_2}$, we have $r \in \mathcal{S}_{\mathbf{\Omega}}$. ■

Finally, we have the following probabilistic version of Corollary 7.

Corollary 12 *Assume that* $\text{rank}(\mathbf{U}^*) \leq \frac{n_1}{6}$ *and* $\text{rank}(\mathbf{U}^*)(n_1 - \text{rank}(\mathbf{U}^*)) \leq n_2$ *and* (15) *holds for* $r = \text{rank}(\mathbf{U}^*)$, *where* $\mathbf{U}^*$ *denotes an optimal solution to the optimization problem* (13). *Then, according to Proposition 11 and Corollary 7, with probability at least* $(1-\epsilon)\left(1 - \exp(-\frac{\sqrt{n_1}}{2})\right)^{n_2}$, $r^* = \text{rank}(\mathbf{U}^*)$. *Similarly, assume that* $\text{rank}(\hat{\mathbf{U}}) \leq \frac{n_1}{6}$ *and* $\text{rank}(\hat{\mathbf{U}})(n_1 - \text{rank}(\hat{\mathbf{U}})) \leq n_2$ *and* (15) *holds for* $r = \text{rank}(\hat{\mathbf{U}})$, *where* $\hat{\mathbf{U}}$ *denotes a suboptimal solution to the optimization problem* (13). *Then, with probability at least* $(1-\epsilon)\left(1 - \exp(-\frac{\sqrt{n_1}}{2})\right)^{n_2}$, $r^* \leq \text{rank}(\hat{\mathbf{U}})$.

3.1.3 NUMERICAL RESULTS

In Fig. 1 and Fig. 2, the x-axis represents the sampling probability, and the y-axis denotes the value of r. The color scale represents the lower bound on the probability of event $r \in \mathcal{S}_{\mathbf{\Omega}}$. For example, as we can observe in Fig. 1, for any $r \in \{1, \ldots, 44\}$ we have $r \in \mathcal{S}_{\mathbf{\Omega}}$ with probability at least 0.6 (approximately based on the color scale since the corresponding points are orange) given that $p = 0.54$.

We consider the sampled matrix $\mathbf{U} \in \mathbb{R}^{300\times 15000}$ and $\mathbf{U} \in \mathbb{R}^{1200\times 240000}$ in Fig. 1 and Fig. 2, respectively. In particular, for fixed values of sampling probability p and r, we first find a "small" ϵ that (15) holds by trial-and-error. Then, according to Proposition 11, we conclude that with probability at least $(1-\epsilon)\left(1 - \exp(-\frac{\sqrt{n_1}}{2})\right)^{n_2}$, $r \in \mathcal{S}_{\mathbf{\Omega}}$.

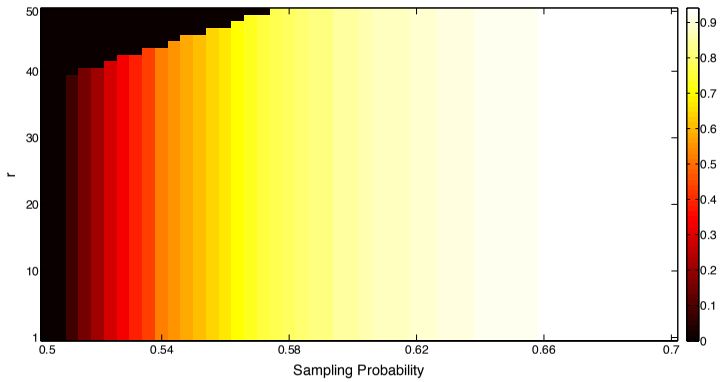

Figure 1: Probability of $r \in \mathcal{S}_{\mathbf{\Omega}}$ as a function of sampling probability for $\mathbf{U} \in \mathbb{R}^{300\times 15000}$.

The purpose of Figs. 3–6 is to show how tight our proposed upper bounds on rank can be. Here, we first generate an $n_1 \times n_2$ random matrix of a given rank r by multiplying a random

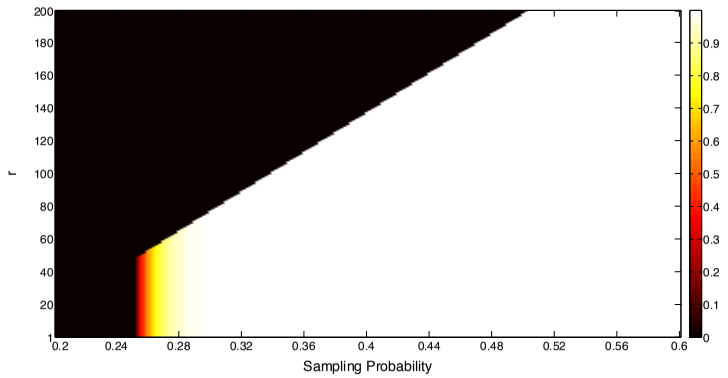

Figure 2: Probability of $r \in \mathcal{S}_{\mathbf{\Omega}}$ as a function of sampling probability for $\mathbf{U} \in \mathbb{R}^{1200\times 240000}$.

(entries are drawn according to a uniform distribution on real numbers within an interval) $n_1 \times r$ matrix and $r \times n_2$ matrix. Then, each entry of the randomly generated matrix is sampled uniformly at random and independently across entries with some sampling probability p. Afterwards, we apply the nuclear norm minimization method proposed in (Candes and Recht, 2012) for matrix completion, where the non-convex objective function in (13) is relaxed by using nuclear norm, which is the convex hull of the rank function, as follows

$$\begin{aligned} &\text{minimize}_{\mathbf{U}'\in\mathbb{R}^{n_1\times n_2}} && \|\mathbf{U}'\|_* \\ &\text{subject to} && \mathbf{U}'_{\mathbf{\Omega}} = \mathbf{U}_{\mathbf{\Omega}}, \end{aligned} \tag{17}$$

where $\|\mathbf{U}'\|_*$ denotes the nuclear norm of $\mathbf{U}'$. Let $\hat{\mathbf{U}}^*$ denote an optimal solution to (17) and recall that $\mathbf{U}^*$ denotes an optimal solution to (13). Since (17) is a convex relaxation to (13), we conclude that $\hat{\mathbf{U}}^*$ is a suboptimal solution to (13), and therefore $\text{rank}(\mathbf{U}^*) \leq \text{rank}(\hat{\mathbf{U}}^*)$. We used the Matlab program found online (Shabat, 2015) to solve (17).

As an example, we generate a random matrix $\mathbf{U} \in \mathbb{R}^{300\times 15000}$ (the same size as the matrix in Fig. 1) of rank r as described above for $r \in \{1, \ldots, 50\}$ and some values of the sampling probability p. Then, we obtain the rank of the completion given by (17) and denote it by r'. Due to the randomness of the sampled matrix, we repeat this procedure 5 times. We calculate the "gap" $r'-r$ in each of these 5 runs and denote the maximum and minimum among these 5 numbers by d_{max} and d_{min}, respectively. Hence, d_{max} and d_{min} represent the loosest (worst) and tightest (best) gaps between the rank obtained by (17) and rank of the original sampled matrix over 5 runs, respectively. In Figs. 3–6, the maximum and minimum gaps are plotted as a function of rank of the matrix, for different sampling probabilities.

We have the following observations.

- According to Fig. 1, for $p = 0.54$ and $p = 0.58$ we can ensure that the rank of any completion is an upper bound on the rank of the sampled matrix or r^* with probability at least 0.6 and 0.8, respectively.

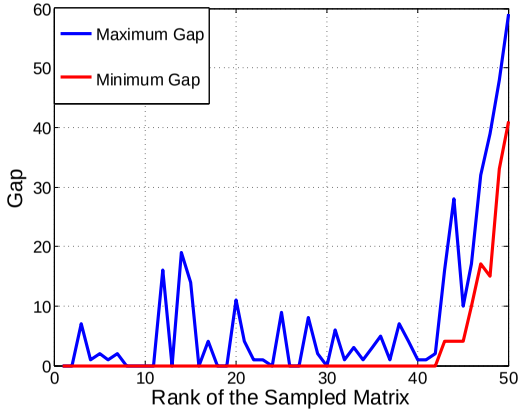

Figure 3: The gaps between the rank of the obtained matrix via (17) and that of the original sampled matrix for $p = 0.46$.

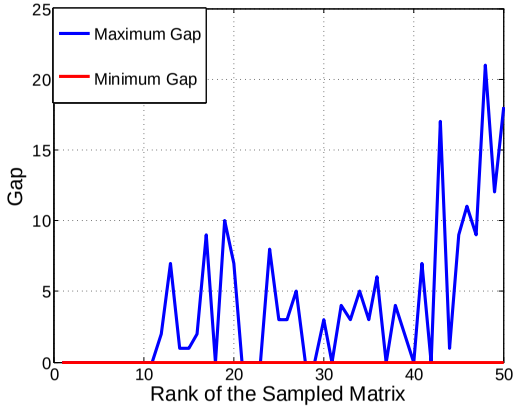

Figure 4: The gaps between the rank of the obtained matrix via (17) and that of the original sampled matrix for $p = 0.50$.

- As we can observe in Figs. 3–6, the defined gap is always a nonnegative number, which is consistent with previous observation that for $p = 0.54$ and $p = 0.58$ we can certify that with high probability (≥ 0.6) the rank of any completion is an upper bound on the rank of the sampled matrix or r^*.

- For $p = 0.54$ and $p = 0.58$ that we have theoretical results (as mentioned in the first observation) the gap obtained by (17) is very close to zero. This phenomenon (that we do not have a rigorous justification for) shows that as soon as we can certify our proposed theoretical

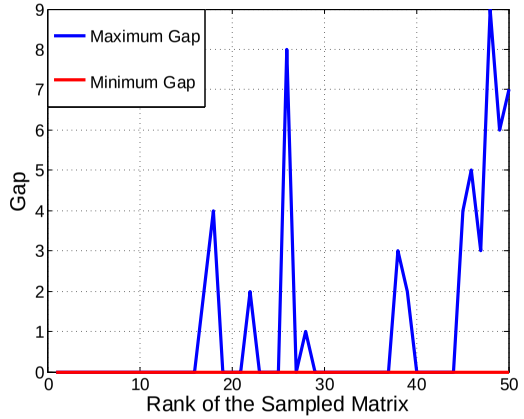

Figure 5: The gaps between the rank of the obtained matrix via (17) and that of the original sampled matrix for $p = 0.54$.

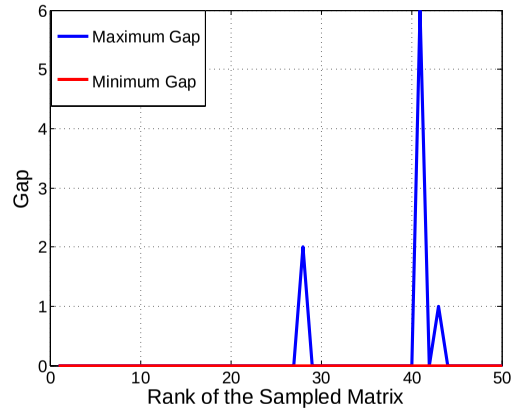

Figure 6: The gaps between the rank of the obtained matrix via (17) and that of the original sampled matrix for $p = 0.58$.

results (i.e., as soon as the rank of a completion provides an upper bound on the rank of the sampled matrix or r^*) by increasing the sampling probability, the upper bound found through (17) becomes very tight; in some cases this bound is exactly equal to r^* (red curves) and in some cases this bound is almost equal to r^* (blue curves). However, these gaps are not small (specially blue curves) for $p = 0.46$ and $p = 0.50$ and note that according to Fig. 1, for these values of p we cannot guarantee the bounds on the value of rank hold with high probability.

3.2 CP-Rank Tensor

Let $\mathbb{P}_i$ denote the Lebesgue measures on $\mathbb{R}^{n_i \times r^*}$, $i = 1, \ldots, d$. In this subsection, we assume that the sampled tensor $\mathcal{U} \in \mathbb{R}^{n_1 \times \cdots \times n_d}$ is chosen generically from the manifold of tensors of rank $r^* = \text{rank}_{\text{CP}}(\mathcal{U})$ (where r^* is unknown), or in other words, the entries of $\mathcal{U}$ are drawn independently with respect to Lebesgue measure on the corresponding manifold. Hence, the probability measures of all statements in this subsection are $\mathbb{P}_1 \times \mathbb{P}_2 \times \ldots \times \mathbb{P}_d$.

Condition $\mathcal{A}_r$: Each row of the d-th matricization of the sampled tensor, i.e., $\mathbf{U}_{(d)}$ includes at least r observed entries.

We construct a binary valued tensor called **constraint tensor** $\breve{\Omega}_r$ based on Ω and a given number r. Consider any subtensor $\mathcal{Y} \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times 1}$ of the tensor $\mathcal{U}$. The sampled tensor $\mathcal{U}$ includes n_d subtensors that belong to $\mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times 1}$ and let $\mathcal{Y}_i$ for $1 \leq i \leq n_d$ denote these n_d subtensors. Define a binary valued tensor $\breve{\mathcal{Y}}_i \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times k_i}$, where $k_i = N_\Omega(\mathcal{Y}_i) - r$ and its entries are described as the following. We can look at $\breve{\mathcal{Y}}_i$ as k_i tensors each belongs to $\mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times 1}$. For each of the mentioned k_i tensors in $\breve{\mathcal{Y}}_i$ we set the entries corresponding to r of the observed entries equal to 1. For each of the other k_i observed entries, we pick one of the k_i tensors of $\breve{\mathcal{Y}}_i$ and set its corresponding entry (the same location as that specific observed entry) equal to 1 and set the rest of the entries equal to 0. In the case that $k_i = 0$ we simply ignore $\breve{\mathcal{Y}}_i$, i.e., $\breve{\mathcal{Y}}_i = \emptyset$

By putting together all n_d tensors in dimension d, we construct a binary valued tensor $\breve{\Omega}_r \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times K}$, where $K = \sum_{i=1}^{n_d} k_i = N_\Omega(\mathcal{U}) - r n_d$ and call it the **constraint tensor**. Observe that each subtensor of $\breve{\Omega}_r$ which belongs to $\mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times 1}$ includes exactly $r + 1$ nonzero entries. In (Ashraphijuo and Wang, 2017b), an example is given on the construction of $\breve{\Omega}_r$.

Condition $\mathcal{B}_r$: $\breve{\Omega}_r$ consists a subtensor $\breve{\Omega}'_r \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times K}$ such that $K = r(\sum_{i=1}^{d-1} n_i) - r^2 - r(d-2)$ and for any $K' \in \{1, 2, \ldots, K\}$ and any subtensor $\breve{\Omega}''_r \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times K'}$ of $\breve{\Omega}'_r$ we have

$$r\left(\left(\sum_{i=1}^{d-1} f_i(\breve{\Omega}''_r)\right) - \min\left\{\max\left\{f_1(\breve{\Omega}''_r), \ldots, f_{d-1}(\breve{\Omega}''_r)\right\}, r\right\} - (d-2)\right) \geq K', \tag{18}$$

where $f_i(\breve{\Omega}''_r)$ denotes the number of nonzero rows of the i-th matricization of $\breve{\Omega}''_r$.

The following lemma is a re-statement of Theorem 1 in (Ashraphijuo and Wang, 2017b).

Lemma 13 *With probability one, there are only finitely many rank-r^* completions of the sampled tensor if and only if Conditions $\mathcal{A}_{r^*}$ and $\mathcal{B}_{r^*}$ hold.*

Definition 14 *Let $\mathcal{S}_\Omega$ denote the set of all natural numbers r such that both Conditions $\mathcal{A}_r$ and $\mathcal{B}_r$ hold.*

Lemma 15 *There exists a number r_Ω such that $\mathcal{S}_\Omega = \{1, 2, \ldots, r_\Omega\}$.*

Proof The proof is similar to the proof of Lemma 3 since the dimension of the manifold of CP rank-r tensors is $r(\sum_{i=1}^{d} n_i) - r^2 - r(d-1)$, which is an increasing function in r. ■

The following theorem gives an upper bound on the unknown rank r^*.

Theorem 16 *With probability one, exactly one of the following statements holds*
(i) $r^* \in \mathcal{S}_\Omega = \{1, 2, \ldots, r_\Omega\}$;
(ii) For any arbitrary completion of the sampled tensor $\mathcal{U}$ of rank r, we have $r \notin \mathcal{S}_\Omega$.

Proof Similar to the proof of Theorem 4, it suffices to show that the assumption $r^* \notin \mathcal{S}_\Omega$ results that there exists a completion of $\mathcal{U}$ of CP rank r, where $r \in \mathcal{S}_\Omega$, with probability zero. Define $\mathcal{V} = (\mathcal{V}_1, \ldots, \mathcal{V}_r)$ as the basis of the rank-r CP decomposition of $\mathcal{U}$ as in (3), where $\mathcal{V}_l = \mathbf{a}_1^l \otimes \mathbf{a}_2^l \otimes \ldots \otimes \mathbf{a}_{d-1}^l \in \mathbb{R}^{n_1 \times \ldots n_{d-1}}$ is a rank-1 tensor and $\mathbf{a}_i^l$ is defined in (3) for $1 \leq l \leq r$ and $1 \leq i \leq d$. Define $\mathcal{Y} = (\mathbf{a}_d^1, \ldots, \mathbf{a}_d^r)$ and $\mathcal{V} \otimes_d \mathcal{Y} = \sum_{l=1}^r \mathcal{V}_l \otimes \mathbf{a}_d^l$. Observe that $\mathcal{U} = \sum_{l=1}^r \mathcal{V}_l \otimes \mathbf{a}_d^l = \mathcal{V} \otimes_d \mathcal{Y}$.

Observe that each row of $\mathbf{U}_{(d)}$ includes at least $r_\Omega + 1$ observed entries since Condition $\mathcal{A}_{r_\Omega}$ holds. Moreover, the existence of a completion of the sampled tensor $\mathcal{U}$ of rank $r \in \mathcal{S}_\Omega$ results in the existence of a basis $\mathcal{V} = (\mathcal{V}_1, \ldots, \mathcal{V}_r)$ such that there exists $\mathcal{Y} = (\mathbf{a}_d^1, \ldots, \mathbf{a}_d^r)$ and $\mathcal{U}_\Omega = (\mathcal{V} \otimes_d \mathcal{Y})_\Omega$. As a result, given $\mathcal{V}$, each observed entry of $\mathcal{U}$ results in a degree-1 polynomial in terms of the entries of $\mathcal{Y}$ as

$$\mathcal{U}(\vec{x}) = \sum_{l=1}^{r} \mathcal{V}_l(x_1, \ldots, x_{d-1}) \mathbf{a}_d^l(x_d). \tag{19}$$

Note that $r_\Omega \geq r$ and each row of $\mathbf{U}_{(d)}$ includes at least $r_\Omega + 1 \geq r + 1$ observed entries. Consider $r+1$ of the observed entries of the first row of $\mathbf{U}_{(d)}$ and we denote them by $\mathcal{U}(\vec{x}_1), \ldots, \mathcal{U}(\vec{x}_{r+1})$, where the last component of the vector $\vec{x}_i$ is equal to one, $1 \leq i \leq r+1$. Similar to the proof of Theorem 4, genericity of $\mathcal{U}$ results in

$$\mathcal{U}(\vec{x}_{r+1}) = \sum_{l=1}^{r} t_l \mathcal{U}(\vec{x}_i), \tag{20}$$

where t_l's are constant scalars, $l = 1, \ldots, r$. On the other hand, according to Lemma 13 there exist at most finitely many completions of the sampled tensor of rank r. Therefore, there exist a completion of $\mathbf{U}$ of rank r with probability zero. Moreover, an equation of the form of (20) holds with probability zero as $r^* \geq r+1$ and $\mathcal{U}$ is chosen generically from the manifold of tensors of rank-r^*. Therefore, there exists a completion of rank r with probability zero. ■

Corollary 17 *Consider an arbitrary number $r' \in \mathcal{S}_\Omega$. Similar to Theorem 16, it follows that with probability one, exactly one of the followings holds*

(i) $r^* \in \{1, 2, \ldots, r'\}$;

(ii) For any arbitrary completion of the sampled tensor $\mathcal{U}$ of rank r, we have $r \notin \{1, 2, \ldots, r'\}$.

Corollary 18 *Assuming that there exists a CP rank-r completion of the sampled tensor $\mathcal{U}$ such that $r \in \mathcal{S}_\Omega$, we conclude that with probability one $r^* \leq r$.*

Corollary 19 *Let $\mathcal{U}^*$ denote an optimal solution to the following NP-hard optimization problem*

$$\begin{aligned} &\text{minimize}_{\mathcal{U}' \in \mathbb{R}^{n_1 \times \cdots \times n_d}} && \text{rank}_{\text{CP}}(\mathcal{U}') \\ &\text{subject to} && \mathcal{U}'_\Omega = \mathcal{U}_\Omega. \end{aligned} \tag{21}$$

Assume that $\text{rank}_{\text{CP}}(\mathcal{U}^*) \in \mathcal{S}_\Omega$. Then, Corollary 18 results that $r^* = \text{rank}_{\text{CP}}(\mathcal{U}^*)$ with probability one.

The following lemma is Lemma 15 in (Ashraphijuo and Wang, 2017b), which is the probabilistic version of Lemma 13 in terms of the sampling probability.

Lemma 20 *Assume that $n_1 = n_2 = \cdots = n_d = n$, $d > 2$, $n > \max\{200, r(d-2)\}$ and $r \leq \frac{n}{6}$. Moreover, assume that the sampling probability satisfies*

$$p > \frac{1}{n^{d-2}} \max\left\{27 \log\left(\frac{n}{\epsilon}\right) + 9 \log\left(\frac{2r(d-2)}{\epsilon}\right) + 18, 6r\right\} + \frac{1}{\sqrt[4]{n^{d-2}}}. \tag{22}$$

Then, with probability at least $(1-\epsilon)\left(1 - \exp(-\frac{\sqrt{n^{d-2}}}{2})\right)^{n^2}$, we have $r \in \mathcal{S}_\Omega$.

The following corollary is the probabilistic version of Corollaries 18 and 19.

Corollary 21 *Assuming that there exists a CP rank-r completion of the sampled tensor $\mathcal{U}$ such that the conditions given in Lemma 20 hold, with the sampling probability satisfying (22), we conclude that with probability at least $(1-\epsilon)\left(1 - \exp(-\frac{\sqrt{n^{d-2}}}{2})\right)^{n^2}$ we have $r^* \leq r$. Therefore, given that (22) holds for $r = \text{rank}(\mathbf{U}^*)$ and $\mathbf{U}^*$ denotes an optimal solution to the optimization problem (21), with probability at least $(1-\epsilon)\left(1 - \exp(-\frac{\sqrt{n^{d-2}}}{2})\right)^{n^2}$ we have $r^* = \text{rank}(\mathbf{U}^*)$.*

3.2.1 NUMERICAL RESULTS

We generate a random tensor $\mathcal{U} \in \mathbb{R}^{8\times8\times8\times8\times8\times8}$ of CP-rank 2 by adding two random rank-1 tensors. The color scale represents the lower bound on the probability that we can guarantee the rank of a given completion is an upper bound on the true value of rank. Then, we solve the following convex optimization problem for different values of the sampling probability.

$$\begin{aligned} &\text{minimize}_{\mathcal{U}' \in \mathbb{R}^{n_1 \times \cdots \times n_d}} && \|\widetilde{\mathbf{U}}'_{(3)}\|_* \\ &\text{subject to} && \mathcal{U}'_\Omega = \mathcal{U}_\Omega. \end{aligned} \tag{23}$$

Note that rank of any of the unfoldings of a tensor is a lower bound on the CP-rank of that tensor. Hence, we minimize the nuclear norm of the unfolding with the possible maximum rank among all unfoldings as $\widetilde{\mathbf{U}}_{(3)} \in \mathbb{R}^{512\times512}$. Then, we use the Matlab toolbox found online "Tensorlab" to calculate the CP-rank of the obtained tensor via solving convex program (23) (there are other methods to calculate CP decomposition, e.g., (Pimentel-Alarcón, 2016)). In Figure 7, gap represents the CP-rank of the solution of (23) minus the CP-rank of the original sampled tensor.

4. Vector-Rank Cases

4.1 Multi-View Matrix

Let $\mathbb{P}_1$ and $\mathbb{P}_2$ denote the Lebesgue measures on $\mathbb{R}^{n \times r_1^*}$ and $\mathbb{R}^{r_1^* \times n_1}$, respectively. Moreover, let $\mathbb{P}_3$ and $\mathbb{P}_4$ denote the Lebesgue measures on $\mathbb{R}^{n \times (r^* - r_1^*)}$ and $\mathbb{R}^{r_2^* \times n_2}$, respectively. In this paper, we assume that $\mathbf{U}$ is chosen generically from the manifold corresponding to rank vector (r_1^*, r_2^*, r^*), i.e., the entries of $\mathbf{U}$ are drawn independently with respect to Lebesgue measure on the corresponding manifold. Hence, the probability measures of all statements in this subsection are $\mathbb{P}_1 \times \mathbb{P}_2 \times \mathbb{P}_3 \times \mathbb{P}_4$.

The following Conditions will be used frequently in this subsection.

Condition A_{r_1,r_2}: Each column of $\mathbf{U}_1$ and $\mathbf{U}_2$ include at least r_1 and r_2 sampled entries, respectively.

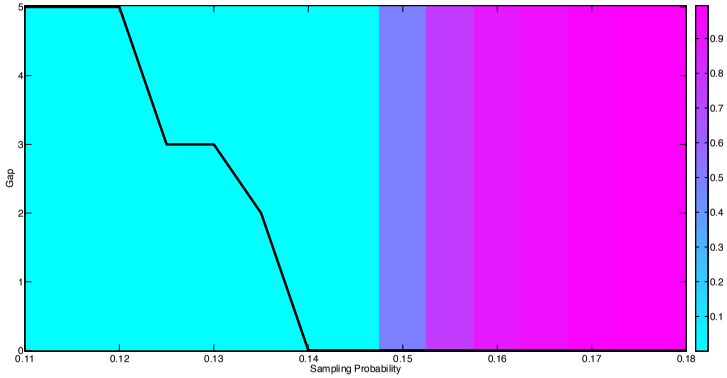

Figure 7: The rank gap as a function of sampling probability for $\mathcal{U} \in \mathbb{R}^{8\times 8\times 8\times 8\times 8\times 8}$ of CP-rank 2.

We construct a binary valued matrix called **constraint matrix** for multi-view matrix $\mathbf{U}$ as $\breve{\mathbf{\Omega}}_{r_1,r_2} = [\breve{\mathbf{\Omega}}_{r_1}|\breve{\mathbf{\Omega}}_{r_2}]$, where $\breve{\mathbf{\Omega}}_{r_1}$ and $\breve{\mathbf{\Omega}}_{r_2}$ represent the constraint matrix for single-view matrices $\mathbf{U}_1$ and $\mathbf{U}_2$ (defined in Section 3.1), respectively.

Condition $B_{r_1,r_2,r}$: $\breve{\mathbf{\Omega}}_{r_1,r_2}$ consists a submatrix $\breve{\mathbf{\Omega}}'_{r_1,r_2} \in \mathbb{R}^{n\times K}$ such that $K = nr - r^2 - r_1^2 - r_2^2 + r(r_1+r_2)$ and for any $K' \in \{1,2,\ldots,K\}$ and any submatrix $\breve{\mathbf{\Omega}}''_{r_1,r_2} \in \mathbb{R}^{n\times K'}$ of $\breve{\mathbf{\Omega}}'_{r_1,r_2}$ we have

$$(r-r_2)\left(f(\breve{\mathbf{\Omega}}''_{r_1}) - r_1\right)^+ + (r-r_1)\left(f(\breve{\mathbf{\Omega}}''_{r_2}) - r_2\right)^+ + (r_1+r_2-r)\left(f(\breve{\mathbf{\Omega}}''_{r_1,r_2}) - (r_1+r_2-r)\right)^+ \geq K', \tag{24}$$

where $f(\mathbf{X})$ denotes the number of nonzero rows of $\mathbf{X}$ for any matrix $\mathbf{X}$ and $\breve{\mathbf{\Omega}}''_{r_1,r_2} = [\breve{\mathbf{\Omega}}''_{r_1}|\breve{\mathbf{\Omega}}''_{r_2}]$, and also $\breve{\mathbf{\Omega}}''_{r_1}$ and $\breve{\mathbf{\Omega}}''_{r_2}$ denote the columns of $\breve{\mathbf{\Omega}}''_{r_1,r_2}$ corresponding to $\breve{\mathbf{\Omega}}_{r_1}$ and $\breve{\mathbf{\Omega}}_{r_2}$, respectively.

The following lemma is a re-statement of Theorem 2 in (Ashraphijuo et al., 2017c).

Lemma 22 *With probability one, there are only finitely many completions of the sampled multi-view data if and only if Conditions $A_{r_1^*,r_2^*}$ and $B_{r_1^*,r_2^*,r^*}$ hold.*

Definition 23 *Denote the rank vector $\underline{r} = (r_1, r_2, r)$. Define the generalized inequality $\underline{r}' \preceq \underline{r}$ as the component-wise set of inequalities, e.g., $r'_1 \leq r_1$, $r'_2 \leq r_2$ and $r' \leq r$.*

Definition 24 *Let $\mathcal{S}_{\mathbf{\Omega}}$ denote the set of all $\underline{r}$ such that both Conditions A_{r_1,r_2} and $B_{r_1,r_2,r}$ hold.*

Lemma 25 *Assume $\underline{r} \in \mathcal{S}_{\mathbf{\Omega}}$. Then, for any $\underline{r}' \preceq \underline{r}$, we have $\underline{r}' \in \mathcal{S}_{\mathbf{\Omega}}$.*

Proof We consider the rank factorization of $\mathbf{U}$ as in (Ashraphijuo et al., 2017c) and similar to the single-view scenario in Lemma 3 each observed entry results in a polynomial in terms of the entries of the components of the decomposition. Note that the dimension of the manifold corresponding to rank vector $\underline{r}$ is equal to $rn+r_1n_1+r_2n_2-r^2-r_1^2-r_2^2+r(r_1+r_2)$ (Ashraphijuo et al., 2017c), and also observe that the fact that $\max\{r_1,r_2\} \leq r \leq r_1+r_2 \leq \min\{2n, n_1+n_2\}$ implies that reducing any of the values r_1, r_2, and r reduces the value of $rn+r_1n_1+r_2n_2-r^2-r_1^2-r_2^2+r(r_1+r_2)$. Hence, the dimension of the manifold corresponding to rank vector $\underline{r}$ is larger than that for rank vector $\underline{r}'$, given $\underline{r}' \preceq \underline{r}$, and thus similar to the proof of Lemma 3, finite completability of data with $\underline{r}$ results finite completability of data with $\underline{r}'$ with probability one. Then, using Lemma 22, the proof is complete. ■

The following theorem provides a relationship between the unknown rank vector $\underline{r}^*$ and $\mathcal{S}_{\mathbf{\Omega}}$.

Theorem 26 *With probability one, exactly one of the following statements holds*
(i) $\underline{r}^* \in \mathcal{S}_{\mathbf{\Omega}}$;
(ii) For any arbitrary completion of the sampled matrix $\mathbf{U}$ of rank vector $\underline{r}$, we have $\underline{r} \notin \mathcal{S}_{\mathbf{\Omega}}$.

Proof Similar to the proof of Theorem 4, suppose that there does not exist a completion of $\mathbf{U}$ of rank vector $\underline{r}$ such that $\underline{r} \in \mathcal{S}_{\mathbf{\Omega}}$. Therefore, it is easily verified that statement (ii) holds and statement (i) does not hold. On the other hand, assume that there exists a completion of $\mathbf{U}$ of rank vector $\underline{r}$, where $\underline{r} \in \mathcal{S}_{\mathbf{\Omega}}$. Hence, statement (ii) does not hold and to complete the proof it suffices to show that with probability one, statement (i) holds. Similar to Theorem 4, we show that assuming $\underline{r}^* \notin \mathcal{S}_{\mathbf{\Omega}}$, there exists a completion of $\mathbf{U}$ of rank vector $\underline{r}$, where $\underline{r} \in \mathcal{S}_{\mathbf{\Omega}}$, with probability zero.

Since $\underline{r}^* \notin \mathcal{S}_{\mathbf{\Omega}}$, according to Lemma 25, for any $\underline{r} \in \mathcal{S}_{\mathbf{\Omega}}$ at least one the following inequalities holds; $r_1 < r_1^*$, $r_2 < r_2^*$ and $r < r^*$. Note that assuming that there exists a completion of $\mathbf{U}_1$ of rank r_1 with probability zero results that there exists a completion of $\mathbf{U}$ of rank vector $\underline{r}$ with probability zero and similar statement holds for r_2 and r. Hence, in any possible scenario ($r_1 < r_1^*$ or $r_2 < r_2^*$ or $r < r^*$) the similar proof as in Theorem 4 (for single-view matrix) results that there exists a completion of $\mathbf{U}$ of rank vector $\underline{r}$, where $\underline{r} \in \mathcal{S}_{\mathbf{\Omega}}$, with probability zero. ■

Corollary 27 *Consider a subset $\mathcal{S}'_{\mathbf{\Omega}}$ of $\mathcal{S}_{\mathbf{\Omega}}$ such that for any two members of $\mathcal{S}_{\mathbf{\Omega}}$ that $\underline{r}' \preceq \underline{r}''$ and $\underline{r}'' \in \mathcal{S}'_{\mathbf{\Omega}}$ we have $\underline{r}' \in \mathcal{S}'_{\mathbf{\Omega}}$. Then, with probability one, exactly one of the followings holds*
(i) $\underline{r}^* \in \mathcal{S}'_{\mathbf{\Omega}}$;
(ii) For any arbitrary completion of $\mathbf{U}$ of rank vector $\underline{r}$, we have $\underline{r} \notin \mathcal{S}'_{\mathbf{\Omega}}$.

Proof Note that the property in the statement of Lemma 25 holds for $\mathcal{S}'_{\mathbf{\Omega}}$ as well as $\mathcal{S}_{\mathbf{\Omega}}$. Moreover, as $\mathcal{S}'_{\mathbf{\Omega}} \subseteq \mathcal{S}_{\mathbf{\Omega}}$, for any $\underline{r} \in \mathcal{S}'_{\mathbf{\Omega}}$ there exists at most finitely many completions of $\mathbf{U}$ of rank vector $\underline{r}$, and therefore the rest of the proof is the same as the proof of Theorem 26. ■

Corollary 28 *Assuming that there exists a completion of $\mathbf{U}$ with rank vector $\underline{r}$ such that $\underline{r} \in \mathcal{S}_{\mathbf{\Omega}}$, then with probability one $\underline{r}^* \preceq \underline{r}$.*

The following lemma which is a re-statement of Theorem 3 in (Ashraphijuo et al., 2017c) gives the number of samples per column that is needed to ensure that Conditions A_{r_1,r_2} and $B_{r_1,r_2,r}$ hold with high probability.

Lemma 29 *Suppose that the following inequalities hold*

$$\begin{aligned} \frac{n}{6} &\geq \max\{r_1, r_2, (r_1+r_2-r)\}, && (25)\\ n_1 &\geq (r-r_2)(n-r_1), && (26)\\ n_2 &\geq (r-r_1)(n-r_2), && (27)\\ n_1+n_2 &\geq (r-r_2)(n-r_1)+(r-r_1)(n-r_2) \\ &+ (r_1+r_2-r)(n-(r_1+r_2-r)). && (28)\end{aligned}$$

Moreover assume that each **column** *of* $\mathbf{U}$ *is observed in at least* l *entries, uniformly at random and independently across entries, where*

$$l > \max\left\{9\ \log\left(\frac{n}{\epsilon}\right) + 3\ \log\left(\frac{3\max\{r-r_2, r-r_1, r_1+r_2-r\}}{\epsilon}\right) + 6, 2r_1, 2r_2\right\}. \quad (29)$$

Then, with probability at least $1-\epsilon$, $\underline{r} \in \mathcal{S}_{\mathbf{\Omega}}$.

The following proposition is the probabilistic version of Theorem 26 in terms of the sampling probability instead of verifying Conditions A_{r_1,r_2} and $B_{r_1,r_2,r}$.

Proposition 30 *Suppose that* (25)-(28) *hold for* $\underline{r}$ *and that each entry of the sampled matrix is observed uniformly at random and independently across entries with probability* p*, where*

$$p > \frac{1}{n}\max\left\{9\ \log\left(\frac{n}{\epsilon}\right) + 3\ \log\left(\frac{3\max\{r-r_2, r-r_1, r_1+r_2-r\}}{\epsilon}\right) + 6, 2r_1, 2r_2\right\} + \frac{1}{\sqrt[4]{n}}.$$

Then, with probability at least $(1-\epsilon)\left(1-\exp(-\frac{\sqrt{n}}{2})\right)^{n_1+n_2}$*, we have* $\underline{r} \in \mathcal{S}_{\mathbf{\Omega}}$.

Proof The proposition is easy to verify using Lemma 29 and Lemma 9 (similar to the proof for Proposition 11). ■

Corollary 31 *Assuming that there exists a completion of* $\mathbf{U}$ *of rank vector* $\underline{r}$ *such that* (25)-(28) *hold and the sampling probability satisfies* (30)*, then with probability at least* $(1-\epsilon)\left(1-\exp(-\frac{\sqrt{n}}{2})\right)^{n_1+n_2}$ *we have* $\underline{r}^* \preceq \underline{r}$.

4.2 Tucker-Rank Tensor

Let $\mathbb{P}_i$ denote the Lebesgue measures on $\mathbb{R}^{n_i \times m_i^*}$, $i = j+1, \ldots, d$, and $\mathbb{P}_0$ denotes the Lebesgue measures on $\mathbb{R}^{m_{j+1}^* \times m_{j+2}^* \times \ldots \times m_d^*}$. In this subsection, we assume that the sampled tensor $\mathcal{U} \in \mathbb{R}^{n_1 \times \ldots \times n_d}$ is chosen generically from the manifold of tensors of rank $\underline{r}^* = \text{rank}_{\text{Tucker}}(\mathcal{U}) = (m_{j+1}^*, \ldots, m_d^*)$ (where $\underline{r}^*$ is unknown), or in other words, the entries of $\mathcal{U}$ are drawn independently with respect to Lebesgue measure on the corresponding manifold. Hence, the probability measures of all statements in this subsection are $\mathbb{P}_0 \times \mathbb{P}_{j+1} \times \mathbb{P}_{j+2} \times \ldots \times \mathbb{P}_d$.

Without loss of generality assume that $m_{j+1}^* \geq \ldots \geq m_d^*$ throughout this subsection. Also, given $\underline{r} = (m_{j+1}, \ldots, m_d)$, define the following function

$$g_{\underline{r}}(x) = \sum_{i=j+1}^{d} \min\left\{r_i, \left(x - \sum_{i'=j+1}^{i-1} r_{i'}\right)^+\right\} r_i. \quad (30)$$

Definition 32 *For any* $i \in \{j+1, \ldots, d\}$ *and* $\mathcal{S}_i \subseteq \{1, \ldots, n_i\}$*, define* $\mathcal{U}^{(\mathcal{S}_i)}$ *as a set containing the entries of* $|\mathcal{S}_i|$ *rows (corresponding to the elements of* $\mathcal{S}_i$*) of* $\mathbf{U}_{(i)}$*. Moreover, define* $\mathcal{U}^{(\mathcal{S}_{j+1}, \ldots, \mathcal{S}_d)} = \mathcal{U}^{(\mathcal{S}_{j+1})} \cup \ldots \cup \mathcal{U}^{(\mathcal{S}_d)}$.

Condition $\mathcal{A}_{\underline{r}}^{\text{Tucker}}$: There exist $\sum_{i=j+1}^{d}(n_i m_i)$ observed entries such that for any $\mathcal{S}_i \subseteq \{1, \ldots, n_i\}$ for $i \in \{j+1, \ldots, d\}$, $\mathcal{U}^{(\mathcal{S}_{j+1}, \ldots, \mathcal{S}_d)}$ includes at most $\sum_{i=j+1}^{d} |\mathcal{S}_i| m_i$ of the mentioned $\sum_{i=j+1}^{d} n_i m_i$ observed entries.

Let $\mathcal{P}$ be a set of $\sum_{i=j+1}^{d}(n_i m_i)$ observed entries such that they satisfy Condition $\mathcal{A}_{\underline{r}}^{\text{Tucker}}$. Now, we construct a $(j+1)^{\text{th}}$-order binary constraint tensor $\breve{\Omega}_{\underline{r}}$ in some sense similar to that in Section 3.2. For any subtensor $\mathcal{Y} \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_j \times 1 \times \cdots \times 1}$ of the tensor $\mathcal{U}$, let $N_\Omega(\mathcal{Y}^{\mathcal{P}})$ denote the number of sampled entries in $\mathcal{Y}$ that belong to $\mathcal{P}$.

The sampled tensor $\mathcal{U}$ includes $n_{j+1} n_{j+2} \cdots n_d$ subtensors that belong to $\mathbb{R}^{n_1 \times n_2 \times \cdots \times n_j \times 1 \times \cdots \times 1}$ and we label these subtensors by $\mathcal{Y}_{(t_{j+1}, \ldots, t_d)}$ where $(t_{j+1}, \ldots, t_d)$ represents the coordinate of the subtensor. Define a binary valued tensor $\breve{\mathcal{Y}}_{(t_{j+1}, \cdots, t_d)} \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_j \times \overbrace{1 \times \ldots \times 1}^{d-j} \times k}$, where $k = N_\Omega(\mathcal{Y}_{(t_{j+1}, \ldots, t_d)}) - N_\Omega(\mathcal{Y}^{\mathcal{P}}_{(t_{j+1}, \ldots, t_d)})$ and its entries are described as the following. We can look at $\breve{\mathcal{Y}}_{(t_{j+1}, \cdots, t_d)}$ as k tensors each belongs to $\mathbb{R}^{n_1 \times n_2 \times \cdots \times n_j \times 1 \times \cdots \times 1}$. For each of the mentioned k tensors in $\breve{\mathcal{Y}}_{(t_{j+1}, \cdots, t_d)}$ we set the entries corresponding to the $N_\Omega(\mathcal{Y}^{\mathcal{P}}_{(t_{j+1}, \ldots, t_d)})$ observed entries that belong to $\mathcal{P}$ equal to 1. For each of the other k observed entries, we pick one of the k tensors of $\breve{\mathcal{Y}}_{(t_{j+1}, \cdots, t_d)}$ and set its corresponding entry (the same location as that specific observed entry) equal to 1 and set the rest of the entries equal to 0.

For the sake of simplicity in notation, we treat tensors $\breve{\mathcal{Y}}_{(t_{j+1}, \cdots, t_d)}$ as a member of $\mathbb{R}^{n_1 \times n_2 \times \cdots \times n_j \times k}$ instead of $\mathbb{R}^{n_1 \times n_2 \times \cdots \times n_j \times \overbrace{1 \times \cdots \times 1}^{d-j} \times k}$. Now, by putting together all $n_{j+1} n_{j+2} \cdots n_d$ tensors in dimension $(j+1)$, we construct a binary valued tensor $\breve{\Omega}_{\underline{r}} \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_j \times K_j}$, where $K_j = N_\Omega(\mathcal{U}) - \sum_{i=j+1}^{d}(n_i m_i)$ and call it the **constraint tensor** (Ashraphijuo et al., 2016a). In (Ashraphijuo et al., 2016a), an example is given on the construction of $\breve{\Omega}_{\underline{r}}$.

Condition $\mathcal{B}_{\underline{r}}^{\text{Tucker}}$: The constraint tensor $\breve{\Omega}_{\underline{r}}$ consists a subtensor $\breve{\Omega}'_{\underline{r}} \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_j \times K}$ such that $K = \left(\Pi_{i=1}^{j} n_i\right)\left(\Pi_{i=j+1}^{d} m_i\right) - \sum_{i=j+1}^{d} m_i^2$ and for any $K' \in \{1, 2, \ldots, K\}$ and any subtensor $\breve{\Omega}''_{\underline{r}} \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times K'}$ of $\breve{\Omega}'_{\underline{r}}$ we have

$$\left(\Pi_{i=j+1}^{d} m_i\right)\left(f_{j+1}(\breve{\Omega}''_{\underline{r}})\right) - g_{\underline{r}}\left(f_{j+1}(\breve{\Omega}''_{\underline{r}})\right) \geq K', \quad (31)$$

where $f_{j+1}(\breve{\Omega}''_{\underline{r}})$ denotes the number of nonzero columns of the $(j+1)$-th matricization of $\breve{\Omega}''_{\underline{r}}$.

The following lemma is a re-statement of Theorem 3 in (Ashraphijuo et al., 2016a).

Lemma 33 *With probability one, there are only finitely many completions of rank* $\underline{r}^*$ *of the sampled tensor if and only if Conditions* $\mathcal{A}_{\underline{r}^*}^{\text{Tucker}}$ *and* $\mathcal{B}_{\underline{r}^*}^{\text{Tucker}}$ *hold.*

Definition 34 *Let* $\mathcal{S}_\Omega$ *denote the set of all rank vectors* $\underline{r}$ *such that both Conditions* $\mathcal{A}_{\underline{r}}^{\text{Tucker}}$ *and* $\mathcal{B}_{\underline{r}}^{\text{Tucker}}$ *hold.*

Lemma 35 *Assume* $\underline{r} \in \mathcal{S}_\Omega$*. Then, for any rank vector* $\underline{r}' \preceq \underline{r}$*, we have* $\underline{r}' \in \mathcal{S}_\Omega$.

Proof Note that the dimension of the manifold corresponding to $\underline{r}$ is $\left(\Pi_{i=1}^{j} n_i\right)\left(\Pi_{i=j+1}^{d} m_i\right) + \sum_{i=j+1}^{d} n_i m_i - \sum_{i=j+1}^{d} m_i^2$, and thus by reducing the value of m_{i_0} by one (for $i_0 \in \{j+1,\dots,d\}$), the value of the mentioned dimension reduces by at least $\left(\Pi_{i=1}^{j} n_i\right) + n_i - 2m_i + 1$, which is greater than zero since $m_i \leq n_i$. The rest of the proof is similar to the proof of Lemma 3. ■

Definition 36 *Define $\mathcal{S}_\Omega(\underline{r})$ as a subset of $\mathcal{S}_\Omega$, which includes all $\underline{r}' \in \mathcal{S}_\Omega$ that $\underline{r}' \preceq \underline{r}$.*

The following theorem gives a relationship between $\underline{r}^*$ and $\mathcal{S}_\Omega$.

Theorem 37 *With probability one, exactly one of the following statements holds*
(i) $\underline{r}^* \in \mathcal{S}_\Omega$;
(ii) For any arbitrary completion of the sampled tensor $\mathcal{U}$ of rank $\underline{r}$, we have $\underline{r} \notin \mathcal{S}_\Omega(\underline{r}^*)$.

Proof Similar to the proof of Theorem 4, to complete the proof it suffices to show that the assumption $\underline{r}^* \notin \mathcal{S}_\Omega$ results that there exists a completion of $\mathcal{U}$ of rank $\underline{r}$, where $\underline{r} \in \mathcal{S}_\Omega(\underline{r}^*)$, with probability zero. Note that $\underline{r} \in \mathcal{S}_\Omega(\underline{r}^*) \subseteq \mathcal{S}_\Omega$ results that Conditions $\mathcal{A}_{\underline{r}}^{\text{Tucker}}$ and $\mathcal{B}_{\underline{r}}^{\text{Tucker}}$ hold. Moreover, note that $\underline{r} \preceq \underline{r}^*$ and since $\underline{r}^* \notin \mathcal{S}_\Omega$ we conclude that there exists $i_0 \in \{j+1,\dots,d\}$ such that $m_{i_0} < m_{i_0}^*$. As a result, $\sum_{i=j+1}^{d} n_i m_i < \sum_{i=j+1}^{d} n_i m_i^*$.

Condition $\mathcal{B}_{\underline{r}}^{\text{Tucker}}$ ensures there exists at least one more observed entry (otherwise the constraint tensor does not exist) besides the $\sum_{i=j+1}^{d} n_i m_i$ mentioned observed entries. Given the basis $\mathcal{C} \in \mathbb{R}^{n_1 \times \dots \times n_j \times m_{j+1} \times \dots \times m_d}$ as in (7), there exist $\sum_{i=j+1}^{d} n_i m_i$ variables in the corresponding Tucker decomposition. However, we have $\sum_{i=j+1}^{d} n_i m_i + 1$ polynomials in terms these $\sum_{i=j+1}^{d} n_i m_i$ variables and therefore the last polynomials can be written as algebraic combination of the other $\sum_{i=j+1}^{d} n_i m_i$ polynomials. This leads to a linear equation in terms of the $\sum_{i=j+1}^{d} n_i m_i + 1$ corresponding observed entries. On the other hand, the $\sum_{i=j+1}^{d} n_i m_i$ observed entries satisfy the property stated as Condition $\mathcal{A}_{\underline{r}}^{\text{Tucker}}$ and it is easily verified that there exist $\sum_{i=j+1}^{d} n_i m_i^*$ entries (observed and non-observed) satisfying Condition $\mathcal{A}_{\underline{r}^*}^{\text{Tucker}}$ such that the union of the mentioned $\sum_{i=j+1}^{d} n_i m_i$ entries with any arbitrary other observed entry be a subset of those $\sum_{i=j+1}^{d} n_i m_i^*$ entries. However, $\mathcal{U}$ is generically chosen from the manifold corresponding to $\underline{r}^*$ and therefore a particular linear equation in terms of the mentioned $\sum_{i=j+1}^{d} n_i m_i^*$ entries holds with probability zero. The rest of the proof is similar to the proof of Theorem 4. ■

Corollary 38 *Assuming that there exists a completion of $\mathcal{U}$ with rank vector $\underline{r}$ such that $\underline{r} \in \mathcal{S}_\Omega$, we conclude that with probability one $\underline{r}^* \preceq \underline{r}$.*

The following lemma is Corollary 2 in (Ashraphijuo et al., 2016a), which ensures that Conditions $\mathcal{A}_{\underline{r}}^{\text{Tucker}}$ and $\mathcal{B}_{\underline{r}}^{\text{Tucker}}$ hold with high probability.

Lemma 39 *Assume that $\sum_{i=j+1}^{d} m_i^2 \leq \Pi_{i=j+1}^{d} m_i$, $\Pi_{i=j+1}^{d} n_i \geq N_j \Pi_{i=j+1}^{d} m_i - \sum_{i=j+1}^{d} m_i^2$, $\Pi_{i=j+1}^{d} m_i \leq N_j$, where $N_j = \Pi_{i=1}^{j} n_i$. Furthermore, assume that we observe each entry of $\mathcal{U}$ with probability p, where*

$$p > \frac{1}{N_j}\left(6\,\log\left(N_j\right) + 2\log\left(\max\left\{\frac{2\sum_{i=j+1}^{d} r_i^2}{\epsilon}, \frac{2\Pi_{i=j+1}^{d} r_i - 2\sum_{i=j+1}^{d} r_i^2}{\epsilon}\right\}\right) + 4\right) + \frac{1}{\sqrt[4]{N_j}}.$$

Then, with probability at least $(1-\epsilon)\left(1-\exp(-\frac{\sqrt{\Pi_{i=1}^{j} n_i}}{2})\right)^{\Pi_{i=j+1}^{d} n_i}$, $\underline{r} \in \mathcal{S}_\Omega$.

The following corollary is the probabilistic version of Theorem 37.

Corollary 40 *Assuming that there exists a completion of the sampled tensor $\mathcal{U}$ of Tucker rank $\underline{r}$ such that the assumptions in Lemma 39 hold and the sampling probability satisfies* (32)*, then with probability at least $(1-\epsilon)\left(1-\exp(-\frac{\sqrt{\Pi_{i=1}^{j} n_i}}{2})\right)^{\Pi_{i=j+1}^{d} n_i}$ we have $\underline{r}^* \preceq \underline{r}$.*

4.2.1 NUMERICAL RESULTS

We generate a random tensor $\mathcal{U} \in \mathbb{R}^{8\times8\times8\times8\times8}$ of Tucker-rank $(1,3,3,2,2)$. The color scale represents the lower bound on the probability that we can guarantee the rank of a given completion is a component-wise upper bound on the true rank. Then, we solve the following convex optimization problem for different values of the sampling probability.

$$\begin{aligned} &\text{minimize}_{\mathcal{U}' \in \mathbb{R}^{n_1 \times \cdots \times n_d}} && \|\sum_{i=1}^{d} \mathbf{U}'_{(i)}\|_* \\ &\text{subject to} && \mathcal{U}'_\Omega = \mathcal{U}_\Omega. \end{aligned} \tag{32}$$

Then, we calculate rank of each matricization of the tensor obtained via solving (32) to find its Tucker-rank. In this scenario, for each component of the Tucker-rank, we find the percentage of error via $\frac{m_i - m_i^*}{n - m_i^*} \times 100\%$, where $n = 8$, m_i and m_i^* are the i-th rank component of the obtained tensor and original tensor, respectively. Hence, 100% error simply means that the corresponding matricization is full rank. In Figure 8, gap represents the average of the defined error over all components of Tucker-rank, i.e., over all matricizations.

4.3 TT-Rank Tensor

Let $\mathbb{P}_i$ denote the Lebesgue measures on $\mathbb{R}^{u_{i-1}^* \times n_i \times u_i^*}$, $i = 1,\dots,d$, where $u_0^* = u_d^* = 1$. In this subsection, we assume that the sampled tensor $\mathcal{U} \in \mathbb{R}^{n_1 \times \dots \times n_d}$ is chosen generically from the manifold of tensors of rank $\underline{r}^* = \text{rank}_{\text{TT}}(\mathcal{U}) = (u_1^*,\dots,u_{d-1}^*)$ (where $\underline{r}^*$ is unknown), or in other words, the entries of $\mathcal{U}$ are drawn independently with respect to Lebesgue measure on the corresponding manifold. Hence, the probability measures of all statements in this subsection are $\mathbb{P}_1 \times \dots \times \mathbb{P}_d$.

Condition $\mathcal{A}_{\underline{r}}^{\text{TT}}$: Each row of the d-th matricization of the sampled tensor, i.e., $\mathbf{U}_{(d)}$ includes at least u_{d-1} observed entries.

We construct the d-way binary valued constraint tensor $\breve{\Omega}_{u_{d-1}}$ similar to that in Section 3.2 as the following. Consider any subtensor $\mathcal{Y} \in \mathbb{R}^{n_1 \times n_2 \times \cdots \times n_{d-1} \times 1}$ of the tensor $\mathcal{U}$. The sampled tensor

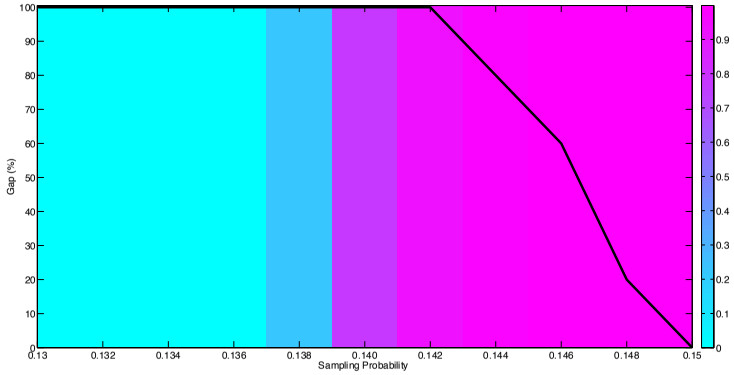

Figure 8: The rank gap as a function of sampling probability for $\mathcal{U} \in \mathbb{R}^{8\times8\times8\times8\times8\times8}$ of Tucker-rank $(1, 3, 3, 2, 2)$.

$\mathcal{U}$ includes n_d subtensors that belong to $\mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times 1}$ and let $\mathcal{Y}_i$ for $1 \leq i \leq n_d$ denote these n_d subtensors. Define a binary valued tensor $\breve{\mathcal{Y}}_i \in \mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times k_i}$, where $k_i = N_\Omega(\mathcal{Y}_i) - u_{d-1}$ and its entries are described as the following. We can look at $\breve{\mathcal{Y}}_i$ as k_i tensors each belongs to $\mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times 1}$. For each of the mentioned k_i tensors in $\breve{\mathcal{Y}}_i$ we set the entries corresponding to u_{d-1} of the observed entries equal to 1. For each of the other k_i observed entries, we pick one of the k_i tensors of $\breve{\mathcal{Y}}_i$ and set its corresponding entry (the same location as that specific observed entry) equal to 1 and set the rest of the entries equal to 0. In the case that $k_i = 0$ we simply ignore $\breve{\mathcal{Y}}_i$, i.e., $\breve{\mathcal{Y}}_i = \emptyset$

By putting together all n_d tensors in dimension d, we construct a binary valued tensor $\breve{\Omega}_{u_{d-1}} \in \mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times K}$, where $K = \sum_{i=1}^{n_d} k_i = N_\Omega(\mathcal{U}) - u_{d-1}n_d$ and call it the **constraint tensor**. Observe that each subtensor of $\breve{\Omega}_{u_{d-1}}$ which belongs to $\mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times 1}$ includes exactly $u_{d-1}+1$ nonzero entries. In (Ashraphijuo and Wang, 2017a), an example is given on the construction of $\breve{\Omega}_{u_{d-1}}$.

Condition $\mathcal{B}^{\mathrm{TT}}_{\underline{r}}$: $\breve{\Omega}_{u_{d-1}}$ consists a subtensor $\breve{\Omega}'_{u_{d-1}} \in \mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times K}$ such that $K = \sum_{i=1}^{d-1} u_{i-1}n_iu_i - \sum_{i=1}^{d-1} u_i^2$ and for any $K' \in \{1, 2, \ldots, K\}$ and any subtensor $\breve{\Omega}''_{u_{d-1}} \in \mathbb{R}^{n_1\times n_2\times\cdots\times n_{d-1}\times K'}$ of $\breve{\Omega}'_{u_{d-1}}$ we have

$$\sum_{i=1}^{d-1} \left(u_{i-1}f_i(\breve{\Omega}''_{u_{d-1}})u_i - u_i^2\right)^+ \geq K', \tag{33}$$

where $f_i(\breve{\Omega}''_{u_{d-1}})$ denotes the number of nonzero rows of the i-th matricization of $\breve{\Omega}''_{u_{d-1}}$.

The following lemma is a re-statement of Theorem 1 in (Ashraphijuo and Wang, 2017a).

Lemma 41 *With probability one, there are only finitely many completions of rank $\underline{r}^*$ of the sampled tensor if and only if Conditions $\mathcal{A}^{TT}_{\underline{r}^*}$ and $\mathcal{B}^{TT}_{\underline{r}^*}$ hold.*

Definition 42 *Let $\mathcal{S}_\Omega$ denote the set of all rank vectors $\underline{r}$ such that both Conditions $\mathcal{A}^{TT}_{\underline{r}}$ and $\mathcal{B}^{TT}_{\underline{r}}$ hold.*

The following lemma will be used in Lemma 44.

Lemma 43 $u_i \leq \min\{u_{i-1}n_i, u_{i+1}n_{i+1}\}$ *for* $1 \leq i \leq d-1$.

Proof We first show that $u_i \leq u_{i-1}n_i$, which is easily verified for $i = 1$ as $\widetilde{\mathbf{U}}_1$ includes n_1 rows and $u_0 = 1$, and therefore assume that $i > 1$. Define the $(d-1)$-way tensor $\mathcal{U}^{l_i} \in \mathbb{R}^{n_1\times\ldots\times n_{i-1}\times n_{i+1}\times\ldots\times n_d}$ such that $\mathcal{U}^{l_i}(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_d) = \mathcal{U}(x_1, \ldots, x_{i-1}, l_i, x_{i+1}, \ldots, x_d)$ for $1 \leq i \leq d$ and $1 \leq l_i \leq n_i$. Also, recall that $\widetilde{\mathbf{U}}^{l_i}_{(i-1)}$ denotes the $(i-1)$-th unfolding of $\mathcal{U}^{l_i}$. Observe that $\widetilde{\mathbf{U}}^{l_i}_{(i-1)}$ is a subset of columns of matrix $\widetilde{\mathbf{U}}_{(i-1)}$ (those columns that correspond to the entries of $\mathcal{U}$ with the i-th component of the location equal to l_i). Therefore, $\mathrm{rank}(\widetilde{\mathbf{U}}^{l_i}_{(i-1)}) \leq \mathrm{rank}(\widetilde{\mathbf{U}}_{(i-1)}) = u_{i-1}$.

On the other hand, observe that $\widetilde{\mathbf{U}}^{l_i}_{(i-1)}$ is a subset of rows of $\widetilde{\mathbf{U}}_{(i)}$ (those rows that correspond to the entries of $\mathcal{U}$ with the i-th component of the location equal to l_i). Hence, the union of rows of $\widetilde{\mathbf{U}}^{l_i}_{(i-1)}$'s for $1 \leq l_i \leq n_i$ constitute all rows of $\widetilde{\mathbf{U}}_{(i)}$. Therefore, $u_i = \mathrm{rank}(\widetilde{\mathbf{U}}_{(i)}) \leq \sum_{l_i=1}^{n_i} \mathrm{rank}(\widetilde{\mathbf{U}}^{l_i}_{(i-1)}) \leq n_iu_{i-1}$. Similarly, we can show that $u_i \leq u_{i+1}n_{i+1}$ to complete the proof. ■

Lemma 44 *Assume $\underline{r} \in \mathcal{S}_\Omega$. Then, for any $\underline{r}' \preceq \underline{r}$, we have $\underline{r}' \in \mathcal{S}_\Omega$.*

Proof Note that the dimension of the manifold corresponding to $\underline{r}$ is $\sum_{i=1}^{d} u_{i-1}n_iu_i - \sum_{i=1}^{d-1} u_i^2$. If we reduce the value of u_i by one, the value of the mentioned dimension reduces by $u_{i-1}n_i + u_{i+1}n_{i+1} - 2u_i + 1$. According to Lemma 43, $u_{i-1}n_i + u_{i+1}n_{i+1} - 2u_i + 1$ is greater than zero, and therefore $\underline{r}' \preceq \underline{r}$ results that the dimension of the manifold corresponding to $\underline{r}$ is greater than that corresponding to $\underline{r}'$. The rest of the proof is similar to the proof of Lemma 3. ■

Definition 45 *Define $\hat{\mathcal{S}}_\Omega$ as the set of all rank vectors $\underline{r} \in \mathcal{S}_\Omega$ such that there exists a rank vector $\underline{r}' \in \mathcal{S}_\Omega$ with $\underline{r} \preceq \underline{r}'$ and $u_{d-1} < u'_{d-1}$ (instead of $u_{d-1} \leq u'_{d-1}$). Note that $\hat{\mathcal{S}}_\Omega$ also satisfies the property in Lemma 44.*

Theorem 46 *With probability one, exactly one of the following statements holds:*
(i) $\underline{r}^* \in \hat{\mathcal{S}}_\Omega$;
(ii) For any arbitrary completion of the sampled tensor $\mathcal{U}$ of rank $\underline{r}$, we have $\underline{r} \notin \hat{\mathcal{S}}_\Omega$.

Proof Similar to the proof of Theorem 4, to complete the proof it suffices to show that the assumption $\underline{r}^* \notin \hat{\mathcal{S}}_\Omega$ results that there exists a completion of $\mathcal{U}$ of rank $\underline{r}$, where $\underline{r} \in \hat{\mathcal{S}}_\Omega$, with probability zero. Define the multiplication $\mathcal{U}^{(1)}\ldots\mathcal{U}^{(d-1)}$ in (9) as the basis of the rank $\underline{r}$ TT decomposition of $\mathcal{U}$. Then, by considering the $(d-1)$-th unfolding of $\mathcal{U}^{(1)}\ldots\mathcal{U}^{(d-1)}$ in TT decomposition we obtain a matrix factorization of the $(d-1)$-th unfolding of $\mathcal{U}$. The rest of the proof is similar to the proof of Theorem 4. ■

Similar to Theorem 46, we can show the following.

Corollary 47 *Consider a subset $\hat{\mathcal{S}}'_\Omega$ of $\hat{\mathcal{S}}_\Omega$ such that for any two members of $\hat{\mathcal{S}}_\Omega$ that $\underline{r}'' \preceq \underline{r}'$ and $\underline{r}' \in \hat{\mathcal{S}}'_\Omega$ we have $\underline{r}'' \in \hat{\mathcal{S}}'_\Omega$. Then, with probability one, exactly one of the followings holds*
(i) $\underline{r}^* \in \hat{\mathcal{S}}'_\Omega$;
(ii) For any arbitrary completion of $\mathcal{U}$ of rank vector $\underline{r}$, we have $\underline{r} \notin \hat{\mathcal{S}}'_\Omega$.

Corollary 48 *Assuming that there exists a completion of $\mathcal{U}$ with rank vector $\underline{r}$ such that $\underline{r} \in \hat{\mathcal{S}}_\Omega$, we conclude that with probability one $\underline{r}^* \preceq \underline{r}$.*

The following lemma is Lemma 14 in (Ashraphijuo and Wang, 2017a), which ensures that Conditions $\mathcal{A}^{\text{TT}}_{\underline{r}}$ and $\mathcal{B}^{\text{TT}}_{\underline{r}}$ hold with high probability.

Lemma 49 *Define $m = \sum_{k=1}^{d-2} u_{k-1}u_k$, $M = n\sum_{k=1}^{d-2} u_{k-1}u_k - \sum_{k=1}^{d-2} u_k^2$ and $u' = \max\left\{\frac{u_1}{u_0}, \ldots, \frac{u_{d-2}}{u_{d-3}}\right\}$. Assume that $n_1 = n_2 = \cdots = n_d = n$, $n > \max\{m, 200\}$ and $u' \leq \min\{\frac{n}{6}, u_{d-2}\}$ hold. Moreover, assume that the sampling probability satisfies*

$$p > \frac{1}{n^{d-2}} \max\left\{27\ \log\left(\frac{n}{\epsilon}\right) + 9\ \log\left(\frac{2M}{\epsilon}\right) + 18, 6u_{d-2}\right\} + \frac{1}{\sqrt[4]{n^{d-2}}}. \tag{34}$$

Then, with probability at least $(1-\epsilon)\left(1-\exp(-\frac{\sqrt{n^{d-2}}}{2})\right)^{n^2}$, we have $\underline{r} \in \mathcal{S}_\Omega$.

The following corollary is the probabilistic version of Corollary 48.

Corollary 50 *Assuming that there exists a completion of the sampled tensor $\mathcal{U}$ of TT rank $\underline{r}$ such that the assumptions in Lemma 49 hold and the sampling probability satisfies* (34)*, then with probability at least $(1-\epsilon)\left(1-\exp(-\frac{\sqrt{n^{d-2}}}{2})\right)^{n^2}$ we have $\underline{r}^* \preceq \underline{r}$.*

4.3.1 NUMERICAL RESULTS

We generate a random tensor $\mathcal{U} \in \mathbb{R}^{8\times8\times8\times8\times8\times8}$ of TT-rank $(1, 2, 4, 1, 1)$. The color scale represents the lower bound on the probability that we can guarantee the rank of a given completion is a component-wise upper bound on the true rank. Then, we solve the following convex optimization problem for different values of the sampling probability.

$$\begin{aligned} &\text{minimize}_{\mathcal{U}' \in \mathbb{R}^{n_1\times\cdots\times n_d}} && \|\sum_{i=1}^{d-1} \widetilde{\mathbf{U}}'_{(i)}\|_* \\ &\text{subject to} && \mathcal{U}'_\Omega = \mathcal{U}_\Omega. \end{aligned} \tag{35}$$

Then, we calculate rank of each unfolding of the tensor obtained via solving (35) to find its TT-rank. In this scenario, for each component of the TT-rank, we find the percentage of error via $\frac{u_i - u_i^*}{\min\{n^i, n^{d-i}\} - u_i^*} \times 100\%$, where $n = 8$, $d = 6$, u_i and u_i^* are the i-th rank component of the obtained tensor and original tensor, respectively. Hence, 100% error simply means that the corresponding unfolding is full rank. In Figure 9, gap represents the average of the defined error over all components of TT-rank, i.e., over all unfoldings.

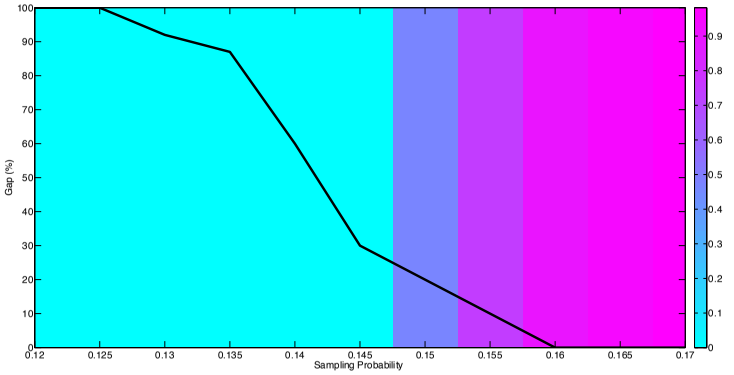

Figure 9: The rank gap as a function of sampling probability for $\mathcal{U} \in \mathbb{R}^{8\times8\times8\times8\times8\times8}$ of TT-rank $(1, 2, 4, 1, 1)$.

5. Conclusions

We make use of the recently developed algebraic geometry analyses that study the fundamental conditions on the sampling patterns for finite completability under a number of low-rank matrix and tensor models to treat the problem of rank approximation for a partially sampled data. Particularly, the goal is to approximate the unknown scalar or vector rank based on the sampling pattern and the rank of a given completion. A number of data models have been treated, including single-view matrix, multi-view matrix, CP tensor, tensor-train tensor and Tucker tensor. First we have provided an upper bound on the unknown scalar rank (for single-view matrix and CP tensor) and an component-wise upper bound on the vector rank (for multi-view matrix, Tucker tensor and TT tensor) with probability one assuming that the sampling pattern satisfies the proposed combinatorial conditions. Moreover, we have also provided probabilistic versions of such bounds that hold with high probability assuming that the sampling probability is above a threshold. In addition, for single-view matrix and CP tensor, these upper bounds can be exactly equal to the unknown scalar rank given the lowest-rank completion. To illustrate how tight our proposed upper bounds are, we have provided some numerical results for the single-view matrix case in which we applied the nuclear norm minimization to find a low-rank completion of the sampled data and observe that the proposed upper bound is almost equal to the true unknown rank.

Abstract

We propose a mixed integer programming (MIP) model and iterative algorithms based on topological orders to solve optimization problems with acyclic constraints on a directed graph. The proposed MIP model has a significantly lower number of constraints compared to popular MIP models based on cycle elimination constraints and triangular inequalities. The proposed iterative algorithms use gradient descent and iterative reordering approaches, respectively, for searching topological orders. A computational experiment is presented for the Gaussian Bayesian network learning problem, an optimization problem minimizing the sum of squared errors of regression models with L1 penalty over a feature network with application of gene network inference in bioinformatics.

Keywords: Bayesian networks, topological orders, Gaussian Bayesian network, directed acyclic graphs

1. Introduction

Directed graph G is a directed acyclic graph (DAG) or acyclic digraph if G does not contain a directed cycle. In this paper, we consider a generic optimization problem over a directed graph with acyclic constraints, which require the selected subgraph to be a DAG.

Let us consider a complete digraph G. Let m be the number of nodes in digraph G, $Y \in \mathbb{R}^{m\times m}$ a decision variable matrix associated with the arcs, where Y_{jk} is related to arc (j,k), $supp(Y) \in \{0,1\}^{m\times m}$ the 0-1 (adjacency) matrix with $supp(Y)_{jk} = 1$ if $Y_{jk} \neq 0$, $supp(Y)_{jk} = 0$ otherwise, $G(supp(Y))$ the sub-graph of G defined by $supp(Y)$, and let $\mathcal{A}$ be the collection of all acyclic subgraphs of G. Then, we can write the optimization problem with acyclic constraints as

$$\min_{Y} \; F(Y) \quad s.t. \quad G(supp(Y)) \in \mathcal{A}, \tag{1}$$

where F is a function of Y.

Acyclic constraints (or DAG constraints) appear in many network structured problems. The maximum acyclic subgraph problem (MAS) is to find a subgraph of G with maximum cardinality while the subgraph satisfies acyclic constraints. MAS can be written in the form of (1) with $F(Y) = -\|supp(Y)\|_0$. Although exact algorithms were proposed for a superclass of cubic graphs (Fernau and Raible, 2008) and for general directed graphs (Kaas, 1981), most of the works have focused on approximations (Even et al., 1998; Hassin and Rubinstein, 1994) or inapproximability (Guruswami et al., 2008) of either MAS or the minimum feedback arc set problem (FAS). FAS of a directed graph G is a subgraph of G that creates a DAG when the arcs in the feedback arc set are removed from G. Note that MAS is closely related to FAS and is dual to the minimum FAS. Finding a feedback arc set with minimum cardinality is $\mathcal{NP}$-complete in general (Karp, 1972). However, minimum FAS is solvable in polynomial time for some special graphs such as planar graphs (Lucchesi and Younger, 1978) and reducible flow graphs (Ramachandran, 1988), and a polynomial time approximation scheme was developed for a special case of minimum FAS, where exactly one arc exists between any two nodes, called tournament (Kenyon-Mathieu and Schudy, 2007).

DAGs are also extensively studied in Bayesian network learning. Given observational data with m features, the goal is to find the true unknown underlying network of the nodes (features) while the selected arcs (dependency relationship between features) do not create a cycle. In the literature, approaches are classified into three categories: (i) score-based approaches that try to optimize a score function defined to measure fitness, (ii) constraint-based approaches that test conditional independence to check existence of arcs between nodes (iii) and hybrid approaches that use both constraint and score-based approaches. Although there are many approaches based on the constraint-based or hybrid approaches, our focus is solving (1) by means of score-based approaches. For a detailed discussion of constraint-based and hybrid approaches and models for undirected graphs, the reader is referred to Aragam and Zhou (2015) and Han et al. (2016).

For estimating the true network structure by a score-based approach, various functions have been used as different functions give different solutions and behave differently. Many works focus on penalized least squares, where penalty is used to obtain sparse solutions. Popular choices of the penalty term include BIC (Lam and Bacchus, 1994), L_0-penalty (Chickering, 2002; Van de Geer and Bühlmann, 2013), L_1-penalty (Han et al., 2016), and concave penalty (Aragam and Zhou, 2015). Lam and Bacchus (1994) use minimum-description length as a score function, which is equivalent to BIC. Chickering (2002) proposes a two-phase greedy algorithm, called greedy equivalence search, with the L_1 norm penalty. Van de Geer and Bühlmann (2013) study the properties of the L_0 norm penalty and show positive aspects of using L_0 regularization. Raskutti and Uhler Raskutti and Uhler (2013) use a variant of the L_0 norm. They use cardinality of the selected subgraph as the score function where the subgraphs not satisfying the Markov assumption are penalized with a very large penalty. Aragam and Zhou (2015) introduce a generalized penalty, which includes the concave penalty, and develop a coordinate descent algorithm. Han et al. (2016) use the L_1 norm penalty and propose a Tabu search based greedy algorithm for reduced arc sets by neighborhood selection in the pre-processing step.

With any choice of a score function, optimizing the score function is computationally challenging, because the number of possible DAGs of G grows super-exponentially in the number of nodes m and learning Bayesian networks is also shown to be $\mathcal{NP}$-complete (Chickering, 1996). Many heuristic algorithms have been developed based on greedy hill climbing (Chickering, 2002; Heckerman et al., 1995; Han et al., 2016) or coordinate descent (Fu and Zhou, 2013), or enumeration (Raskutti and Uhler, 2013) when the score function

itself is the main focus. There also exist exact solution approaches based on mathematical programming. One of the natural approaches is based on cycle prevention constraints, which are reviewed in Section 2. The model is covered in Han et al. (2016) as a benchmark for their algorithm, but the MIP based approach does not scale; computational time increases drastically as data size increases and the underlying algorithm cannot solve larger instances. Baharev et al. (2015) studied MIP models for minimum FAS based on triangle inequalities and set covering models. Several works have been focused on the polyhedral study of the acyclic subgraph polytopes (Bolotashvili et al., 1999; Goemans and Hall, 1996; Grötschel et al., 1985; Leung and Lee, 1994). In general, MIP models have gotten relatively less attention due to the scalability issue.

In this paper, we propose an MIP model and iterative algorithms based on the following well-known property of DAGs (Cook et al., 1998).

Property 1 *A directed graph is a DAG if and only if it has a topological order.*

A *topological order* or *topological sort* of a DAG is a linear ordering of all of the nodes in the graph such that the graph contains arc (u, v) if and only if u appears before v in the order (Cormen et al., 2009). Suppose that Z is the adjacency matrix of an acyclic graph. Then, by sorting the nodes of acyclic graph $G(Z)$ based on the topological order, we can create a lower triangular matrix from Z, where row and column indices of the lower triangular matrix are in the topological order. Then, any arc in the lower triangular matrix can be used without creating a cycle. By considering all arcs in the lower triangular matrix, we can optimize F in (1) without worrying to create a cycle. This is an advantage compared to arc-based search, where acyclicity needs to be examined whenever an arc is added. Although the search space of topological orders is very large, a smart search strategy for a topological order may lead to a better algorithm than the existing arc-based search methods. Node orderings are used for Bayesian Network learnings based on Markov chain Monte Carlo methods (Ellis and Wong, 2008; Friedman and Koller, 2003; Niinimäki et al., 2016) as alternatives to network structure-based approaches.

The proposed MIP assigns node orders to all nodes and add constraints to satisfy Property 1. The iterative algorithms search over the topological order space by moving from one topological order to another order. The first algorithm uses the gradient to find a better topological order and the second algorithm uses historical choice of arcs to define the score of the nodes.

With the proposed MIP model and algorithms for (1), we consider a Gaussian Bayesian network learning problem with L_1 penalty for sparsity, which is discussed in detail in Section 4. Out of many possible models in the literature, we pick the L_1-penalized least square model from recently published work of Han et al. (2016), which solves the problem using a Tabu search based greedy algorithm. The algorithm is one of the latest algorithms based on arc search and is shown to be scalable when m is large. Further, their score function, L_1 penalized least squares, is convex and can be solved by standard mathematical optimization packages. Hence, we select the score function from Han et al. (2016) and use their algorithm as a benchmark. In the computational experiment, we compare the performance of the proposed MIP model and algorithms against the algorithm in Han et al. (2016) and other available MIP models for synthetic and real instances.

Our contributions are summarized in the following.

1. We consider a general optimization problem with acyclic constraints and propose an MIP model and iterative algorithms for the problem based on the notion of topological orders.

2. The proposed MIP model has significantly fewer constraints than the other MIP models in the literature, while maintaining the same order of the number of variables. The computational experiment shows that the proposed MIP model outperforms the other MIP models when the subgraph is sparse.

3. The iterative algorithms based on topological orders outperform when the subgraph is dense. They are more scalable than the benchmark algorithm of Han et al. (2016) when the subgraph is dense.

In Section 2, we present the new MIP model along with two MIP models in the literature. In Section 3, we present two iterative algorithms based on different search strategies for topological orders. The Gaussian Bayesian network learning problem with L_1-penalized least square is introduced and computational experiment are presented in Sections 4 and 5, respectively.

In the rest of the paper, we use the following notation.

$J = \{1, \cdots, m\}$ = index set of the nodes
$J^k = J \setminus \{k\}$ = index set of the nodes excluding node k, $k \in J$
$Z = supp(Y) \in \{0, 1\}^{m \times m}$
π = topological order

Given π, we define $\pi_k = q$ to denote that the order of node k is q. For example, given three nodes a, b, c, and topological order $b - c - a$, we have $\pi_a = 3$, $\pi_b = 1$, and $\pi_c = 2$. With this notation, if $\pi_j > \pi_k$, then we can add an arc from j to k.

2. MIP Formulations based on Topological Order

In this section, we present three MIP models for (1). The first and second models, denoted as MIPcp and MIPin, respectively, are models in the literature for similar problems with acyclic constraints. The third model, denoted as MIPto, is the new model we propose based on Property 1.

A popular mathematical programming based approach for solving (1) is the cutting plane algorithm, which is well-known for the traveling salesman problem formulation. Let $\mathcal{C}$ be the set of all possible cycles and $C_l \in \mathcal{C}$ be the set of the arcs defining a cycle. Let $H(supp(Y), C_l)$ be a function that counts the number of selected arcs in $supp(Y)$ from C_l. Then, (1) can be solved by

$$\textbf{MIPcp} \quad \min_{Y} \; F(Y) \quad s.t. \quad H(supp(Y), C_l) \leq |C_l| - 1, C_l \in \mathcal{C}, \tag{2}$$

which can be formulated as an MIP. Note that (2) has exponentially many constraints due to the cardinality of $\mathcal{C}$. Therefore, it is not practical to pass all cycles in $\mathcal{C}$ to a solver. Instead, the cutting plane algorithm starts with an empty active cycle set $\mathcal{C}^A$ and iteratively adds cycles to $\mathcal{C}^A$. That is, the algorithm iteratively solves

$$\min_{Y} \; F(Y) \quad s.t. \quad H(supp(Y), C_l) \leq |C_l| - 1, C_l \in \mathcal{C}^A, \tag{3}$$

with the current active set $\mathcal{C}^A$, detects cycles from the solution, and adds the cycles to $\mathcal{C}^A$. The algorithm terminates when there is no cycle detected from the solution of (3). One of the drawbacks of the cutting plane algorithm based on (3) is that in the worst case we can add all exponentially many constraints. In fact, Han et al. (2016) study the same model and concluded that the cutting plane algorithm does not scale.

Baharev et al. (2015) recently presented MIP models for the minimum feedback arc set problem based on linear ordering and triangular inequalities, where the acyclic constraints presented were previously used for cutting plane algorithms for the linear ordering problem (Grötschel et al., 1984; Mitchell and Borchers, 2000). For any F, we can write the following MIP model based on triangular inequalities presented in Baharev et al. (2015), Grötschel et al. (1984), and Mitchell and Borchers (2000).

$$
\begin{aligned}
\textbf{MIPin} \quad \min \quad & F(Y) && && (4a)\\
s.t. \quad & Z = supp(Y), && && (4b)\\
& Z_{qj} + Z_{jk} - Z_{qk} \leq 1, && 1 \leq q < j < k \leq m, && (4c)\\
& -Z_{qj} - Z_{jk} + Z_{qk} \leq 0, && 1 \leq q < j < k \leq m, && (4d)\\
& Z_{jk} \in \{0,1\}, && 1 \leq j < k \leq m && (4e)
\end{aligned}
$$

Note that Z_{jk} is not defined for all $j \in J^k$ and $k \in J$. Instead of having a full matrix of binary variables, the formulation only uses lower triangle of the matrix using the fact that $Z_{jk} + Z_{kj} = 1$. We can also use this technique to any of the MIP models presented in this paper. However, for ease of explanation, we will use the full matrix, while the computational experiment is done with the reduced number of binary variables. Therefore, the cutting plane algorithm with MIPcp should be more scalable than the implementation in Han et al. (2016), which has twice more binary variables.

Baharev et al. (2015) also provides a set covering based MIP formulation. The idea is similar to MIPcp. In the set covering formulation, each row and column represents a cycle and an arc, respectively. Similar to MIPcp, existence of exponentially many cycles is a drawback of the formulation and Baharev et al. (2015) use the cutting plane algorithm.

Next, we propose an MIP model based on Property 1. Although MIPin uses significantly less constraints than MIPcp, MIPin still has $O(m^3)$ constraints which grows rapidly in m. On the other hand, the MIP model we propose has $O(m^2)$ variables and $O(m^2)$ constraints. In addition to Z, let us define decision variable matrix $O \in \{0,1\}^{m \times m}$.

$$
O_{kq} = \begin{cases} 1 & \text{if } \pi_k = q, \\ 0 & \text{otherwise,} \end{cases} \qquad k \in J, q \in J
$$

Then, we have the following MIP model.

$$
\begin{aligned}
\textbf{MIPto} \quad \min \quad & F(Y) && && (5a)\\
s.t. \quad & Z = supp(Y), && && (5b)\\
& Z_{jk} - mZ_{kj} \leq \sum_{r \in J} r(O_{kr} - O_{jr}), && j \in J^k, k \in J, && (5c)\\
& Z_{jk} + Z_{kj} \leq 1, && j \in J^k, k \in J, && (5d)\\
& \sum_{q \in J^k} O_{kq} = 1, && k \in J, && (5e)\\
& \sum_{k \in J^q} O_{kq} = 1, && q \in J, && (5f)\\
& Z, O \in \{0,1\}^{m \times m}, Y \text{ unrestricted} && && (5g)
\end{aligned}
$$

The key constraint in (5) is (5c). Recall that Z_{jk} indicates which node comes first in the topological order and O_{kr} stores the exact location in the order. With these definitions, (5c) forces correct values of Z_{jk} and Z_{kj} by comparing the order difference. Recall that we can reduce the number of binary variables Z_{jk}'s by plugging $Z_{jk} + Z_{kj} = 1$, but we keep the full matrix notation for ease of explanation. We next show that (5) correctly solves (1).

Proposition 1 *An optimal solution to* (5) *is an optimal solution to* (1).

Proof By Property 1, any DAG has a corresponding topological order. Let π^* be the topological order defined by an optimal solution Y^* for (1). Note that (5e) and (5f) define a topological order. Hence, it suffices to show that (5) gives a DAG given π^*. Note that the right hand side of (5c) measures the difference in the topological order between nodes j and k. If the value is positive, it implies $\pi_k > \pi_j$. Consider (5c) for j_1 and j_2 with $\pi^*_{j_2} > \pi^*_{j_1}$. When $j = j_1$ and $k = j_2$, we have $\sum_{r \in J} r(O_{j_2 r} - O_{j_1 r}) > 0$ in (5c) and at most one of $z_{j_1 j_2}$ and $z_{j_2 j_1}$ can be 1 by (5d). When $j = j_2$ and $k = j_1$, we have $\sum_{r \in J} r(O_{j_1 r} - O_{j_2 r}) < 0$ in (5c) and we must have $z_{j_1 j_2} = 1$ by the left hand side of (5c). Therefore, we have correct value $z_{j_1 j_2} = 1$ when $\pi^*_{j_2} > \pi^*_{j_1}$. This completes the proof. ■

In Table 1, we compare the MIP models introduced in this section. Although all three MIP models have $O(m^2)$ binary variables, MIPto has more binary variables than MIPcp and MIPin due to O_{kq}'s. MIP models MIPin and MIPto have polynomially many constraints, whereas MIPcp has exponentially many constraints. MIPto has the smallest number of constraints among the three MIP models. In the computational experiment, we use a variation of the cutting plane algorithm for MIPcp as it has exponentially many constraints. For MIPin and MIPto, we do not use a cutting plane algorithm.

3. Algorithms based on Topological Order

Although the MIP models introduced in Section 2 guarantee optimality, the execution time for solving an integer programming problem can be exponential in problem size. Further, the execution time could increase drastically in m, as all of the models require at least

Name	Reference	# binary variables	# constraints
MIPcp	(2)	$O(m^2)$	exponential
MIPin	(4)	$O(m^2)$	$O(m^3)$
MIPto	(5)	$O(m^2)$	$O(m^2)$

Table 1: Number of binary variables and constraints of MIP models

$O(m^2)$ binary variables and $O(m^2)$ constraints. In order to deal with larger graphs, we propose iterative algorithms for (1) based on Property 1. Observe that, if we are given a topological order of the nodes, then Z and O are automatically determined in (5). In other words, we can easily obtain a subset of the arcs such that all of the arcs can be used without creating a cycle. Let $\bar{R}$ be the determined adjacency matrix given topological order $\bar{\pi}$. In detail, we set

$$\bar{R}_{jk} = 1 \text{ if } \bar{\pi}_j > \bar{\pi}_k,\ \bar{R}_{jk} = 0 \text{ otherwise.}$$

Let $adj(\bar{\pi})$ be the function generating $\bar{R}$ given input topological order $\bar{\pi}$. If we are given $\bar{\pi}$, then we can generate $\bar{R}$ by $adj(\bar{\pi})$, and solving (1) can be written as

$$\min_{Y} \ F(Y) \quad s.t. \quad \bar{R} \geq supp(Y). \tag{6}$$

Note that (6) has acyclic constraint $\bar{R} \geq supp(Y)$, not $\bar{R} = supp(Y)$. The inequality is needed when we try to obtain a sparse solution, i.e., only a subset of the arcs is selected among all possible arcs implied by $\bar{R}$. As long as we satisfy the inequality, Y forms an acyclic subgraph. Hence, $\bar{R}$ can be different from adjacency matrix $supp(Y)$ in an optimal solution of (6), and any arc (j,k) such that $\bar{R}_{jk} = 1$ can be selected without creating a cycle. For this reason, we call $\bar{R}$ an *adjacency candidate matrix*. The algorithms proposed later in this section solve (6) by providing different $\bar{\pi}$ and $\bar{R} = adj(\bar{\pi})$ in each iteration. In fact, (6) is separable into m sub problems if F is separable. Let Y_k and Z_k be the k^{th} columns of Y and R, respectively, for node k. Then, solving

$$\min_{Y_k} \ F_k(Y_k) \quad s.t. \quad \bar{R}_k \geq supp(Y_k), \tag{7}$$

for all $k \in J$ gives the same solution as solving (6) if F is separable as $F(Y) = \sum_{k \in J} F_k(Y_k)$.

In Section 3.1, a local improvement algorithm for a given topological order is presented. The algorithm swaps pairs of nodes in the order. In both of the iterative algorithms proposed in Sections 3.2 and 3.3, we use the local improvement algorithm presented in the following section.

3.1 Topological Order Swapping Algorithm

Algorithm 1 tries to improve the solution by swapping the topological order. In each iteration, the algorithm determines the nodes to swap that have order s_1 and s_2 in Line 3, where $s_2 = s_1 + 1$ implies that we select two nodes which are neighbors in the current topological order. Then in Line 4, the actual node indices k_1 and k_2 such that $\pi_{k_1} = s_1$ and $\pi_{k_2} = s_2$ are detected. The condition in Line 5 is to avoid meaningless computation when Y^* is sparse. If $|Y^*_{k_2 k_1}| > 0$, we know for sure that $Y^*_{k_2 k_1} = 0$ after swapping the orders of

k_1 and k_2 and thus we will get a different solution. However, if $Y^*_{k_2 k_1} = 0$, we will still have $Y^*_{k_2 k_1} = 0$ after the swap forced by the new order. In Line 6, we create a new topological order $\bar{\pi}$ by swapping nodes k_1 and k_2 in π^*. After obtaining adjacency candidate matrix $\bar{R}$ in Line 7, we solve (6) with $\bar{R}$. It is worth noting that, if F is separable, we only need to solve (7) with $k = k_1$ and k_2 because the values of $\bar{R}$ are the same with R^* except for k_1 and k_2 as the order difference was 1 in π^*. In Line 9, we update the best solution if the new solution is better. The iterations continue until there is no improvement in the past m iterations, which implies that we would swap the same nodes if we proceed after this iteration. Algorithm 1 is illustrated by the following toy example.

Algorithm 1 TOSA (Topological Order Swapping Algorithm)

Require: Y', R', π'
Ensure: Best solution Y^*, R^*, π^*
1: $(Y^*, R^*, \pi^*) \leftarrow (Y', R', \pi')$, $t \leftarrow 0$
2: **While** there is an improvement in the past m iterations
3: $t \leftarrow t+1$, $s_1 \leftarrow (t \bmod (m-1)) + 1$, $s_2 \leftarrow s_1 + 1$
4: $(k_1, k_2) \leftarrow$ node indices satisfying $\pi_{k_1} = s_1$ and $\pi_{k_2} = s_2$
5: **If** $|Y^*_{k_2 k_1}| > 0$ **then**
6: $\bar{\pi} \leftarrow \pi^*$, $\bar{\pi}_{k_1} = s_2$, $\bar{\pi}_{k_2} = s_1$
7: $\bar{R} \leftarrow adj(\bar{\pi})$
8: $\bar{Y} \leftarrow$ solve (6) with $\bar{R}$
9: **If** $F(\bar{Y}) < F(Y^*)$ **then** update (Y^*, R^*, π^*)
10: **End if**
11: **End While**

Example 1 *Consider a graph with $m = 4$ nodes. Let us assume that inputs are $\pi' = (2,3,1,4)$ with corresponding order $3-1-2-4$,*

$$Y' = \begin{bmatrix} 0 & 0 & 0.5 & 0 \\ 0 & 0 & 0.5 & 0 \\ 0 & 0 & 0 & 0 \\ 0.4 & 0.8 & 0.1 & 0 \end{bmatrix}, \text{ and } R' = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 \end{bmatrix}.$$

In iteration 1, $t = 1$, $s_1 = 1$, $s_2 = 2$, $k_1 = 3$, and $k_2 = 1$. Hence, we are swapping nodes 3 and 1. Since $|Y^*_{13}| = 0.5 > 0$, $\bar{\pi} = (1,3,2,4)$ is created in Line 6, where the associated order is $1-3-2-4$. If $\bar{\pi}$ gives an improved objective function value, then π^* is updated in Line 9. Let us assume that π^* is not updated. In iteration 2, $t = 2$, $s_1 = 2$, $s_2 = 3$, $k_1 = 1$, and $k_2 = 2$. Since $|Y^*_{21}| = 0$, Lines 6 - 9 are not executed. □

3.2 Iterative Reorering Algorithm

We propose an iterative reordering algorithm based on Property 1, which solves (6) in each iteration aiming to optimize (1). In each iteration of the algorithm, all nodes are sorted based on scores defined by (i) merit scores of the arcs, (ii) historical choice of the arcs (used as weights), (iii) and some random components. Then the sorted node order is directly

used as a topological order. The selected arcs by the topological order give updates on arc weights. Let us first define notation.

ν = uniform random variable on $[\nu_{lb}, \nu_{ub}]$, $\nu_{lb} < 1 < \nu_{ub}$
ρ_{jk} = pre-determined merit score of arc (j,k) for $j \in J, k \in J$
w_{jk} = weight of arc (j,k) for $j \in J, k \in J$
c_k = score of node k, $k \in J$

The range $[\nu_{lb}, \nu_{ub}]$ of the uniform random variable ν balances the randomness and structured scores. Note that ρ_{jk} should be determined based on the data and the characteristic of the problem considered, where larger ρ_{jk} implies that arc (j,k) is attractive. Based on the arc merit scores ρ, the score for node k, $k \in J$, is defined as

$$c_k = \nu \cdot \big(\sum_{j \in J^k} w_{jk}\rho_{jk} \big), \quad k \in J, \tag{8}$$

which can be interpreted as a weighted summation of ρ_{jk}'s multiplied by perturbation random number ν. Hence, nodes with high scores are attractive. Initially, all arcs have equal weights and the weights are updated in each iteration based on the topological order in the iteration. If $\bar{R} = adj(\bar{\pi})$ is the adjacency candidate matrix in the iteration, then, the weights are updated by

$$w_{jk} = w_{jk} + 1, \quad \text{if } \bar{R}_{jk} = 1. \tag{9}$$

The overall algorithmic framework is summarized in Algorithm 2. In Line 1, weights w_{jk}'s are initialized to 1 and $\bar{t}$, which counts the number of iterations without a best solution update, is initialized. Also, a random order π^* of the nodes is generated, and the corresponding solution becomes the best solution. In each iteration, first node scores c_k's are calculated (Line 3), then topological order $\bar{\pi}$ is obtained by sorting the nodes, and finally adjacency candidate matrix $\bar{R}$ is generated (Line 4). Then, in Lines 5 and 6, solution $\bar{Y}$ is obtained by solving (6) with $\bar{R}$ and the best solution is updated if available. In Lines 7 - 10, *TOSA* is executed if the current solution is within a certain percentage α from the best solution. Lines 11 and 12 update $\bar{t}$, and Line 13 updates w_{jk}'s. This ends the iteration and the algorithm continues until $\bar{\pi}$ is converged or there is no update of the best solution in the last t^* iterations. Algorithm 2 is illustrated by the following toy example.

Example 2 *Consider a graph with $m = 3$ nodes. In the current iteration, let us assume that we are given*

$$\rho = \begin{bmatrix} 0 & 0.5 & 0.5 \\ 0.2 & 0 & 0.2 \\ 0.3 & 0.3 & 0 \end{bmatrix} \text{ and } w = \begin{bmatrix} 0 & 1 & 2 \\ 1 & 0 & 1 \\ 2 & 1 & 0 \end{bmatrix}.$$

Note that we have $\sum_{j \in J^1} w_{j1}\rho_{j1} = 0.2 \cdot 1 + 0.3 \cdot 2 = 0.8$, $\sum_{j \in J^2} w_{j2}\rho_{j2} = 0.5 \cdot 1 + 0.3 \cdot 1 = 0.8$, and $\sum_{j \in J^3} w_{j3}\rho_{j3} = 0.4 \cdot 2 + 0.2 \cdot 1 = 1$. If random numbers ($\nu$) are 0.9, 1.1, 0.8 for nodes 1,2, and 3, respectively, then by (8)*, $c_1 = 0.9 \cdot 0.8 = 0.72$, $c_2 = 1.1 \cdot 0.8 = 0.88$, and $c_3 = 0.8 \cdot 1 = 0.8$. Then in Line 4, we obtain $\bar{\pi} = (3,1,2)$, with corresponding order $2-3-1$, and $\bar{R} = [0,1,1;0,0,0;0,1,0]$. After obtaining $\bar{Y}$ and updating the best solution in Lines 5-12, the weights are updated by* (9) *as follows.*

Algorithm 2 IR (Iterative Reordering)

Require: Merit score $\rho \in \mathbb{R}^{m \times m}$, termination parameter t^*, *TOSA* execution parameter α
Ensure: Best solution Y^*, R^*, π^*
1: $w_{jk} \leftarrow 1$, $\pi^* \leftarrow$ a random order, $R^* \leftarrow adj(\pi^*)$, $\bar{\pi} \leftarrow \pi^*$, $Y^* \leftarrow$ solve (6) with R^*, $\bar{t} \leftarrow 0$
2: **While** (i) $\bar{\pi}$ is not convergent or (ii) $\bar{t} < t^*$
3: Calculate score c_k by (8)
4: $\bar{\pi} \leftarrow$ sort nodes with respect to c_k, $\bar{R} \leftarrow adj(\bar{\pi})$
5: $\bar{Y} \leftarrow$ solve (6) with $\bar{R}$
6: **If** $F(\bar{Y}) < F(Y^*)$ **then** update (Y^*, R^*, π^*)
7: **If** $F(\bar{Y}) < F(Y^*) \cdot (1+\alpha)$
8: $(Y', R', \pi') \leftarrow TOSA(\bar{Y}, \bar{R}, \bar{\pi})$,
9: **If** $F(Y') < F(Y^*)$ **then** update (Y^*, R^*, π^*)
10: **End If**
11: **If** (Y^*, R^*, π^*) is updated **then** $\bar{t} \leftarrow 0$
12: **Else** $\bar{t} \leftarrow \bar{t} + 1$
13: Update weights by (9)
14: **End While**

$$w_{new} = \begin{bmatrix} 0 & 1 & 2 \\ 1 & 0 & 1 \\ 2 & 1 & 0 \end{bmatrix} + \bar{R} = \begin{bmatrix} 0 & 2 & 3 \\ 1 & 0 & 1 \\ 2 & 2 & 0 \end{bmatrix}$$

This ends the current iteration. □

3.3 Gradient Descent Algorithm

In this section, we propose a gradient descent algorithm based on Property 1. The algorithm iteratively executes: (i) moving toward an improving direction by gradients, (ii) DAG structure is recovered and topological order is obtained by a projection step. The algorithm is based on the standard gradient descent framework while the projection step takes care of the acyclicity constraints by generating a topological order from the current (possibly cyclic) solution matrix. In order to distinguish the solutions with and without the acyclicity property, we use the following notation.

$U^t \in \mathbb{R}^{m \times m}$ = decision variable matrix without acyclicity requirement in iteration t
$Y^t \in \mathbb{R}^{m \times m}$ = decision variable matrix satisfying $G(supp(Y^t)) \in \mathcal{A}$ in iteration t

Let γ^t be the step size in iteration t, $\nabla F(Y^t)$ be the derivative of F at Y^t, and $G^t \in \mathbb{R}^{m \times m}$ be a weight matrix that weighs each element. We assume $\|\nabla F(Y^t)\|_\infty \leq M_1$ for a constant M_1, where $\|\cdot\|_\infty$ is the uniform (infinity) norm. The update formula

$$U^t = Y^t - \gamma^t \big[\nabla F(Y^t) \circ G^t \big], \quad t \geq 0, \tag{10}$$

updates Y^t based on the weighted gradient, where $\circ$ represents the entrywise or Hadamard product of the two matrices. Given topological order π^t, we define G^t as

$$G^t_{jk} = \left(1 + \frac{1}{\pi^t_k}\right)^{\pi^t_k}, \quad j \in J^k \tag{11}$$

to balance gradients of the nodes with different orders (small and large values of π^t_k). For nodes k_1 and k_2 with $\pi^t_{k_1} = 1$ and $\pi^t_{k_2} = m$, most of the gradients for node k_1 are zero and most of the gradients for node k_2 are nonzero. Weight (11) tries to adjust this gap. Note that we have $2 \leq G^t_{jk} \leq e$ for any large m. Since U^t may not satisfy acyclic constraints, in order to obtain a DAG, the algorithm needs to solve the projection problem

$$Y^* = \text{argmin}_Y \ \|Y - U^t\|_2^2 \quad s.t. \quad G(supp(Y)) \in \mathcal{A}, \tag{12}$$

where $\|\cdot\|_2$ is the L_2 norm.

Proposition 2 *If U^t is arbitrary, then optimization problem (12) is $\mathcal{NP}$-hard.*

Proof Recall that feedback arc set is $\mathcal{NP}$-complete (Karp, 1972) and maximum acyclic subgraph is the dual of the feedback arc set problem. With $U^t = 1$, (12) becomes the weighted maximum acyclic subgraph problem. Therefore, (12) is $\mathcal{NP}$-complete. ■

Because solving (12) to optimality does not guarantee an optimal solution for (1), we use a greedy strategy to solve (12). The greedy algorithm, presented in Algorithm 3, sequentially determines and fixes the topological order of a node where in each iteration the problem is solved optimally given the currently fixed nodes and corresponding orders. The detailed derivations of the algorithm and the proof that each iteration is optimal, given already fixed node orders, are available in Appendix 6. In other words, we show that Line 3 is 'locally' optimal, i.e., it selects the best next node given that the order $q+1, q+2, \cdots, m$ is fixed. In each iteration, in Line 3, the algorithm first calculates score $\sum_{j\in\bar{J}}(\bar{U}^t_{jk})^2$ for each node k in $\bar{J}$ and picks node k^* with the minimum value. Then, in Line 4, the order of the selected node is fixed to q. The fixed node is then excluded from the active set $\bar{J}$ and iterate q is decreased by 1 in Line 5. At the end of the algorithm, we can determine $\bar{Y}$ based on the order $\bar{\pi}$ determined and (18) in Appendix 6. We illustrate Algorithm 3 by the following example.

Example 3 *Consider a graph with $m = 3$ nodes. Given U^t, the algorithm returns $\bar{Y}$ presented in the following.*

$$U^t = \begin{bmatrix} 0 & 1 & 2 \\ 4 & 0 & 2 \\ 5 & 2 & 0 \end{bmatrix} \quad \bar{Y} = \begin{bmatrix} 0 & 0 & 0 \\ 4 & 0 & 2 \\ 5 & 0 & 0 \end{bmatrix}$$

Algorithm 3 starts with $q = 3$ and $\bar{J} = \{1, 2, 3\}$. In iteration 1, node 2 is selected to have $\pi_2 = 3$ based on argmin$\{4^2 + 5^2, 1^2 + 2^2, 2^2 + 2^2\}$. Then, set $\bar{J}$ and integer q are updated to $\bar{J} = \{1, 3\}$ and $q = 2$. In iteration 2, node 3 is selected to have $\pi_3 = 2$ based on argmin$\{5^2, 2^2\}$. Then, set $\bar{J}$ and integer q are updated to $\bar{J} = \{1\}$ and $q = 1$. In iteration 3, node 1 is selected. Hence, we have node order 1-3-2 and we obtain $\bar{Y}$ presented above with objective function value $\|\bar{Y} - U^t\|_2^2 = 1^2 + 2^2 + 2^2 = 9$. □

Algorithm 3 Greedy

Require: $U^t \in \mathbb{R}^{m\times m}$
Ensure: $\bar{Y}$ feasible to (12), topological order $\bar{\pi}$
1: $q \leftarrow m$, $\bar{J} \leftarrow J$
2: **While** $\bar{J} \neq \emptyset$
3: $\quad k^* = \text{argmin}_{k\in\bar{J}}\left\{\sum_{j\in\bar{J}}(U^t_{jk})^2\right\}$
4: $\quad \bar{\pi}_{k^*} = q$
5: $\quad \bar{J} \leftarrow \bar{J} \setminus \{k^*\}, q \leftarrow q - 1$
6: **End While**
7: Determine $\bar{Y}$ by (18) in Appendix 6

The overall gradient descent algorithm for (1) is presented in Algorithm 4. In Line 1, the algorithm generates a random order π^* and obtain corresponding R^* and Y^* and save them as the best solution. In each iteration of the loop, Lines 3-6 follow the standard gradient descent algorithm. The weighted gradient H^t is calculated in Line 3, and the step size is determined in Line 4 based on the ratio between $\max_{j\in J^k, k\in J}|H^t_{jk}|$ and $\max_{j\in J^k,k\in J}|Y^t_{jk}|$. In Line 5, the solution is updated based on the weighted gradient and, in Line 6, the greedy algorithm is used to obtain the projected solution and the topological order. Observe that we do not directly use the projected solution. This is because the projected solution is not necessarily optimal given π^{t+1}. Hence, in Line 7, a new solution Y^{t+1} is obtained based on π^{t+1}. In Lines 9 - 12, $TOSA$ is executed if the current solution is within a certain percentage from the current best solution. Lines 13 and 14 update $\bar{t}$ and Line 15 copies Y^* to Y^{t+1} if $\bar{t} \geq t^*_2$ in order to focus on the solution space near Y^*. The algorithm continues until Y^t is convergent or $\bar{t} \geq t^*_1$.

In gradient based algorithms, it is common to have γ^t depend only on t, but in our case dependency on H^t and Y^t is justifiable since we multiply the gradient by G^t. We next show the convergence of Y^t in Algorithm 4 when $t^*_1 = t^*_2 = \infty$. This makes the algorithm not to terminate unless Y^t has converged and modification of Y^t in Line 15 is not executed. Further, we assume the following for the analysis.

Assumption 1 *For any non-zero element Y^t_{jk}, $j, k \in J$, of Y^t in any iteration t, we assume $\varepsilon < |Y^t_{jk}| < M_2$, where ε is a small positive number and M_2 is a large enough number.*

Note that Assumption 1 is a mild assumption, as ignoring near-zero values of Y^t happens in practice anyway due to finite precision. For notational convenience, let $L^t = \gamma^t \nabla F(Y^t) \circ G^t = \gamma^t H^t$ be the second term in (10). Then, U^t can be written as $U^t = Y^t - L^t = Y^t - \gamma^t H^t$. In the following lemma, we show that the node orders converge.

Lemma 3 *If t is sufficiently large satisfying $\sqrt{t} > \frac{(M_1 e)^2}{\varepsilon(\sqrt{M_2^2 + \varepsilon^2/m} - M_2)}$, then $\pi^t = \pi^{t+1}$.*

Proof Recall that Y^t is obtained by solving (20) and we know the corresponding node order π^t. Let $k_1, k_2, \cdots, k_m$ be the node indices defined based on π^t. In other words, node k_1 appears first, followed by nodes k_2, k_3, and so on in the topological order π^t. In the proof, we

Algorithm 4 GD (Gradient Descent)

Require: Parameters t_1^* and t_2^*, *TOSA* execution parameter α
Ensure: Best solution Y^*, R^*, π^*
1: $t \leftarrow 1$, $\bar{t} \leftarrow 0$, $\pi^* \leftarrow$ a random order, $R^* \leftarrow adj(\pi^*)$, $Y^* \leftarrow$ solve (6) with R^*
2: **While** (i) Y^t is not convergent or (ii) $\bar{t} < t_1^*$
3: $H^t \leftarrow \nabla F(Y^t) \circ G^t$, G^t defined in (11)
4: $\gamma^t \leftarrow \frac{\|H^t\|_\infty}{\|Y^t\|_\infty}/\sqrt{t}$
5: $U^t \leftarrow Y^t - \gamma^t H^t$
6: $\pi^{t+1} \leftarrow$ *Greedy*(U^t)
7: $Y^{t+1} \leftarrow$ solve (6) with $R^{t+1} = adj(\pi^{t+1})$
8: **If** $F(Y^{t+1}) < F(Y^*)$ **then** $(Y^*, R^*, \pi^*) \leftarrow (Y^{t+1}, R^{t+1}, \pi^{t+1})$
9: **If** $F(\bar{Y}) < F(Y^*) \cdot (1+\alpha)$
10: $(Y', R', \pi') \leftarrow TOSA(Y^{t+1}, R^{t+1}, \pi^t)$,
11: **If** $F(Y') < F(Y^*)$ **then** $(Y^*, R^*, \pi^*) \leftarrow (Y', R', \pi'), (Y^{t+1}, R^{t+1}, \pi^{t+1}) \leftarrow (Y', R', \pi')$
12: **End If**
13: **If** (Y^*, R^*, π^*) is updated **then** $\bar{t} \leftarrow 0$
14: **Else** $\bar{t} \leftarrow \bar{t} + 1$
15: **If** $\bar{t} \geq t_2^*$ **then** $Y^{t+1} \leftarrow Y^*$
16: $t \leftarrow t + 1$
17: **End While**

show that there is no change in the node order when the condition $\sqrt{t} > \frac{(M_1 e)^2}{\varepsilon(\sqrt{M_2^2+\varepsilon^2/m}-M_2)}$ is met, where M_1 and M_2 are the upper bounds for $\|\nabla F(Y^t)\|_\infty$ and $\|Y^t\|_\infty$, respectively, as assumed. We first derive

$$\|L^t\|_\infty = \left\|\gamma^t H^t\right\|_\infty = \left\|\frac{1}{\sqrt{t}}\frac{\|H^t\|_\infty}{\|Y^t\|_\infty}H^t\right\|_\infty \leq \frac{1}{\sqrt{t}}\frac{\left(\|H^t\|_\infty\right)^2}{\|Y^t\|_\infty} < \frac{1}{\sqrt{t}}\frac{(M_1 e)^2}{\varepsilon}, \tag{13}$$

where the last inequality holds since (i) $\|Y^t\|_\infty > \varepsilon$ by Assumption 1, (ii) $\|H^t\|_\infty = \|\nabla F(Y^t) \circ G^t\|_\infty \leq M_1 e$ because $\|\nabla F(Y^t)\|_\infty \leq M_1$ by the assumption and $\|G^t\|_\infty \leq e$, where e is natural number.

Now let us consider $q = \bar{q}$ in Algorithm 3 to decide node order $\bar{q}$ in iteration $t+1$ and assume $\pi_{k_r}^t = \pi_{k_r}^{t+1}$ for $r = m, m-1, \cdots, \bar{q}-1$. Note that we currently have $\bar{J} = \{k_1, k_2, \cdots, k_{\bar{q}}\}$.

1. For $k_{\bar{q}}$, we derive $\sum_{j\in\bar{J}}(U_{jk_{\bar{q}}}^t)^2 = \sum_{j\in\bar{J}}(Y_{jk_{\bar{q}}}^t - L_{jk_{\bar{q}}}^t)^2 = \sum_{j\in\bar{J}}(L_{jk_{\bar{q}}}^t)^2 < m\left[\frac{(M_1 e)^2}{\sqrt{t}\varepsilon}\right]^2$, where the second equality holds since $Y_{jk_{\bar{q}}}^t = 0$ for all $j \in \bar{J}$ since $\pi_{k_{\bar{q}}} = \bar{q}$ and no arc can be used to the nodes in $\bar{J}$, and the last inequality holds due to (13) and $|\bar{J}| \leq m$.

2. For all other nodes $k_r \in \bar{J} \setminus \{k_{\bar{q}}\}$, we derive

$$\begin{aligned}
\textstyle\sum_{j\in\bar{J}}(U_{jk_r}^t)^2 &= \textstyle\sum_{j\in\bar{J}}(Y_{jk_r}^t - L_{jk_r}^t)^2 \\
&= \textstyle\sum_{j\in\bar{J}}(Y_{jk_r}^t)^2 + \sum_{j\in\bar{J}}(L_{jk_r}^t)^2 - 2\sum_{j\in\bar{J}} Y_{jk_r}^t \cdot L_{jk_r}^t \\
&> \textstyle\sum_{j\in\bar{J}}(Y_{jk_r}^t)^2 - 2\sum_{j\in\bar{J}} Y_{jk_r}^t \cdot L_{jk_r}^t \\
&> \varepsilon^2 - 2\textstyle\sum_{j\in\bar{J}} Y_{jk_r}^t \cdot L_{jk_r}^t \\
&\geq \varepsilon^2 - 2\textstyle\sum_{j\in\bar{J}} |Y_{jk_m}^t \cdot L_{jk_r}^t| \\
&> \varepsilon^2 - 2M_2\frac{m(M_1 e)^2}{\sqrt{t}\varepsilon}
\end{aligned}$$

where the fourth line holds due to $|Y_{jk_r}^t| > \varepsilon$ by Assumption 1, and the sixth line holds due to $|Y_{jk}^t| \leq M_2$, $|\bar{J}| \leq m$, and $|L_{jk_r}^t| < \frac{(M_1 e)^2}{\sqrt{t}\varepsilon}$ by (13).

Combining the two results for $k_{\bar{q}}$ and $k_r \in \bar{J} \setminus \{k_{\bar{q}}\}$, we obtain $\sum_{j\in\bar{J}}(U_{jk_{\bar{q}}}^t)^2 < m\left[\frac{(M_1 e)^2}{\sqrt{t}\varepsilon}\right]^2 < \varepsilon^2 - 2M_2\frac{m(M_1 e)^2}{\sqrt{t}\varepsilon} < \sum_{j\in\bar{J}}(U_{jk_r}^t)^2$, for any $r \in \{1, 2, \cdots, \bar{q}-1\}$, where the second inequality holds due to the condition $\sqrt{t} > \frac{(M_1 e)^2}{\varepsilon(\sqrt{M_2^2+\varepsilon^2/m}-M_2)}$. The result implies that we must have $\pi_{k_{\bar{q}}}^{t+1} = \pi_{k_{\bar{q}}}^t = \bar{q}$ by Line 3 in Algorithm 3.

Note that, when $\bar{q} = m$, we have $J = \bar{J}$ and the assumption of $\pi_{k_r}^t = \pi_{k_r}^{t+1}$ for $r = m, m-1, \cdots, \bar{q}-1$ automatically holds. By iteratively applying the above derivation technique from $q = m$ to 1, we can show that $\pi^t = \pi^{t+1}$. ■

When (6) is solved with the identical node orders, the resulting solutions are equivalent. Hence, the following proposition holds.

Proposition 4 *In Algorithm 4, Y^t converges in t.*

4. Estimation of Gaussian Bayesian Networks

In this section, we introduce the Gaussian Bayesian network learning problem, which follows the form of (1). The goal is to learn or estimate unknown structure between the nodes of a graph, where the error is normally distributed. The network can be estimated by optimizing a score function, testing conditional independence, or a mix of the two, as described in Section 1. Among the three categories, we select the score based approach with the L_1-penalized least square function recently studied in Han et al. (2016).

Let $X \in \mathbb{R}^{n\times m}$ be a data set with n observations and m features. Let $I = \{1, \cdots, n\}$ and $J = \{1, \cdots, m\}$ be the index set of observations and features, respectively. For each $k \in J$, we build a regression model in order to explain feature k using a subset of variables in J^k. In other words, we set feature k as the response variable and a sparse subset of J^k as explanatory variables of the regression model for variable k. In order to obtain a subset of J^k, the LASSO penalty function is added. Considering regression models for all $k \in J$ together, the problem can be represented on a graph. Each feature is a node in the graph, and the directed arc from node j to node k represents explanatory and response variable relationship between node j and k. The goal is to minimize the sum of penalized SSE over all regression models for $k \in J$, while the selected arcs do not create a cycle.

Let β_{jk}, $j \in J^k$, $k \in J$, be the coefficient of attribute j for dependent variable k. Then the problem can be written as

$$\min_{\beta} \frac{1}{n} \sum_{k\in J} \sum_{i\in I} (x_{ik} - \sum_{j\in J^k} \beta_{jk} x_{ij})^2 + \lambda \sum_{k\in J} \sum_{j\in J^k} |\beta_{jk}| \quad s.t. \quad G(supp(\beta)) \in \mathcal{A}, \tag{14}$$

which follows the form of (1). In Han et al. (2016), individual weights are used for the penalty term, i.e., $\lambda \sum_{k\in J} \sum_{j\in J^k} w_{jk}|\beta_{jk}|$, however, in the computational experiment, we set all weights equal to 1 for simplicity.

Let $Z_{jk} = 1$ if attribute j is used for dependent variable k and $Z_{jk} = 0$ otherwise. Then, we can formulate MIPto for (14) as

$$\min \quad \frac{1}{n} \sum_{k\in J} \sum_{i\in I} (x_{ik} - \sum_{j\in J^k} \beta_{jk} x_{ij})^2 + \lambda \sum_{k\in J} \sum_{j\in J^k} |\beta_{jk}| \tag{15a}$$

$$s.t. \quad |\beta_{jk}| \le M Z_{jk}, \qquad j \in J^k, k \in J, \tag{15b}$$

$$Z_{jk} - m Z_{kj} \le \sum_{r\in J} r(O_{kr} - O_{jr}), \qquad j \in J^k, k \in J, \tag{15c}$$

$$Z_{jk} + Z_{kj} \le 1, \qquad j \in J^k, k \in J, \tag{15d}$$

$$\sum_{q\in J} O_{kq} = 1, \qquad k \in J, \tag{15e}$$

$$\sum_{k\in J} O_{kq} = 1, \qquad q \in J, \tag{15f}$$

$$Z, O \in \{0,1\}^{m\times m}, \tag{15g}$$

$$\beta_{jk} \text{ not restricted}, \qquad j \in J^k \cup \{0\}, k \in J, \tag{15h}$$

where M is a large constant. Note that (15b) is the linear constraint corresponding to $Z = supp(Y)$ in (5). Similarly, (15a), (15b), (4c) - (4e) and (15h) can be used to formulate MIPin for (14). For MIPcp, (15a), (15b), (15h), and the constraints in (2) can be used for (14).

Note that M in (15b) plays an important role in computational efficiency and optimality. If M is too small, the MIP model cannot guarantee optimality. If M is too large, the solution time can be as large as enumeration. The algorithm for getting a valid value for M in Park and Klabjan (2013) can be used. However, the valid value of big M for multiple linear regression is often too large (Park and Klabjan, 2013). For (15), we observed that a simple heuristic presented in Section 5 works well.

In each iteration of IR (Algorithm 2) and GD (Algorithm 4), we are given topological order $\bar{\pi}$ and matrix $\bar{R} = adj(\bar{\pi})$. Let $S^k = \{j \in J^k | \bar{R}_{jk} = 1\}$ be the set of selected candidate arcs for dependent variable k. Given fixed $\bar{R}$, (14) is separable into m LASSO linear regression problems

$$\min \quad \frac{1}{n} \sum_{i\in I} (x_{ik} - \sum_{j\in S^k} \beta_{jk} x_{ij})^2 + \lambda \sum_{j\in S^k} |\beta_{jk}|, \quad k \in J. \tag{16}$$

5. Computational Experiment

For all computational experiments, a server with two Xeon 2.70GHz CPUs and 24GB RAM is used. Although there are many papers studying Bayesian network learning with various error measures and penalties, here we focus on minimizing the LASSO type objective (SSE and penalty) and we picked one of the latest paper of Han et al. (2016) with the same objective function as a benchmark.

The MIP models MIPcp, MIPin, and MIPto are implemented with CPLEX 12.6 in C#. For MIPcp, instead of implementing the original cutting plane algorithm, we use CPLEX Lazy Callback, which is similar to the cutting plane algorithm. Instead of solving (3) to optimally from scratch in each iteration, we solve (2) with Lazy Callback, which allows updating (adding) constraints (cycle prevention constraints) in the process of the branch and bound algorithm whenever an integer solution with cycles is found. Given a solution with the cycles, we detect all cycles and add cycle prevention constraints for the detected cycles.

For MIPcp, MIPin, and MIPto, we set big M as follows. Given λ, we solve (14) without acyclic constraints. Hence, we are allowed to use all arcs in J^k for each model $k \in J$. Then, we obtain the estimated upper bound for big M by

$$M = 2\Big(\max_{j\in J^k, k\in J} |\beta_{jk}|\Big). \tag{17}$$

We observed that the above formula gives large enough big M for all cases in the following experiment. In Appendix 6, we present comparison of regression coefficients of implanted network (DAG) with big M values by (17). The result shows that the big M value in (17) is always valid for all cases considered.

We compare our algorithms and models with the algorithm in Han et al. (2016), which we denote as DIST here. Their algorithm starts with neighborhood selection (NS), which filters unattractive arcs and removes them from consideration. The procedure is specifically developed for high dimensional variable selection when m is much larger than n. In our experiment, many instances considered are not high dimensional and some have dense solutions. Further, by filtering arcs, there exists a probability that an arc in the optimal solution can be removed. Hence, we deactivated the neighborhood selection step of their original algorithm, where the R script of the original algorithm is available on the journal website.

For GD and IR, the algorithms are written in R (R Core Team, 2016). We use glmnet package (Friedman et al., 2010) function glmnet for solving LASSO linear regression problems in (16). For IR, we use parameters $\alpha = 0.01$, $t^* = 10$, $\nu_{lb} = 0.8$, and $\nu_{ub} = 1.2$. For GD, we use parameters $\alpha = 0.01$, $t_1^* = 10$, and $t_2^* = 5$. Because both GD and IR start with a random solution, they perform different with different random solutions. Further, since we observe that the execution time of GD and IR are much faster than DIST, we decided to run GD and IR with 10 different random seeds and report the best solution. To emphasize the number of different random seeds for GD and IR, we use the notation GD10 and IR10 in the rest of the section.

We first test all algorithms with synthetic instances generated using R package pcalg (Kalisch et al., 2012). Function randomDAG is used to generate a DAG and function rmvDAG is used to generate multivariate data with the standard normal error distribution. First,

a DAG is generated by randomDAG function. Next, the generated DAG and random coefficients are used to create each column (with standard normal error added) by rmvDAG function which uses linear regression as the underlying model. After obtaining the data matrix from the package, we standardize each column to have zero mean with standard deviation equal to one. The DAG used to generate the multivariate data is considered as the true structure or true arc set while it may not be the optimal solution for the score function. The random instances are generated for various parameters described in the following.

m: number of features (nodes)
n: number of observations
s: expected number of true arcs per node
d: expected density of the adjacency matrix of the true arcs

By changing the ranges of the above parameters, three classes of random instances are generated.

Sparse data sets: The expected total number of true arcs is controlled by s and most of the instances have a sparse true arc set. We use $n \in \{100, 200, 300\}$, $m \in \{20, 30, 40, 50\}$, and $s \in \{1, 2, 3\}$ to generate 10 instances for each (n, m, s) triplet. This yields a total of 360 random instances.

Dense data sets: The expected total number of true arcs is controlled by d and most of the instances have a dense true arc set compared with the sparse data sets. We use $n \in \{100, 200, 300\}$, $m \in \{20, 30, 40, 50\}$, and $d \in \{0.1, 0.2, 0.3\}$ to generate 10 instances for each (n, m, d) triplet, and thus we have a total of 360 random instances.

High dimensional data sets: The instances are high dimensional ($m \geq n$) and very sparse. The expected total number of true arcs is controlled by s. We use $n = 100$ and $m \in \{100, 150, 200\}$, and $s \in \{0.5, 1, 1.5\}$ to generate 10 instances for each (m, s) pair, which yields a total of 90 random instances.

We use four λ values differently defined for each data set in order to cover the expected number of arcs with the four λ values. For each sparse instance, we solve (14) with $\lambda \in \{1, 0.5, 0.1, 0.05\}$. For dense data sets, a wide range of λ values are needed to obtain selected arc sets that have similar cardinalities with the true arc sets. Hence, for each dense instance, instead of fixed values over all instances in the set, we use λ values based on expected density d: $\lambda = \lambda_0 \cdot 10^{-(10 \cdot d - 1)}$, where $\lambda_0 \in \{1, 0.1, 0.01, 0.001\}$. For each high dimensional instance, we use $\lambda \in \{1, 0.8, 0.6, 0.4\}$. Observe that the expected densities of the adjacency matrices vary across the three data sets. The sparse instances have expected densities between 0.02 and 0.15, the dense instances have expected densities between 0.1 and 0.3, and the high dimensional instances have expected densities between 0.002 and 0.015. Hence, different ranges of λ values are necessary.

For all of the results presented in this section, we present the average performance by n, m, s, d and λ. For example, the result for $n = 100$ and $m = 20$ are the averages of 120 and 90 instances, respectively. In all of the comparisons, we use the following metrics.

time: computation time in seconds
δ_{sol}: relative gap (%) from the best objective value among the compared algorithms or models. For example, if we compare the three MIP models, δ_{sol} of an MIP model is the relative gap from the best of the three objective function values obtained by the MIP models.
$\|z\|_0$: number of arcs selected (number of nonzero regression coefficients β_{jk}'s)

In comparing the performance metrics, we use plot matrices. In each Figure 1, 2, 3, 5, and 6, multiple bar plots form a matrix. The rows of the plot matrix correspond to performance metrics and the columns stand for parameters used for result aggregation. For example, the left top plot in Figure 1 shows execution times of the algorithms where the results are aggregated by n (the number of observations), because the first row and first column of the plot matrix in Figure 1 are for execution times and n, respectively.

In Section 5.1, we compare the performance of iterative algorithms GD10 and IR10 and the benchmark algorithm DIST. In Section 5.2, we compare the performance of MIP models MIPcp, MIPin, and MIPto. We also compare all models and algorithms with a subset of the synthetic instances in Section 5.2. Finally, in Section 5.4, we solve a popular real instance of Sachs et al. (2005) in the literature.

5.1 Comparison of Iterative Algorithms

In this section, we compare the performance of GD10, IR10, and DIST by *time*, δ_{sol}, and $\|z\|_0$ for each of the three data sets.

In Figure 1, the result for the sparse data sets is presented. The bar plot matrix presents the performance measures aggregated by n, m, s, and λ.

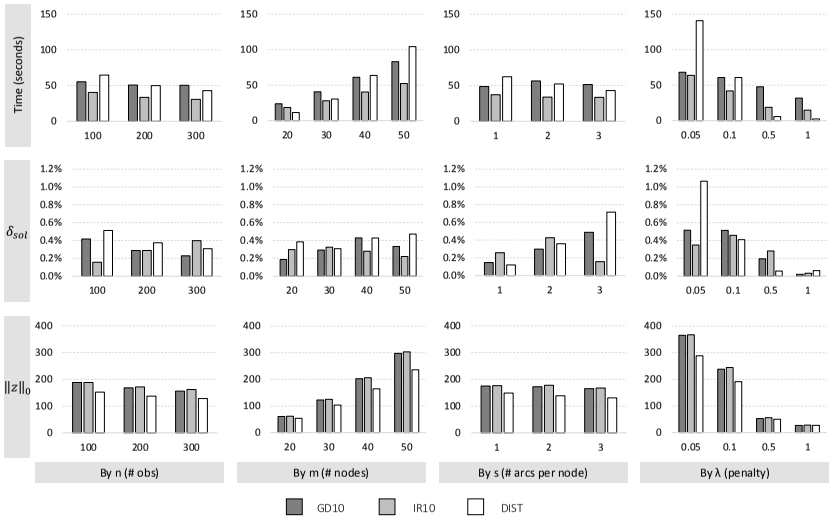

Figure 1: Performance of GD10, IR10, and DIST (sparse data)

The computation time of all three algorithms increases in increasing m and decreasing λ, where the computation time of DIST increases faster than the other two. The computation time of DIST is approximately 10 times faster than the GD10 time when $\lambda = 1$, but 2 times slower when $\lambda = 0.05$. With increasing n, the computation times of all algorithms stay the same or decrease. This can be seen counter-intuitive because larger instances do not increase time. However, a larger number of observations can make predictions more accurate and could reduce search time for unattractive subsets. Especially, the computation time of DIST decreases in increasing n. We think this is because more observations give better local selection in the algorithm when adding and removing arcs. The number of selected arcs ($\|z\|_0$) of GD10 and IR10 is greater than DIST for all cases because the topological order based algorithms are capable of using the maximum number of arcs $\left(\frac{m(m-1)}{2}\right)$, while arc selection based algorithms, such as DIST, are struggling to select many arcs without violating acyclic constraints. In terms of the solution quality, all algorithms have δ_{sol} less than 1.2% and perform good. However, we observe several trends. As λ decreases (required to select more arcs), GD10 and IR10 start to outperform. We also observe that, as the problem requires to select more arcs (increasing m, increasing s, and decreasing λ), GD10 and IR10 perform better. As n increases, δ_{sol} of GD10 and DIST decrease, whereas δ_{sol} of IR10 increases.

The result for the dense data sets is presented in Figure 2. The bar plot matrix presents the performance measures aggregated by n, m, d, and λ_0. Recall that, for the dense data set, we solve (14) with $\lambda = \lambda_0 \cdot 10^{-(10 \cdot d-1)}$ and $\lambda_0 \in \{1, 0.1, 0.01, 0.001\}$. For simplicity of presenting the aggregated result, we use λ_0 in the plot matrix, while λ values are used for actual computation.

The computation time of all three algorithms again increases in increasing m and decreasing λ, where the computation time of DIST increases faster than the other two. Compare to the result for the sparse data sets, the execution times are all larger for the dense data set. The number of selected arcs ($\|z\|_0$) of GD10 and IR10 is again greater than DIST for all cases, where $\|z\|_0$ is twice larger for GD10 and IR10 when m or d is large, or λ is small. In terms of the solution quality, GD10 and IR10 outperform in most of the cases, while δ_{sol} values of DIST increase fast in changing m, d, and λ. The values of δ_{sol} for all algorithms are larger than the sparse data sets result. GD10 and IR10 are better for most of the cases. In general, we again observe that GD10 and IR10 perform better when the problem requires to select more arcs.

The result for the high dimensional data sets is presented in Figure 3. The bar plot matrix presents the performance measures aggregated by m, s, and λ, while n is excluded from the matrix as we fixed n to 100.

The computation time of all three algorithms again increases in increasing m and decreasing λ. However, unlike the previous two sets, the computation times of GD10 and IR10 increase faster than DIST. This is due to the efficiency of the topological order based algorithms. When a very small portion of the arcs should be selected in the solution, topological orders are not informative. For example, consider a graph with three nodes A, B, C and assume that only one arc, (A, B), is selected due to a large penalty. For this case, three topological orders $A-B-C$, $A-C-B$, and $C-A-B$ can represent the selected arc. The third row of Figure 3 shows that $\|z\|_0$ of the three algorithms are very similar, while DIST has much smaller values for the previous two data sets. This implies that arc based search

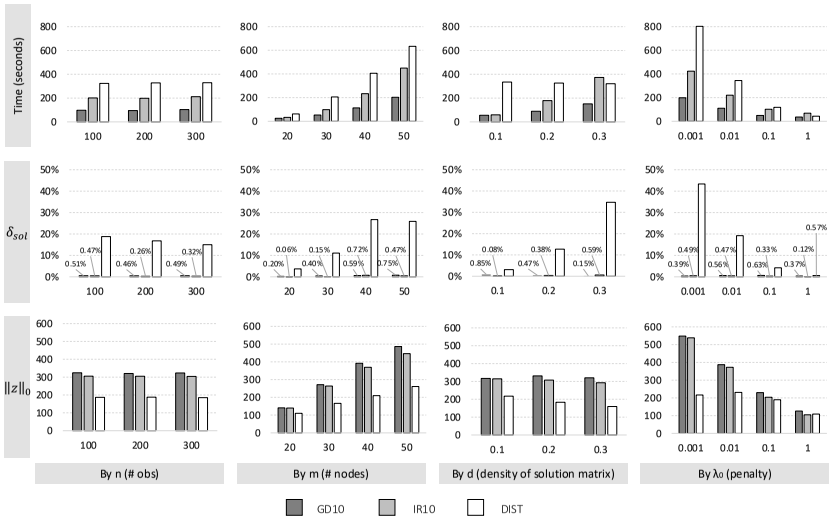

Figure 2: Performance of GD10, IR10, and DIST (dense data)

by DIST does not have difficulties preventing cycles and the algorithm can decide whether to include arcs easier. The comparison of δ_{sol} values also show that arc based search is competitive. Although all algorithms have δ_{sol} values less than 0.5%, we find clear evidence that the performance of IR10 decreases in increasing m and s and decreasing λ. Although the δ_{sol} values of GD10 and DIST are similar, considering the fast computing time of DIST, we recommend to use DIST for very sparse high dimensional data.

In Figure 4, we present combined results of all three data sets by relating solution densities and δ_{sol}. Observe that, for each quadruplet of $n, m, s(\text{or } d), \lambda$, we have results from 10 random instances for each algorithm. Value δ_{sol} is the average of the 10 results for each quadruplet and for each algorithm, $AvgDen$ is the average density of the adjacency matrices of the 10 results and the three algorithms. In Figure 4, we present a scatter plot of $ln(1+AvgDen)$ and $ln(1+100 \cdot \delta_{\text{sol}})$. Each point in the plot is the average of 10 results by an algorithm and each algorithm has 324 points displayed [1]. The numbers in the parenthesis along the axes are the corresponding values of δ_{sol} and $AvgDen$. In the plot, we first observe that the algorithms perform similarly when the solutions are sparse and the δ_{sol} values have large variance when the solutions are dense. When the log transformed solution density is less than 2, the average δ_{sol} values of GD10, IR10, and DIST are 0.06%, 0.15%, and 0.04%, respectively. However, the solution quality of DIST drastically decreases as the solutions become denser. This makes sense because sparse solutions can be efficiently searched by

1. $324 = (3 \cdot 4 \cdot 3 \cdot 4) + (3 \cdot 4 \cdot 3 \cdot 4) + (1 \cdot 3 \cdot 3 \cdot 4)$, where the three terms are for the three data sets and each term is obtained by multiplying the number of parameters $n, m, s(d)$, and λ, respectively.

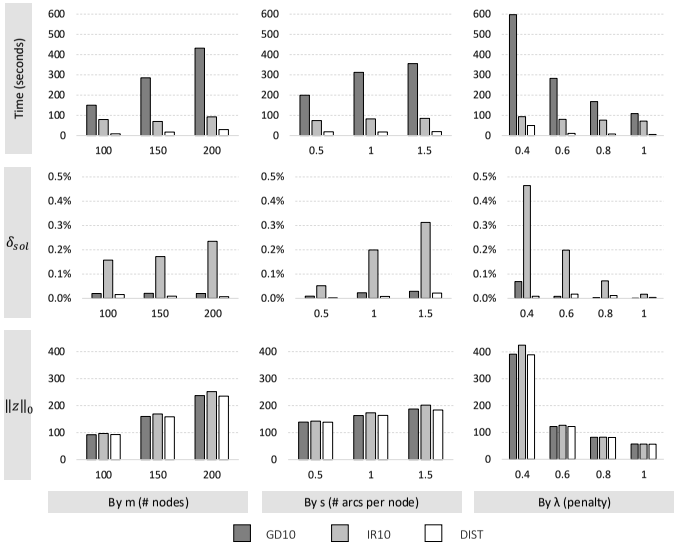

Figure 3: Performance of GD10, IR10, and DIST (high dimensional data)

arc-based search, while dense solutions are not easy to obtain by adding or removing arcs one by one. This also explains the relatively small and large δ_{sol} values for dense and spares solutions, respectively, by the topological order based algorithms. Between GD10 and IR10, we do not observe a big difference.

5.2 Comparison of MIP Models

In this section, we compare the performance of MIPto, MIPin, and MIPcp using *time*, δ_{sol}, and $\|z\|_0$ and the following additional metric.

δ_{IP}: the optimality gap (%) obtained by CPLEX within allowed $15 \cdot m$ seconds

Due to scalability issues of all models, we only use the sparse data with $m = 20, 30, 40$. We also limit $n = 100$. For all instances, we use the $15 \cdot m$ seconds time limit for CPLEX. For example, we have a time limit of 300 seconds for instances with $m = 20$.

The result is presented in Figure 5. Comparing the time of all models with the time limit for CPLEX, we observe that MIPin and MIPcp were able to terminate with optimality for several instances when $m = 20$ and $\lambda = 1$. This implies that MIPin and MIPcp are efficient when the problem is small and the number of selected arcs $\|z\|_0$ is small. However, in general, δ_{IP} values tend to be consistent with different models, while they increase in increasing m and s and in decreasing λ for all three MIP models. The execution times of all models increase in increasing m and s, and in decreasing λ. The same trend can be

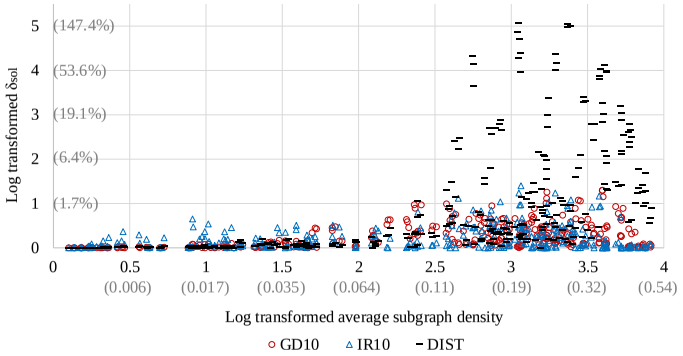

Figure 4: Scatter plot of δ_{sol} and average solution densities

found for δ_{IP} for all models. By comparing δ_{sol} values, we observe that MIPin is best when $m = 20$ and 30. However, the performance of MIPin drops drastically as m and s increase and λ decreases. Actually, MIPin fails to obtain a reasonably good solution within the time limit for several instances. This gives large δ_{sol} values and increases the average. The δ_{sol} values of MIPto are smaller than MIPcp when m and s are small, while MIPcp outperforms when $m = 40$ or $s = 3$.

5.3 Comparison of all MIP Models and Algorithms

In Figure 6, we compare all models and algorithms for selected sparse instances with $n = 100$ and $m \in \{20, 30, 40\}$, which were used to test MIP models. In the plot matrix, we show the average computation time and δ_{sol} (gap from the best objective value among the six models and algorithms) by m, s, and λ. Note that δ_{sol} values of a few MIPin results are not fully displayed in the bar plots due to their large values. Instead, the actual numbers are displayed next to the corresponding bar. The result shows that MIP models spent more time while the solution qualities are inferior in general. The values of δ_{sol} for the MIP models are competitive only when λ is large, which requires sparse solution. However, even for this case, MIP models spend longer time than the algorithms. Hence, ignoring the benefit of knowing and guaranteeing optimality by the MIP models, we conclude that the algorithms perform better for all cases.

The primary reason for the inferior performance of the MIP models is the difficulty of solving integer programming problems. Further, all of the MIP models have at least $O(m^2)$ binary variables and $O(m^2)$ constraints and the problem complexity grows fast. Finally, large values of big M in (15b) make the problem even more difficult. Due to non-tight values of big M, fathoming does not happen frequently in the branch and bound procedure. Hence, at least for sparse Gaussian Bayesian network learning, the MIP models may not be the best option unless other complicated constraints, which cannot be easily dealt with iterative algorithms, are needed.

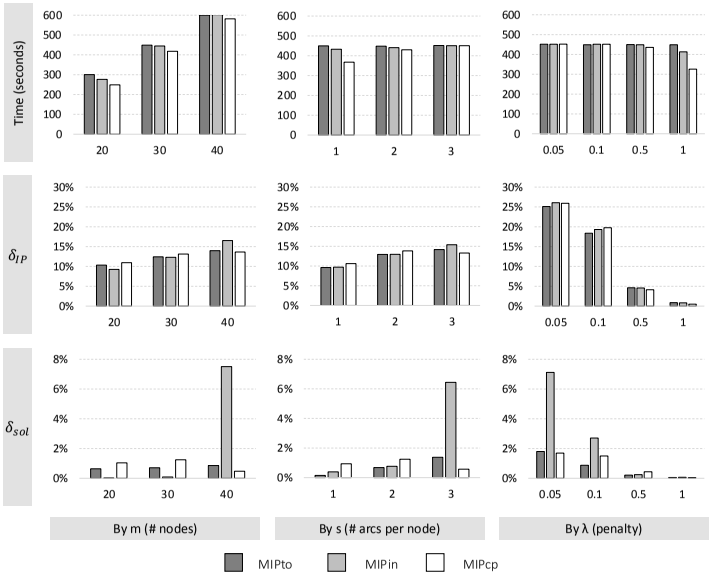

Figure 5: Performance of MIPto, MIPin, and MIPcp (sparse data with $n = 100$ and $m \in \{20, 30, 40\}$)

5.4 Real Data Example

In this section, we study the flow cytometry data set from Sachs et al. (2005) by solving (14). The data set has been studied in many works including Friedman et al. (2008), Shojaie and Michailidis (2010), Fu and Zhou (2013), and Aragam and Zhou (2015). The data set is often used as a benchmark as the casual relationships (underlying DAG) are known. It has $n = 7466$ cells obtained from multiple experiments with $m = 11$ measurements. The known structure contains 20 arcs. For the experiment, we standardize each column to have zero mean with standard deviation equal to one.

In Table 2, we compare the performance of the three algorithms GD10, IR10, and DIST for various values of λ. The MIP models are excluded due to scalability issue [2]. We compare the previously used performance measures execution time, solution cardinalities ($\|z\|_0$), and solution quality (δ_{sol}). In addition, we also compare sensitivities (true positive ratio) of the solutions. By comparing with the known structure with 20 arcs, we calculate directed true

2. Although m is small, with n =7466 observations, the MIP models have at least $7466 \cdot 11 \cdot 2 = 164{,}252$ continuous variables and $7466 \cdot 11 = 82{,}126$ constraints just for the residual terms. Combined with the complexity increment due to the binary variables and acyclicity constraints, it was not feasible to obtain a reasonable solution by any of the MIP models.

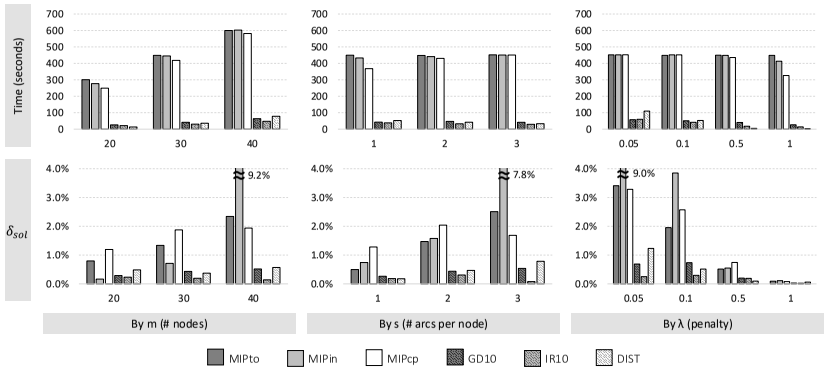

Figure 6: Performance of all models and algorithms (sparse data with $n = 100$ and $m \in \{20, 30, 40\}$)

positive (dTP) and undirected true positive (uTP). If arc (j, k) is in the known structure, dTP counts only if arc (j, k) is in the algorithm's solution, whereas uTP counts either of arcs (j, k) or (k, j) is in the algorithm's solution.

The solution times of the three algorithms are all within a few seconds, as m is small. Also, the solution cardinalities ($\|z\|_0$) are similar. The best δ_{sol} value among the three algorithms in each row is in boldface. We observe that GD10 provides the best solution (smallest δ_{sol}) in most cases and IR10 is the second best. The δ_{sol} values of DIST increase as λ increases. This is consistent with the findings in Section 5.1. Note that the density of the underlying structure is $20/11^2 = 0.165$, which is dense. This explains the good performance of GD10 and IR10. On the other hand, even though GD10 provides the best objective function values for most of the cases, the dTP and uTP values of GD10 are not always the best. The highest value among the three algorithms in each row is in boldface. While δ_{sol} values of DIST are the largest among the three algorithms, dTP and uTP values are the best in some cases. When λ is small, DIST tends to have higher dTP and uTP. However, as λ increases, GD10 gives the best dTP and uTP values. To further improve the prediction power, we may need weighting features or observations.

From Table 2, we observe that a slight change in solution quality δ_{sol} affects the final selection of DAG significantly. Also, the best objective function value does not necessarily give the highest true positive value since the L_1-norm penalized least square (14) may not be the best score function. In Figure 7, we present the graphs of known casual interactions (a), estimated subgraph by GD10 (b), IR10 (c), and DIST (d). All graphs are obtained with $\lambda = 0.25$, but the numbers of arcs are different (see Table 2). In fact, the difference between δ_{sol} values of IR10 and DIST is less than 1% while the subgraphs have only 10 common arcs.

6. Conclusion

We propose an MIP model and iterative algorithms based on topological order. Although the computational experiment is conducted for Gaussian Bayesian network learning, all the proposed model and algorithms are applicable for problems following the form in (1). While many MIP models and algorithms are designed based on arc search, using topological order provides some advantages that improve solution quality and algorithm efficiency.

1. DAG constraints (acyclicity constraints) are automatically satisfied when arcs from high order nodes to low order nodes are used.

2. In applying the concept for MIP, a lower number of constraints is needed ($O(m^2)$) whereas arc based modeling can have exponentially many constraints in the worst case.

3. In applying the concept in designing iterative algorithms, one of the biggest merits is the capability of utilizing the maximum number of arcs possible ($\frac{m(m-1)}{2}$), while arc based algorithms struggle with using all possible arcs.

The proposed MIP model has the smallest number of constraints while the number of binary variables is in the same order with the already known MIP models. It performs as good as a cutting plane algorithm. The proposed iterative algorithms get the biggest benefit when the solution matrix is dense. The result presented in Section 5.1 clearly indicates that the topological order based algorithms outperform when the density of the resulting solution is high. On the other hand, arc-based search algorithms, represented by DIST in our experiment, can be efficient when the desired solutions are very sparse.

Comparing all models and algorithms used in the experiment, we observe that the MIP models are not competitive or scale well compared to the heuristic algorithms except for small instances. The experiment shows that the solution times of the MIP models are significantly affected by the number of nodes m. For Gaussian Bayesian network learning, we observe that large n could also decrease the MIP model efficiency even when m is small (Section 5.4). Among the iterative algorithms, we recommend DIST for very sparse high dimensional data and GD10 and IR10 for dense data. Among the two topological order based algorithms, GD10 performs slightly better and is more stable.

Appendix A. Greedy Algorithm for Projection Problem

In this section, we present the detail derivations and proofs of Algorithm 3 (*greedy*). The algorithm sequentially determines topological order by optimizing the projection problem given an already fixed order up to the iteration point. Solving the projection problem is $\mathcal{NP}$-complete and our algorithm may not give a global optimal solution. However, the result of this section shows that Algorithm 3 gives an optimal choice of the next node to have fixed order given pre-fixed orders.

We start by describing some properties of Y^* in the following three lemmas. For the following lemmas, let π_j^* represent the topological order of node j defined by Y^*.

Lemma 5 *For any Y_{jk}^*, we must have either $Y_{jk}^* = 0$ or $Y_{jk}^* = U_{jk}^t$.*

Proof For a contradiction, let us assume that there exist indices q and r such that $Y_{qr}^* \neq 0$ and $Y_{qr}^* \neq U_{qr}^t$. Let us create a new solution $\bar{Y}$ such that $\bar{Y} = Y^*$ except $\bar{Y}_{qr} = U_{qr}^t$. Note that $\bar{Y}$ is a feasible solution to (12) because $supp(\bar{Y}) \leq supp(Y^*)$ element-wise since $Y_{qr}^* \neq 0$. Further, we have $\|Y^* - U^t\|_2 > \|\bar{Y} - U^t\|_2$ because $(Y_{qr}^* - U_{qr}^t)^2 > 0 = (\bar{Y}_{qr} - U_{qr}^t)^2$ and $\bar{Y} = Y^*$ except $Y_{qr}^* \neq \bar{Y}_{qr}$. This contradicts optimality of Y^*. ■

Note that Lemma 5 implies that solving (12) is essentially choosing between 0 and U_{jk}^* for Y_{jk}^*. This selection is also based on the following property.

Lemma 6 *If $\pi_j^* > \pi_k^*$, then $Y_{jk}^* = U_{jk}^t$.*

Proof For a contradiction, let us assume that there exist indices q and r such that $Y_{qr}^* \neq U_{qr}^t$ while $\pi_q^* > \pi_r^*$. Let us create a new solution $\bar{Y}$ such that $\bar{Y} = Y^*$ except $\bar{Y}_{qr} = U_{qr}^t$.

1. If $Y_{qr}^* \neq 0$, then $\bar{Y}$ is a DAG since $supp(\bar{Y}) \leq supp(Y^*)$ element-wise.
2. If $Y_{qr}^* = 0$, then arc (q, r) can be used in the solution without creating a cycle because $\pi_q^* > \pi_r^*$. Hence, $\bar{Y}$ is a DAG.

Therefore, $\bar{Y}$ is a feasible solution to (12). However, it is easy to see that $\|\bar{Y} - U^t\|_2 < \|Y^* - U^*\|_2$ because $(Y_{qr}^* - U_{qr}^t)^2 > 0 = (\bar{Y}_{qr} - U_{qr}^t)^2$. This contradicts optimality of Y^*. ■

Given the topological order by Y^*, let $\hat{J}^k = \{j \in J^k | \pi_j^* > \pi_k^*\}$ be the subset of J^k such that the nodes in $\hat{J}^k$ are earlier than node k. Combining Lemmas 5 and 6, we conclude that Y^* has the following structure.

$$Y_{jk}^* = \begin{cases} U_{jk}^t & \text{if } j \in \hat{J}^k, \\ 0 & \text{if } j \in J \setminus \hat{J}^k, \end{cases} \qquad k \in J \tag{18}$$

Further, we can calculate node k's contribution to the objective function value without explicitly using Y^*.

Lemma 7 *For each node $k \in J$, it contributes*

$$\sum_{j \in J \setminus \hat{J}^k} (U_{jk}^t)^2$$

to the objective function value for (12)*. In other words, the contribution of node k is the squared sum of U_{jk}^t for nodes with $\pi_j^* < \pi_k^*$.*

Proof For node k, we can derive

$$\sum_{j \in J}(Y_{jk}^* - U_{jk}^t)^2 = \sum_{j \in J \setminus \hat{J}^k}(Y_{jk}^* - U_{jk}^t)^2 = \sum_{j \in J \setminus \hat{J}^k}(U_{jk}^t)^2,$$

where both equal signs are due to (18). The first equality is due to $Y_{jk}^* = U_{jk}^t$ for $j \in \hat{J}^k$ and the second equality holds since $Y_{jk}^* = 0$ for $j \in J \setminus \hat{J}^k$. ■

We next detail the derivation of the greedy algorithm presented in Algorithm 3. Let $\bar{J} \subseteq J$ be the index set of yet-to-be-ordered nodes and $\bar{J}^c = J \setminus \bar{J}$ be the index set of the nodes that have already been ordered. The procedure is equivalent to iteratively solving

$$k^* = \text{argmin}_{k \in \bar{J}} \Big\{ \min_{Y_k} \big\{ \sum_{j \in J} (Y_{jk} - U_{jk}^t)^2 \big\} \Big\}, \tag{19}$$

where $Y_k = [Y_{1k}, Y_{2k}, \cdots, Y_{mk}] \in \mathbb{R}^{m \times 1}$ is the column in Y corresponding to node k. Set $\bar{J}$ is updated by $\bar{J} = \bar{J} \setminus \{k^*\}$ and $\pi_{k^*}^* = |\bar{J}|$ after solving (19). We propose an algorithm to solve (19) based on the properties of Y^* described in Lemmas 5 - 7. Given $\bar{J}$, we solve

$$k^* = \text{argmin}_{k \in \bar{J}} \Big\{ \sum_{j \in \bar{J}} (U_{jk}^t)^2 \Big\}. \tag{20}$$

Next, we show that solving (20) gives an optimal solution $\bar{Y}_{jk^*}$, $j \in J^k$ to (19). We can actually replicate the properties of Y^* for $\bar{Y}_{jk^*}$.

Lemma 8 *An optimal solution to* (19) *must have either $\bar{Y}_{jk^*} = 0$ or $\bar{Y}_{jk^*} = U_{jk^*}^t$ for all $j \in J^k$.*

Lemma 9 *An optimal solution to* (19) *must have $\bar{Y}_{jk^*} = U_{jk^*}^t$ for $j \in J \setminus \bar{J}$.*

Lemma 10 *An optimal solution to* (19) *must satisfy $\sum_{j \in J}(\bar{Y}_{jk^*} - U_{jk^*}^t)^2 = \sum_{j \in \bar{J}}(U_{jk^*}^t)^2$*

The proofs are omitted as they are similar to the proofs of Lemmas 5 - 7, respectively. Note that, by Lemma 10, we show the equivalence of $\sum_{j \in J}(Y_{jk^*} - U_{jk^*}^t)^2$ and $\sum_{j \in \bar{J}}(U_{jk^*}^t)^2$. This result also holds for each term, $k \in \bar{J}$, of the argmin function in (19). Hence, the following lemma holds.

Lemma 11 *Solving* (20) *is equivalent to solving* (19)*.*

Observe that (20) is used in Line 3 of the greedy algorithm in Algorithm 3. Hence, by property (19), the algorithm gives an optimal choice of node to be fixed with the pre-fixed topological order.

Appendix B. Summary Statistics for Maximum Coefficients

In this section, we show that the heuristic formula (17) for selecting big M gives reasonable and large enough values. Note that, when creating a synthetic instance, we used a random DAG to generate multivariate data. Although the optimal DAG for the penalized least

squares is unknown, with appropriate penalty constants, we can use the implanted DAG to obtain coefficients estimation. That is, we calculate

$$\hat{B} = \max_{j \in J^k, k \in K} |\hat{\beta}_{jk}|$$

by using the implanted DAG. The $\hat{B}$ value is then compared with the big M value in (17) for all instances used for MIP models (sparse data with $n = 100$ and $m \in \{20, 30, 40\}$). We calculate minimum, average, and maximum of $\hat{B}$ and M by m, s, and λ. The result is presented in Table 3. Note that we have $\hat{B} < M$ for all columns Min, Avg, and Max and for all rows. Although only the summary statistics are presented in Table 3, we observed that M is greater than $\hat{B}$ for all cases considered.

By		$\hat{B}$			M		
Param	Value	Min	Avg	Max	Min	Avg	Max
m	20	0.17	0.65	1.48	0.33	1.34	3.73
	30	0.18	0.62	0.95	0.36	1.32	3.10
	40	0.18	0.63	1.03	0.36	1.33	3.30

Abstract

Learning control has become an appealing alternative to the derivation of control laws based on classic control theory. However, a major shortcoming of learning control is the lack of performance guarantees which prevents its application in many real-world scenarios. As a step towards widespread deployment of learning control, we provide stability analysis tools for controllers acting on dynamics represented by Gaussian processes (GPs). We consider differentiable Markovian control policies and system dynamics given as (i) the mean of a GP, and (ii) the full GP distribution. For both cases, we analyze finite and infinite time horizons. Furthermore, we study the effect of disturbances on the stability results. Empirical evaluations on simulated benchmark problems support our theoretical results.

Keywords: Stability, Reinforcement Learning, Control, Gaussian Process

1. Introduction

Learning control based on Gaussian process (GP) forward models has become a viable approach in the machine learning and control theory communities. Many successful applications impressively demonstrate the efficiency of this approach (Deisenroth et al., 2015; Pan and Theodorou, 2014; Klenske et al., 2013; Maciejowski and Yang, 2013; Nguyen-Tuong and Peters, 2011; Engel et al., 2006; Kocijan et al., 2004). In contrast to classic control theory methods, learning control does not presuppose a detailed understanding of the underlying dynamics but tries to infer the required information from data. Thus, relatively little expert knowledge about the system dynamics is required and fewer assumptions, such as a parametric form and parameter estimates, must be made. Employing Gaussian processes as forward models for learning control is particularly appealing as they incorporate uncertainty about the system dynamics. GPs infer a distribution over all plausible models given the observed data instead of one (possibly erroneous) model and, thus, avoid severe modeling errors. Furthermore, obtaining a task solution by a learning process can significantly decrease the involved manual effort.

Unfortunately, performance guarantees rarely exist for arbitrary system dynamics and policies learned from data. An important and well-established type of performance guarantee is *(asymptotic) stability*. A *stability region* in the state space ensures, that all trajectories starting in this region converge to the target. Classic control theory offers a rich variety of stability analysis, e.g., for linear, nonlinear, and stochastic systems (Khalil, 2014; Khasminskii and Milstein, 2011; Skogestad and Postlethwaite, 2005; Kushner, 1967). In a preliminary study (Vinogradska et al., 2016), we introduced a tool to analyze the stability of learned policies for closed-loop control systems with transition dynamics given as a GP. This tool handled two types of dynamics: dynamics given as (i) the mean of a GP, and (ii) the full GP distribution. While the first case results in a deterministic closed-loop system, uncertainty is present in the second case. As propagating distributions through a GP is analytically intractable, we proposed a novel approach for approximate multi-step-ahead predictions based on numerical quadrature. Finally, we were able to analyze asymptotic stability of the deterministic dynamics in case (i), but in case (ii) only finite time horizons were considered. Furthermore, the results were limited to GPs with squared exponential kernel.

In this paper, we substantially extend our previous work (Vinogradska et al., 2016) and move to a solid foundation for a stability analysis tool. For this detailed study on stability of closed-loop control systems, we consider dynamics given as (i) the mean of a GP, and (ii) the full GP distribution. In both cases, we analyze finite as well as infinite time horizons. For dynamics given as the mean of a GP, we obtain a region of starting points in the state space such that the target state is reached up to a given tolerance at the (finite) time horizon. For infinite time horizons, we construct a stability region in the state space. Furthermore, we study the behavior of dynamics given by the mean of a GP when disturbances are present. Here, we derive criteria for the disturbance such that the closed-loop control system remains stable. For full GP dynamics, we propose an algorithm to find a region of starting points in the state space such that the probability of the state to be in the target region at the (finite) time horizon is at least a given minimum probability. As the GP predictive distribution at any query point is Gaussian, the probability to transition to a point arbitrarily far from the current point is greater than zero and, thus, the system will eventually leave any compact set. Hence, for full GP dynamics the notions of deterministic analysis do not apply. Here, we extend the previous results (Vinogradska et al., 2016) substantially and analyze asymptotic behavior of closed-loop control systems with full GP dynamics. Employing methods from Markov chain theory, we show that for many choices of the prior the system converges to a unique, invariant limiting distribution.

This paper lays a foundation for theoretical stability analysis for control of probabilistic models learned from data. The proposed approaches provide stability guarantees for many

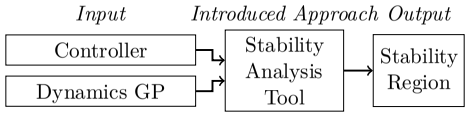

Figure 1: We present a tool to analyze stability for a given controller and Gaussian process (GP) dynamics model. Our tool analytically derives a stability region where convergence to the goal is guaranteed. Thus, we can provide stability guarantees for many of the existing GP based learning control approaches.

existing learning control approaches based on GPs. The paper is organized as follows: first, we briefly review related work and introduce the problem to be addressed. Section 2 provides necessary background for the stability analysis. In Section 3, we analyze closed-loop control systems with dynamics given as the mean of a GP. Subsequently, we study the case when the dynamics are given as the full GP distribution in Section 4. Section 5 provides empirical evaluations on benchmark control tasks. A conclusion is given in Section 6.

1.1 Related Work

To date, only very few special cases of system dynamics and policies learned from data have been analyzed with respect to stability. For example, Perkins and Barto (2003) and Nakanishi et al. (2002) analyze the scenario of an agent switching between given safe controllers. Kim and Ng (2005) monitor stability while learning control for the special case of a linear controller and linear dynamics. Recently, stability properties of autoregressive systems with dynamics given as the mean of a GP were analyzed by Beckers and Hirche (2016), who derive an upper bound on the number of equilibrium points for squared exponential and some special cases of polynomial covariance functions. Furthermore, the authors compute an invariant set and show the boundedness of all system trajectories. However, no control inputs are considered in this work and no asymptotic stability results are given. Furthermore, the full GP distribution is not considered in (Beckers and Hirche, 2016). To the best of our knowledge, stability analysis for closed-loop control with probabilistic models, such as GPs, and arbitrary policies has not been addressed so far.

In classic control theory, the first formal analysis of closed-loop dynamics dates back to the 19th century (Routh, 1877; Hurwitz, 1895; Lyapunov, 1892). Lyapunov's approach allows to analyze stability for nonlinear deterministic systems $\dot{x} = f(x)$. It studies the system behavior around *equilibrium points*, i.e., points, where all derivatives $\dot{x}$ of the state x vanish and the system comes to a hold. An equilibrium point x_e is *stable*, if for every $\varepsilon > 0$ a $\delta > 0$ exists such that $\|x(t) - x_e\| < \epsilon$ for every solution $x(t)$ of the differential equation with $\|x(t_0) - x_e\| < \delta$ and $t \geq t_0$. The equilibrium point is *asymptotically stable*, if it is stable and δ can be chosen such that $\|x(t) - x_e\| \to 0$ as $t \to \infty$, see (Khalil, 2014). One approach to proving stability of x_e is to find a *Lyapunov function*, i.e., a non-negative function, that vanishes only at x_e and decreases along system trajectories. This approach can be applied to nonlinear dynamics. However, finding a Lyapunov function is typically challenging as there exists no general method for this task.

Additionally to the difficulty of finding a suitable Lyapunov function, classical Lyapunov approaches are highly challenging as proving nonnegativity of a nonlinear function is in general intractable. In (Parrilo, 2000), a relaxation of the positive definiteness problem for polynomials was introduced: a polynomial is clearly nonnegative, if it can be written as a sum of squares (SOS) of polynomials. Fortunately, checking whether a polynomial can be written as SOS can be formulated as a semidefinite program (SDP) and can be solved in polynomial time. Thus, for polynomial system dynamics one can search for polynomial Lyapunov functions conveniently by solving the corresponding SDP. This SOS relaxation has been successfully applied to a number of nonlinear stability problems as finding the region of attraction of a system (Chesi, 2004; Majumdar et al., 2014), robust analysis (Topcu et al., 2010b) or controller design (Moore and Tedrake, 2014). While there are some limitations to these methods (Majumdar et al., 2014; Ahmadi and Parrilo, 2011), SOS approaches are of high practical importance. However, SOS methods can only be applied directly to polynomial dynamics. Nonpolynomial dynamics must be recast as polynomial systems by an (automated) procedure (Papachristodoulou and Prajna, 2005). This recasting procedure introduces new variables and constraints for each nonpolynomial term and can, thus, significantly increase the size of the SDP that must be solved. Especially for nonparametric and nonpolynomial models as, e.g., a GP with squared exponential or Matérn kernels, recasting often leads to SDPs that are computationally infeasible (Topcu et al., 2010a).

For consideration of uncertainty in the dynamics, stochastic differential equations (SDEs) have been introduced (Adomian, 1983). SDEs are differential equations where some terms are stochastic processes. In the presence of uncertainty, x_e is *stable in probability*, if for every $\varepsilon > 0$ and $p > 0$, there exists $\delta > 0$ such that $\mathrm{P}\{\|x(t) - x_e\| > \varepsilon\} < p$ for $t > t_0$ and solutions $x(t)$ with $\|x(t_0) - x_e\| < \delta$. Furthermore, x_e is *asymptotically stable in probability*, if it is stable in probability and $\mathrm{P}\{\|x(t) - x_e\| > \varepsilon\} \to 0$ for a suitable δ, see (Khasminskii and Milstein, 2011). Stability follows from the existence of a *supermartingale*, a stochastic Lyapunov function analogue. However, supermartingales exist only if the noise vanishes at the equilibrium point. Relaxing the supermartingale criterion allows for stability statements for a finite time horizon (Steinhardt and Tedrake, 2012; Kushner, 1966). Kushner's (1966) approach requires a supermartingale to be found manually, which is challenging in most cases. Steinhardt and Tedrake (2012) address this difficulty by constructing a supermartingale via SOS programming. This approach is suitable for systems with polynomial dynamics and shares some of the difficulties of SOS approaches as described above.

When controlling a system, uncertainty may arise from modeling inaccuracies, the presence of (external) disturbances and the lack of data, as some system parameters are not known in advance but only during operation. Robustness of nonlinear systems to structured or unstructured uncertainty has been considered in classical control theory, e.g., via the small gain theorem (Zhou and Doyle, 1998). However, these approaches typically lead to an infinite number of nonlinear matrix inequalities and cannot be solved analytically. Another approach is to take uncertainty into account when designing a controller. Thus, a controller must be suitable for a family of systems that is specified, e.g., by bounds for model parameters or for nonparametric uncertainties as bounds for the operator norm of the unknown dynamics. Robust control (Skogestad and Postlethwaite, 2005; Zhou and Doyle, 1998) designs a single controller that is provably stable for all systems in the specified family – often at cost of overall controller performance. Adaptive control (Narendra and Annaswamy, 2012; Tao,

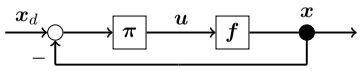

Figure 2: A closed-loop control structure with controller $\boldsymbol{\pi}$ and the system dynamics $\boldsymbol{f}$. We study stability for two types of dynamics: (i) the mean of the GP and (ii) the full GP predictive distribution.

2003) instead adjusts control parameters online in order to achieve prespecified performance, which can be computationally demanding. Both schemes require stability analysis of the dynamics system, e.g., via Lyapunov functions as described above.

1.2 Problem Statement

The goal of this paper is to provide an automated tool to analyze stability of a closed-loop structure when the dynamics model is given as a GP, see Figure 1. As inputs, our tool expects a control policy and a GP dynamics model. It checks the stability of the corresponding closed-loop structure and returns a stability region. Trajectories starting in this region are guaranteed to converge to the target (in probability). Subsequently, we discuss the different components of the tool in more detail.

We consider controllers which depend only on the current state and are differentiable with respect to the state. The dynamics model is given as a GP with stationary covariance function. This covariance function is assumed to have bounded derivatives with respect to all input dimensions and bounded prior mean. We consider a discrete-time system $\boldsymbol{x}^{(t+1)} = \boldsymbol{f}(\boldsymbol{x}^{(t)}, \boldsymbol{u}^{(t)})$ with $\boldsymbol{x}^{(t)} \in \mathbb{R}^D$, $\boldsymbol{u}^{(t)} \in \mathbb{R}^F$, $t = 1, 2, \ldots$ and a controller $\boldsymbol{\pi}\colon \mathbb{R}^D \to \mathbb{R}^F$, whose objective is to move the system to a desired state $\boldsymbol{x}^d$, see Figure 2. In this paper, we study two possible cases for the dynamics $\boldsymbol{f}$: (i) the mean of a GP and (ii) the full GP predictive distribution. Note, that in the second case, distributions have to be propagated through the GP resulting in non-Gaussian state distributions.

2. Preliminaries

In this section, we introduce basic concepts for the proposed stability analysis. First, we briefly review Gaussian process regression, as GPs are employed to describe the considered dynamics. Second, we recap numerical quadrature, as it is the basis for the uncertainty propagation method proposed in Section 4.

2.1 Gaussian Process Regression

Given noisy observations $\mathscr{D} = \{(\boldsymbol{z}^i, y^i = f(\boldsymbol{z}^i) + \varepsilon^i) \mid 1 \leq i \leq N\}$, where $\varepsilon^i \sim \mathcal{N}(0, \sigma_n^2)$, the prior on the values of f is $\mathcal{N}(0, K(Z,Z) + \sigma_n^2 I)$. The covariance matrix $K(Z,Z)$ is defined by the choice of covariance function k as $[K(Z,Z)]_{ij} = k(\boldsymbol{z}^i, \boldsymbol{z}^j)$. One commonly employed covariance function is the squared exponential

$$k(\boldsymbol{z}, \boldsymbol{w}) = \sigma_f^2 \exp\left(-\frac{1}{2}(\boldsymbol{z} - \boldsymbol{w})^\intercal \Lambda^{-1} (\boldsymbol{z} - \boldsymbol{w})\right),$$

with signal variance σ_f^2 and squared lengthscales $\Lambda = \operatorname{diag}(l_1^2, \ldots, l_{D+F}^2)$ for all input dimensions. Given a query point $\boldsymbol{z}_*$, the conditional probability of $f(\boldsymbol{z}_*)$ is

$$f(\boldsymbol{z}_*) \mid \mathscr{D} \sim \mathcal{N}(\boldsymbol{k}(\boldsymbol{z}_*, Z)\boldsymbol{\beta},\ k(\boldsymbol{z}_*, \boldsymbol{z}_*) - \boldsymbol{k}(\boldsymbol{z}_*, Z)(K(Z,Z) + \sigma_n^2 I)^{-1}\boldsymbol{k}(Z, \boldsymbol{z}_*)) \tag{1}$$

with $\boldsymbol{\beta} = (K(Z,Z) + \sigma_n^2 I)^{-1}\boldsymbol{y}$. The hyperparameters, e.g. $\sigma_n^2, \sigma_f^2, \Lambda$ for the squared exponential kernel, are estimated by maximizing the log marginal likelihood of the data (Rasmussen and Williams, 2005).

In this paper, $\boldsymbol{f}$ models system dynamics. It takes state-action pairs $\boldsymbol{z} = (\boldsymbol{x}, \boldsymbol{u})^\intercal$ and outputs successor states $\boldsymbol{f}(\boldsymbol{x},\boldsymbol{u})$. As these outputs are multivariate, we train conditionally independent GPs for each output dimension. We write $\sigma_{n,m}^2$, $\sigma_{f,m}^2, \Lambda_m$ for the GP hyperparameters in output dimension m and k_m for the corresponding covariance function.

2.2 Numerical Quadrature

Numerical quadrature approximates the value of an integral

$$\int_a^b f(\boldsymbol{x}) d\boldsymbol{x} \approx \sum_{i=1}^{p} w_i f(\boldsymbol{\xi}_i)$$

given a finite number p of function evaluations. A widely used class of quadrature rules are interpolatory quadrature rules, which integrate all polynomials up to a certain degree exactly. In this paper, we employ Gaussian quadrature rules, where the evaluation points $\boldsymbol{\xi}_1, \ldots, \boldsymbol{\xi}_p$ are chosen to be the roots of certain polynomials from orthogonal polynomial families. They achieve the highest accuracy possible for univariate interpolatory formulæ (Süli and Mayers, 2003). For multivariate integrals, the quadrature problem is significantly harder. While many formulæ for the univariate case can straightforwardly be generalized to multivariate integrals, they often suffer from the curse of dimensionality. However, quadrature methods that scale better and are feasible for up to 20 dimensions have been developed. See (Skrainka and Judd, 2011) for an overview.

3. Stability of GP Mean Dynamics

A wide variety of dynamics can be modeled well by the mean of a GP (Micchelli et al., 2006) due to the universal approximation property of many kernels. Thus, stability of systems with GP mean forward dynamics is an interesting problem. Please note that stability of closed-loop control systems with dynamics given as the mean of a GP is a classical problem from nonlinear control with a particular choice of dynamics function. Classical approaches to solve this problem have been discussed in Section 1.1 and range from direct Lyapunov approaches to the more recent SOS approach to construct polynomial Lyapunov functions. However, for GP mean dynamics, finding a Lyapunov function directly seems even more challenging than for a classical ODE derived from expert knowledge about the physical system. On the other hand, constructing a polynomial Lyapunov function as the solution of an SOS problem is typically computationally infeasible for these dynamics systems, as the nonparametric nature of GP mean functions results in a large number of nonpolynomial terms that significantly increase the complexity of the underlying semidefinite program (see Section 1.1). Thus, we propose an alternative approach to address this problem.

In this section, we provide tools to check the stability of a closed-loop control structure with a given differentiable Markovian control policy π and GP mean dynamics. For this class of forward dynamics, the next state $\boldsymbol{x}^{(t+1)}$ is given as the mean of the GP predictive distribution at the inputs $\boldsymbol{x}^{(t)}, \boldsymbol{u} = \boldsymbol{\pi}(\boldsymbol{x}^{(t)})$. Firstly, we consider infinite time horizons. In this case, we attempt to find a region of starting points in the state space, such that trajectories starting in this region are guaranteed to converge to the desired point $\boldsymbol{x}^d$ as $t \to \infty$. To obtain this result, we analyze the sensitivity of the GP predictive mean to variations in the input space and derive upper bounds for the distance of the predictions at two different points. This analysis can be used to find a region around the target point $\boldsymbol{x}^d$, where the next state is closer to $\boldsymbol{x}^d$ than the point before. It follows straightforwardly, that the full metric ball of maximal radius, which lies completely inside this region, is a stability region. All trajectories that start inside of this metric ball converge to the target point as $t \to \infty$. Furthermore, we will show that in this metric ball, the distance of the current state to the target decreases exponentially. We will exploit this statement to derive some finite time horizon and robustness results. For finite time horizons, we aim to find a region in the state space, such that the state does not deviate more than a given tolerance from the target when the time horizon is reached. The robustness analysis deals with asymptotic stability of the GP mean dynamics when disturbances are present. We derive conditions for these disturbances, such that convergence to the target state $\boldsymbol{x}^d$ is still guaranteed.

In the following, we will briefly review the notion of stability employed for the analysis and derive the main result of this section: an algorithm to find a stability region. After proving correctness of this algorithm, we will derive statements on finite time stability of the GP mean dynamics and on infinite time stability of the disturbed system.

3.1 Stability Notion

If the system dynamics $\boldsymbol{f}$ is given by the mean of a GP, the resulting closed-loop structure is deterministic. To assess the quality of a controller $\boldsymbol{\pi}$, which aims to stabilize the system at the reference point $\boldsymbol{x}^d$, we propose an algorithm to find a stability region of the closed-loop system.

Definition 1 *The reference point $\boldsymbol{x}^d$ is* stable, *if for every $\varepsilon > 0$ there exists $\delta > 0$, such that $\|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| < \varepsilon$ for $t = 1, 2, \dots$ and $\|\boldsymbol{x}^{(0)} - \boldsymbol{x}^d\| < \delta$. If $\boldsymbol{x}^d$ is stable and there exists a $\delta_0 > 0$ such that $\|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| \to 0$ for $t \to \infty$, $\|\boldsymbol{x}^{(0)} - \boldsymbol{x}^d\| < \delta_0$, $\boldsymbol{x}^d$ is* asymptotically stable. *A subset X^c of the state space is a* stability region, *if $\|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| \to 0$ as $t \to \infty$ for all $\boldsymbol{x}^{(0)} \in X^c$.*

Please note that $\boldsymbol{\pi}$ is implicit in this definition, as the states $\boldsymbol{x}^{(t)}$ for $t = 1, 2, \dots$ depend on $\boldsymbol{\pi}$ via $\boldsymbol{x}^{(t+1)} = \boldsymbol{f}(\boldsymbol{x}^{(t)}, \boldsymbol{\pi}(\boldsymbol{x}^{(t)}))$. This definition matches Lyapunov's stability notion (Khalil, 2014). We will present an algorithm that checks asymptotic stability of $\boldsymbol{x}^d$ by constructing a stability region X^c.

When the time horizon considered is finite, we are interested in finding all starting states, such that the distance to the target is at most a given $\varepsilon > 0$.

Definition 2 *A subset X^c of the state space is an (ε, T)-*stability region, *if $\|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| < \varepsilon$ holds for all $\boldsymbol{x}^0 \in X^c$ and $t \geq T$.*

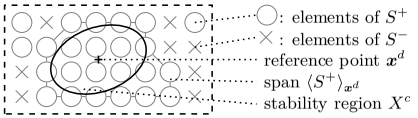

Figure 3: Basic idea of Algorithm 1 to construct a stability region: for a finite set of states S, employ upper bound from Lemma 3 to check whether the successor state is closer to $\boldsymbol{x}^d$, obtaining sets S^+ and S^-. Return metric ball of maximal radius that fits into the span $\langle S^+ \rangle_{\boldsymbol{x}^d}$ as stability region X^c. For $\boldsymbol{x}^{(0)} \in X^c$, the controlled system never leaves X^c and converges to $\boldsymbol{x}^d$ as $t \to \infty$.

In the following, we propose an algorithm to verify asymptotic stability of $\boldsymbol{x}^d$ as in Definition 1 and prove its correctness. Subsequently, we show how to find finite time statements as in Definition 2.

3.2 Algorithm Sketch

In this section, we derive an algorithm, that can find a stability region of a closed-loop control structure with GP mean dynamics. To find a stability region, we analyze how the distance between the current state and the target evolves. The basic idea of the algorithm involves *positively invariant sets*, i.e., sets that once entered, the system will never leave again (Blanchini, 1999). More precisely, we aim to find all $\boldsymbol{x}$, such that

$$\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\| < \gamma \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| \tag{2}$$

for $\boldsymbol{x}^{(t)} = \boldsymbol{x}$ and a fixed $0 < \gamma < 1$. Assume there is a region containing $\boldsymbol{x}^d$ where Eq. (2) holds. For all states in this region, the distance to the target point decreases in one time step. If it is possible to fit a full metric ball centered at the target point $\boldsymbol{x}^d$ in this region, then all trajectories starting in the ball will never leave it. In addition, the distance of the current state to the reference point $\boldsymbol{x}^d$ will decrease in every step by at least factor γ. Thus, it follows immediately from the existence of such a ball that the target point is asymptotically stable. However, finding a region in closed form where Eq. (2) holds, is usually intractable. Instead, we follow an algorithmic approach to construct a stability region.

The proposed algorithm (Alg. 1) finds a region where Eq. (2) holds if one exists. It employs an upper bound for $\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\|$, that depends only on $\boldsymbol{x}^{(t)}$. With this upper bound we can check whether Eq. (2) holds for a (finite) set of points. However, to find a continuous state space region where Eq. (2) holds, this upper bound must allow for generalization from discrete points. More precisely, we need an upper bound of $\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\|$ that depends on $\boldsymbol{x}^{(t)}$ smoothly, thus, having bounded gradients, and can be handled conveniently. We employ an upper bound derived from sensitivity analysis of the GP mean to variations in the input space. This bound depends on $\boldsymbol{x}^{(t)}$ in a way that can be exploited to compute a finite set of points S, e.g., a grid that is sufficient to consider as follows: For any grid point, we check if Eq. (2) holds, obtaining the set S^+ with the grid points that fulfill Eq. (2) and the rest in S^-. Let $\langle S^+ \rangle_{\boldsymbol{x}^d}$ be the polygon spanned by the connected component of

Algorithm 1 Stability region X^c for GP mean dynamics

    X^c ← B(x^d) fi
return X^c
```

S^+, which contains $\boldsymbol{x}^d$. We can choose S such that Eq. (2) holds for all points in $\langle S^+\rangle_{\boldsymbol{x}^d}$, see Figure 3. Algorithm 1 gives an overview, Sec. 3.3 provides technical details and proves correctness of the approach.

3.3 Correctness of the Algorithm

In this section, we elaborate on the computation steps of Algorithm 1 and prove that the returned state space region X^c is a stability region of the closed-loop system in the sense of Definition 1. Fundamental to Algorithm 1 is the upper bound for $\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\|$, which can be obtained as follows. We denote $\hat{\boldsymbol{x}} \coloneqq (\boldsymbol{x}, \boldsymbol{\pi}(\boldsymbol{x}))^\intercal$ and recall that $\boldsymbol{f}(\hat{\boldsymbol{x}})$ is the GP predictive mean at $\hat{\boldsymbol{x}}$, see Eq. (1).

Lemma 3 *Let $\hat{\boldsymbol{x}}, \hat{\boldsymbol{x}}^d \in \mathbb{R}^{D+F}$ and $B \in \mathbb{R}^{D\times D}$ be a positive definite matrix. The distance of GP predictive means $\boldsymbol{f}(\hat{\boldsymbol{x}})$ and $\boldsymbol{f}(\hat{\boldsymbol{x}}^d)$ in the metrics induced by B is bounded by*

$$\|\boldsymbol{f}(\hat{\boldsymbol{x}}) - \boldsymbol{f}(\hat{\boldsymbol{x}}^d)\|_B^2 \leq (\hat{\boldsymbol{x}} - \hat{\boldsymbol{x}}^d)^\intercal M(\boldsymbol{x}, \boldsymbol{x}^d, \boldsymbol{\pi})(\hat{\boldsymbol{x}} - \hat{\boldsymbol{x}}^d) =: C(\boldsymbol{x}, \boldsymbol{x}^d, \boldsymbol{\pi})$$

with a symmetric matrix M. This matrix can be constructed explicitly and depends on $\boldsymbol{x}, \boldsymbol{x}^d$ and the policy $\boldsymbol{\pi}$.

Proof This statement is obviously true for $\boldsymbol{x} = \boldsymbol{x}^d$, so let $\boldsymbol{x} \neq \boldsymbol{x}^d$. Evaluating

$$\|\boldsymbol{f}(\hat{\boldsymbol{x}}) - \boldsymbol{f}(\hat{\boldsymbol{x}}^d)\|_B^2 = \sum_{m,m'=1}^{D} \sum_{i,k=1}^{N} b_{mm'}(k_m(\hat{\boldsymbol{x}}, \hat{\boldsymbol{x}}^i) - k_m(\hat{\boldsymbol{x}}^d, \hat{\boldsymbol{x}}^i))(k_{m'}(\hat{\boldsymbol{x}}, \hat{\boldsymbol{x}}^k) - k_{m'}(\hat{\boldsymbol{x}}^d, \hat{\boldsymbol{x}}^k))\beta_{mi}\beta_{m'k} \quad (3)$$

we realize the need for an upper bound of $k_m(\hat{\boldsymbol{x}}, \hat{\boldsymbol{x}}^i) - k_m(\hat{\boldsymbol{x}}^d, \hat{\boldsymbol{x}}^i)$. Recall that the covariance functions k_m are differentiable with bounded derivatives with respect to $\boldsymbol{x}$ and also, that the control policy π is differentiable with respect to the state $\boldsymbol{x}$. Thus, we can integrate the gradient field of k_m along a curve $\boldsymbol{\tau}$ from $\hat{\boldsymbol{x}}^d$ to $\hat{\boldsymbol{x}}$. As this path integral does not depend on the particular curve $\boldsymbol{\tau}$, we may choose $\boldsymbol{\tau} = \boldsymbol{\tau}^{D+F} \dots \boldsymbol{\tau}^1$ as the curve along the edges of the hypercube defined by $\hat{\boldsymbol{x}}^d$ and $\hat{\boldsymbol{x}}$, i.e., $\boldsymbol{\tau}_p^j(t) = \hat{x}_p$ if $p \leq j-1$, $\boldsymbol{\tau}_p^j(r) = \hat{x}_p^d + r(\hat{x}_p - \hat{x}_p^d)$ with

$r \in [0;1]$ if $p = j$, and $\boldsymbol{\tau}_p^j(t) = \hat{x}_p^d$ otherwise. This definition yields

$$k_m(\hat{\boldsymbol{x}}, \hat{\boldsymbol{x}}^i) - k_m(\hat{\boldsymbol{x}}^d, \hat{\boldsymbol{x}}^i) = \sum_{j=1}^{D+F} \int_{\hat{x}_j^d}^{\hat{x}_j} \frac{\partial k_m(\boldsymbol{\chi}, \hat{\boldsymbol{x}}^i)}{\partial \chi_j}\bigg|_{\boldsymbol{\chi}=\boldsymbol{\tau}^j} d\chi_j \quad (4)$$

and we compute the partial derivatives $\partial k_m(\hat{\boldsymbol{x}}, \hat{\boldsymbol{x}}^d)/\partial \hat{x}_j$ in all state-action space dimensions $1 \leq j \leq D+F$.

We rewrite the sum in Eq. (3) by substituting Eq. (4) and the partial derivatives of the covariance functions. To find an upper bound for this sum, we estimate the occurring integrals by the product of integration interval length and an upper or lower mean value according to the sign of the respective summand. The necessary upper and lower mean values can be obtained via Riemannian upper and lower sums or the upper and lower bounds for the partial derivatives of k with respect to $\boldsymbol{x}$. Sorting the summands by products of integration interval lengths $(\hat{x}_j - \hat{x}_j^d)(\hat{x}_p - \hat{x}_j^d)$, this sum can be rewritten as a quadratic form. The entries of M can be chosen to form a symmetric matrix by making $M_{pj} = M_{jp}$ half of the coefficient of $(\hat{x}_j - \hat{x}_j^d)(\hat{x}_p - \hat{x}_p^d)$. ■

For any point in the state action space, we can find an upper bound for the distance of its prediction and the target point. Note that this distance estimated by Lemma 3 depends heavily on the eigenvalues of $M(\boldsymbol{x}, \boldsymbol{x}^d, \boldsymbol{\pi})$. This fact is exploited to compute a grid S, which constitutes the first step of Algorithm 1. As M is constructed as a symmetric matrix, the eigenvalue problem is well conditioned, i.e., when M is perturbed, the change in the eigenvalues of M is at most as large as the perturbation.

Lemma 4 *Let $\boldsymbol{x}, \boldsymbol{z} \in \mathbb{R}^D$ and $M(\boldsymbol{x}, \boldsymbol{x}^d, \pi)$, B be as defined in Lemma 3. If $\|\boldsymbol{f}(\hat{\boldsymbol{x}}) - \boldsymbol{f}(\hat{\boldsymbol{x}}^d)\|_B < c\|\boldsymbol{x} - \boldsymbol{x}^d\|$ for $c < 1$, there exist Δ_j such that $\|\boldsymbol{f}(\hat{\boldsymbol{z}}) - \boldsymbol{f}(\hat{\boldsymbol{x}}^d)\|_B < c\|\boldsymbol{z} - \boldsymbol{x}^d\|$, for all $\boldsymbol{z}$ with $|\hat{z}_j - \hat{x}_j| < \Delta_j$, $1 \leq j \leq D+F$.*

Proof Solving for the eigenvalues of $M(\boldsymbol{x}, \boldsymbol{x}^d, \boldsymbol{\pi})$, the set $Q_{\boldsymbol{x}} \coloneqq \{\boldsymbol{v} \in \mathbb{R}^{D+F} \mid (\boldsymbol{v} - \hat{\boldsymbol{x}}^d)^\intercal M(\boldsymbol{x}, \boldsymbol{x}^d, \boldsymbol{\pi})(\boldsymbol{v} - \hat{\boldsymbol{x}}^d) < a\}$ can be determined. It is symmetric to the axes defined by the eigenvectors of $M(\boldsymbol{x}, \boldsymbol{x}^d, \boldsymbol{\pi})$ and meets them at $\pm a^{-1}\sqrt{\lambda}$. For $\boldsymbol{z} = \boldsymbol{x} + \boldsymbol{\Delta}$ we want to ensure $\boldsymbol{z} \in Q_{\boldsymbol{z}}$, if $\boldsymbol{x} \in Q_{\boldsymbol{x}}$. Thus, we estimate how much the eigenvalues of $M(\boldsymbol{z}, \boldsymbol{x}^d, \boldsymbol{\pi})$ differ from those of $M(\boldsymbol{x}, \boldsymbol{x}^d, \boldsymbol{\pi})$. As $M(\boldsymbol{x}, \boldsymbol{x}^d, \boldsymbol{\pi})$ is symmetric, the eigenvalue problem has condition $\kappa(\lambda, M(\boldsymbol{x}, \boldsymbol{x}^d, \boldsymbol{\pi})) = 1$ for any eigenvalue λ. Thus, $|\partial\lambda/\partial\hat{x}_j| \leq \|\partial M(\boldsymbol{x}, \boldsymbol{x}^d, \boldsymbol{\pi})/\partial\hat{x}_j\|$. Computing $\|\partial M(\boldsymbol{x}, \boldsymbol{x}^d, \boldsymbol{\pi})/\partial\hat{x}_j\|$ or upper bounds for this expression allows solving for all Δ_j. ■

We are now able to compute a grid S, such that it is sufficient to check Eq. (2) for all grid points to retrieve a (continuous) stability region. While the grid width may become small, there is a lower bound for it. As the GP falls back to the prior far away from training data, the entries of M are bounded for bounded mean priors and, being continuous, Lipschitz. Thus, a lower bound exists.

Theorem 5 *The region X^c returned by Algorithm 1 is a stability region. All trajectories starting in X^c move closer to the desired point $\boldsymbol{x}^d$ in each step. Convergence to $\boldsymbol{x}^d$ is guaranteed for all points in X^c as $t \to \infty$.*

Proof We exploit Lemma 4 to compute a grid S as the first step in Algorithm 1. Employing Lemma 3, the algorithm checks for all points in S whether Eq. (2) holds, obtaining the sets S^+ and S^-, respectively. Lemma 4 ensures that Eq. (2) also holds for all points inside the polygon $\langle S^+ \rangle_{\boldsymbol{x}^d}$. For every point in $\langle S^+ \rangle_{\boldsymbol{x}^d}$, the next state is closer to the target point $\boldsymbol{x}^d$. Fitting a full metric ball $\mathcal{B}(\boldsymbol{x}^d)$ in $\langle S^+ \rangle_{\boldsymbol{x}^d}$, we recover an invariant set X^c. More precisely, the trajectories starting in X^c move closer to $\boldsymbol{x}^d$ with every time step. ■

Theorem 5 provides an asymptotic stability result for closed-loop control systems with dynamics given as the mean of a GP and can, thus, can be applied to a broad class of dynamics systems. However, the procedure is based on a grid in the state space and as a consequence suffers from the curse of dimensionality. This limitation is not surprising, as it is well known that estimating stability regions of high degree is NP-hard (Ahmadi et al., 2013). However, several approaches can help to scale the proposed method to higher dimensions. Instead of computing a global grid width $\boldsymbol{\Delta}$ as in Lemma 4, the proof can straightforwardly be adapted to compute local grid widths. Such local grid widths depend on the magnitude of the derivatives of the GP mean with respect to the inputs and, thus, can be substantially larger than the global one, e.g., when moving away from training data or where the dynamics is very slow. With this technique, the number of grid points can be greatly reduced. Furthermore, as we are constructing an inner approximation to the full stability region, the order of the grid points processed by Algorithm 1 can be modified to avoid redundant computations. When starting at the equilibrium point and expanding the considered grid points spherically according to the chosen distance metrics, computation can be stopped as soon as the first grid point is tested to lie outside the stability region. This first negative test point limits the stability region and all grid points with the same or greater distance to $\boldsymbol{x}^d$ need not be considered anymore.

3.4 Finite Time Horizons and Robustness

In this section, we will employ the proposed Algorithm 1 to derive results for finite time horizons and stability in the presence of disturbances.

3.4.1 Finite Time GP Mean Stability

Above, we proposed an algorithm to check asymptotic stability of the target $\boldsymbol{x}^d$ and to find a stability region, if one exists. In this section, we are interested in finding all starting states which deviate from the target by at most a given tolerance $\varepsilon > 0$ after $T < \infty$ timesteps. State space regions that fulfill this criterion were introduced in Definition 2 as (ε, T)-*stability regions*.

The main result of this section follows from the infinite time horizon results of Sec. 3.3. Recall that Algorithm 1 computes a state space region X^c and $\gamma < 1$, such that

$$\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\| < \gamma \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\|$$

for all $\boldsymbol{x}^{(t)} \in X^c$. We can exploit this result to find a state space region $X^c_{\varepsilon,T}$, such that $\|\boldsymbol{x}^{(T)} - \boldsymbol{x}^d\| < \varepsilon$ for all $\boldsymbol{x}^{(0)} \in X^c_{\varepsilon,T}$.

Lemma 6 *Let $\varepsilon > 0$, $T < \infty$ and $X^c \subseteq X, \gamma < 1$ such that $\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\| < \gamma \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\|$ for all $t = 1, 2, \ldots$ and $\boldsymbol{x}^{(0)} \in X^c$. Then $\|\boldsymbol{x}^{(T)} - \boldsymbol{x}^d\| < \varepsilon$ for all $\boldsymbol{x}^{(0)} \in X^c$ with $\|\boldsymbol{x}^{(0)} - \boldsymbol{x}^d\| < \varepsilon / \gamma^T$.*

Proof Choosing $\boldsymbol{x}^{(0)} \in X^c$ and iteratively employing $\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\| < \gamma \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\|$ we get

$$\|\boldsymbol{x}^{(T)} - \boldsymbol{x}^d\| < \gamma^T \|\boldsymbol{x}^{(0)} - \boldsymbol{x}^d\| \overset{!}{<} \varepsilon.$$

Solving for ε, we obtain $\|\boldsymbol{x}^{(0)} - \boldsymbol{x}^d\| < \varepsilon / \gamma^T$ and, thus, $X^c_{\varepsilon,T} \coloneqq \mathcal{B}_{\varepsilon/\gamma^T}(\boldsymbol{x}^d)$ is an (ε, T)-stability region. ■

Lemma 6 enables finite time horizon statements. For a given tolerance ε we can compute a region $X^c_{\varepsilon,T}$ such that $\|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| < \varepsilon$ for all $t \geq T$ if $\boldsymbol{x}^{(0)} \in X^c_{\varepsilon,T}$. Such stability statements are relevant for many applications as controllers are often designed for finite system runtimes.

3.4.2 Robustness of GP Mean Dynamics

In this section, we will analyze the behavior of closed-loop control systems with dynamics given as the mean of a GP when disturbances are present. More precisely, we assume that the next state is given as

$$\boldsymbol{x}^{(t+1)} = \boldsymbol{f}\left(\boldsymbol{x}^{(t)}, \boldsymbol{u}^{(t)}\right) + \boldsymbol{r}^{(t)} \tag{5}$$

with the disturbance $\boldsymbol{r}^{(t)} < \infty$ at time t, that does not depend on the system state. We aim to find conditions for $\boldsymbol{r}^{(t)} < \infty$ such that $\boldsymbol{x}^{(t)}$ still converges to $\boldsymbol{x}^d$ as $t \to \infty$. Let $R^{(t)} \coloneqq \|\boldsymbol{r}^{(t)}\|$ be the magnitude of the disturbance at time t. Based on Equation (2) we derive an upper bound for $R^{(t)}$. Recall that Algorithm 1 returns a stability region X^c, which is a full metric ball and let ρ be the radius of this ball. Convergence to the target state is guaranteed, as long as the system does not leave X^c and $R^{(t)} \to 0$ as $t \to \infty$.

Theorem 7 *Let X^c be a full metric ball of radius ρ that is a stability region of the undisturbed closed-loop control system with GP mean dynamics. For $\boldsymbol{x}^{(0)} \in X^c$, the system in Eq. (5) converges to the target state $\boldsymbol{x}^d$, if*

$$R^{(t)} \leq \rho - \gamma \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| \tag{6}$$

for all t and there exists some T_0 such that

$$R^{(t)} < (c - \gamma) \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| \tag{7}$$

with a constant $c < 1$ holds for all $t \geq T_0$.

Proof Firstly, we will show that $\boldsymbol{x}^{(t+1)} \in X^c$, if $\boldsymbol{x}^{(t)} \in X^c$ and Eq. (6) holds. Employing Equation (5), we get

$$\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\| = \|\boldsymbol{f}(\boldsymbol{x}^{(t)}, \boldsymbol{u}^{(t)}) + \boldsymbol{r}^{(t)} - \boldsymbol{x}^d\| \leq \|\boldsymbol{f}(\boldsymbol{x}^{(t)}, \boldsymbol{u}^{(t)}) - \boldsymbol{x}^d\| + R^{(t)} \tag{8}$$

and assuming $\boldsymbol{x}^{(t)} \in X^c$, it follows

$$\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\| \leq \gamma \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| + R^{(t)}. \tag{9}$$

It follows $\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\| \leq \rho$, if $R^{(t)} \leq \rho - \gamma \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\|$ and, thus, $\boldsymbol{x}^{(t+1)} \in X^c$. By induction, $\boldsymbol{x}^{(t)} \in X^c$ for all $t > 0$, if $\boldsymbol{x}^{(0)} \in X^c$ and Equation (6) holds for all t.

If the disturbance $\boldsymbol{r}^{(t)}$ vanishes after a finite number of time steps, it is sufficient to ensure Equation (6) to show convergence to the target state. After this finite number of

disturbed steps, the system state will still lie in X^c and for all time steps to come, the dynamics will resemble the non-disturbed dynamics. Convergence is then guaranteed by Theorem 5.

Next, we will show that $\boldsymbol{x}^{(t)}$ converges to $\boldsymbol{x}^d$, if the disturbance $\boldsymbol{r}^{(t)}$ decreases sufficiently fast, as stated in Equation (7). For $\boldsymbol{x}^{(t)} \in X^c$, Equation (9) holds. To ensure convergence to $\boldsymbol{x}^d$, we aim to decrease the distance to the target state with every time step. Thus,

$$\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\| \leq \gamma \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| + R^{(t)} \overset{!}{<} c \, \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| \tag{10}$$

for a constant $c < 1$. Solving for $R^{(t)}$, we obtain Eq. (7). ■

This theorem provides a criterion for the disturbance such that the closed-loop control system will still converge to the target state. However, in practice, Equations (6) and (7) may be difficult to verify, as they involve $\|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\|$ for all t. We derive a closed-form upper bound for the magnitude $R^{(t)}$ of the disturbance $\boldsymbol{r}^{(t)}$.

Lemma 8 *The Inequality (6) holds for all t, if*

$$R^{(t)} \leq \rho - \left(\gamma^t \|\boldsymbol{x}^{(0)} - \boldsymbol{x}^d\| + \sum_{k=1}^{t-1} \gamma^k R^{(k)} \right). \tag{11}$$

The inequality (7) holds for $t \geq T_0$, if

$$R^{(t)} \leq (c^{t+1} - \gamma c^t) \|\boldsymbol{x}^{T_0} - \boldsymbol{x}^d\|. \tag{12}$$

Proof Both inequalities can be obtained by iteratively applying Eqs. (6) and (7).

$$\begin{aligned}
\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\| &\leq \gamma \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| + R^{(t)} \\
&\leq \gamma \left(\gamma \|\boldsymbol{x}^{(t-1)} - \boldsymbol{x}^d\| + R^{(t-1)} \right) + R^{(t)} \\
&\leq \gamma^t \|\boldsymbol{x}^{(0)} - \boldsymbol{x}^d\| + \sum_{k=1}^{t-1} \gamma^k R^{(k)} + R^{(t)} \overset{!}{<} \rho
\end{aligned}$$

and analogously

$$\begin{aligned}
\|\boldsymbol{x}^{(t+1)} - \boldsymbol{x}^d\| &\leq \gamma \|\boldsymbol{x}^{(t)} - \boldsymbol{x}^d\| + R^{(t)} \\
&< \gamma (c \|\boldsymbol{x}^{(t-1)} - \boldsymbol{x}^d\|) + R^{(t)} \\
&< \gamma c^t \|\boldsymbol{x}^{(T_0)} - \boldsymbol{x}^d\| + R^{(t)} \overset{!}{<} c^{t+1} \|\boldsymbol{x}^{(T_0)} - \boldsymbol{x}^d\|.
\end{aligned}$$

■

Employing Lemma 8, we can analyze stability for disturbed system trajectories, if the magnitude of the disturbance (or an upper bound for the magnitude) is known for every time step.

4. Stochastic Stability of GP Dynamics

In this section, we study closed-loop systems with dynamics given as a full GP distribution. For any query point $\boldsymbol{x}^{(t)}$ a GP predicts the next state $\boldsymbol{x}^{(t+1)}$ to be normally distributed. If, however, $\boldsymbol{x}^{(t)}$ is not a point, but a distribution, the integral

$$p\left(\boldsymbol{x}^{(t+1)}\right) = \int_{\mathbb{R}^D} p\left(\boldsymbol{x}^{(t+1)} \mid \boldsymbol{x}^{(t)}\right) p\left(\boldsymbol{x}^{(t)}\right) d\boldsymbol{x}^{(t)} \tag{13}$$

determines the next state distribution. Note that $p(\boldsymbol{x}^{(t+1)} \mid \boldsymbol{x}^{(t)})$ is Gaussian with respect to $\boldsymbol{x}^{(t+1)}$. The next state distribution $p(\boldsymbol{x}^{(t+1)})$, however, is not Gaussian, even if $p(\boldsymbol{x}^{(t)})$ is. Generally, $p(\boldsymbol{x}^{(t+1)})$ is analytically intractable and only approximations, e.g., via moment matching (Quiñonero-Candela et al., 2003) or linearization (Ko and Fox, 2008), can be computed. These methods suffer from severe inaccuracies in many cases, e.g., they cannot handle distributions with multiple modes. Also, no pointwise approximation error bounds are available. Thus, these methods are unsuitable for stability analysis. In this paper, we propose numerical quadrature (Sec. 4.2.1) to approximate $p(\boldsymbol{x}^{(t+1)})$, instead. This technique yields significantly better results, e.g., it can handle distributions with multiple modes. In addition, error analysis is readily available (Wasowicz, 2006; Masjed-Jamei, 2014) and can be employed to derive stability guarantees for a finite time horizon.

We will also analyze the closed-loop system behaviour for infinite time horizons. The proposed numerical quadrature approximation converges to a stationary limiting distribution. Unfortunately, the error bounds based on quadrature error analysis do not apply when infinitely many timesteps are taken. However, we will show that closed-loop control systems with GP dynamics expose the same infinite time horizon behavior – they converge to a stationary distribution.

In the following, we will discuss *finite time stochastic stability*, introduce an algorithm to find a stability region based on numerical quadrature, and prove its correctness. Subsequently, we will elaborate on the construction of good quadrature rules for multi-step-ahead predictions. Finally, we will analyze the system behavior for infinite time horizons.

4.1 Stability Notion

Consider a deterministic system, that is locally, but not globally, asymptotically stable. Adding noise to the system may render the target point unstable. Especially when noise is unbounded (e.g., Gaussian), all trajectories will eventually leave any ball around the target point with probability one. For this reason, in the study of SDEs, other stability notions than Lyapunov's, are common. In particular, bounding the probability to drift away from the target over a finite time T is desirable, as in the following definition (Kushner, 1966).

Definition 9 *Let Q_1, Q_2 be subsets of the state space X, with Q_2 open and $Q_1 \subset Q_2 \subset X$. The system is* finite time stable *with respect to $Q_1, Q_2, 1-\lambda, T$, if $\boldsymbol{x}^{(0)} \in Q_1$ implies $P\{\boldsymbol{x}^{(t)} \in Q_2\} \geq 1 - \lambda$ for all $t \leq T$.*

However, we are interested in finding a set Q_s of initial conditions, such that the goal Q is reached within time T with a desired probability (cf. Steinhardt and Tedrake 2012).

Definition 10 *The set Q_s is a stability region with respect to the target region Q, time horizon T and success probability $1-\lambda$, if $P\{\boldsymbol{x}^{(T)} \in Q\} \geq 1 - \lambda$ holds for all $\boldsymbol{x}^{(0)} \in Q_s$ with $\lambda > 0$ and the target region $Q \subset X$.*

Algorithm 2 Stability region for GP dynamics

Compute quadrature $\boldsymbol{w}, \boldsymbol{\xi}$ based on Eq. (18) and Lemma 11, such that $\|\epsilon_T\|_{\mathcal{C}(X)} < e_{\text{tol}}$
$\boldsymbol{\phi} \leftarrow (\boldsymbol{f}(\boldsymbol{\xi}_1, \boldsymbol{\pi}(\boldsymbol{\xi}_1)), \ldots, \boldsymbol{f}(\boldsymbol{\xi}_N, \boldsymbol{\pi}(\boldsymbol{\xi}_N)))^\intercal$
$\boldsymbol{m} \leftarrow (\int_Q \phi_1(\boldsymbol{x})d\boldsymbol{x}, \ldots, \int_Q \phi_N(\boldsymbol{x})d\boldsymbol{x})^\intercal$
for $\boldsymbol{x} \in S$ **do**
  $p(\boldsymbol{x}^{(1)}) \leftarrow \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{\pi}(\boldsymbol{x}))$
  $\boldsymbol{x}^{(T)} \leftarrow \boldsymbol{\alpha}^{(T)}\boldsymbol{\phi}$
  $P_{min}\{\boldsymbol{x}^{(T)} \in Q\} \leftarrow \boldsymbol{\alpha}^{(T)}\boldsymbol{m} - \text{vol}(Q)\|\epsilon_T\|_{\mathcal{C}(X)}$
  if $P_{min}\{\boldsymbol{x}^{(T)} \in Q\} > 1-\lambda$ **then** $S^+ \leftarrow S^+ \sqcup \{\boldsymbol{x}\}$ **fi**
od
return $X^c \leftarrow \langle S^+ \rangle$

This definition focuses on reaching a target Q after time T, whereas Definition 9 bounds the exit probability from a region Q_2 within time $0 \leq t \leq T$. The methods proposed in this paper can be employed to analyze stability in the sense of both definitions. In the following, we will present an algorithm to find a stability region according to Definition 10.

4.2 Algorithm Sketch

We will now discuss how to find a stability region as in Definition 10 for a closed-loop system with GP dynamics. To analyze system behavior, the capability to compute next state distributions is crucial. As discussed previously, Eq. (13) is analytically intractable and approximation methods must be employed. We propose numerical quadrature to approximately propagate distributions. We will show that numerical quadrature approximates state distributions as Gaussian mixture models. Fortunately, computation of multi-step-ahead predictions becomes convenient and fast even for long time horizons. However, relying on approximations of the state distribution is not sufficient for stability guarantees. The error introduced by approximation and error propagation must be bounded to recover reliable statements on the probability for $\boldsymbol{x}^{(T)}$ to be in a set Q. This error bound $\epsilon_t(\boldsymbol{x})$ at time t can be obtained following one of the available quadrature error analyses, e.g., by Masjed-Jamei (2014).

With numerical quadrature and quadrature error analysis, we can compute a lower bound for the *success probability*, i.e., the probability for $\boldsymbol{x}^{(T)}$ to be in the target set Q. A priori, this enables checking success probabilities for a finite set of points. Fortunately, as in the case of GP mean dynamics, the statement can be generalized to continuous regions. Our algorithm constructs a grid in the state space and computes success probabilities for all grid points. We prove that a stability region can be inferred from these grid point results.

In the following, we elaborate on numerical quadrature as approximate inference method and, studying quadrature error propagation, prove the correctness of the proposed approach. The presented tool is outlined in Algorithm 2.

4.2.1 Numerical Quadrature Uncertainty Propagation

In most applications, especially when the states have physical interpretations, the state space is bounded. For this reason, we assume $X = [a_1, b_1] \times \cdots \times [a_D, b_D]$ and solve

$$F[p(\boldsymbol{x}^{(t)})] := \int_X p(\boldsymbol{x}^{(t+1)} \mid \boldsymbol{x}^{(t)}) p(\boldsymbol{x}^{(t)}) d\boldsymbol{x}^{(t)}. \tag{14}$$

We propose numerical quadrature to approximate this integral. We choose a composed Gaussian product quadrature rule, which will be detailed in Section 4.4. For the rest of this section, it is sufficient to note that our quadrature rule provides a set of evaluation points $\mathbb{X}$ and positive weights w_n for all nodes $\boldsymbol{\xi}^n \in \mathbb{X}$. Integral (14) is then approximated by

$$F[p(\boldsymbol{x}^{(t)})] \approx \sum_{\boldsymbol{\xi}^n \in \mathbb{X}} w_n p(\boldsymbol{x}^{(t+1)} \mid \boldsymbol{x}^{(t)} = \boldsymbol{\xi}^n) p(\boldsymbol{x}^{(t)} = \boldsymbol{\xi}^n), \tag{15}$$

resulting in a weighted sum of Gaussian distributions. The approximate state distribution at time $t+1$ can be given by

$$p(\boldsymbol{x}^{(t+1)}) \approx \boldsymbol{\phi}^\intercal \boldsymbol{\alpha}^{(t+1)} \tag{16}$$

with $\alpha_n^{(t+1)} := w_n p(\boldsymbol{x}^{(t)} = \boldsymbol{\xi}^n), \phi_n(\boldsymbol{x}) := p(\boldsymbol{x}^{(t+1)} = \boldsymbol{x} \mid \boldsymbol{x}^{(t)} = \boldsymbol{\xi}^n)$. Note that the Gaussian basis functions $\phi_n(\boldsymbol{x})$ do not change over time, so the state distribution at time t is represented by the weight vector $\boldsymbol{\alpha}^{(t)}$. To propagate any distribution multiple steps through the GP, the basis functions ϕ_n must be calculated only once and the task reduces to sequential updates of the weight vector $\boldsymbol{\alpha}$. As $p(\boldsymbol{x}^{(t)}) \approx \boldsymbol{\phi}^\intercal \boldsymbol{\alpha}^{(t)}$, the weight vector $\boldsymbol{\alpha}^{(t+1)}$ is given by

$$\boldsymbol{\alpha}^{(t+1)} = \text{diag}(\boldsymbol{w})\Phi\boldsymbol{\alpha}^{(t)} = (\text{diag}(\boldsymbol{w})\Phi)^t \boldsymbol{\alpha}^{(1)} \tag{17}$$

with the matrix Φ, $\Phi_{i\,j} = \phi_j(\boldsymbol{\xi}^i)$ with $1 \leq i, j \leq n$, which contains the basis function values at all grid points. In practice, it is helpful to normalize the matrix $\text{diag}(\boldsymbol{w})\Phi$ such that each column sums to 1. In this case, unit vectors will be mapped to unit vectors. This ensures that our approximate state distribution is in fact a probability density, i.e., integrates to 1.

Our algorithm aims to find a stability region Q_s, i.e., a region where the success probability is at least $1-\lambda$ for a given time horizon T, target region Q, and $\lambda > 0$. Computing $\boldsymbol{m} = \int_Q \boldsymbol{\phi}(\boldsymbol{x})d\boldsymbol{x}$, the probability for $\boldsymbol{x}^{(T)}$ to be in Q is approximately $\boldsymbol{m}^\intercal \boldsymbol{\alpha}^{(T)}$.

4.3 Correctness of the Algorithm

We will now show that the region returned by Algorithm 2 is a stability region as in Definition 10. In Section 4.2.1, we proposed numerical quadrature to approximate GP predictions when the input is a distribution. However, to obtain stability guarantees it is not sufficient to consider approximate solutions. For a lower bound on the success probability, additional knowledge about the approximation error and how it is propagated through the dynamics GP is essential.

When approximate inference steps are cascaded for multi-step-ahead predictions, errors are introduced and propagated through the dynamics. Typically, error propagation fortifies initial errors with every time step. The difference of approximation and true distribution after a finite time is bounded. Fortunately, numerical quadrature allows to control this error bound by refining the used quadrature rule.

The derivation of an upper bound for the approximation error after a finite number of time steps relies heavily on quadrature error analysis, i.e., upper bounds for the errors that are made in one time step when numerical quadrature is employed. Several error analyses for numerical quadrature are available (Masjed-Jamei, 2014; Davis et al., 2014; Wasowicz, 2006; Evans, 1994) with the classic analyses relying on higher order derivatives of the function to be integrated. We will employ the error analysis by Masjed-Jamei (2014) that requires first order derivatives only. More precisely (Masjed-Jamei 2014, Theorem 2.1), for a differentiable function f with $\nu_1(x) \leq f'(x) \leq \nu_2(x)$ with continuous functions ν_1, ν_2 the quadrature error is upper and lower bounded

$$m \leq \sum_{i=1}^{N} w_i f(\xi_i) - \int_a^b f(x)dx \leq M \tag{18}$$

with the bounds

$$m = \sum_{i=0}^{N} \int_{\xi_i}^{\xi_{i+1}} \left(\nu_1(t) \frac{v_i(t) + |v_i(t)|}{2} + \nu_2(t) \frac{v_i(t) - |v_i(t)|}{2} \right) dt$$

$$M = \sum_{i=0}^{N} \int_{\xi_i}^{\xi_{i+1}} \left(\nu_1(t) \frac{v_i(t) - |v_i(t)|}{2} + \nu_2(t) \frac{v_i(t) + |v_i(t)|}{2} \right) dt$$

for $\xi_0 = a$, $\xi_{N+1} = b$ and $v_i = t - \left(a + \sum_{j=1}^{i} w_i\right)$, $i = 0, \ldots, n$. In the following, we employ this result to derive an error bound for the pointwise approximation error of the proposed multi-step-ahead predictions based on numerical quadrature.

Lemma 11 *Let $\boldsymbol{x}^{(0)} \in X$ and ϵ_T be the pointwise approximation error $\epsilon_T(\boldsymbol{x}) = p(\boldsymbol{x}^{(T)} = \boldsymbol{x}) - \boldsymbol{\phi}(\boldsymbol{x})^\intercal \boldsymbol{\alpha}^{(T)}$ at time T. There exists an upper bound for $\|\epsilon_T\|_{\mathcal{C}(X)}$ that can be controlled by the choice of quadrature rule.*

Proof The statement obviously holds for $T = 0$ and for $T = 1$, as $p(\boldsymbol{x}^{(1)})$ is Gaussian and computed exactly. If $T \geq 2$, an error is introduced as $p(\boldsymbol{x}^{(t)})$ cannot be computed analytically for $t \geq 2$. Employing numerical quadrature to compute $p(\boldsymbol{x}^{(2)})$, we obtain $p(\boldsymbol{x}^{(2)}) = \boldsymbol{\phi}^\intercal \boldsymbol{\alpha}^{(2)} + \epsilon_2$ with our approximation $\boldsymbol{\phi}^\intercal \boldsymbol{\alpha}^{(2)}$ and the unknown initial quadrature error $\epsilon_2(\boldsymbol{x})$. However, the error analysis by Masjed-Jamei (2014, Theorem 2.1) gives us a bound for $\|\epsilon_2\|_{\mathcal{C}(X)} := \max_{\boldsymbol{x} \in X} |\epsilon_2(\boldsymbol{x})|$. When propagating further, an unknown, bounded error term and an approximation term must be handled. For the approximation term, we get $F[\boldsymbol{\phi}^\intercal \boldsymbol{\alpha}^{(t)}] = \boldsymbol{\phi}^\intercal \boldsymbol{\alpha}^{(t+1)} + \boldsymbol{\epsilon}^\intercal \boldsymbol{\alpha}^{(t)}$ with quadrature error bounds $\boldsymbol{\epsilon} = (\epsilon_i(\boldsymbol{x}))_i$ for the integrals (14), when setting $p(\boldsymbol{x}^{(t)}) = \phi_i$. The error term $\epsilon_t(\boldsymbol{x})$ is propagated to $F[\epsilon_t]$ with $\max_{\boldsymbol{x} \in X} |F[\epsilon_t]| \leq C \|\epsilon_t\|_{\mathcal{C}(X)}$ and $C = \max_{\boldsymbol{x} \in X} \int p(\boldsymbol{x}^{(t+1)} \,|\, \boldsymbol{x}^{(t)}) d\boldsymbol{x}^{(t)}$. Finally, the error at time T is bounded by $\|\epsilon_T\|_{\mathcal{C}(X)} \leq \|\boldsymbol{\epsilon}\|^\intercal \boldsymbol{\alpha}^{(T-1)} + \sum_{t=2}^{T-2} C^t \|\boldsymbol{\epsilon}\|^\intercal \boldsymbol{\alpha}^{(t)} + C^{t-1} \|\epsilon_2\|$, where $\boldsymbol{\epsilon}$ and ϵ_2 can

be made arbitrarily small by refining the quadrature rule. ■

Lemma 11 theoretically enables stability guarantees for finite time horizons T. However, as with any approximation of the distribution (14), this error bound grows exponentially with T, while quadrature error decreases polynomially with function evaluations. This drawback limits real-word application of Lemma 11 to small T, but we found that typically, approximation behaves far better than the worst-case bound.

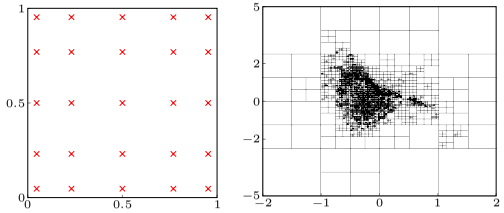
For any starting point, we can now compute the approximate state distribution at time T and a lower bound on the success probability, i.e., the probability for $\boldsymbol{x}^{(T)}$ to be in the target region Q. It remains to show that it is sufficient to compute the success probability for a discrete set of starting states and generalize to the underlying continuous state space region.

Lemma 12 *Let $\boldsymbol{x}, \boldsymbol{z} \in \mathbb{R}^D$ be starting states and $T \in \mathbb{N}$. If $P\{\boldsymbol{x}^{(T)} \in Q\} \geq 1 - \lambda$, there exist Δ_j such that $P\{\boldsymbol{z}^{(T)} \in Q\} \geq 1 - \lambda$ for all $\boldsymbol{z}$ with $|z_j - x_j| < \Delta_j$, $1 \leq j \leq D$.*

Proof Firstly, we note that the absolute error bound does not depend on the starting state. The state distribution $p(\boldsymbol{x}^{(1)})$ is the GP prediction at the query point $\boldsymbol{x}^{(0)}$. Thus, for $T = 1$ the claim follows from Lemma 4. When $t \geq 2$, only an approximation of the state distribution is known. The mixture model weights at time $t = 2$ depend only on the values of $p(\boldsymbol{x}^{(1)})$ at the set of evaluation points $\mathbb{X}$. Thus, the lemma follows for $T = 2$. If $t > 2$, the difference of the approximate distributions for the starting points $\boldsymbol{x}$ and $\boldsymbol{z}$ is

$$\boldsymbol{\phi}^\intercal (\boldsymbol{\alpha}_{\boldsymbol{x}}^{(t)} - \boldsymbol{\alpha}_{\boldsymbol{z}}^{(t)}) = \boldsymbol{\phi}^\intercal (\mathrm{diag}(\boldsymbol{w}) \Phi)^{t-2} (\boldsymbol{\alpha}_{\boldsymbol{x}}^{(2)} - \boldsymbol{\alpha}_{\boldsymbol{z}}^{(2)}).$$

Thus, the difference in approximate probability mass is linear in $(\boldsymbol{\alpha}_{\boldsymbol{x}}^{(2)} - \boldsymbol{\alpha}_{\boldsymbol{z}}^{(2)})$. This fact concludes the proof. ■



Finally, we are able to prove the main result of this section, the correctness of Algorithm 2.

Theorem 13 *The region X^c returned by Algorithm 2 is a stability region in the sense of Definition 10. For all starting points $\boldsymbol{x}^{(0)} \in X^c$, the probability mass in the target region Q at time T is at least $1 - \lambda$.*

Proof For the first step in Algorithm 2 we exploit Lemma 12 to construct a grid S. For S, stability follows for the region around the grid points S^+ with success probability greater than $1-\lambda$. Secondly, employing Lemma 11 we determine a quadrature rule that ensures the pointwise error at time T to be at most e_{tol}. Finally, we compute approximate success probabilities for all grid points, as in Sec. 4.2.1. Subtracting the maximum error mass $e_{\mathrm{tol}} \,\mathrm{vol}(Q)$ in target region Q, we obtain all grid points S^+, which have a success probability of at least $1-\lambda$. ■

4.4 Construction of Numerical Quadratures for Uncertainty Propagation

In the sections above, we introduced numerical quadrature to approximate GP predictions at uncertain inputs and showed that this approximate inference method can be used to derive finite time horizon stability guarantees. The presented theoretical results are valid for any choice of quadrature rule that allows for quadrature error analysis. However, in practice, the

(a) Product Quadrature (b) Mountain Car

Figure 4: Construction of suitable quadrature rules. Plot (a) shows the nodes of a Gaussian product quadrature rule on the unit square. Here, the quadrature rule for the unit square was constructed as an outer product of the Gaussian quadrature rule with 5 nodes. The state space partition for the mountain car system obtained with Algorithm 3 is shown in (b). For each rectangle in this partition, a Gaussian product quadrature such as (a) is employed.

choice of a suitable quadrature rule is crucial to the applicability of the proposed algorithm. Thus, in the following, we will elaborate on how to find "good" quadrature rules for a given GP dynamics and control policy.

Gaussian product quadrature extends univariate Gaussian quadrature to a multivariate rule using a product grid of evaluation points. This construction has some desirable properties, such as positive quadrature weights and readily available quadrature nodes. However, being an outer product of one-dimensional rules, it suffers from the curse of dimensionality. In this paper, we apply numerical quadrature to integrals as in Equation (14). Typically, the system trajectories are not uniformly spread over the state space. Instead, they are concentrated in a significantly smaller region. We exploit this observation to improve the efficiency of product grid quadrature and cope with the curse of dimensionality. For this purpose, we partition the state space $X = X_1 \sqcup \cdots \sqcup X_L$ and apply a Gaussian product quadrature to each obtained subregion X_l. The next state distribution, cf. Equation (14), can be written as

$$F[p(\boldsymbol{x}^{(t)})] \coloneqq \int_X p(\boldsymbol{x}^{(t+1)} \mid \boldsymbol{x}^{(t)}) p(\boldsymbol{x}^{(t)}) d\boldsymbol{x}^{(t)} = \sum_{l=1}^{L} \int_{X_l} p(\boldsymbol{x}^{(t+1)} \mid \boldsymbol{x}^{(t)}) p(\boldsymbol{x}^{(t)}) d\boldsymbol{x}^{(t)}$$

and, applying a numerical quadrature rule with nodes $\mathbb{X}_l$ for each integral, we get

$$F[p(\boldsymbol{x}^{(t)})] \approx \sum_{l=1}^{L} \sum_{\boldsymbol{\xi}^n \in \mathbb{X}_l} w_{nl} p(\boldsymbol{x}^{(t+1)} \mid \boldsymbol{x}^{(t)} = \boldsymbol{\xi}^n) p(\boldsymbol{x}^{(t)} = \boldsymbol{\xi}^n).$$

Setting $\mathbb{X} = \mathbb{X}_1 \sqcup \cdots \sqcup \mathbb{X}_L$, we recover Equation (15). Thus, composed quadrature rules can be handled just as a single Gaussian product rule. We exploit this to construct quadrature rules which are efficient for the computation of next state distributions for our particular GP

Algorithm 3 Construction of composed quadrature rules

Input: dynamics GP $\boldsymbol{f}$: $\left(\boldsymbol{x}^{(t)}, \boldsymbol{u}^{(t)}\right) \mapsto \boldsymbol{x}^{(t+1)}$, control policy $\boldsymbol{\pi}$: $\boldsymbol{x} \mapsto \boldsymbol{\pi}_{\boldsymbol{\theta}}(\boldsymbol{x})$ with parameters $\boldsymbol{\theta}$, state space X, maximum partition size $L_{\max}$
Output: composed quadrature rule with nodes $\mathbb{X}$ and weight vector $\boldsymbol{w}$

dynamics model and controller. In other words, we aim to find a partition $X = X_1 \sqcup \cdots \sqcup X_L$ of the state space, such that integral (14) is approximated well by the resulting quadrature rule. For this purpose, we maintain a partition of the state space, sample mean trajectories $\boldsymbol{\tau} = \boldsymbol{\tau}_0, \ldots, \boldsymbol{\tau}_H$ and subdivide regions X_l that were visited and fulfill a certain criterion. More precisely, we subdivide X_l if X_l does not contain enough quadrature nodes to integrate predictive distributions from the dynamics GP well. To estimate whether X_l should be divided, we introduce

$$\rho_l(\boldsymbol{\tau}) \coloneqq \frac{\operatorname{vol}(X_l)}{|\mathbb{X}_l| \min_{\boldsymbol{\tau}_i \in X_l} \operatorname{Var}(\boldsymbol{\tau}_i)}, \tag{19}$$

where $\operatorname{Var}(\boldsymbol{\tau}_i)$ denotes the variance of the GP predictive distribution at the point $\boldsymbol{\tau}_i$, and subdivide X_l if $\rho_l(\boldsymbol{\tau})$ is greater than 1. This criterion relates the higher order derivatives of GP predictions which fall inside X_l with the quadrature node density in X_l. Constructing a composed quadrature rule with this approach will concentrate most quadrature nodes in state space regions that are visited frequently when following system trajectories. Algorithm 3 summarizes our approach and Figure 4 illustrates the constructed quadrature rules.

4.5 GP Dynamics with Infinite Time Horizons

In Section 4.2, we proposed numerical quadrature to approximate next state distributions for closed-loop control systems, where the dynamics is given as a full Gaussian process. For this approximate inference, pointwise error bounds are available. Based on this error analysis, we were able to derive stability guarantees for finite time horizons. In this section, we analyze the case when the time horizon is infinite. Unfortunately, error bounds as in Section 4.3 cannot be given in this case. As we will see, the numerical quadrature approximation converges to a stationary limit distribution, i.e., this distribution does not depend on the starting state, as t goes to infinity. As the quadrature error cannot be bounded in this case, there is no guarantee that the system dynamics will converge to the same distribution. However, we will show that closed-loop control systems with GP dynamics also converge to a stationary distribution as $t \to \infty$ for many choices of the prior. We will first analyze

the behavior of the proposed numerical quadrature approximation and subsequently study asymptotic behavior of closed-loop control systems with GP dynamics.

4.5.1 Asymptotic Behavior of NQ Approximated GP Dynamics

In this section we study the properties of numerical quadrature as approximate inference when the time horizon is infinite. Recall that with numerical quadrature the state distribution is approximated by

$$p(\boldsymbol{x}^{(t)}) \approx \boldsymbol{\phi}^\intercal \boldsymbol{\alpha}^{(t)} \tag{16 revisited}$$

with Gaussian basis functions $\boldsymbol{\phi} = (\phi_1, \dots, \phi_N)^\intercal$, that do not change over time, and the weight vector $\boldsymbol{\alpha}^{(t)}$ at time t. As stated in Equation (17), the weight vector $\boldsymbol{\alpha}^{(t)}$ is updated by

$$\boldsymbol{\alpha}^{(t+1)} = \operatorname{diag}(\boldsymbol{w})\Phi\boldsymbol{\alpha}^{(t)} \tag{17 revisited}$$

with the positive matrix $\operatorname{diag}(\boldsymbol{w})\Phi$ as in Section 4.2.1. More precisely, $\operatorname{diag}(\boldsymbol{w})\Phi$ is a left stochastic matrix. Thus, any column vector $\boldsymbol{\beta}$ with norm $\|\boldsymbol{\beta}\|_1 = 1$ is mapped to a unit vector, i.e. $\|\operatorname{diag}(\boldsymbol{w})\Phi\boldsymbol{\beta}\|_1 = 1$. In this case, Equation (17) represents a power iteration which leads to the following theorem.

Theorem 14 *Let $(\mathbb{X}, \boldsymbol{w})$ be a quadrature rule with positive weights $\boldsymbol{w}$ on the state space X and $\boldsymbol{f}\colon (\boldsymbol{x}^{(t)}, \boldsymbol{u}^{(t)}) \mapsto \boldsymbol{x}^{(t+1)}$ be a dynamics GP. The approximate state distribution $p(\boldsymbol{x}^{(t)}) \approx \boldsymbol{\phi}^\intercal\boldsymbol{\alpha}^{(t)}$ obtained by cascading approximate one step ahead predictions with the quadrature $(\mathbb{X}, \boldsymbol{w})$ converges to a unique stationary distribution, independent of the starting distribution, as $t \to \infty$.*

Proof Consider Equation (17). The matrix $\operatorname{diag}(\boldsymbol{w})\Phi$ has norm one, as each of its columns sums to one. Thus, as the starting weights $\boldsymbol{\alpha}^{(0)}$ form a stochastic vector, Equation (17) takes the form of a power iteration, see (Golub and Van Loan, 2013, Section 7.3). By the Perron-Frobenius theorem the largest magnitude eigenvalue λ_1 of $\operatorname{diag}(\boldsymbol{w})\Phi$ is positive and simple. More precisely, the eigenvalue of $\operatorname{diag}(\boldsymbol{w})\Phi$ with the highest absolute value is $\lambda_1 = 1$. The corresponding dominant eigenvector $\boldsymbol{v}_1$ is positive. No other eigenvectors of $\operatorname{diag}(\boldsymbol{w})\Phi$ are non-negative. Thus, the power iteration in Equation (17) converges to the dominant eigenvector, if $\boldsymbol{\alpha}^{(0)}$ has a nonzero projection on the eigenspace of $\lambda_1 = 1$. As $\boldsymbol{\alpha}^{(0)}$ is a non-negative unit vector and $\boldsymbol{v}_1$ is positive, the projection to the dominant eigenspace is ${\boldsymbol{v}_1}^\intercal\boldsymbol{\alpha}^{(0)} > 0$. Thus, the numerical quadrature approximation of $p(\boldsymbol{x}^{(t)})$ converges to $\boldsymbol{\phi}^\intercal\boldsymbol{v}_1$. ■

This theorem shows that the numerical quadrature approximation to the system state converges to a stationary distribution. The limiting distribution corresponds to the dominant eigenvector of the iteration matrix $\operatorname{diag}(\boldsymbol{w})\Phi$ and does not depend on the starting state. However, no bound for the approximation error can be obtained for the limit $t \to \infty$. Thus, in contrast to finite time horizon analysis, no statement about the true system state follows from this result. In the following, we will study asymptotic behavior of closed-loop control systems with GP dynamics to see whether the (exact) system state converges to a limiting distribution as well.

4.5.2 Asymptotic Behavior of GP Dynamics

We have seen that employing the numerical quadrature approximation for next state distributions, closed-loop control systems with GP dynamics converge to a limiting distribution.

In this section, we will show that these closed-loop control systems expose the same behavior even if no approximations are employed. More precisely, a closed-loop control system with dynamics given as a GP will finally converge to a limiting distribution that is independent of the starting state for many common choices of the prior. To obtain this result, we apply Markov Chain theory as in (Meyn and Tweedie, 2009).

Consider a Markov chain $\boldsymbol{\Sigma} = \{\boldsymbol{\Sigma}_1, \boldsymbol{\Sigma}_2, \dots\}$ with the random variables $\boldsymbol{\Sigma}_t$ taking values in $\mathbb{R}^D$ and a *Markov kernel* $P\colon \mathbb{R}^D \times \mathcal{B}(\mathbb{R}^D) \to \mathbb{R}$, i.e., $P(\cdot, A)$ is a non-negative measurable function on $\mathbb{R}^D$, $P(\boldsymbol{x}, \cdot)$ is a probability measure on $\mathcal{B}(\mathbb{R}^D)$ and

$$\mathbb{P}_\mu[\boldsymbol{\Sigma}_0 \in A_0, \cdots, \boldsymbol{\Sigma}_n \in A_n] = \int_{\boldsymbol{y}_0 \in A_0} \cdots \int_{\boldsymbol{y}_{n-1} \in A_{n-1}} \mu(d\boldsymbol{y}_0) P(\boldsymbol{y}_0, d\boldsymbol{y}_1) \cdots P(\boldsymbol{y}_{n-1}, A_n) \tag{20}$$

for any initial distribution μ and $n \in \mathbb{N}$. We will employ some definitions and results from (Meyn and Tweedie, 2009) to prove our claim.

Definition 15 *The following definitions will help describing Markov chains and the sets they (re-)enter.*

1. *For $A \in \mathcal{B}(\mathbb{R}^D)$ and $\Sigma_0 \in A$, the* first return time *τ_A is given as*

   $$\tau_A \coloneqq \min\{n \geq 1 \colon \boldsymbol{\Sigma}_n \in A\}.$$

   We also define the return time probability *$L(\boldsymbol{x}, A) \coloneqq \mathbb{P}_{\boldsymbol{x}}(\tau_A < \infty)$.*

2. *We call $\boldsymbol{\Sigma}$ φ-*irreducible*, if there exists a measure φ on $\mathcal{B}(\mathbb{R}^D)$, such that $\varphi(A) > 0$ implies $L(\boldsymbol{x}, A) > 0$ for all $\boldsymbol{x} \in X$ and $A \in \mathcal{B}(\mathbb{R}^D)$. ψ is a* maximal irreducibility measure*, if $\boldsymbol{\Sigma}$ is ψ-irreducible and $\varphi \prec \psi$, i.e., $\psi(A) = 0 \Rightarrow \varphi(A) = 0$, for all irreducibility measures φ of $\boldsymbol{\Sigma}$.*

3. *We say that the set $C \in \mathcal{B}(\mathbb{R}^D)$ is* small*, if there exists a probability measure ν, such that $P^n(\boldsymbol{x}, A) \geq \delta\nu(A)$ with some integer n, $\delta > 0$ for all $\boldsymbol{x} \in C$ and all $A \in \mathcal{B}(\mathbb{R}^D)$.*

For finite or countable state spaces, a Markov kernel defines the probability to move from one state to another. The state space partitions into *communication classes*, such that all states in one class can be reached with positive probability from any other state in the same class. If there is only one communication class, the Markov chain is called irreducible – its analysis cannot be further reduced to the consideration of multiple chains with smaller state spaces. The communication structure has an immense effect on the long term behavior of a Markov chain. However, when considering general state spaces (e.g., continuous as in our case), the probability to reach one single state will be zero. The concept of communication is thus generalized to Borel sets via irreducibility measures. Every irreducible Markov chain has maximum irreducibility measures, see Theorem 16. While these are not unique, all maximum irreducibility measures of a Markov chain are equivalent, i.e., they have the same null sets. Small sets play an important role in the analysis of Markov chains on general state spaces, as they behave analogously to single states in discrete state spaces. Sets which consist of one single point, are small. However, it can be shown that for irreducible Markov chains, any set that will be entered with positive probability contains a non-trivial small set (Meyn and Tweedie, 2009, Theorem 5.2.2).

Theorem 16 *Let $\mathbf{\Sigma}$ be φ-irreducible. Then there exists a maximal irreducibility measure ψ, which is equivalent to*

$$\psi'(A) \coloneqq \int_X \varphi(d\boldsymbol{y}) K_{a\frac{1}{2}}(\boldsymbol{y}, A)$$

with the transition kernel $K_{a\frac{1}{2}}(\boldsymbol{y}, A) = \sum_{n=1}^{\infty} P^n(\boldsymbol{x}, A) 2^{-(n+1)}$.

Proof The proof is given in (Meyn and Tweedie, 2009, Proposition 4.2.2). ■

We aim to analyze the asymptotic behavior of Markov chains that are defined by our closed-loop control structure with GP dynamics. One type of asymptotic behavior that is well-known from Markov chains on discrete state spaces is periodicity. The notion of periodicity can be extended to Markov chains on general state spaces as follows.

Definition 17 *Let $\mathbf{\Sigma}$ be irreducible with maximal irreducibility measure ψ. The* period *of $\mathbf{\Sigma}$ is the largest integer $d > 0$, such that there exist non-empty, pairwise disjoint sets $X_1, \cdots, X_d \subseteq \mathbb{R}^D$ with*

$$P(\boldsymbol{x}, X_{i+1}) = 1 \text{ for all } \boldsymbol{x} \in X_i, 1 \leq i \leq d-1 \text{ and } P(\boldsymbol{x}, X_1) = 1 \text{ for } \boldsymbol{x} \in X_d$$

and

$$\psi\left(\bigcup_{i=1}^{d} X_i\right) = 1.$$

If $d = 1$ we call $\mathbf{\Sigma}$ aperiodic*, if $d > 1$ the Markov chain $\mathbf{\Sigma}$ is* periodic*.*

Next, we apply the definitions above to establish some properties of closed-loop control systems with GP dynamics. Fortunately, the topology of $\mathbb{R}^D$ and the Gaussian state predictions obtained from a GP largely facilitate the analysis.

Lemma 18 *The Markov chain $\mathbf{\Sigma}$ on $\mathbb{R}^D$ defined by a GP forward dynamics is irreducible with respect to the Lebesgue measure λ and aperiodic. Also, all compact sets are small.*

Proof The transition probabilities are Gaussian, i.e.,

$$P(\boldsymbol{x}, \cdot) = \mathcal{N}(\boldsymbol{m}(\boldsymbol{x}), S(\boldsymbol{x}))$$

and the Markov kernel has a Gaussian density $q\colon \mathbb{R}^D \times \mathbb{R}^D \to \mathbb{R}$. Thus, $q(\boldsymbol{x}, \boldsymbol{y}) > 0$ for all $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^D$ and for any $A \subseteq \mathbb{R}^D$ with $\lambda(A) > 0$ it holds

$$P(\boldsymbol{x}, A) = \int_A q(\boldsymbol{x}, \boldsymbol{y}) \lambda(d\boldsymbol{y}) > 0,$$

so $\mathbf{\Sigma}$ is irreducible with respect to the Lebesgue measure λ.

Assume $\mathbf{\Sigma}$ has period $d > 1$, i.e., $P(\boldsymbol{x}, X_i) = 1$ for $\boldsymbol{x} \in X_{i-1}$, then $1 = P(\boldsymbol{x}, X_i) = \int_{X_i} q(\boldsymbol{x}, \boldsymbol{y}) \lambda(d\boldsymbol{y})$ and, as $q > 0$, it follows that the complement $\overline{X}_i$ of X_i is a λ-null set, i.e., $\lambda(\overline{X}_i) = 0$. However, as X_i, X_j are disjoint for $j \neq i$ it holds $X_j \subseteq \overline{X}_i$. It follows $\lambda(X_j) = 0$ for $j \neq i$. Analogously as for X_i, $\lambda(\overline{X}_j) = 0$. As λ is a non-trivial measure, this is a contradiction. Thus, $d = 1$ and $\mathbf{\Sigma}$ is aperiodic.

Finally, as P has a continuous, positive density, there is a lower bound $\delta > 0$ for this density on any compact set. Thus, all compact sets are small. ■

Above, we showed that the Markov chains considered are aperiodic. The Markov chain can still re-enter sets infinitely often with positive probability. A stronger form of this property is Harris recurrence. As we will see later, Harris recurrence along with some other properties implies the existence and uniqueness of an invariant state distribution.

Definition 19 *Let $A \in \mathcal{B}(\mathbb{R}^D)$ and consider the event*

$$\{\mathbf{\Sigma} \in A \text{ infinitely often}\} \coloneqq \bigcap_{N=1}^{\infty} \bigcup_{k=N}^{\infty} \{\mathbf{\Sigma}_k \in A\}.$$

The set A is called Harris recurrent*, if*

$$Q(\boldsymbol{x}, A) \coloneqq \mathbb{P}_{\boldsymbol{x}}\{\mathbf{\Sigma} \in A \text{ infinitely often}\} = 1.$$

The Markov chain $\mathbf{\Sigma}$ is Harris recurrent, if it is ψ-irreducible and $A \in \mathcal{B}(X)$ is Harris recurrent if $\psi(A) > 0$.

We say that the measure μ is an invariant measure *for the Markov kernel P, if*

$$\mu(A) = \int_X \mu(d\boldsymbol{x}) P(\boldsymbol{x}, A),$$

or shortly $\mu P = \mu$.

The Markov chain $\mathbf{\Sigma}$ is positive Harris recurrent*, if it is Harris recurrent and admits an invariant probability measure.*

Finally, we can state some conditions for the existence and uniqueness of an invariant state distribution as well as convergence of the system state to this distribution (in total variation).

Theorem 20 *If the chain $\mathbf{\Sigma}$ is φ-irreducible, aperiodic and positive Harris recurrent, then it admits a unique invariant probability measure $\mu^*$and for all probability measures ν it holds*

$$\|\nu P^n - \mu^*\|_{TV} \coloneqq \sup_{A \in \mathcal{B}(\mathbb{R}^D)} |\mu^*(A) - \nu(A)| \to 0$$

as $n \to \infty$.

Proof The proof can be found in (Meyn and Tweedie, 2009, Theorem 13.0.1). ■

To employ this theorem to our case of closed-loop control systems with GP dynamics, it remains to establish Harris recurrence. However, it can be challenging to verify the definition directly. Fortunately, drift criteria can be employed. In the following, we will write $Pf \coloneqq \int P(\boldsymbol{x}, d\boldsymbol{y}) f(\boldsymbol{y})$ for any function $f\colon \mathbb{R}^D \to \mathbb{R}$ for notational convenience.

Theorem 21 *Let P be a φ-irreducible and aperiodic Markov kernel. If there exists a function $V\colon \mathbb{R}^D \to [0, \infty)$ with*

$$PV \leq V + c\mathbb{1}_A \tag{21}$$

for a small set A, a constant $c < \infty$, and the sets $\{\boldsymbol{x} \mid V(\boldsymbol{x}) \leq r\}$ are small for all $r \in \mathbb{R}$, then P is Harris recurrent. P is positive Harris recurrent, if Eq. (21) can be modified to

$$PV \leq V - \varepsilon + c\mathbb{1}_A \tag{22}$$

for some $\varepsilon > 0$.

Proof The proof can be found in (Meyn and Tweedie, 2009, Theorems 9.1.8, 11.0.1). ■

Such a function V is called *drift function*. It is the stochastic analogue to a Lyapunov function. Inequality (21) states that whenever the system state is outside of the small set A, V is expected to decrease in the following step. Thus, the system tends towards the minimum of V, which is a recurrent behavior. The speed of convergence can be incorporated in a drift criterion as well.

Definition 22 *The Markov Kernel P has* geometric drift *towards a set A, if there exists a function $V\colon \mathbb{R}^D \to [1,\infty]$, finite for some $\boldsymbol{x}$, and $\beta < 1, c < \infty$, such that*

$$PV \leq \beta V + c\mathbb{1}_A. \tag{23}$$

We say that a φ-irreducible Markov Kernel P with invariant probability measure μ^* is V-geometrically ergodic *on a set A for a function $V\colon \mathbb{R}^D \to [1,\infty]$, if*

$$\sup_{|f|\leq V} \left| \int f d(P^n(\boldsymbol{x},\cdot) - \mu^*) \right| \leq cV(\boldsymbol{x})\rho^n \tag{24}$$

for all $\boldsymbol{x} \in A$, a constant $c < \infty$ and $\rho < 1$ and $V(\boldsymbol{x}) < \infty$ for all $\boldsymbol{x} \in A$.

We will employ geometric drift functions to prove the convergence of Markov chains generated by closed-loop control systems with GP forward dynamics at an exponential convergence speed, irrespective of the starting state. Studying the drift function $V(\boldsymbol{x}) = 1 + \|\boldsymbol{x}\|^2$, the following criterion for geometric ergodicity can be derived.

Theorem 23 *A Markov kernel P with Gaussian transition probabilites has V-geometric drift towards a compact set if and only if*

$$\limsup_{\|\boldsymbol{x}\|\to\infty} \frac{\|\boldsymbol{m}(\boldsymbol{x})\|^2 + \operatorname{tr}(S(\boldsymbol{x}))}{\|\boldsymbol{x}\|^2} < 1 \tag{25}$$

with the mean map $\boldsymbol{m}(\boldsymbol{x})$ and variance map $S(\boldsymbol{x})$. It follows that P has a unique invariant probability measure μ^* and is V-geometrically ergodic.

Proof The proof is given in (Hansen, 2003, Lemma 3.2, Corollary 3.3). ■

Finally, we can prove the main result of this section, the convergence of many closed-loop control systems with GP dynamics towards a unique, invariant limiting distribution that is independent of the starting state.

Theorem 24 *Any discrete-time closed-loop control system with state space $\mathbb{R}^D$, where the forward dynamics is given as GP with zero-mean prior and stationary covariance function, is geometrically ergodic, i.e., the system has a unique invariant probability measure and the Markov chains generated by the system converge to its stationary distribution with exponential speed, see Equation (24).*

Proof We have to verify Eq. (25). As the GP predictions fall back to the zero mean prior far away from the training data, $\|\boldsymbol{m}(\boldsymbol{x})\|^2 + \operatorname{tr}(S(\boldsymbol{x}))$ converges to $\sum_{k=1}^{D} \sigma_{k,f}^2$ as $\|\boldsymbol{x}\| \to \infty$. Thus,

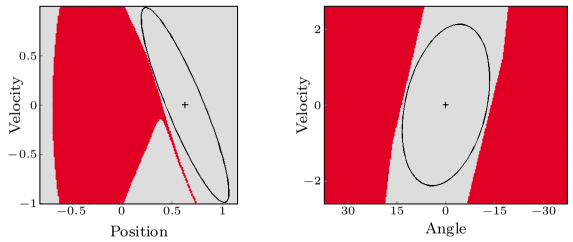
$$\limsup_{\|\boldsymbol{x}\|\to\infty} \frac{\|\boldsymbol{m}(\boldsymbol{x})\|^2 + \operatorname{tr}(S(\boldsymbol{x}))}{\|\boldsymbol{x}\|^2} = 0 < 1,$$

which concludes the proof. ■

This theorem gives us a strong result about the asymptotic behavior of closed-loop control systems with dynamics given as a GP with stationary covariance function and zero mean prior. This result applies to many learning control approaches in the literature.

5. Empirical Evaluation

In this section, we evaluate the previously obtained theoretical results on two benchmark tasks: mountain car and inverted pendulum. Moreover, the performance of the proposed uncertainty propagation is compared to the state-of-the-art moment matching approach and Monte Carlo sampling. We begin with a brief introduction of the test-beds.



Mountain Car. A car with limited engine power has to reach a desired point in the mountainscape (Sutton and Barto, 1998). The state space has two dimensions: position and velocity of the car. We analyze stability of a PD-controller $\pi((x,\dot{x})^\intercal) = K_p x + K_d \dot{x}$. The gains are chosen as $K_p = 25$ and $K_d = 1$ and the control signal is limited to $u_{\max} = 4$. The GP dynamics model was trained on 250 data points from trajectories with random starting points and control gains.

Inverted Pendulum. In the inverted pendulum task, the goal is to bring the pendulum to an upright position with limited torque (see Doya, 2000) and balance it there. The system state has two dimensions: pendulum angle and velocity. We evaluate stability of a PD-controller with $K_p = 6$, $K_d = 3$ and control limit $u_{\max} = 1.2$. The dynamics GP was trained on 200 points from rollouts with random starting points and control gains.

Cart-Pole. In the cart-pole domain (Deisenroth et al., 2015), a cart with an attached free-swinging pendulum is running on a track of limited length. The goal is to swing the pendulum up and balance it, with the cart in the middle of the track. The state space has four dimensions: position of the cart x, velocity of the cart $\dot{x}$, angle of the pendulum ϑ and the angular velocity $\dot{\vartheta}$. A horizontal force with $u_{\max} = 10$ can be applied to the cart. To demonstrate the proposed approach we analyze stability of the cart-pole system for a PD-controller with randomly chosen gains. The dynamics GP was trained on 250 points from rollouts with sampled starting state and control gains.

5.1 Stability of GP Predictive Mean Dynamics

To evaluate the presented theory on stability of the closed-loop control system with GP mean dynamics, a stability region is determined as described in Section 3. We compare this region to the true stability region, empirically obtained as follows. A grid on the state space is defined and rollouts from every grid point are computed. After a sufficiently long time (1000s), we check whether the state has converged to the target point. Thus, we empirically determine a region of starting points, where the system converges to the desired state. Figure 5 shows the obtained regions for the mountain car and pendulum systems. In both cases the theoretically obtained stability region, which is marked by an ellipsoid, is a subset of the empirically determined region. This effect is due to our analysis yielding a full metric ball centered around the target point, although the full stability region is not necessarily convex. Also, trajectories which first move away from the target point, but finally

(a) Mountain Car (b) Inverted Pendulum

Figure 5: Stability regions for GP mean dynamics on the two benchmark tasks. This figure shows empirically obtained stability regions in gray, points that did not converge in red. The ellipsoid indicates the stability region returned by Algorithm 1.

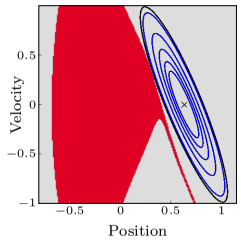


Figure 6: Finite time stability of GP mean dynamics. The black ellipsoid marks the (infinite time) stability region obtained with Algorithm 1. The blue ellipsoids mark the (ε, T)-stability regions with $\varepsilon = 0.05$ and $T = 10, 20, 30, 40, 50$ timesteps (inner to outer ellipsoid). For any starting point inside of one blue ellipsoid, the distance to the target is less than ε after T timesteps.

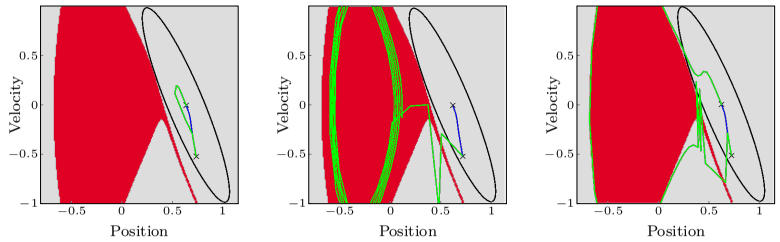
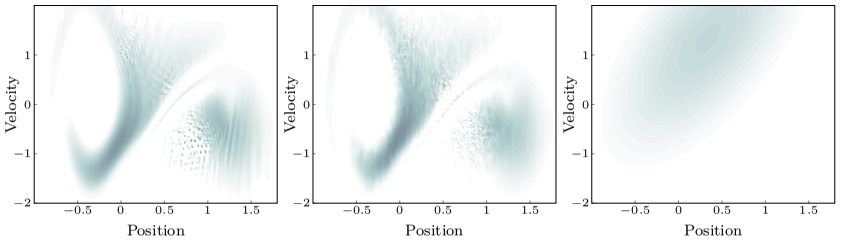
converge to it, are not considered in the presented theory. Instead, all trajectories starting in the theoretically obtained stability region move towards the target point contractively.

Next, we compute finite time (ε, T)-stability regions as in Lemma 6. Figure 6 shows the obtained regions for $\varepsilon = 0.05$ and different choices of T. By construction, these are full metric balls around the reference point and lie completely inside of the stability region obtained with Algorithm 1.

Finally, we consider robustness of the GP mean dynamics. We introduce disturbances and apply the convergence criteria from Theorem 7 and Lemma 8. We sample the starting time and duration as well as the magnitude of the disturbance. The direction of the disturbance is then sampled independently for every time step where a disturbance is present. The results are shown in Figure 7. Note that robustness results such as Theorem 7 and Lemma 8 must





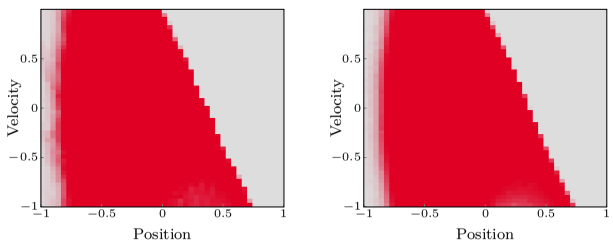


Figure 7: Robustness of GP mean dynamics. Disturbances were sampled for a finite time period. The undisturbed trajectory is colored blue, the distrubed trajectories are colored green. Our robustness criterion from Theorem 7 and Lemma 8 guarantees the convergence of the disturbed trajectory in the left picture. For both other pictures, our criterion cannot guarantee convergence of the disturbed trajectory to the target. As such criteria must be based on worst case estimates of the disturbance, some disturbed trajectories still converge to the target (as in the right picture).

(a) Our Numerical Quadrature (b) Monte Carlo Sampling (c) Moment Matching

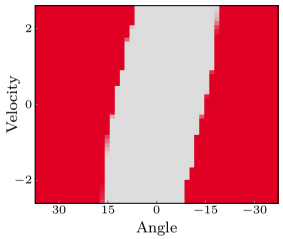

Figure 8: This figure illustrates multi-step-ahead prediction when the input is a distribution. Starting with a normally distributed state centered around the inflection point of the right slope in the mountain car domain, we compute a rollout incorporating uncertainty. The plots show the state distribution after T=30 time steps obtained with our numerical quadrature approach (a), moment matching (c) and the reference Monte Carlo sampling result (b).

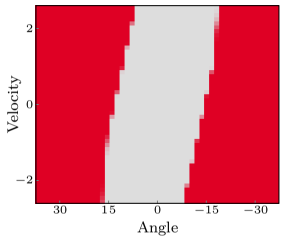
consider the worst case scenario. Thus, there are trajectories where the robustness criteria are not able to guarantee convergence, although they converge to the target state.



(a) Mountain Car, Our NQ

(b) Mountain Car, MC Sampling

(c) Pendulum, Our NQ

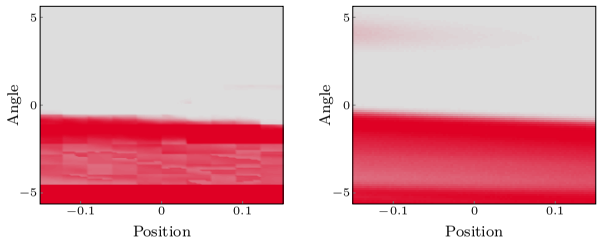
(d) Pendulum, MC Sampling

Figure 9: Success probabilities for dynamics given as GP full distribution and a time horizon of 100s. The color scale encodes the success probability from zero (red) to one (gray). The mountain car ((a) and (b)) and inverted pendulum ((c) and (d)) results were obtained with the proposed numerical quadrature (NQ) and Monte Carlo (MC).

5.2 Numerical Quadrature Uncertainty Propagation

The key to stability analysis for closed-loop systems with dynamics given as full GP distribution is the prediction at uncertain inputs. We compare the performance of the presented approximate inference to the state-of-the-art moment matching (MM) method and Monte Carlo (MC). Consider the following scenario: in the mountain car domain, we position the car on the right slope with some positive velocity. Furthermore, we introduce small Gaussian uncertainty about the starting state. We employ a constant control signal, that is too small to bring the car up directly. We compute rollouts, propagating state distributions through the GP with (i) the presented numerical quadrature (NQ), (ii) MM as in (Deisenroth, 2010), and (iii) MC. The resulting distributions for a time horizon of 3s are shown in Figure 8. The MM approximation differs significantly from MC and NQ results, concentrating most of the probability mass, where the MC approximation has very low probability density. The NQ result closely matches the distribution obtained with MC.

5.3 Stability of Gaussian Process Dynamics



Employing numerical quadrature, we determine success probabilities for the two test-beds and a time horizon of 100s. To obtain the stability region for a particular choice of λ, all pixels whose color corresponds to a value higher then or equal to λ must be selected. As Figure 9 shows, the obtained stability regions match the empirical MC results. The error bound from Lemma 11 can demand for extremely fine quadrature rules to obtain a stability region estimate that matches the true stability region closely. Please note that quadrature rules with less nodes also allow for a guaranteed stability region, however this region can be significantly smaller than the true stability region. For long time horizons, the requirements to obtain a very accurate inner approximation of the stability region can become computationally infeasible. However, we found that the real-world results are substantially better than this worst-case bound. We also experienced computation time ($\approx$ 120s) for NQ to be a fraction of the time required for long time MC predictions. Of course, this will not hold for systems with many state dimensions and our particular setup of product quadrature rules, as these rules suffer from the curse of dimensionality. However, there are various approaches to overcome this drawback of NQ (Heiss and Winschel, 2008; Novak and Ritter, 1996; Xiao and Gimbutas, 2010; Ryu and Boyd, 2015) and our analysis holds for arbitrary quadrature rules.

To show how the proposed approach can be scaled to higher dimensions, we compute success probabilities for the four-dimensional cart-pole system. We employ Algorithm 3 to construct a suitable quadrature rule. However, the quadrature rule CN:3-1 (Stroud, 1971; code from Burkardt, 2014) is applied to each subregion instead of the Gaussian product rule as for the previous examples. This quadrature rule has 8 nodes as opposed to 16 nodes for the Gaussian product rule of the same exactness. Please note also that all necessary computations for the proposed approach can be executed in parallel. Thus, we conduct these computations on a GPU, which leads to a significant speedup and overall computation time comparable to the 2D examples ($\approx$ 140s). The result is shown in Figure 10. As for the other benchmark problems, the obtained stability region closely matches the true stability region of the system.

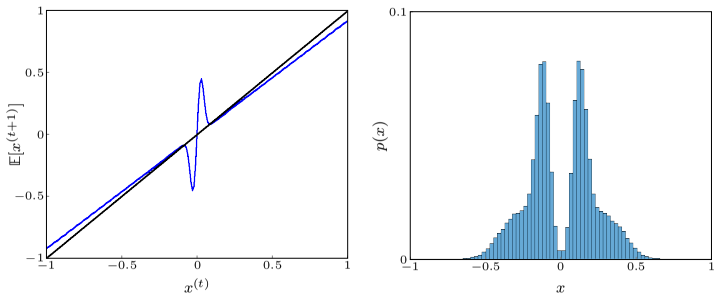
To evaluate the results on convergence of GP dynamics to a stationary distribution, we considered the dynamics shown in the left plot of Figure 11. The GP mean dynamics has two attractors and their regions of attraction partition the interval $[-1; 1]$. However, when considering the uncertainty, the system has an invariant probability measure (shown in Figure 11 on the right) to which it converges irrespective of the starting point.

6. Conclusion

Gaussian Processes provide a flexible, non-parametric, Bayesian approach to modeling unknown system dynamics from observations. Thus, GP dynamics are a viable approach for learning model-based control. There has been remarkable research in this field that advanced these methods to become an appealing alternative to classic control. For widespread real-world application of learning control based on GP forward dynamics models, performance guarantees are crucial, especially in safety-critical applications. However, stability analysis of closed-loop control with GP forward dynamics learned from data has barely been analyzed so far. In this paper, we laid a foundation for stability analysis of closed-loop control with

(a) Cart-Pole, Our NQ (b) Cart-Pole, MC Sampling

Figure 10: Success probabilities for the cart-pole system. The dynamics are given as GP full distribution and the time horizon is 100s. The color scale encodes the success probability from zero (red) to one (gray). The plots show the results for $\dot{x} = 0, \dot{\theta} = 0$ obtained with numerical quadrature (a) and Monte Carlo sampling (b).



GP dynamics. Subsequently, we conclude the paper with a short summary of the main contributions and a brief outlook on possible future work in this direction.

6.1 Summary of Contributions

In this paper, we analyzed stability of closed-loop control systems with Gaussian process forward model dynamics. We considered two possible types of system dynamics: (i) the mean and (ii) the full GP predictive distribution.

In the first case, we studied asymptotic stability as well as finite time horizons and robustness to disturbances. We presented an algorithm to construct a region in the state space such that trajectories starting inside this region are guaranteed to converge to the target point and stay there for all times. For finite time horizons, we showed how to find a state space region such that the target state will be reached at time horizon up to a certain tolerance. Studying robustness, we derived a criterion for disturbances such that the system remains asymptotically stable. The theoretical results have been evaluated on benchmark problems and compared to empirically obtained results.

In the second case, we introduced a novel approach based on numerical quadrature to approximately propagate uncertainties through a GP. In contrast to other state-of-the-art methods, our approach can model complex distributions with multiple modes. Evaluation results closely match the true distribution approximated by extensive sampling. We used the introduced approximate inference method to derive finite-time stability guarantees based on quadrature error analysis. Empirical Monte Carlo results confirm our theoretical results on the two benchmark problems. Furthermore, we considered the system behavior when the time horizon is infinite. We showed that, applying numerical quadrature to propagate distributions through the GP, the system state converges to a limiting distribution that does not depend on the starting state. Motivated by this result, we studied the system behavior

(a) Forward Dynamics Function (b) Invariant Limiting Distribution

Figure 11: Asymptotic behavior of closed-loop systems with GP dynamics. Plot (a) shows the mean dynamics function with the mean $m(x)$ of the GP prediction at the query point x on the y axis. When considering the mean dynamics, there are two fixpoints $x_1 = -0.1$ and $x_2 = 0.1$. For any starting point $-1 < x < 0$, the mean trajectory converges to x_1 and analogously for all $0 < x < 1$ the trajectories converge to x_2. Now we consider the full GP dynamics and take the uncertainty into account. Plot (b) shows a histogram of the probability density after 10000 time steps when starting at $x = -0.1$, obtained with Monte Carlo. This result matches the histogram obtained when starting at $x = 0.1$ or at any other point. Thus, the system converges to a unique, invariant limiting distribution.

for infinite time horizons without applying any approximate inference steps. We succeeded to show that closed-loop control systems with dynamics given as full GP distribution converge to a unique and invariant limiting distribution that does not depend on the starting state for many choices of the covariance function. Overall, the proposed methods provide stability guarantees for many existing learning control approaches based on GPs.

6.2 Discussion and Next Steps

While the proposed methods apply to many interesting examples of learning control in the literature, the analysis could be extended in several directions. Firstly, for closed-loop control with GP dynamics, we considered GPs with stationary covariance functions and zero mean prior. To include other choices of the prior, e.g., nonstationary covariance functions and unbounded mean priors, novel criteria to ensure Harris recurrence must be found. Another interesting question is how the stability of GP dynamics is affected by disturbances in the input space. While some results could straightforwardly be followed for dynamics given as the mean of a GP, the task seems a lot more challenging when uncertainty is included. Many of the subtle, intricate arguments applied to show convergence of the system to a limiting distribution must be carefully reconsidered when disturbances are present.

Secondly, the obtained results are stability results for closed-loop control systems with dynamics given as a GP. The GP training data have a huge impact on the quality of the GP dynamics model when compared to the physical system the data was collected from. In this direction, criteria to evaluate the quality of a learned model would further support the application of learning control for real-world problems.

Another interesting research direction is encouraged by the presented result on asymptotic stability of closed-loop control systems with GP dynamics. This paper proves the existence of a limiting distribution the system will converge to. This distribution is unique and invariant. However, little more is known about the limiting distribution. Further research in this direction could help for a better understanding of the behavior of learned dynamics and also be directly employed in learning control – possibly by optimizing the limiting distribution itself instead of local approximations as, e.g., system trajectories.

Abstract

We consider the optimization of a quadratic objective function whose gradients are only accessible through a stochastic oracle that returns the gradient at any given point plus a zero-mean finite variance random error. We present the first algorithm that achieves jointly the optimal prediction error rates for least-squares regression, both in terms of forgetting the initial conditions in $O(1/n^2)$, and in terms of dependence on the noise and dimension d of the problem, as $O(d/n)$. Our new algorithm is based on averaged accelerated regularized gradient descent, and may also be analyzed through finer assumptions on initial conditions and the Hessian matrix, leading to dimension-free quantities that may still be small in some distances while the "optimal" terms above are large. In order to characterize the tightness of these new bounds, we consider an application to non-parametric regression and use the known lower bounds on the statistical performance (without computational limits), which happen to match our bounds obtained from a single pass on the data and thus show optimality of our algorithm in a wide variety of particular trade-offs between bias and variance.

Keywords: convex optimization, least-squares regression, stochastic gradient, accelerated gradient, non-parametric estimation

1. Introduction

Many supervised machine learning problems are naturally cast as the minimization of a smooth function defined on a Euclidean space. This includes least-squares regression, logistic regression (see, e.g., Hastie et al., 2009) or generalized linear models (McCullagh and Nelder, 1989). While small problems with few or low-dimensional input features may be solved precisely by many potential optimization algorithms (e.g., Newton method), large-scale problems with many high-dimensional features are typically solved with simple gradient-based iterative techniques whose per-iteration cost is small.

In this paper, we consider a quadratic objective function f whose gradients are only accessible through a stochastic oracle that returns the gradient at any given point plus a zero-mean finite variance random error. In this stochastic approximation framework (Robbins and Monro, 1951), it is known that two quantities dictate the behavior of various algorithms, namely the covariance matrix V of the noise in the gradients, and the deviation $\theta_0 - \theta_*$ between the initial point of the algorithm θ_0 and any of the global minimizer θ_* of f. This leads to a "bias/variance" decomposition (Bach and Moulines, 2013; Hsu et al., 2014) of the performance of most algorithms as the sum of two terms: (a) the bias term characterizes how fast initial conditions are forgotten and thus is increasing in a well-chosen norm of $\theta_0 - \theta_*$; while (b) the variance term characterizes the effect of the noise in the gradients, independently of the starting point, and with a term that is increasing in the covariance of the noise.

For quadratic functions with (a) a noise covariance matrix V which is proportional (with constant σ^2) to the Hessian of f (a situation which corresponds to least-squares regression) and (b) an initial point characterized by the norm $\|\theta_0 - \theta_*\|^2$, the optimal bias and variance terms are known *separately* from the optimization and statistical theories. On the one hand, the optimal bias dependency after n iterations is proportional to $\frac{L\|\theta_0-\theta_*\|^2}{n^2}$, where L is the largest eigenvalue of the Hessian of f. This rate is achieved by accelerated gradient descent (Nesterov, 1983, 2004), and is known to be optimal if the number of iterations n is less than the dimension d of the underlying predictors, but the algorithm is not robust to random or deterministic noise in the gradients (d'Aspremont, 2008; Schmidt et al., 2011; Devolder et al., 2014). On the other hand, the optimal variance term is proportional to $\frac{\sigma^2 d}{n}$ (Tsybakov, 2008); it is known to be achieved by averaged gradient descent (Bach and Moulines, 2013), for which the bias term only achieves $\frac{L\|\theta_0-\theta_*\|^2}{n}$ instead of $\frac{L\|\theta_0-\theta_*\|^2}{n^2}$.

Our first contribution in this paper is to present a novel algorithm which attains optimal rates for *both the variance and the bias terms*. This algorithm analyzed in Section 4 is averaged accelerated gradient descent; beyond obtaining jointly optimal rates, our result shows that averaging is beneficial for accelerated techniques and provides a provable robustness to noise.

While optimal when measuring performance in terms of the dimension d and the initial distance to optimum $\|\theta_0 - \theta_*\|^2$, these rates are not adapted in many situations where either d is larger than the number of iterations n (i.e., the number of observations for regular stochastic gradient descent) or $L\|\theta_0 - \theta_*\|^2$ is much larger than n^2. Our second contribution is to provide in Section 5 an analysis of a new algorithm (based on some additional regularization) that can adapt our bounds to finer assumptions on $\theta_0 - \theta_*$ and the Hessian of the problem, leading in particular to dimension-free quantities that can thus be extended to the Hilbert space setting (in particular for non-parametric estimation).

In order to characterize the optimality of these new bounds, our third contribution is to consider an application to non-parametric regression in Section 6 and use the known lower bounds on the statistical performance (without computational limits), which happen to match our bounds obtained from a single pass on the data and thus show optimality of our algorithm in a wide variety of particular trade-offs between bias and variance.

Our paper is organized as follows: in Section 2, we present the main problem we tackle, namely least-squares regression, then introduce the two algorithms that we consider in

Section 2.2, as well as the two types of oracles on the gradient in Section 2.3. In Section 3, we present new results for averaged stochastic gradient descent that set the stage for Section 4, where we present our main novel result leading to an accelerated algorithm which is robust to noise. Our tighter analysis of convergence rates based on finer dimension-free quantities is presented in Section 5, and their optimality for kernel-based non-parametric regression is studied in Section 6. Organization of the main results is summarized in the Table 1 bellow.

	Averaged Algo.	**Averaged Accelerated Algo.**
Dimension dependent rates	*Section 3*	*Section 4*
Additive Noise	Lemma 1$^\diamondsuit$	Theorem 3
Multiplicative Noise	Theorem 2$^\diamondsuit$	$\natural$
Dimension independent rates	*Section 5*	*Section 5*
Additive Noise	$\sharp$	Theorem 5
Multiplicative Noise	4^{th} remark after Cor. 6$^\flat$	$\natural$
Kernel regression setting	*Section 6*	*Section 6*
Additive Noise	$\sharp$	Theorem 8
Multiplicative Noise	Theorem 7$^\flat$	$\natural$

Table 1: Organization of the paper. $\diamondsuit$: We extend results from (Bach and Moulines, 2013) to the setting in which extra regularization is added; $\sharp$: apart from Lemma 1 which is useful to develop intuition of the different terms in the upper bound, we do not state result for the averaged algorithm with additive noise, as the most powerful result is for the multiplicative noise; $\flat$: these results recover results from Dieuleveut and Bach (2015) (with the use of an extra regularization); $\natural$: it is still an open problem to get results in the accelerated setting for a multiplicative noise oracle.

2. Least-Squares Regression

In this section, we present our least-squares regression framework, which is risk minimization with the square loss, together with the main assumptions regarding our model and our algorithms. These algorithms will rely on stochastic gradient oracles, which will come in two kinds, an additive noise which does not depend on the current iterate, which will correspond in practice to the full knowledge of the covariance matrix, and a "multiplicative/additive" noise, which corresponds to the regular stochastic gradient obtained from a single pair of observations. This second oracle is much harder to analyze.

2.1 Statistical Assumptions

We consider the following general setting:

- $\mathcal{H}$ is a d-dimensional Euclidean space with $d \geq 1$. The (temporary) restriction to finite dimension will be relaxed in Section 6.

- The observations $(x_n, y_n) \in \mathcal{H} \times \mathbb{R}$, $n \geq 1$, are independent and identically distributed (i.i.d.), and such that $\mathbb{E}\|x_n\|^2$ and $\mathbb{E}y_n^2$ are finite.

- We consider the *least-squares regression* problem, namely the minimization of the expected loss $f(\theta) = \frac{1}{2}\mathbb{E}(\langle x_n, \theta\rangle - y_n)^2$ which is a quadratic function.

We first introduce an assumption on the distribution of x_n.

Covariance matrix. We denote by $\Sigma = \mathbb{E}(x_n \otimes x_n) \in \mathbb{R}^{d\times d}$ the population covariance matrix, which is the Hessian of f at all points. Without loss of generality, we can assume Σ is invertible by reducing $\mathcal{H}$ to the minimal subspace where all x_n, $n \geq 1$, lie almost surely. This implies that all eigenvalues of Σ are strictly positive (but they may be arbitrarily small). Following Bach and Moulines (2013), we assume there exists $R > 0$ such that

$$\mathbb{E}\|x_n\|^2 x_n \otimes x_n \preccurlyeq R^2\Sigma, \tag{$\mathcal{A}_1$}$$

where $A \preccurlyeq B$ means that $B - A$ is positive semi-definite. This assumption implies in particular that (a) $\mathbb{E}\|x_n\|^4$ is finite and (b) $\operatorname{tr}\Sigma = \mathbb{E}\|x_n\|^2 \leq R^2$ since taking the trace of the previous inequality we get $\mathbb{E}\|x_n\|^4 \leq R^2\mathbb{E}\|x_n\|^2$ and using Cauchy-Schwarz inequality we get $\mathbb{E}\|x_n\|^2 \leq \sqrt{\mathbb{E}\|x_n\|^4} \leq R\sqrt{\mathbb{E}\|x_n\|^2}$.

Assumption $(\mathcal{A}_1)$ is satisfied, for example, for least-square regression with almost surely bounded data, since $\|x_n\|^2 \leq R^2$ almost surely implies $\mathbb{E}\|x_n\|^2 x_n \otimes x_n \preccurlyeq \mathbb{E}\left[R^2 x_n \otimes x_n\right] = R^2\Sigma$. This assumption is also true for data with infinite support and a bounded *kurtosis* for the projection of the covariates x_n on any direction $z \in \mathcal{H}$, e.g, for which there exists $\kappa > 0$, such that:

$$\forall z \in \mathcal{H}, \quad \mathbb{E}\langle z, x_n\rangle^4 \leq \kappa\langle z, \Sigma z\rangle^2. \tag{1}$$

Indeed, by Cauchy-Schwarz inequality, Equation (1) implies for all $(z, t) \in \mathcal{H}^2$, the following bound $\mathbb{E}\langle z, x_n\rangle^2\langle t, x_n\rangle^2 \leq \kappa\langle z, \Sigma z\rangle\langle t, \Sigma t\rangle$, which in turn implies that for all positive semi-definite symmetric matrices M, N, we have $\mathbb{E}\langle x_n, Mx_n\rangle\langle x_n, Nx_n\rangle \leq \kappa \operatorname{tr}(M\Sigma)\operatorname{tr}(N\Sigma)$. Equation (1), which is true for Gaussian vectors with $\kappa = 3$, thus implies $(\mathcal{A}_1)$ for $R^2 = \kappa \operatorname{tr}\Sigma = \kappa\mathbb{E}\|x_n\|^2$.

In the next two paragraphs, we introduce some quantities that will be important in the analysis, in order to get tighter bounds.

Eigenvalue decay. Most convergence bounds depend on the dimension d of $\mathcal{H}$. However it is possible to derive dimension-free and often tighter convergence rates by considering bounds depending on the value $\operatorname{tr}\Sigma^b$ for $b \in [0, 1]$. Given b, if we consider the eigenvalues of Σ ordered in decreasing order, which we denote by s_i, then $\operatorname{tr}\Sigma^b = \sum_i s_i^b$, and the eigenvalues decay[1] at least as $\frac{(\operatorname{tr}\Sigma^b)^{1/b}}{i^{1/b}}$. Moreover, it is known that $(\operatorname{tr}\Sigma^b)^{1/b}$ is decreasing in b and thus, the smaller the b, the stronger the assumption. For b going to 0 then $\operatorname{tr}\Sigma^b$ tends to d and we are back in the classical low-dimensional case. When $b = 1$, we simply get $\operatorname{tr}\Sigma = \mathbb{E}\|x_n\|^2$, which will correspond to the weakest assumption in our context.

1. Indeed for any $i \geq 1$, we have $is_i^b \leq \sum_{t=1}^i s_t^b \leq \operatorname{tr}(\Sigma^b)$.

Optimal predictor. In finite dimension the regression function $f(\theta) = \frac{1}{2}\mathbb{E}(\langle x_n, \theta\rangle - y_n)^2$ always admits a global minimum $\theta_* = \Sigma^\dagger \mathbb{E}(y_n x_n)$. When initializing algorithms at $\theta_0 = 0$ or regularizing by the squared norm, rates of convergence generally depend on $\|\theta_*\|$, a quantity which could be arbitrarily large.

However there exists a systematic upper-bound[2] $\|\Sigma^{\frac{1}{2}}\theta_*\| \leq 2\sqrt{\mathbb{E}y_n^2}$. This leads naturally to the consideration of convergence bounds depending on $\|\Sigma^{r/2}\theta_*\|$ for $r \leq 1$. In infinite dimension this will correspond to assuming $\|\Sigma^{r/2}\theta_*\| < \infty$. This new assumption relates the optimal predictor with sources of ill-conditioning (since Σ is the Hessian of the objective function f), the smaller r, the stronger our assumption, with $r = 1$ corresponding to no assumption at all, $r = 0$ to θ_* in $\mathcal{H}$ and $r = -1$ to a convergence of the bias of least-squares regression with averaged stochastic gradient descent in $O\big(\frac{\|\Sigma^{-1/2}\theta_*\|^2}{n^2}\big)$(Dieuleveut and Bach, 2015; Défossez and Bach, 2015). In this paper, we will use arbitrary initial points θ_0 and thus our bounds will depend on $\|\Sigma^{r/2}(\theta_0 - \theta_*)\|$.

Finally , we make an assumption on the joint distribution of (x_n, y_n).

Noise. We denote by $\varepsilon_n = y_n - \langle \theta_*, x_n\rangle$ the residual for which we have $\mathbb{E}[\varepsilon_n x_n] = 0$. Although we do not have $\mathbb{E}[\varepsilon_n | x_n] = 0$ in general unless the model is well-specified, we assume the noise to be a structured process such that there exists $\sigma > 0$ with

$$\mathbb{E}[\varepsilon_n^2 x_n \otimes x_n] \preccurlyeq \sigma^2 \Sigma. \tag{$\mathcal{A}_2$}$$

Assumption $(\mathcal{A}_2)$ is satisfied for example for data almost surely bounded or when the model is well-specified, (e.g., $y_n = \langle \theta_*, x_n\rangle + \varepsilon_n$, with $(\varepsilon_n)_{n\in\mathbb{N}}$ i.i.d. of variance σ^2 and independent of x_n).

2.2 Averaged Gradient Methods and Acceleration

We focus in this paper on stochastic gradient methods with and without acceleration for the least-squares function regularized by $\frac{\lambda}{2}\|\theta - \theta_0\|^2$ for $\lambda \in \mathbb{R}^+$. The regularization will be useful when deriving tighter convergence rates in Section 5, and it has the additional benefit of making the problem λ-strongly-convex. Stochastic gradient descent (referred to from now on as "SGD"), applied to the regularized problem, can be described for $n \geq 1$ as

$$\theta_n = \theta_{n-1} - \gamma f_n'(\theta_{n-1}) - \gamma\lambda(\theta_{n-1} - \theta_0), \tag{2}$$

starting from $\theta_0 \in \mathcal{H}$, where $\gamma > 0$ is either called the step-size in optimization or the learning rate in machine learning, and $f_n'(\theta_{n-1})$ is an unbiased estimate of the gradient of f at θ_{n-1}, that is, its conditional expectation given all other sources of randomness is equal to $f'(\theta_{n-1})$.

Accelerated stochastic gradient descent is defined, for the regularized problem, by an iterative system with two parameters (θ_n, ν_n) satisfying for $n \geq 1$

$$\begin{aligned} \theta_n &= \nu_{n-1} - \gamma f_n'(\nu_{n-1}) - \gamma\lambda(\nu_{n-1} - \theta_0) \\ \nu_n &= \theta_n + \delta\big(\theta_n - \theta_{n-1}\big), \end{aligned} \tag{3}$$

2. Indeed for all $\theta \in \mathbb{R}^d$ and in particular $\theta = 0$, by Minkowski's inequality, $\|\Sigma^{\frac{1}{2}}\theta_*\| - \sqrt{\mathbb{E}y_n^2} = \sqrt{\mathbb{E}\langle\theta_*, x_n\rangle^2} - \sqrt{\mathbb{E}y_n^2} \leq \sqrt{\mathbb{E}(\langle\theta_*, x_n\rangle - y_n)^2} \leq \sqrt{\mathbb{E}(\langle\theta, x_n\rangle - y_n)^2} \leq \sqrt{\mathbb{E}(y_n)^2}$.

starting from $\theta_0 = \nu_0 \in \mathcal{H}$, with $\gamma, \delta \in \mathbb{R}^2$ and $f_n'(\theta_{n-1})$ described as before. It may be reformulated as the following second-order recursion

$$\theta_n = (1 - \gamma\lambda)\big(\theta_{n-1} + \delta(\theta_{n-1} - \theta_{n-2})\big) - \gamma f_n'\big(\theta_{n-1} + \delta(\theta_{n-1} - \theta_{n-2})\big) + \gamma\lambda\theta_0.$$

The *momentum* coefficient $\delta \in \mathbb{R}$ is chosen to accelerate the convergence rate (Nesterov, 1983; Beck and Teboulle, 2009) and has its roots in the heavy-ball algorithm from Polyak (1964). We especially concentrate here, following Polyak and Juditsky (1992), on the average of the sequence

$$\bar{\theta}_n = \frac{1}{n+1}\sum_{i=0}^{n}\theta_n, \tag{4}$$

and we note that it can be computed online as $\bar{\theta}_n = \frac{n}{n+1}\bar{\theta}_{n-1} + \frac{1}{n+1}\theta_n$.

The key ingredient in the algorithms presented above is the unbiased estimate on the gradient $f_n'(\theta)$, which can take two forms that we now describe in our setting.

2.3 Additive versus Multiplicative Stochastic Oracles on the Gradient

We consider the standard stochastic approximation framework (Kushner and Yin, 2003). That is, we let $(\mathcal{F}_n)_{n\geq 0}$ be the increasing family of σ-fields that are generated by all variables (x_i, y_i) for $i \leq n$, and such that for each $\theta \in \mathcal{H}$ the random variable $f_n'(\theta)$ is square-integrable and $\mathcal{F}_n$-measurable with $\mathbb{E}[f_n'(\theta)|\mathcal{F}_{n-1}] = f'(\theta)$, for all $n \geq 0$. Consequently it is of the form

$$f_n'(\theta) = f'(\theta) - \xi_n, \tag{$\mathcal{A}_3$}$$

where the noise process ξ_n is $\mathcal{F}_n$-measurable with $\mathbb{E}[\xi_n|\mathcal{F}_{n-1}] = 0$ and $\mathbb{E}[\|\xi_n\|^2]$ is finite. We will consider two different gradient oracles.

Additive noise. The first oracle is the sum of the true gradient $f'(\theta)$ and an independent zero-mean noise that does not depend on θ. This oracle is equal to

$$f_n'(\theta) = \Sigma\theta - y_n x_n. \tag{5}$$

Since $f'(\theta) = \Sigma\theta - \mathbb{E}y_n x_n$, the oracle above has a noise vector $\xi_n = y_n x_n - \mathbb{E}y_n x_n$ independent of θ and therefore satisfies Assumption $(\mathcal{A}_3)$. Furthermore we also assume that there exists $\tau \in \mathbb{R}$ such that

$$\mathbb{E}[\xi_n \otimes \xi_n] \preccurlyeq \tau^2\Sigma, \tag{$\mathcal{A}_4$}$$

that is, the noise has a particular structure adapted to least-squares regression. For optimal results for unstructured noise, with convergence rate for the noise part in $O(1/\sqrt{n})$, see Lan (2012). Our oracle above with an additive noise which is independent of the current iterate corresponds to the first setting studied in stochastic approximation (Robbins and Monro, 1951; Duflo, 1997; Polyak and Juditsky, 1992). While used by Bach and Moulines (2013) as an artifact of proof, for least-squares regression, such an additive noise corresponds to the situation where the distribution of x is known so that the population covariance matrix is computable, but the distribution of the outputs $(y_n)_{n\in\mathbb{N}}$ remains unknown. Thus it may be seen as an intermediate set-up between regression estimation with fixed and random design (see, e.g., Györfi et al., 2006, Section 1.9).

Assumption $(\mathcal{A}_4)$ will be satisfied, for example if the outputs are almost surely bounded because $\mathbb{E}[\xi_n \otimes \xi_n] \preccurlyeq \mathbb{E}[y_n^2 x_n \otimes x_n] \preccurlyeq \tau^2 \Sigma$ if $y_n^2 \leq \tau^2$ almost surely. But it will also be for data satisfying Equation (1) since we will have

$$\begin{aligned}\mathbb{E}[\xi_n \otimes \xi_n] &\preccurlyeq \mathbb{E}[y_n^2 x_n \otimes x_n] = \mathbb{E}[(\langle \theta_*, x_n\rangle + \varepsilon_n)^2 x_n \otimes x_n] \\ &\preccurlyeq 2\mathbb{E}[\langle \theta_*, x_n\rangle^2 x_n \otimes x_n] + 2\sigma^2 \Sigma \preccurlyeq 2(\kappa \|\Sigma^{1/2}\theta_*\|^2 + \sigma^2)\Sigma \preccurlyeq 2(4\kappa \mathbb{E}[y_n^2] + \sigma^2)\Sigma,\end{aligned}$$

and thus Assumption $(\mathcal{A}_4)$ is satisfied with $\tau^2 = 2(4\kappa \mathbb{E}[y_n^2] + \sigma^2)$.

Stochastic noise ("multiplicative/additive"). This corresponds to:

$$f_n'(\theta) = (\langle x_n, \theta\rangle - y_n) x_n = (\Sigma + \zeta_n)(\theta - \theta_*) - \Xi_n, \tag{6}$$

with $\zeta_n = x_n \otimes x_n - \Sigma$ and $\Xi_n = (y_n - \langle x_n, \theta_*\rangle) x_n = \varepsilon_n x_n$. This oracle corresponds to regular SGD, which is often referred to as the least-mean-square (LMS) algorithm for least-squares regression, where the noise comes from sampling a single pair of observations. While still satisfying Assumption $(\mathcal{A}_3)$, it combines an additive noise Ξ_n independent of θ as in Eq. (5) and a multiplicative noise ζ_n. This multiplicative noise makes this stochastic oracle harder to analyze which explains why it is often approximated by an additive noise oracle. However it is the most widely used and most practical one. Note that for the oracle in Eq. (6), from Equation $(\mathcal{A}_2)$, we have $\mathbb{E}[\Xi_n \otimes \Xi_n] \preccurlyeq \sigma^2 \Sigma$. It has a similar form to Assumption $(\mathcal{A}_4)$ which is valid for the additive noise oracle in Eq. (5): we use different constants σ^2 and τ^2 to highlight the difference between these two oracles.

3. Averaged Stochastic Gradient Descent

In this section, we provide convergence bounds for regularized averaged stochastic gradient descent. The main novelty compared to the work of Bach and Moulines (2013) is (a) the presence of regularization, which will be useful when deriving tighter convergence rates in Section 5 and (b) a much simpler proof. We first consider the additive noise in Section 3.1 before considering the multiplicative/additive noise in Section 3.2.

3.1 Additive Noise

We study here the convergence of the averaged SGD recursion defined by Eq. (2) under the simple oracle defined in Eq. (5). For least-squares regression, it takes the form:

$$\theta_n = \big[I - \gamma\Sigma - \gamma\lambda I\big]\theta_{n-1} + \gamma y_n x_n + \lambda\gamma\theta_0. \tag{7}$$

This is an easy adaptation of the work of Bach and Moulines (2013, Lemma 2) for the regularized case.

Lemma 1 *Assume $(\mathcal{A}_4)$. Consider the recursion in Eq. (7) with any regularization parameter $\lambda \in \mathbb{R}_+$ and any constant step-size γ such that $\gamma(\Sigma + \lambda I) \preccurlyeq I$. Then*

$$\mathbb{E} f(\bar{\theta}_n) - f(\theta_*) \leq \Big(\lambda + \frac{1}{\gamma n}\Big)^2 \|\Sigma^{1/2}(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\|^2 + \frac{\tau^2 \operatorname{tr}\big[\Sigma^2(\Sigma + \lambda I)^{-2}\big]}{n}. \tag{8}$$

We can make the following observations:

- The proof (see Appendix A) relies on the fact that $\theta_n - \theta_*$ is obtainable in closed form since the cost function is quadratic and thus the recursions are linear, and follows from Polyak and Juditsky (1992).
- The constraint on the step-size γ is equivalent to $\gamma(L + \lambda) \leqslant 1$ where L is the largest eigenvalue of Σ and we thus recover the usual step-size from deterministic gradient descent (Nesterov, 2004).
- When n tends to infinity, the algorithm converges to the minimum of $f(\theta) + \frac{\lambda}{2}\|\theta - \theta_0\|^2$ and our performance guarantee becomes $\lambda^2 \|\Sigma^{1/2}(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\|^2$. This is the standard "bias term" from regularized ridge regression (Hsu et al., 2014) which we naturally recover here. The term $\frac{\tau^2}{n} \operatorname{tr}\big[\Sigma^2(\Sigma + \lambda I)^{-2}\big]$ is usually referred to as the "variance term" (Hsu et al., 2014), and is equal to $\frac{\tau^2}{n}$ times the quantity $\operatorname{tr}\big[\Sigma^2(\Sigma + \lambda I)^{-2}\big]$, which is often called the degrees of freedom of the ridge regression problem (Gu, 2013).
- For finite n, the first term in Eq. (8) is the usual bias term which depends on the distance from the initial point θ_0 to the objective point θ_* with an appropriate norm. It includes a regularization-based component which is proportional to λ^2 and optimization-based component which depends on $(\gamma n)^{-2}$. The regularization-based bias appears because the algorithm tends to minimize the regularized function instead of the true function f.
- Given Eq. (8), it is natural to set $\lambda\gamma = \frac{1}{n}$, and the two components of the bias term are exactly of the same order leading to $\frac{4}{\gamma^2 n^2}\|\Sigma^{1/2}(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\|^2$. It corresponds up to a constant factor to the bias term of regularized least-squares (Hsu et al., 2014), but it is achieved by an algorithm accessing only n stochastic gradients. Note that when λ or γ depend on n, this term is not necessarily of order $O(n^{-2})$, as the numerator might be arbitrarily large. Note also that here as in the rest of the paper, we only prove results in the finite horizon setting, meaning that the number of samples is known in advance and the parameters γ, λ may be chosen as functions of n, but remain constant along the iterations (when λ or γ depend on n, our bounds only hold for the last iterate).
- Note that the bias term can also be bounded by $\frac{1}{\gamma n}\|\Sigma^{1/2}(\Sigma + \lambda I)^{-1/2}(\theta_0 - \theta_*)\|^2$ only when $\|\theta_0 - \theta_*\|$ is finite (note the difference in the powers of n and $(\Sigma + \lambda I)^{-1}$). See the proof in Appendix A.2 for details.
- The second term in Eq. (8) is the variance term. It depends on the noise in the gradient. When this one is not structured the variance turns to be also bounded by $\gamma \operatorname{tr}\big(\Sigma(\Sigma + \lambda I)^{-1}\mathbb{E}[\xi_n \otimes \xi_n]\big)$ (see Appendix A.3) and we recover for $\gamma = O(1/\sqrt{n})$, the usual rate of $\frac{1}{\sqrt{n}}$ for SGD in the smooth case (Shalev-Shwartz et al., 2009).
- Overall we get the same performance as the empirical risk minimizer with fixed design, but with an algorithm that performs a single pass over the data.
- When $\lambda = 0$ we recover Lemma 2 of Bach and Moulines (2013). In this case the variance term $\frac{\tau^2 d}{n}$ is optimal over all estimators in $\mathcal{H}$ (Tsybakov, 2008) even without

computational limits, in the sense that no estimator that uses the same information can improve upon this rate.

3.2 Multiplicative/Additive Noise

When the general stochastic oracle in Eq. (6) is considered, the regularized LMS algorithm defined by Eq. (2) takes the form:

$$\theta_n = \big[I - \gamma x_n \otimes x_n - \gamma\lambda I\big]\theta_{n-1} + \gamma y_n x_n + \lambda\gamma\theta_0. \tag{9}$$

We have a very similar result with an additional corrective term (second line below) compared to Lemma 1.

Theorem 2 *Assume* $(\mathcal{A}_{1,2})$*. Consider the recursion in Eq.* (9)*. For any regularization parameter* $\lambda \in \mathbb{R}^+$ *and for any constant step-size* γ *such that* $2\gamma(R^2+2\lambda) \leq 1$ *we have:*

$$\begin{aligned}\mathbb{E}f(\bar\theta_n) - f(\theta_*) \;\leqslant\; & 3\Big(2\lambda + \frac{1}{\gamma n}\Big)^2 \|\Sigma^{1/2}(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)\|^2 + \frac{6\sigma^2}{n+1}\operatorname{tr}\big[\Sigma^2(\Sigma+\lambda I)^{-2}\big] \\ & + 3\frac{\big\|(\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)\big\|^2 \operatorname{tr}(\Sigma(\Sigma+\lambda I)^{-1})}{\gamma^2(n+1)^2}.\end{aligned}$$

We can make the following remarks:

- The proof (see Appendix B) relies on a bias-variance decomposition, each term being treated separately. We adapt a proof technique from Bach and Moulines (2013) which considers the difference between the recursions in Eq. (9) and in Eq. (7).
- As in Lemma 1, the bias term can also be bounded by $\frac{1}{\gamma n}\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)\|^2$ and the variance term by $\gamma\operatorname{tr}[\Sigma(\Sigma+\lambda I)^{-1}\xi_n\otimes\xi_n]$ (see proof in Appendices B.4 and B.5). This is useful in particular when considering unstructured noise.
- The variance term is the same as in the previous case. However there is a residual term that now appears when we go to the fully stochastic oracle (second line). This term will go to zero when γ tends to zero and can be compared to the corrective term which also appears when Hsu et al. (2014) go from fixed to random design. Nevertheless our bounds are more concise than theirs, making significantly fewer assumptions and relying on an efficient single-pass algorithm.
- In this setting, the step-size may not exceed $1/(2(R^2+2\lambda))$, whereas with an additive noise in Lemma 1 the condition is $\gamma \leq 1/(L+\lambda)$, a quantity which can be much bigger than $1/(2(R^2+2\lambda))$, as L is the spectral radius of Σ whereas R^2 is of the order of $\operatorname{tr}(\Sigma)$. Note that in practice, computing L is as hard as computing θ_* so that the step-size $\gamma \propto 1/R^2$ is a good practical choice. See Défossez and Bach (2015) for larger allowed step-sizes that require more information.
- For $\lambda = 0$ the error is bounded by $\frac{3(1+d)}{(\gamma n)^2}\|\Sigma^{-1/2}(\theta_0-\theta_*)\|^2 + \frac{6\sigma^2 d}{n+1}$. We recover results from Défossez and Bach (2015) with a non-asymptotic bound but we lose the advantage of having an asymptotic equivalent (i.e., a limit rather than an upper-bound). We note that the assumption $(\mathcal{A}_{1,2})$ are close to the minimal assumptions required to obtain the optimal rate of convergence of $\sigma^2 d/n$ (Lecué and Mendelson, 2016; Oliveira, 2016)

4. Accelerated Stochastic Averaged Gradient Descent

We study the convergence under the stochastic oracle from Eq. (5) of averaged *accelerated* stochastic gradient descent defined by Eq. (3) which can be rewritten for the least-squares function f as a second-order iterative system with constant coefficients:

$$\theta_n = \big[I - \gamma\Sigma - \gamma\lambda I\big]\big[\theta_{n-1} + \delta(\theta_{n-1}-\theta_{n-2})\big] + \gamma y_n x_n + \gamma\lambda\theta_0. \tag{10}$$

When using averaging, we refer to this algorithm as "averaged-accelerated-SGD".

Theorem 3 *Assume* $(\mathcal{A}_4)$*. For any regularization parameter* $\lambda \in \mathbb{R}_+$ *and for any constant step-size* $\gamma(\Sigma+\lambda I) \preccurlyeq I$*, we have for any* $\delta \in \big[\frac{1-\sqrt{\gamma\lambda}}{1+\sqrt{\gamma\lambda}}, 1\big]$*, for the recursion in Eq. (10):*

$$\mathbb{E}f(\bar\theta_n) - f(\theta_*) \leq 2\Big(\lambda + \frac{36}{\gamma(n+1)^2}\Big)\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)\|^2 + 8\tau^2\frac{\operatorname{tr}\big[\Sigma^2(\Sigma+\lambda I)^{-2}\big]}{n+1}.$$

The numerical constants are partially artifacts of the proof (see Appendices C and E). Thanks to a wise use of tight inequalities, the bound is independent of δ and valid for all $\lambda \in \mathbb{R}_+$. This results in the simple following corollary for $\lambda = 0$, which corresponds to the particularly simple recursion (with averaging to obtain $\bar\theta_n$):

$$\theta_n = \big[I - \gamma\Sigma\big](2\theta_{n-1} - \theta_{n-2}) + \gamma y_n x_n. \tag{11}$$

Corollary 4 *Assume* $(\mathcal{A}_4)$*. For any constant step-size* $\gamma\Sigma \preccurlyeq I$*, we have for* $\delta = 1$*,*

$$\mathbb{E}f(\bar\theta_n) - f(\theta_*) \leq 36\frac{\|\theta_0-\theta_*\|^2}{\gamma(n+1)^2} + 8\frac{\tau^2 d}{n+1}. \tag{12}$$

We can make the following observations:

- The proof technique relies on direct moment computations in each eigensubspace obtained by O'Donoghue and Candès (2013) in the deterministic case. Indeed as Σ is a symmetric matrix, the space can be decomposed on an orthonormal eigenbasis of Σ, and the iterations are decoupled in such an eigenbasis. Although we only provide an upper-bound, this is in fact an equality plus other exponentially small terms as shown in the proof which relies on linear algebra, with difficulties arising from the fact that this second-order system can be expressed as a linear stochastic dynamical system with non-symmetric matrices. We only provide a result for additive noise.
- The first bound $\frac{1}{\gamma n^2}\|\theta_0-\theta_*\|^2$ in Eq. (12) corresponds to the usual accelerated rate. It has been shown by Nesterov (2004) to be the optimal rate of convergence for optimizing a quadratic function with a first-order method that can access only to sequences of gradients when $n \leq d$. We recover by averaging an algorithm dedicated to strongly-convex function the traditional convergence rate for non-strongly convex functions. Even if it seems surprising, the algorithm works also for $\lambda = 0$ and $\delta = 1$ (see also simulations in Section 7).

- The second bound in Eq. (12) also matches the optimal statistical performance $\frac{\tau^2 d}{n}$ described in the observations following Lemma 1. Accordingly this algorithm achieves joint bias/variance optimality (when measured in terms of τ^2 and $\|\theta_0 - \theta_*\|^2$).

- We have the same rate of convergence for the bias when compared to the regular Nesterov acceleration without averaging studied by Flammarion and Bach (2015), which corresponds to choosing $\delta_n = 1 - 2/n$ for all n. However if the problem is μ-strongly convex, this latter was shown to also converge at the linear rate $O\big((1-\gamma\mu)^n\big)$ and thus is adaptive to hidden strong-convexity (since the algorithm does not need to know μ to run). This explains that it ends up converging faster for quadratic function since for large n the convergence at rate $1/n^2$ becomes slower than the one at rate $(1-\gamma\mu)^n$ even for very small μ. This is confirmed in our experiments in Section 7. Thanks to this adaptivity, we can also show using the same tools and considering its weighted average $\tilde{\theta}_n = \frac{2}{n(n+1)}\sum_{k=0}^n k\theta_k$ that the bias term of $\mathbb{E}f(\tilde{\theta}_n) - f(\theta_*)$ has a convergence rate of order $\big(\lambda^2 + \frac{1}{\gamma^2(n+1)^4}\big)\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)\|^2$ without any change in the variance term. This has to be compared to the bias of averaged SGD $\big(\lambda + \frac{1}{\gamma(n+1)^2}\big)\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)\|^2$ in Section 3 and may lead to faster convergence for the bias in presence of hidden strong-convexity.

- Overall, the bias term is improved whereas the variance term is not degraded and acceleration is thus robust to noise in the gradients. Thereby, while second-order finite difference methods for optimizing quadratic functions in the singular case, such as conjugate gradient (Polyak, 1987, Section 6.1) are notoriously highly sensitive to noise, we are able to propose a version which is robust to stochastic noise.

- Note that when there is no assumption on the covariance of the noise we still have the variance bounded by $\frac{\gamma n}{2}\operatorname{tr}\big[\Sigma(\Sigma+\lambda I)^{-1}V\big]$; setting $\gamma = 1/n^{3/2}$ and $\lambda = 0$ leads to the bound $\frac{\|\theta_0-\theta_*\|^2}{\sqrt{n}} + \frac{\operatorname{tr} V}{\sqrt{n}}$. We recover the usual rate for accelerated stochastic gradient in the non-strongly-convex case (Xiao, 2010). When the values of the bias and the variance are known, we can achieve the optimal trade-off of Lan (2012) $\frac{R^2\|\theta_0-\theta_*\|^2}{n^2} + \frac{\|\theta_0-\theta_*\|\sqrt{\operatorname{tr} V}}{\sqrt{n}}$ for $\gamma = \min\Big\{1/R^2, \frac{\|\theta_0-\theta_*\|}{\sqrt{\operatorname{tr} V}n^{3/2}}\Big\}$.

5. Tighter Dimension-Independent Convergence Rates

We have seen in Corollary 4 above that the averaged accelerated gradient algorithm matches the lower bounds $\tau^2 d/n$ and $\frac{L}{n^2}\|\theta_0-\theta_*\|^2$ for the prediction error. However the algorithm performs better in almost all cases except the worst-case scenarios corresponding to the lower bounds. For example the algorithm may still predict well when the dimension d is much bigger than n. Similarly the norm of the optimal predictor $\|\theta_*\|^2$ may be huge and the prediction still good, as gradients algorithms happen to be adaptive to the difficulty of the problem: indeed, if the problem is simpler, the convergence rate of the gradient algorithm will be improved. In this section, we provide such a theoretical guarantee.

The following bound stands for the averaged *accelerated* algorithm. It extends previously known bounds in the kernel least-mean-squares setting (Dieuleveut and Bach, 2015).

Theorem 5 *Assume ($\mathcal{A}_4$); for any regularization parameter $\lambda \in \mathbb{R}_+$ and for any constant step-size such that $\gamma(\Sigma+\lambda I) \preccurlyeq I$ we have for $\delta \in \big[\frac{1-\sqrt{\gamma\lambda}}{1+\sqrt{\gamma\lambda}}, 1\big]$, for the recursion in Eq. (10):*

$$\mathbb{E}f(\bar{\theta}_n) - f(\theta_*) \leq \min_{r\in[0,1],\ b\in[0,1]} \left[2\|\Sigma^{r/2}(\theta_0-\theta_*)\|^2\ \lambda^{-r}\left(\frac{36}{\gamma(n+1)^2} + \lambda\right) + 8\frac{\tau^2\operatorname{tr}(\Sigma^b)\lambda^{-b}}{n+1}\right].$$

The proof is straightforward by upper bounding the terms coming from regularization, depending on $\Sigma(\Sigma+\lambda I)^{-1}$, by a power of λ times the considered quantities. More precisely, the quantity $\operatorname{tr}(\Sigma(\Sigma+\lambda I)^{-1})$ can be seen as an effective dimension of the problem (Gu, 2013), and is upper bounded by $\lambda^{-b}\operatorname{tr}(\Sigma^b)$ for any $b \in [0;1]$. Similarly, $\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1/2}\theta_*\|^2$ can be upper bounded by $\lambda^{-r}\|\Sigma^{r/2}(\theta_0-\theta_*)\|^2$. A detailed proof of these results is given in Appendix D.

In order to benefit from the acceleration, we choose $\lambda = (\gamma n^2)^{-1}$. With such a choice we have the following corollary:

Corollary 6 *Assume ($\mathcal{A}_4$), for any constant step-size $\gamma(\Sigma+\lambda I) \preccurlyeq I$, we have for $\lambda = \frac{1}{\gamma(n+1)^2}$ and $\delta \in \big[1-\frac{2}{n+2}, 1\big]$, for the recursion in Eq. (10):*

$$\mathbb{E}f(\bar{\theta}_n) - f(\theta_*) \leq \min_{r\in[0,1],\ b\in[0,1]} \left[74\ \frac{\|\Sigma^{r/2}(\theta_0-\theta_*)\|^2}{\gamma^{1-r}(n+1)^{2(1-r)}} + 8\frac{\tau^2\gamma^b\operatorname{tr}(\Sigma^b)}{(n+1)^{1-2b}}\right].$$

We can make the following observations:

- The algorithm is independent of r and b, thus all the bounds for different values of (r,b) are valid. This is a strong property of the algorithm, which is indeed adaptative to the regularity and the effective dimension of the problem (once γ is chosen). In situations in which either d is larger than n or $L\|\theta_0-\theta_*\|^2$ is larger than n^2, the algorithm can still enjoy good convergence properties, by adapting to the best values of b and r.

- For $b = 0$ we recover the variance term of Corollary 4, but for $b > 0$ and fast decays of eigenvalues of Σ, the bound may be much smaller; note that we lose in the dependency in n, but typically, for large d, this can be advantageous.

- For $r = 0$ we recover the bias term of Corollary 4 and for $r = 1$ (no assumption at all) the bias is bounded by $\|\Sigma^{1/2}\theta_*\|^2 \leq 4R^2$, which is not going to zero. The smaller r is, the stronger the decrease of the bias with respect to n is (which is coherent with the fact that we have a stronger assumption). Moreover, r is only considered between 0 and 1: indeed, if $r < 0$, the constant$\|(\gamma\Sigma)^{r/2}(\theta_0-\theta_*)\|$ is bigger than $\|\theta_0-\theta_*\|$, but the dependence on n cannot improve beyond $(\gamma n^2)^{-1}$. This is a classical phenomenon called "saturation" (Engl et al., 1996). It is linked with the uniform averaging scheme: here, the bias term cannot forget the initial condition faster than n^{-2}.

- A similar result happens to hold, for averaged gradient descent, with $\lambda = (\gamma n)^{-1}$:

$$\mathbb{E}f(\bar{\theta}_n) - f(\theta_*) \leq \min_{\substack{r\in[-1,1]\\ b\in[0,1]}} \left[(18 + \operatorname{Res}(b,r,n,\gamma))\ \frac{\|\Sigma^{r/2}(\theta_0-\theta_*)\|^2}{\gamma^{1-r}(n+1)^{(1-r)}} + 6\frac{\sigma^2\gamma^b\operatorname{tr}(\Sigma^b)}{(n+1)^{1-b}}\right], \quad (13)$$

where $\mathrm{Res}(b, r, n, \gamma))$ corresponds to a residual term, which is smaller than $\mathrm{tr}(\Sigma^b) n^b \gamma^{1+b}$ if $r \geq 0$ and does not exist otherwise. The bias term's dependence on n is degraded, thus the "saturation" limit is logically pushed down to $r = -1$, which explains the $[-1; 1]$ interval for r. The choice $\lambda = (\gamma n)^{-1}$ arises from Th. 2, in order to balance both components of the bias term $\lambda + (\gamma n)^{-1}$. This result is proved in Appendix D. This recovers the result of Dieuleveut and Bach (2015).

- Considering a non-uniform averaging, as proposed after Theorem 2 the $\min_{0 \leq r \leq 1}$ in Th. 5 and Corollary 6 can be extended to $\min_{-1 \leq r \leq 1}$. Indeed, considering a non-uniform averaging allows to have a faster decreasing bias, pushing the saturation limit observed below.

In finite dimension these bounds for the bias and the variance cannot be said to be optimal independently in any sense we are aware of. Indeed, in finite dimension, the asymptotic rate of convergence for the bias (respectively the variance), when n goes to ∞ is governed by $L\|\theta_0 - \theta_*\|^2/n^2$ (resp. $\tau^2 d/n$). However, we show in the next section that in the setting of non parametric learning in kernel spaces, these bounds lead to the optimal statistical rate of convergence among all estimators (independently of their computational cost). Moving to the infinite-dimensional setting allows to characterize the optimality of the bounds by showing that they achieve the statistical rate when optimizing the bias/variance tradeoff in Corollary 6.

6. Rates of Convergence for Kernel Regression

Computational convergence rates give the speed at which an objective function can decrease depending on the amount of computation which is allowed. Typically, they show how the error decreases with respect to the number of iterations, as in Theorem 2. Statistical rates, however, show how close one can get to some objective given some amount of information which is provided. Statistical rates do not depend on some chosen algorithm: these bounds do not involve computation, on the contrary, they state the best performance that no algorithm can beat, given the information, and without computational limits. In particular, any lower bound on the statistical rate implies a lower bound on the computational rates, if each iteration corresponds to access to some new information, here pairs of observations. Interestingly, many algorithms for the past few years have proved to match, with minimal computations (in general one pass through the data), the statistical rate, emphasizing the importance of carrying together optimization and approximation in large scale learning, as described by Bottou and Bousquet (2008). In a similar flavor, it also appears that regularization can be accomplished through early stopping (Yao et al., 2007; Rudi et al., 2015), highlighting this interplay between computation and statistics.

To characterize the optimality of our bounds, we will show that averaged-accelerated-SGD matches the statistical lower bound in the context of non-parametric estimation. Even if it may be computationally hard or impossible to implement averaged-accelerated-SGD with additive noise in the kernel-based framework below (see remarks following Theorem 8), it leads to the optimal statistical rate for a broader class of problems than averaged-SGD, showing that for a wider set of trade-offs, acceleration is optimal.

A natural extension of the finite-dimensional analysis is the non-parametric setting, especially with reproducing kernel Hilbert spaces. In the setting of non-parametric regression, we consider a probability space $\mathcal{X} \times \mathbb{R}$ with probability distribution ρ, and assume that we are given an i.i.d. sample $(x_i, y_i)_{i=1,\dots,n} \sim \rho^{\otimes n}$, and denote by ρ_X the marginal distribution of x_n in $\mathcal{X}$; the aim of non-parametric least-squares regression is to find a function $g : \mathcal{X} \to \mathbb{R}$, which minimizes the expected risk:

$$f(g) = \frac{1}{2}\mathbb{E}_\rho[(g(x_n) - y_n)^2]. \tag{14}$$

The optimal function g is the conditional expectation $g(x) = \mathbb{E}_\rho(y_n|x)$. In the kernel regression setting, we consider as hypothesis space a reproducing kernel Hilbert space (Aronszajn, 1950; Steinwart and Christmann, 2008; Schölkopf and Smola, 2002) associated with a kernel function K. The space $\mathcal{H}$ is a subspace of the space of squared integrable functions $L^2_{\rho_X}$. We look for a function $g_{\mathcal{H}}$ which satisfies: $f(g_{\mathcal{H}}) = \inf_{g \in \mathcal{H}} f(g)$, and $g_{\mathcal{H}}$ belongs to the closure $\bar{\mathcal{H}}$ of $\mathcal{H}$ (meaning that there exists a sequence of function $g_n \in \mathcal{H}$ such that $\|g_n - g_H\|_{L^2_{\rho_X}} \to 0$). When $\mathcal{H}$ is dense, the minimum is attained for the regression function defined above. This function however *is not* in $\mathcal{H}$ in general. Moreover there exists an operator $\Sigma : \mathcal{H} \to \mathcal{H}$, which extends the finite-dimensional population covariance matrix, that will allow the characterization of the smoothness of $g_{\mathcal{H}}$. This operator is known to be trace class when $\mathbb{E}_{\rho_X}[K(x_n, x_n)] < \infty$.

Data points x_i are mapped into the RKHS, via the feature map: $x \mapsto K_x$, where $K_x : \mathcal{H} \to \mathbb{R}$ is a function in the RKHS, such that $K_x : y \mapsto K(x, y)$. The reproducing property[3] allows to express the minimization problem (14) as a least-squares linear regression problem: for any $g \in \mathcal{H}$, $f(g) = \frac{1}{2}\mathbb{E}_\rho[(\langle g, K_{x_n}\rangle_{\mathcal{H}} - y_n)^2]$, and can thus be seen as an extension to the infinite-dimensional setting of linear least-squares regression.

However, in such a setting, both quantities $\|\Sigma^{r/2}\theta_*\|_{\mathcal{H}}$ (where $\|\cdot\|_{\mathcal{H}}$ stands for the norm associated with the inner product in the Hilbert space $\mathcal{H}$) and $\mathrm{tr}(\Sigma^b)$ *may exist or not*. It thus arises as a natural *assumption* to consider the smaller $r \in [-1; 1]$ and the smaller $b \in [0; 1]$ such that

- $\|\Sigma^{r/2}\theta_*\|_{\mathcal{H}} < \infty$ (meaning that $\Sigma^{r/2}\theta_* \in \mathcal{H}$), $(\mathcal{A}_5)$
- $\mathrm{tr}(\Sigma^b) < \infty$. $(\mathcal{A}_6)$

The quantities considered in Sections 2 and 5 are the natural finite-dimensional twins of these assumptions. However in infinite dimension a quantity may exist or not and it is thus an assumption to consider its existence, whereas it can only be characterized by its value, big or small, in finite dimension. The first assumption is generally called the "source condition", the second one the "capacity condition".

In the last decade, De Vito et al. (2005); Cucker and Smale (2002) studied non-parametric least-squares regression in the RKHS framework. These works were extended to derive rates of convergence depending on assumption $(\mathcal{A}_5)$: Ying and Pontil (2008) studied unregularized stochastic gradient descent and derived asymptotic rate of convergence $O(n^{-\frac{1-r}{2-r}})$, for $r \leq 1$ and proved that one could derive similar rates of convergence for $0 \leq r \leq 1$ from

3. It states that for any function $g \in \mathcal{H}$, $\langle g, K_x\rangle_{\mathcal{H}} = g(x)$, where $\langle \cdot, \cdot \rangle_{\mathcal{H}}$ denotes the scalar product in the Hilbert space.

Zhang (2004), who studies stochastic gradient descent with averaging; whereas Tarrès and Yao (2011) give similar performance for $-1 \leq r \leq 0$. Interestingly, Ying and Pontil (2008) do not have saturation, meaning that the rate still improves for r smaller than -1. As it will appear, any algorithm based on a uniform averaging scheme faces a saturation issue : one cannot forget initial conditions faster than n^{-2}, which makes the algorithm sub-optimal in situations in which the optimal predictor is very smooth ($\mathcal{A}_5$ holds with $r \leq -1$). However, these papers only prove rates in the capacity-independent setting, meaning without assumption on the spectrum of the covariance matrix. Although the rate $O(n^{-\frac{1-r}{2-r}})$ is optimal in this setting, it comes from a worst-case analysis. Considering the capacity-dependent setting is more challenging, but allows to derive tighter and more realistic rates (a capacity condition always stands under the trace class assumption that is made). Moreover, the capacity-independent setting also does not allow to recover finite-dimensional rates. Up to our knowledge, there is no one pass stochastic gradient algorithm which does not have saturation while getting the minimax rate under both the capacity condition and source condition. In a recent work, Lin and Rosasco (2016) achieves optimality without saturation with multiple passes. We show in the next paragraphs that we can derive a tighter and optimal rate for both averaged-SGD (recovering results from Dieuleveut and Bach (2015)) and averaged-accelerated-SGD, for a larger class of kernels for the latter. Note that the averaging scheme for the RKHS setting was originally considered by Yao (2006).

We will first describe results for averaged-SGD, then increase the validity region of these rates (which depends on r, b) using averaged accelerated SGD. We show that the derived rates match statistical rates for our setting and thus our algorithms reach the optimal prediction performance for certain b and r.

6.1 Averaged SGD

We have the following result, proved in Appendix D and following from Theorem 2: for some fixed b, r, we choose the best step-size γ, that optimizes the bias-variance trade-off, while still satisfying the constraint $\gamma \leq 1/(2R^2)$. We get a result for the stochastic oracle (multiplicative/additive noise).

Theorem 7 *With $\lambda = \frac{1}{\gamma n}$, we have, if $r \leq b$, under Assumptions $(\mathcal{A}_{1,2,5,6})$ and the stochastic oracle Eq. (6), for any constant step-size γ such that $2\gamma(R^2 + 2\lambda) \leq 1$, with $\gamma \propto n^{\frac{-b+r}{b+1-r}}$, for the recursion in Eq. (9):*

$$\mathbb{E} f(\bar{\theta}_n) - f(\theta_*) \quad \leq \quad \left((27 + o(1)) \left\| \Sigma^{r/2} (\theta_0 - \theta_*) \right\|^2 + 6\sigma^2 \operatorname{tr}(\Sigma^b) \right) n^{-\frac{1-r}{b+1-r}}.$$

We can make the following remarks:

- The term $o(1)$ stands for a quantity which is decreasing to 0 when $n \to \infty$. More specifically, this constant is smaller than $3 \operatorname{tr}(\Sigma^b)$ divided by n^χ, where χ is bigger than 0 (see Appendix D). The result comes from Eq. (13) (which follows from Theorem 5), with the choice of the optimal step-size.
- We recover the same errors bounds as in Dieuleveut and Bach (2015), but with a simpler analysis resulting from the consideration of the regularized version of the problem associated with a choice of λ. However, we only recover rates in the finite horizon setting.
- This result shows that we get the optimal rate of convergence under Assumptions $(\mathcal{A}_{5,6})$, for $r \leq b$. This point will be discussed in more details after Theorem 8.

We now turn to the averaged accelerated SGD algorithm. We prove that it enjoys the optimal rate of convergence for a larger class of problems, but only for the additive noise which corresponds to knowing the distribution of x_n.

6.2 Averaged-Accelerated SGD

Similarly, choosing the best step-size γ, it comes from Theorem 5, that in the RKHS setting, under additional Assumptions $(\mathcal{A}_{5,6})$, we have for the the averaged accelerated algorithm the following result:

Theorem 8 *With $\lambda = \frac{1}{\gamma n^2}$, we have, if $r \leq b + 1/2$, under Assumptions $(\mathcal{A}_{4,5,6})$, for any constant step-size $\gamma \leq \frac{1}{L+\lambda}$, with $\gamma \propto n^{\frac{-2b+2r-1}{b+1-r}}$, for the recursion in Eq. (10):*

$$\mathbb{E} f(\bar{\theta}_n) - f(\theta_*) \quad \leq \quad \left(74 \left\| \Sigma^{r/2} (\theta_0 - \theta_*) \right\|^2 + 8\tau^2 \operatorname{tr}(\Sigma^b) \right) n^{-\frac{1-r}{b+1-r}}.$$

We can make the following remarks:

- The rate $\frac{1-r}{b+1-r}$ is always between 0 and 1, and improves when our assumptions gets stronger (r getting smaller, b getting smaller). Ultimately, with $b \to 0$, and $r \to -1$, we recover the finite-dimensional n^{-1} rate.
- We can achieve this optimal rate when $r \leq b + 1/2$. Beyond, if $r > b + 1/2$, the rate is only $n^{-2(1-r)}$. Indeed, the bias term cannot decrease faster than $n^{-2(1-r)}$, as γ is compelled to be upper bounded.
- The same phenomenon appears in the un-accelerated averaged situation, as shown by Theorem 7, but the critical value was then $r \leq b$. There is thus a region (precisely $b < r \leq b + 1/2$) in which only the accelerated algorithm gets the optimal rate of convergence. Note that we increase the optimality region towards optimization problems which are more ill-conditioned, naturally benefiting from acceleration.
- This algorithm cannot be computed in practice (at least with computational limits). Indeed, without any further assumption on the kernel K, it is not possible to compute images of vectors by the covariance operator Σ in the RKHS. However, as explained in the following remark, this is enough to show some form of optimality of our algorithm.

  Note that the easy computability is a great advantage of the multiplicative/additive noise variant of the algorithms, for which the current point θ_n can always be expressed as a finite sum of features $\theta_n = \sum_{i=1}^n \alpha_i K_{x_i}$, with $\alpha_i \in \mathbb{R}$, leading to a tractable algorithm. An accelerated variant of SGD naturally arises from our algorithm, when considering this stochastic oracle from Eq. (6). Such a variant can be implemented but does not behave similarly for large step sizes, say, $\gamma \simeq 1/(2R^2)$. It is an open problem to prove convergence results for averaged accelerated gradient under this multiplicative/additive noise.

- These rates happen to be optimal from a statistical perspective, meaning that no algorithm which is given access to the sample points and the distribution of x_n can perform better for all functions that satisfy assumption $(\mathcal{A}_6)$, for a kernel satisfying $(\mathcal{A}_5)$. Indeed it is equivalent to assuming that the function lives in some ellipsoid in the space of squared integrable functions. Note that the statistical minimization problem (and thus the lower bound) does not depend on the kernel, and is valid without computational limits. The case of learning with kernels is studied by Caponnetto and De Vito (2007) which shows these minimax convergence rates under $(\mathcal{A}_{5,6})$, under assumption that $-1 \leq r \leq 0$ (but state that it can be easily extended to $0 \leq r \leq 1$). They do not assume knowledge of the distribution of the inputs; however, Massart (2007) and Tsybakov (2008) discuss optimal rates on ellipsoids, and Györfi et al. (2006) proves similar results for certain class of functions under a known distribution for the input data, showing that the knowledge of the distribution does not make any difference. This minimax statistical rate stands without computational limits and is thus valid for both algorithms (additive noise that corresponds to knowing Σ, and multiplicative/additive noise). The optimal tradeoff is derived for an extended region of b, r (namely $r \leq b + 1/2$ instead of $r \leq b$) in the accelerated case which shows the improvement upon non-accelerated averaged SGD.

- The choice of the optimal γ is difficult in practice, as the parameters b, r are unknown, and this remains an open problem in general (see, e.g., Birgé, 2001, for some methods for non-parametric regression), even if in the capacity-independent setting, Orabona (2014) has proposed an algorithm that adapts to the unknown parameter r.

- Note that we do not give rates in terms of norm in the RHKS (i.e., an upper bound on $\|\bar{\theta}_n - \theta_*\|_{\mathcal{H}}$), because we mainly aim at extending optimality of prediction error rate to ill-conditioned cases (i.e. situations for which $r \geq b \geq 0$). In such a situation, Hilbert spaces norm bounds would not be relevant as the optimal estimator does not even live in the RKHS.

7. Experiments

We illustrate now our theoretical results on synthetic examples. For $d = 25$ we consider normally distributed inputs x_n with random covariance matrix Σ which has eigenvalues $1/i^3$, for $i = 1, \dots, d$, and random optimum θ_* and starting point θ_0 such that $\|\theta_0 - \theta_*\| = 1$. The outputs y_n are generated from a linear function with homoscedastic noise with unit signal to noise-ratio ($\sigma^2 = 1$), we take $R^2 = \operatorname{tr} \Sigma$ the average radius of the data and a step-size $\gamma = 1/R^2$ and $\lambda = 0$. The additive noise oracle is used. We show results averaged over 10 replications.

We compare the performance of averaged SGD (AvSGD), AccSGD (usual Nesterov acceleration for convex functions) and our novel averaged accelerated SGD from Section 4 AvAccSGD (which is not the averaging of AccSGD because the momentum term is proportional to $1 - 3/n$ for AccSGD instead of being equal to 1 for AvAccSGD), on two different problems: one deterministic ($\|\theta_0 - \theta_*\| = 1$, $\sigma^2 = 0$) which will illustrate how the bias term behaves, and one purely stochastic ($\|\theta_0 - \theta_*\| = 0$, $\sigma^2 = 1$) which will illustrate how the variance term behaves. For the bias (left plot of Figure 1), AvSGD converges at

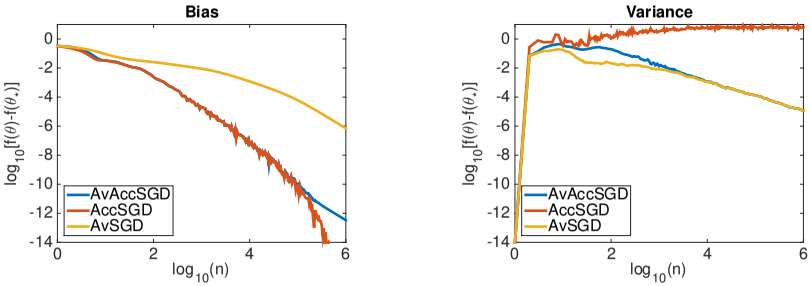

Figure 1: Synthetic problem ($d = 25$) and $\gamma = 1/R^2$. Left: Bias. Right: Variance.

speed $O(1/n)$, while AvAccSGD and AccSGD converge both at speed $O(1/n^2)$. However, as mentioned in the observations following Corollary 4, AccSGD takes advantage of the hidden strong convexity of the least-squares function and starts converging linearly at the end. For the variance (right plot of Figure 1), AccSGD is not converging to the optimum and keeps oscillating whereas AvSGD and AvAccSGD both converge to the optimum at a speed $O(1/n)$. However AvSGD remains slightly faster in the beginning.

Note that for small n, or when the bias $L\|\theta_0 - \theta_*\|^2/n^2$ is much bigger than the variance $\sigma^2 d/n$, the bias may have a stronger effect, although asymptotically, the variance always dominates. It is thus essential to have an algorithm which is optimal in both regimes; this is achieved by AvAccSGD.

8. Conclusion

In this paper, we showed that stochastic *averaged* accelerated gradient descent was robust to structured noise in the gradients present in least-squares regression. Beyond being the first algorithm which is jointly optimal in terms of both bias and finite-dimensional variance, it is also adapted to finer assumptions such as fast decays of the covariance matrices or optimal predictors with large norms.

Our current analysis is performed for least-squares regression. While it could be directly extended to smooth losses through efficient online Newton methods (Bach and Moulines, 2013), an extension to all smooth or self-concordant-like functions (Bach, 2014) would widen its applicability. Moreover, our accelerated gradient analysis is performed for additive noise (i.e., for least-squares regression, with knowledge of the population covariance matrix) and it would be interesting to study the robustness of our results in the contexts of least-mean squares and online learning. Finally, our analysis relies on single observations per iteration and could be made finer by using mini-batches (Cotter et al., 2011; Dekel et al., 2012), which should not change the variance term but could impact the bias term.

Acknowledgments

The authors would like to thank Damien Garreau for interesting discussions and the reviewers for their constructive and helpful comments.

Appendix A. Proofs of Section 3

We first prove the results of Section 3.

A.1 Proof of Lemma 1

We proof here Lemma 1 which is the extension of Lemma 2 of Bach and Moulines (2013) for the regularized case. The proof technique relies on the fact that recursions in Eq. (7) are linear since the cost function is quadratic which allows us to obtain $\theta_n - \theta_*$ in closed form.

For any regularization parameter $\lambda \in \mathbb{R}_+$ and any constant step-size $\gamma(\Sigma + \lambda I) \preccurlyeq I$ we may rewrite the regularized stochastic gradient recursion in Eq. (7) as:

$$\theta_n - \theta_* = \big[I - \gamma\Sigma - \gamma\lambda I\big](\theta_{n-1} - \theta_*) + \gamma\xi_n + \lambda\gamma(\theta_0 - \theta_*).$$

We thus get for $n \geq 1$ the expansion

$$\begin{aligned}
\theta_n - \theta_* &= (I - \gamma\Sigma - \gamma\lambda I)^n(\theta_0 - \theta_*) + \gamma\sum_{k=1}^{n}(I - \gamma\Sigma - \gamma\lambda I)^{n-k}\xi_k \\
&\quad + \gamma\lambda\sum_{k=1}^{n}(I - \gamma\Sigma - \gamma\lambda I)^{n-k}(\theta_0 - \theta_*) \\
&= (I - \gamma\Sigma - \gamma\lambda I)^n(\theta_0 - \theta_*) + \gamma\sum_{k=1}^{n}(I - \gamma\Sigma - \gamma\lambda I)^{n-k}\xi_k \\
&\quad + \lambda\big[I - (I - \gamma\Sigma - \gamma\lambda I)^n\big](\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*) \\
&= (I - \gamma\Sigma - \gamma\lambda I)^n[I - \lambda(\Sigma + \lambda I)^{-1}](\theta_0 - \theta_*) + \gamma\sum_{k=1}^{n}(I - \gamma\Sigma - \gamma\lambda I)^{n-k}\xi_k \\
&\quad + \lambda(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*).
\end{aligned}$$

We then have using the definition of the average

$$\begin{aligned}
n(\bar{\theta}_{n-1} - \theta_*) &= \sum_{j=0}^{n-1}(\theta_j - \theta_*) \\
&= \sum_{j=0}^{n-1}(I - \gamma\Sigma - \gamma\lambda I)^j[I - \lambda(\Sigma + \lambda I)^{-1}](\theta_0 - \theta_*) + \gamma\sum_{j=0}^{n-1}\sum_{k=1}^{j}(I - \gamma\Sigma - \gamma\lambda I)^{n-k}\xi_k \\
&\quad + n\lambda(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*).
\end{aligned}$$

For which we will compute the two sums separately

$$\begin{aligned}
&\sum_{j=0}^{n-1}(I - \gamma\Sigma - \gamma\lambda I)^j[I - \lambda(\Sigma + \lambda I)^{-1}](\theta_0 - \theta_*) \\
&\qquad = \frac{1}{\gamma}\big[I - (I - \gamma\Sigma - \gamma\lambda I)^n\big](\Sigma + \lambda I)^{-1}[I - \lambda(\Sigma + \lambda I)^{-1}](\theta_0 - \theta_*),
\end{aligned}$$

and

$$\begin{aligned}
\gamma\sum_{j=0}^{n-1}\sum_{k=1}^{j}(I - \gamma\Sigma - \gamma\lambda I)^{j-k}\xi_k &= \gamma\sum_{k=1}^{n-1}\Big(\sum_{j=k}^{n-1}(I - \gamma\Sigma - \gamma\lambda I)^{j-k}\Big)\xi_k \\
&= \gamma\sum_{k=1}^{n-1}\Big(\sum_{j=0}^{n-1-k}(I - \gamma\Sigma - \gamma\lambda I)^{j}\Big)\xi_k \\
&= \sum_{k=1}^{n-1}\big[I - (I - \gamma\Sigma - \gamma\lambda I)^{n-k}\big](\Sigma + \lambda I)^{-1}\xi_k.
\end{aligned}$$

Gathering the three terms together, we thus have

$$\begin{aligned}
n(\bar{\theta}_{n-1} - \theta_*) &= \frac{1}{\gamma}\big[I - (I - \gamma\Sigma - \gamma\lambda I)^n\big](\Sigma + \lambda I)^{-1}[I - \lambda(\Sigma + \lambda I)^{-1}](\theta_0 - \theta_*) \\
&\quad + \sum_{k=1}^{n-1}\big[I - (I - \gamma\Sigma - \gamma\lambda I)^{n-k}\big](\Sigma + \lambda I)^{-1}\xi_k + n\lambda(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*) \\
&= \Big[\frac{1}{\gamma}\big[I - (I - \gamma\Sigma - \gamma\lambda I)^n\big][I - \lambda(\Sigma + \lambda I)^{-1}] + n\lambda I\Big](\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*) \\
&\quad + \sum_{k=1}^{n-1}\big[I - (I - \gamma\Sigma - \gamma\lambda I)^{n-k}\big](\Sigma + \lambda I)^{-1}\xi_k.
\end{aligned}$$

Using standard martingale square moment inequalities which amount to consider ξ_i, $i = 1, \ldots, n$ independent, the variance of the sum is the sum of variances and we have for $V = \mathbb{E}\xi_n \otimes \xi_n$

$$\begin{aligned}
&n^2\mathbb{E}\|\Sigma^{1/2}(\bar{\theta}_{n-1} - \theta_*)\|^2 = \textstyle\sum_{k=1}^{n-1}\operatorname{tr}\big[I - (I - \gamma\Sigma - \gamma\lambda I)^{n-k}\big]^2\Sigma(\Sigma + \lambda I)^{-2}V \\
&+ \Big\|\Big[\frac{1}{\gamma}\big[I - (I - \gamma\Sigma - \gamma\lambda I)^n\big][I - \lambda(\Sigma + \lambda I)^{-1}] + n\lambda I\Big]\Sigma^{1/2}(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\Big\|^2. \quad (15)
\end{aligned}$$

Since all the matrices in this equality are symmetric positive-definite we are allowed to bound

$$\begin{aligned}
\Big[\frac{1}{\gamma}\big[I - (I - \gamma\Sigma - \gamma\lambda I)^n\big][I - \lambda(\Sigma + \lambda I)^{-1}] + n\lambda I\Big] &\preccurlyeq \Big(\frac{1}{\gamma} + n\lambda\Big)I \quad (16) \\
\big[I - (I - \gamma\Sigma - \gamma\lambda I)^{n-k}\big]^2 &\preccurlyeq I.
\end{aligned}$$

This concludes proof of the Lemma 1

$$\mathbb{E}\|\Sigma^{1/2}(\bar{\theta}_{n-1}-\theta_*)\|^2 \leq \Big(\frac{1}{n\gamma}+\lambda\Big)^2\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)\|^2 + \frac{1}{n}\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-2}V. \quad (17)$$

A.2 Proof When Only $\|\theta_0-\theta_*\|$ Is Finite

Unfortunately $\|\Sigma^{-1}(\theta_0-\theta_*)\|$ may not be finite. However we can use that for all $u\in[0,1]$ we have $\frac{1-(1-u)^n}{nu}\leq 1$[4] and have therefore the bound

$$\begin{aligned}
&\Big[\frac{1}{\gamma}\big[I-(I-\gamma\Sigma-\gamma\lambda I)^n\big][I-\lambda(\Sigma+\lambda I)^{-1}]+n\lambda I\Big][\Sigma+\lambda I]^{-1}\\
&\preccurlyeq \Big[\frac{1}{\gamma}\big[I-(I-\gamma\Sigma-\gamma\lambda I)^n\big]+n\lambda I\Big][\Sigma+\lambda I]^{-1}\\
&\preccurlyeq \Big[\frac{1}{\gamma}\big[I-(I-\gamma\Sigma-\gamma\lambda I)^n\big][\Sigma+\lambda I]^{-1}+n\lambda[\Sigma+\lambda I]^{-1}\Big]\\
&\preccurlyeq I+nI.
\end{aligned}$$

Combining with Eq. (16) we have

$$\Big\|\Big[\frac{1}{\gamma}\big[I-(I-\gamma\Sigma-\gamma\lambda I)^n\big][I-\lambda(\Sigma+\lambda I)^{-1}]+n\lambda I\Big]\Sigma^{1/2}(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)\Big\|^2 \leq (n+1)\Big(\frac{1}{\gamma}+n\lambda\Big)\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)\|^2,$$

which implies that

$$\mathbb{E}\|\Sigma^{1/2}(\bar{\theta}_{n-1}-\theta_*)\|^2 \leq 2\Big(\frac{1}{n\gamma}+\lambda\Big)\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)\|^2 + \frac{1}{n}\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-2}V, \quad (18)$$

which is interesting when only $\|\theta_0-\theta_*\|$ is finite.

A.3 Proof When the Noise Is Not Structured

The bound in Eq. (17) becomes less interesting when the noise is not structured. However using the same technique we have that $\big[I-(I-\gamma\Sigma-\gamma\lambda I)^{n-k}\big]^2(\Sigma+\lambda I)^{-1}\preccurlyeq(n-k)\gamma I$ and we get the following upper-bound on the variance

$$\begin{aligned}
\sum_{k=1}^n \operatorname{tr}\big[I-(I-\gamma\Sigma-\gamma\lambda I)^{n-k}\big]^2\Sigma(\Sigma+\lambda I)^{-2}V &\leq \gamma\sum_{k=1}^n(n-k)\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-1}V\\
&\leq \gamma\frac{n(n+1)}{2}\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-1}V.
\end{aligned}$$

4. since $\frac{1-(1-u)^n}{u}=\sum_{k=0}^n(1-u)^k\leq n$

Therefore we get

$$\mathbb{E}\|\Sigma^{1/2}(\bar{\theta}_{n-1}-\theta_*)\|^2 \leq \Big(\frac{1}{n\gamma}+\lambda\Big)^2\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)\|^2 + \gamma\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-1}V, \quad (19)$$

which is meaningful when the noise is not structured.

Appendix B. Proof of Theorem 2

In this section, we will prove Theorem 2. The proof relies on a decomposition of the error as the sum of three main terms which will be studied separately. We state decomposition in Section B.1 then prove upper bounds for the different terms in Sections B.2 and B.3.

B.1 Expansion of the Recursion

We may rewrite the regularized stochastic gradient recursion as:

$$\begin{aligned}
\theta_n &= \big[I-\gamma x_n\otimes x_n-\gamma\lambda I\big]\theta_{n-1}+\gamma\varepsilon_n x_n+\gamma\langle x_n,\theta_*\rangle x_n+\lambda\gamma\theta_0\\
\theta_n-\theta_* &= \big[I-\gamma x_n\otimes x_n-\gamma\lambda I\big](\theta_{n-1}-\theta_*)+\gamma\varepsilon_n x_n+\lambda\gamma(\theta_0-\theta_*).
\end{aligned}$$

For $i\geqslant k$, let

$$M(i,k)=\big[I-\gamma x_i\otimes x_i-\gamma\lambda I\big]\cdots\big[I-\gamma x_k\otimes x_k-\gamma\lambda I\big]$$

be an operator from $\mathcal{H}$ to $\mathcal{H}$. We have the expansion

$$\theta_n-\theta_*=M(n,1)(\theta_0-\theta_*)+\gamma\sum_{k=1}^n M(n,k+1)\varepsilon_k x_k+\gamma\sum_{k=1}^n M(n,k+1)\lambda(\theta_0-\theta_*).$$

Our goal is to study these three terms separately and bound $\|\Sigma^{1/2}(\bar{\theta}_n-\theta_*)\|$ for each of them.

B.2 Regularization-Based Bias Term

This is the term: $\theta_n-\theta_*=\gamma\sum_{k=1}^n M(n,k+1)\lambda(\theta_0-\theta_*)$, which corresponds to the recursion

$$\theta_n-\theta_*=\big(I-\gamma x_n\otimes x_n-\gamma\lambda I\big)(\theta_{n-1}-\theta_*)+\lambda\gamma(\theta_0-\theta_*), \quad (20)$$

initialized with $\theta_0=\theta_*$, and no noise.

Following the proof technique of Bach and Moulines (2013), we are going to consider a related recursion by replacing in Equation (20) the operator $x_n\otimes x_n$ by its expectation Σ. Thus, we consider η_n defined as

$$\eta_n-\theta_*=\gamma\sum_{k=1}^n(I-\gamma\Sigma-\lambda\gamma I)^{n-k}\lambda(\theta_0-\theta_*),$$

which satisfies the recursion (with initialization $\eta_0=\theta_*$) and

$$\eta_n-\theta_*=\big[I-\gamma\Sigma-\lambda\gamma I\big](\eta_{n-1}-\theta_*)+\lambda\gamma(\theta_0-\theta_*).$$

In order to bound $\|\Sigma^{1/2}(\theta_n-\theta_*)\|$, we will independently bound $\|\Sigma^{1/2}(\eta_n-\theta_*)\|$ and $\|\Sigma^{1/2}(\theta_n-\eta_n)\|$ using Minkowski's inequality.

Bounding $\|\Sigma^{1/2}(\theta_n - \eta_n)\|$. We have $\theta_0 - \eta_0 = 0$, and

$$\theta_n - \eta_n = \big[I - \gamma x_n \otimes x_n - \lambda\gamma I\big](\theta_{n-1} - \eta_{n-1}) + \gamma\big[\Sigma - x_n \otimes x_n\big](\eta_{n-1} - \theta_*).$$

We can now bound the recursion for $\theta_n - \eta_n$ as follows, using standard online learning proofs (Nemirovski et al., 2009):

$$\begin{aligned}\|\theta_n - \eta_n\|^2 \leqslant\ & \|\theta_{n-1} - \eta_{n-1}\|^2 - 2\gamma\big\langle \theta_{n-1} - \eta_{n-1}, (x_n \otimes x_n + \lambda I)(\theta_{n-1} - \eta_{n-1})\big\rangle \\ & + 2\gamma\big\langle \theta_{n-1} - \eta_{n-1}, \big[\Sigma - x_n \otimes x_n\big](\eta_{n-1} - \theta_*)\big\rangle \\ & + \gamma^2\big\| \big[x_n \otimes x_n + \lambda I\big](\theta_{n-1} - \eta_{n-1}) - \big[\Sigma - x_n \otimes x_n\big](\eta_{n-1} - \theta_*)\big\|^2.\end{aligned}$$

By taking conditional expectations given $\mathcal{F}_{n-1}$, we get, using first the fact that $\mathbb{E}(\Sigma - x_n \otimes x_n | \mathcal{F}_{n-1}) = 0$ and the inequality $(a+b)^2 \leq 2(a^2+b^2)$, then developing and using $\mathbb{E}[(x_n \otimes x_n)^2] \leq R^2\Sigma$, which is assumption $\mathcal{A}_1$.

$$\begin{aligned}\mathbb{E}\big(\|\theta_n - \eta_n\|^2 | \mathcal{F}_{n-1}\big) \leqslant\ & \|\theta_{n-1} - \eta_{n-1}\|^2 - 2\gamma\big\langle \theta_{n-1} - \eta_{n-1}, (\Sigma + \lambda I)(\theta_{n-1} - \eta_{n-1})\big\rangle \\ & + 2\gamma^2\mathbb{E}\big(\big\| \big[x_n \otimes x_n + \lambda I\big](\theta_{n-1} - \eta_{n-1})\big\|^2 | \mathcal{F}_{n-1}\big) \\ & + 2\gamma^2\mathbb{E}\big(\big\| \big[\Sigma - x_n \otimes x_n\big](\eta_{n-1} - \theta_*)\big\|^2 | \mathcal{F}_{n-1}\big) \\ \leqslant\ & \|\theta_{n-1} - \eta_{n-1}\|^2 - 2\gamma\big\langle \theta_{n-1} - \eta_{n-1}, (\Sigma + \lambda I)(\theta_{n-1} - \eta_{n-1})\big\rangle \\ & + 2\gamma^2\big\langle \theta_{n-1} - \eta_{n-1}, (R^2\Sigma + \lambda^2 I + 2\lambda\Sigma)(\theta_{n-1} - \eta_{n-1})\big\rangle \\ & + 2\gamma^2 R^2\langle \eta_{n-1} - \theta_*, \Sigma\rangle \\ \leqslant\ & \|\theta_{n-1} - \eta_{n-1}\|^2 - 2\gamma\big[1 - \gamma(R^2 + 2\lambda)\big]\big\langle \theta_{n-1} - \eta_{n-1}, \Sigma(\theta_{n-1} - \eta_{n-1})\big\rangle \\ & + 2\gamma^2 R^2\langle \eta_{n-1} - \theta_*, \Sigma(\eta_{n-1} - \theta_*)\rangle.\end{aligned}$$

This leads by taking full expectations and moving terms to

$$\begin{aligned}\mathbb{E}\big\langle \theta_{n-1} - \eta_{n-1}, \Sigma(\theta_{n-1} - \eta_{n-1})\big\rangle \leqslant\ & \frac{1}{2\gamma\big[1 - \gamma(R^2 + 2\lambda)\big]}\big[\mathbb{E}\|\theta_{n-1} - \eta_{n-1}\|^2 - \mathbb{E}\|\theta_n - \eta_n\|^2\big] \\ & + \frac{\gamma R^2}{1 - \gamma(R^2 + 2\lambda)}\langle \eta_{n-1} - \theta_*, \Sigma(\eta_{n-1} - \theta_*)\rangle.\end{aligned}$$

Thus, if $\gamma(R^2 + 2\lambda) \leqslant \frac{1}{2}$

$$\begin{aligned}\mathbb{E}\big\langle \theta_{n-1} - \eta_{n-1}, \Sigma(\theta_{n-1} - \eta_{n-1})\big\rangle \leqslant\ & \frac{1}{\gamma}\big[\mathbb{E}\|\theta_{n-1} - \eta_{n-1}\|^2 - \mathbb{E}\|\theta_n - \eta_n\|^2\big] \\ & + 2\gamma R^2\mathbb{E}\langle \eta_{n-1} - \theta_*, \Sigma(\eta_{n-1} - \theta_*)\rangle.\end{aligned}$$

This leads to, summing and using initial conditions $\theta_0 - \eta_0 = 0$, then using convexity to upper bound $\big\langle \bar\theta_n - \bar\eta_n, \Sigma(\bar\theta_n - \bar\eta_n)\big\rangle \leq \frac{1}{n+1}\sum_{k=0}^n \big\langle \theta_k - \eta_k, \Sigma(\theta_k - \eta_k)\big\rangle$,

$$\mathbb{E}\big\langle \bar\theta_n - \bar\eta_n, \Sigma(\bar\theta_n - \bar\eta_n)\big\rangle \leqslant \frac{2\gamma R^2}{n+1}\sum_{k=0}^n \langle \eta_k - \theta_*, \Sigma(\eta_k - \theta_*)\rangle.$$

Bounding $\|\Sigma^{1/2}(\eta_n - \theta_*)\|$. Moreover we have:

$$\begin{aligned}\eta_n - \theta_* &= \lambda(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*) - (I - \gamma\Sigma - \lambda\gamma I)^n\big[\lambda(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\big] \\ \bar\eta_n - \theta_* &= \lambda(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*) - \frac{1}{n+1}\sum_{k=0}^n (I - \gamma\Sigma - \lambda\gamma I)^k\big[\lambda(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\big] \\ &= \lambda(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*) \\ &\qquad - \frac{1}{n+1}\gamma^{-1}(\Sigma + \lambda I)^{-1}\big[I - (I - \gamma\Sigma - \lambda\gamma I)^{n+1}\big]\big[\lambda(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\big].\end{aligned}$$

This leads using Minkowski inequality to

$$\begin{aligned}\big(\mathbb{E}\|\Sigma^{1/2}(\eta_n - \theta_*)\|^2\big)^{1/2} &\leqslant \|\lambda\Sigma^{1/2}(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\| \\ \big(\mathbb{E}\|\Sigma^{1/2}(\bar\eta_n - \theta_*)\|^2\big)^{1/2} &\leqslant \|\lambda\Sigma^{1/2}(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\|.\end{aligned}$$

Thus this part is such that

$$\begin{aligned}\big(\mathbb{E}\|\Sigma^{1/2}(\bar\theta_n - \theta_*)\|^2\big)^{1/2} &\leqslant \|\lambda\Sigma^{1/2}(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\| \\ &\quad + \Big(2\gamma R^2\|\lambda\Sigma^{1/2}(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\|^2\Big)^{1/2} \\ &\leqslant \|\lambda\Sigma^{1/2}(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\|\big(1 + \sqrt{2\gamma R^2}\big),\end{aligned}$$

that gives the first bound on the regularization-based bias

$$\mathbb{E}\|\Sigma^{1/2}(\bar\theta_n - \theta_*)\|^2 \leqslant \|\lambda\Sigma^{1/2}(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\|^2\big(1 + \sqrt{2\gamma R^2}\big)^2. \tag{21}$$

B.3 Expansion without the Regularization Term

We will follow here the outline of the proof of Györfi and Walk (1996) which considers a full expansion of the function value $\|\Sigma^{1/2}(\bar\theta_n - \theta_*)\|^2$. This corresponds to

$$\theta_n - \theta_* = M(n,1)(\theta_0 - \theta_*) + \gamma\sum_{k=1}^n M(n,k+1)\varepsilon_k x_k.$$

We have

$$\mathbb{E}\sum_{i=0}^n\sum_{j=0}^n \langle \theta_i - \theta_*, \Sigma(\theta_j - \theta_*)\rangle = \mathbb{E}\sum_{i=0}^n \langle \theta_i - \theta_*, \Sigma(\theta_i - \theta_*)\rangle + 2\mathbb{E}\sum_{i=0}^{n-1}\sum_{j=i+1}^n \langle \theta_i - \theta_*, \Sigma(\theta_j - \theta_*)\rangle.$$

Moreover,

$$
\begin{aligned}
&\mathbb{E}\sum_{i=0}^{n-1}\sum_{j=i+1}^{n}\langle\theta_i-\theta_*,\Sigma(\theta_j-\theta_*)\rangle\\
&=\mathbb{E}\sum_{i=0}^{n-1}\sum_{j=i+1}^{n}\Big\langle\theta_i-\theta_*,\Sigma\Big[M(j,i+1)(\theta_i-\theta_*)+\sum_{k=i+1}^{j}M(j,k+1)\gamma\varepsilon_k x_k\Big]\Big\rangle\\
&=\mathbb{E}\sum_{i=0}^{n-1}\sum_{j=i+1}^{n}\langle\theta_i-\theta_*,\Sigma M(j,i+1)(\theta_i-\theta_*)\rangle \text{ because } \varepsilon_k x_k \text{ and } \theta_i \text{ are independent,}\\
&=\mathbb{E}\sum_{i=0}^{n-1}\sum_{j=i+1}^{n}\langle\theta_i-\theta_*,\Sigma(I-\gamma\Sigma-\gamma\lambda I)^{j-i}(\theta_i-\theta_*)\rangle \text{ as } M(j,i+1) \text{ and } \theta_i \text{ are independent,}\\
&=\mathbb{E}\sum_{i=0}^{n-1}\Big\langle\theta_i-\theta_*,\gamma^{-1}\Sigma(\Sigma+\lambda I)^{-1}\big[(I-\gamma\Sigma-\gamma\lambda I)-(I-\gamma\Sigma-\gamma\lambda I)^{n-i+1}\big](\theta_i-\theta_*)\Big\rangle\\
&\leqslant\mathbb{E}\sum_{i=0}^{n}\Big\langle\theta_i-\theta_*,\gamma^{-1}\Sigma(\Sigma+\lambda I)^{-1}(I-\gamma\Sigma-\gamma\lambda I)(\theta_i-\theta_*)\Big\rangle \text{ using } (\Sigma+\lambda I)\preccurlyeq I,\\
&=\gamma^{-1}\mathbb{E}\sum_{i=0}^{n}\langle\theta_i-\theta_*,\Sigma(\Sigma+\lambda I)^{-1}(\theta_i-\theta_*)\rangle-\mathbb{E}\sum_{i=0}^{n}\langle\theta_i-\theta_*,\Sigma(\theta_i-\theta_*)\rangle.
\end{aligned}
$$

We thus simply need to bound $\gamma^{-1}\mathbb{E}\sum_{i=0}^{n}\langle\theta_i-\theta_*,\Sigma(\Sigma+\lambda I)^{-1}(\theta_i-\theta_*)\rangle$, to get a bound on $n^2\mathbb{E}\|\Sigma^{1/2}(\bar\theta_n-\theta_*)\|^2$.

Recursion on operators. We have:

$$
\begin{aligned}
\mathbb{E}\big[M(i,k)\Sigma(\Sigma+\lambda I)^{-1}M(i,k)^*\big] &= \mathbb{E}\Big[M(i,k+1)\big[I-\gamma x_k\otimes x_k-\gamma\lambda I\big]\Sigma(\Sigma+\lambda I)^{-1}\\
&\quad\big[I-\gamma x_k\otimes x_k-\gamma\lambda I\big]M(i,k+1)^*\Big]\\
&= \mathbb{E}\Big[M(i,k+1)\Big(\Sigma(\Sigma+\lambda I)^{-1}-2\gamma\Sigma+\gamma^2\big[x_k\otimes x_k\\
&\quad+\lambda I\big]\Sigma(\Sigma+\lambda I)^{-1}\big[x_k\otimes x_k+\lambda I\big]\Big)M(i,k+1)^*\Big]\\
&\preccurlyeq \mathbb{E}\Big[M(i,k+1)\big[\Sigma(\Sigma+\lambda I)^{-1}-2\gamma\Sigma\\
&\quad+\gamma^2(R^2+2\lambda)\Sigma\big]M(i,k+1)^*\Big]\\
&= \mathbb{E}\Big[M(i,k+1)\Sigma(\Sigma+\lambda I)^{-1}M(i,k+1)^*\Big]\\
&\quad-\gamma(2-\gamma(R^2+2\lambda))\mathbb{E}\Big[M(i,k+1)\Sigma M(i,k+1)^*\Big],
\end{aligned}
$$

which leads to

$$
\begin{aligned}
\mathbb{E}\Big[M(i,k+1)\Sigma M(i,k+1)^*\Big] &\preccurlyeq \frac{1}{\gamma(2-\gamma(R^2+2\lambda))}\Big(E\Big[M(i,k+1)\Sigma(\Sigma+\lambda I)^{-1}M(i,k+1)^*\Big]\\
&\quad-E\Big[M(i,k)\Sigma(\Sigma+\lambda I)^{-1}M(i,k)^*\Big]\Big). \qquad (22)
\end{aligned}
$$

Using the operator T on matrices defined below, this corresponds to showing

$$
(I-\gamma T)\big[\Sigma(\Sigma+\lambda I)\big]\preccurlyeq\Sigma(\Sigma+\lambda I)-\gamma\Sigma.
$$

Noise term. For $\theta_0-\theta_*=0$, we have:

$$
\begin{aligned}
&\mathbb{E}\langle\theta_i-\theta_*,\Sigma(\Sigma+\lambda I)^{-1}(\theta_i-\theta_*)\rangle\\
=\;&\gamma^2\mathbb{E}\sum_{k=1}^{i}\sum_{j=1}^{i}\varepsilon_j x_j^*M(i,j+1)^*\Sigma(\Sigma+\lambda I)^{-1}M(i,k+1)\varepsilon_k x_k \text{ by expanding all terms,}\\
=\;&\gamma^2\mathbb{E}\sum_{k=1}^{i}\varepsilon_k x_k^*M(i,k+1)^*\Sigma(\Sigma+\lambda I)^{-1}M(i,k+1)\varepsilon_k x_k \text{ using independence,}\\
=\;&\gamma^2\operatorname{tr}\Big(\sum_{k=1}^{i}\mathbb{E}\varepsilon_k^2x_kx_k^*\mathbb{E}M(i,k+1)^*\Sigma(\Sigma+\lambda I)^{-1}M(i,k+1)\Big)\\
\leqslant\;&\gamma^2\sigma^2\operatorname{tr}\Big(\sum_{k=1}^{i}\mathbb{E}M(i,k+1)\Sigma M(i,k+1)^*\Sigma(\Sigma+\lambda I)^{-1}\Big)\\
&\text{using our assumption regarding the noise.}
\end{aligned}
$$

Using the recurrence between operators

$$
\begin{aligned}
&\mathbb{E}\langle\theta_i-\theta_*,\Sigma(\Sigma+\lambda I)^{-1}(\theta_i-\theta_*)\rangle\\
\leqslant\;&\frac{\gamma\sigma^2}{2-\gamma(R^2+2\lambda)}\operatorname{tr}\sum_{k=1}^{i}\Big(E\Big[M(i,k+1)\Sigma(\Sigma+\lambda I)^{-1}M(i,k+1)^*\Sigma(\Sigma+\lambda I)^{-1}\Big]\\
&-E\Big[M(i,k)\Sigma(\Sigma+\lambda I)^{-1}M(i,k)^*\Sigma(\Sigma+\lambda I)^{-1}\Big]\Big)\\
\leqslant\;&\frac{\gamma\sigma^2}{2-\gamma(R^2+2\lambda)}\operatorname{tr}\Big(E\Big[M(i,i+1)\Sigma(\Sigma+\lambda I)^{-1}M(i,i+1)^*\Sigma(\Sigma+\lambda I)^{-1}\Big]\\
&-E\Big[M(i,1)\Sigma(\Sigma+\lambda I)^{-1}M(i,1)^*\Sigma(\Sigma+\lambda I)^{-1}\Big]\Big) \text{ by summing,}\\
\leqslant\;&\frac{\gamma\sigma^2}{2-\gamma(R^2+2\lambda)}\operatorname{tr}\Sigma^2(\Sigma+\lambda I)^{-2}.
\end{aligned}
$$

This implies that for the noise process

$$
\mathbb{E}\|\Sigma^{1/2}(\bar\theta_n-\theta_*)\|^2\leqslant\Big(\frac{\sigma^2}{n+1}\operatorname{tr}\big[\Sigma^2(\Sigma+\lambda I)^{-2}\big]\Big)\frac{1}{1-\gamma(R^2/2+\lambda)}.
$$

Note that when γ tends to zero, we recover the optimal variance term.

Noiseless term. Without noise, we then need to bound:

$$
\gamma^{-1}\mathbb{E}\sum_{i=0}^{n}\langle\theta_i-\theta_*,\Sigma(\Sigma+\lambda I)^{-1}(\theta_i-\theta_*)\rangle,
$$

with $\theta_i - \theta_* = M(i,1)(\theta_0 - \theta_*)$, that is

$$\gamma^{-1}\mathbb{E}\sum_{i=0}^{n} \operatorname{tr}\Big[M(i,1)^*\Sigma(\Sigma+\lambda I)^{-1}M(i,1)(\theta_0-\theta_*)(\theta_0-\theta_*)^*\Big].$$

We follow here the proof of Défossez and Bach (2015) and consider the operator T from symmetric matrices to symmetric matrices defined as

$$TA = (\Sigma+\lambda I)A + A(\Sigma+\lambda I) - \gamma E\big[(x_n\otimes x_n+\lambda I)A(x_n\otimes x_n+\lambda I)\big].$$

of the form $TA = (\Sigma+\lambda I)A + (\Sigma+\lambda I)A - \gamma SA$.

The operator S is self-adjoint and positive. Moreover:

$$\begin{aligned}
\langle A, SA\rangle &= \mathbb{E}\operatorname{tr}\big[A(x_n\otimes x_n+\lambda I)A(x_n\otimes x_n+\lambda I)\big]\\
&= \operatorname{tr}\big[2A^2\lambda\Sigma+\lambda^2A^2\big] + \mathbb{E}\operatorname{tr}\big[\langle x_n, Ax_n\rangle^2\big]\\
&\leqslant \operatorname{tr}\big[2A^2\lambda\Sigma+\lambda^2A^2\big] + \mathbb{E}\operatorname{tr}\big[\|x_n\|^2x_n\otimes x_n, A^2\big] \text{ using Cauchy-Schwarz inequality,}\\
&\leqslant \operatorname{tr}\big[2A^2\lambda\Sigma+\lambda^2A^2\big] + R^2\operatorname{tr}\Sigma A^2\\
&\leqslant (R^2+2\lambda)\operatorname{tr}\big[\Sigma+\lambda I]A^2.
\end{aligned}$$

We have for any symmetric matrix A:

$$\mathbb{E}M(i,1)^*AM(i,1) = (I-\gamma T)^iA.$$

Thus,

$$\gamma^{-1}\mathbb{E}\sum_{i=0}^{n}\operatorname{tr}\Big[M(i,1)^*\Sigma(\Sigma+\lambda I)^{-1}M(i,1)(\theta_0-\theta_*)(\theta_0-\theta_*)^*\Big] = \gamma^{-1}\mathbb{E}\sum_{i=0}^{n}\langle\langle(I-\gamma T)^iA, E_0\rangle\rangle$$

with $E_0 = (\theta_0-\theta_*)(\theta_0-\theta_*)^*$ and $A = \Sigma(\Sigma+\lambda I)^{-1}$. This leads to

$$\gamma^{-1}\mathbb{E}\langle\langle\gamma^{-1}T^{-1}(I-(I-\gamma T)^{n+1})A, E_0\rangle\rangle,$$

where $\langle\langle\cdot,\cdot\rangle\rangle$ denote the dot-product between self-adjoint operators.

The sum is less than its limit for $n\to\infty$, and thus, we can get rid of the term $(I-\gamma T)^{n+1}$, and we need to bound

$$\gamma^{-2}\langle\langle M, E_0\rangle\rangle = \gamma^{-2}\langle\langle T^{-1}(\Sigma(\Sigma+\lambda I)^{-1}), E_0\rangle\rangle,$$

with $M := T^{-1}\big[\Sigma(\Sigma+\lambda I)^{-1}\big]$, i.e., such that

$$\begin{aligned}
\Sigma(\Sigma+\lambda I)^{-1} &= (\Sigma+\lambda I)M + M(\Sigma+\lambda I) - \gamma\mathbb{E}(x_n\otimes x_n+\lambda I)M(x_n\otimes x_n+\lambda I)\\
&= (\Sigma+\lambda I)M + M(\Sigma+\lambda I) - \gamma SM. \qquad (23)
\end{aligned}$$

So that :

$$\begin{aligned}
M &= \big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1}\big[\Sigma(\Sigma+\lambda I)^{-1}\big] + \gamma\big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1}SM\\
&= \frac{1}{2}\Sigma(\Sigma+\lambda I)^{-2} + \gamma\big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1}SM.
\end{aligned}$$

The operator $(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)$ is self adjoint, and so is its inverse, thus:

$$\begin{aligned}
\gamma^{-2}\langle\langle M, E_0\rangle\rangle &= \gamma^{-2}\langle\langle\frac{1}{2}\Sigma(\Sigma+\lambda I)^{-2} + \gamma\big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1}SM, E_0\rangle\rangle\\
&= \frac{1}{2}\gamma^{-2}\langle\langle\Sigma(\Sigma+\lambda I)^{-2}, E_0\rangle\rangle + \gamma^{-1}\langle\langle SM, \big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1}E_0\rangle\rangle\\
&= \frac{1}{2}\gamma^{-2}\operatorname{tr}(\Sigma(\Sigma+\lambda I)^{-2}E_0) + \gamma^{-1}\langle\langle SM, \big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1}E_0\rangle\rangle.
\end{aligned}$$

Moreover,

$$\begin{aligned}
E_0 &= (\theta_0-\theta_*)(\theta_0-\theta_*)^*\\
&= (\Sigma+\lambda I)^{1/2}(\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)(\theta_0-\theta_*)^*(\Sigma+\lambda I)^{-1/2}(\Sigma+\lambda I)^{+1/2}\\
&\preccurlyeq [(\theta_0-\theta_*)^*(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)]\ \ (\Sigma+\lambda I),\\
&\qquad \text{as } (\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)(\theta_0-\theta_*)^*(\Sigma+\lambda I)^{-1/2} \preccurlyeq (\theta_0-\theta_*)^*(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)I.
\end{aligned}$$

Thus, as $[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)]^{-1}$ is an non-decreasing operator on $(S_n(\mathbb{R}), \preccurlyeq)$ (see technical Lemma 15 in Appendix E):

$$\begin{aligned}
&\big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1}E_0\\
\preccurlyeq\ &\big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1}\big([(\theta_0-\theta_*)^*(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)](\Sigma+\lambda I)\big)\\
=\ &\frac{(\theta_0-\theta_*)^*(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)}{2}I.
\end{aligned}$$

Thus as SM is positive :

$$\gamma^{-2}\langle\langle M, E_0\rangle\rangle \leq \frac{1}{2\gamma^2}\operatorname{tr}(\Sigma(\Sigma+\lambda I)^{-2}E_0) + \frac{(\theta_0-\theta_*)^*(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)}{2\gamma}\operatorname{tr}(SM).$$

Moreover we can upper bound $\operatorname{tr}(SM)$: using Equation (23) we have

$$\operatorname{tr}(\Sigma(\Sigma+\lambda I)^{-1}) = 2\operatorname{tr}(\Sigma+\lambda I)M - \gamma\operatorname{tr}\mathbb{E}(x_n\otimes x_n+\lambda I)M(x_n\otimes x_n+\lambda I)$$

then, using Assumption $(\mathcal{A}_1)$:

$$\operatorname{tr}\mathbb{E}(x_n\otimes x_n+\lambda I)M(x_n\otimes x_n+\lambda I) \leqslant R^2\operatorname{tr}M\Sigma + 2\operatorname{tr}M\Sigma\lambda + \lambda^2\operatorname{tr}M \leqslant (R^2+2\lambda)\operatorname{tr}M(\Sigma+\lambda I).$$

This implies

$$\begin{aligned}
\operatorname{tr}\big[\Sigma(\Sigma+\lambda I)^{-1}\big] &\geqslant \big(\frac{2}{R^2+2\lambda}-\gamma\big)\operatorname{tr}\mathbb{E}(x_n\otimes x_n+\lambda I)M(x_n\otimes x_n+\lambda I),\\
&\geqslant \frac{1}{R^2+2\lambda}\operatorname{tr}\mathbb{E}(x_n\otimes x_n+\lambda I)M(x_n\otimes x_n+\lambda I) \text{ since } \gamma(R^2+2\lambda)\leqslant 1,\\
&\geqslant \frac{1}{R^2+2\lambda}\operatorname{tr}SM.
\end{aligned}$$

Thus finally:

$$\begin{aligned}
\gamma^{-2}\langle\langle M, E_0\rangle\rangle \leq\ &\frac{1}{2\gamma^2}\operatorname{tr}E_0\Sigma(\Sigma+\lambda I)^{-2}\\
&+ \frac{(\theta_0-\theta_*)^*(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)}{2\gamma}(R^2+2\lambda)\operatorname{tr}(\Sigma(\Sigma+\lambda I)^{-1}),
\end{aligned}$$

which leads to the desired error term.

B.4 Proof When Only $\|\theta_0 - \theta_*\|$ Is Finite

When $\lambda = 0$, without noise, we then need to bound:

$$\gamma^{-1}\mathbb{E}\sum_{i=0}^{n}\langle\theta_i - \theta_*, \theta_i - \theta_*\rangle,$$

with $\theta_i - \theta_* = M(i,1)(\theta_0 - \theta_*)$, that is

$$\gamma^{-1}\mathbb{E}\sum_{i=0}^{n}\operatorname{tr}\Big[M(i,1)^*M(i,1)(\theta_0 - \theta_*)(\theta_0 - \theta_*)^*\Big].$$

By definition of $M(i,1)$ we have that $\mathbb{E}M(i,1)^*M(i,1) \preccurlyeq I$ leading to

$$\gamma^{-1}\mathbb{E}\sum_{i=0}^{n}\langle\theta_i - \theta_*, \theta_i - \theta_*\rangle \leq \frac{(n+1)\|\theta_0 - \theta_*\|^2}{\gamma}.$$

For the regularization-based bias we also have

$$\|\lambda\Sigma^{1/2}(\Sigma + \lambda I)^{-1}(\theta_0 - \theta_*)\|^2 \leq \lambda\|\Sigma^{1/2}(\Sigma + \lambda I)^{-1/2}(\theta_0 - \theta_*)\|^2.$$

B.5 Proof When the Noise Is Not Structured

For $\|\theta_0 - \theta_*\| = 0$ we have $\theta_n - \theta_* = \gamma\sum_{k=1}^{n} M(n,k+1)\varepsilon_k x_k$ which leads to

$$\mathbb{E}\|\Sigma^{1/2}(\theta_n - \theta_*)\|^2 = \gamma^2\sum_{k=1}^{n}\operatorname{tr}\mathbb{E}M(n,k+1)^*\Sigma M(n,k+1)V,$$

where $V = \mathbb{E}\varepsilon_k^2 x_k x_k^*$. And using the recursion on operators in Eq. (22) by changing order of elements we have

$$\begin{aligned}\mathbb{E}\Big[M(n,k+1)^*\Sigma M(n,k+1)\Big] \preccurlyeq \frac{1}{\gamma(2-\gamma(R^2+2\lambda))}\Big(&E\Big[M(n,k+1)^*\Sigma(\Sigma+\lambda I)^{-1}M(n,k+1)\Big]\\ &- E\Big[M(n,k)^*\Sigma(\Sigma+\lambda I)^{-1}M(n,k)\Big]\Big).\end{aligned}$$

And by adding the terms

$$\mathbb{E}\|\Sigma^{1/2}(\theta_n - \theta_*)\|^2 \preccurlyeq \frac{\gamma^2}{\gamma(2-\gamma(R^2+2\lambda))}\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-1}V,$$

We conclude by convexity

$$\mathbb{E}\|\Sigma^{1/2}(\bar{\theta}_n - \theta_*)\|^2 \preccurlyeq \frac{\gamma^2}{\gamma(2-\gamma(R^2+2\lambda))}\operatorname{tr}\Sigma(\Sigma+\lambda I)^{-1}V.$$

Appendix C. Convergence of Accelerated Averaged Stochastic Gradient Descent

We now prove Theorem 3. We thus consider iterates satisfying Eq. (10), under Assumptions $(\mathcal{A}_3)$, $(\mathcal{A}_4)$. We consider a fixed step size γ such that $\gamma(\Sigma + \lambda I) \preccurlyeq I$. Seeing Eq. (10) as a linear second order for θ_n, we will derive from exact calculations a decomposition of the errors a sum of three terms that will be studied independently. The proof is organized as follows: in Section C.1, we state the formulation as a second order linear system and derive the three main terms that have to be studied (see Lemma 9). Section C.2 studies asymptotic behaviors of the three terms, ignoring some exponentially decreasing terms, in order to give insight of how they behave. This section is not necessary for the proof, indeed a direct and exact calculation in the eigenbasis of Σ, following O'Donoghue and Candès (2013), is provided in Section C.3. Results are summed up in Section C.4.

C.1 General Expansion

We study the regularized stochastic accelerated gradient descent recursion defined for $n \geq 1$ by

$$\begin{aligned}\theta_n &= \nu_{n-1} - \gamma f'(\nu_{n-1}) - \gamma\lambda(\nu_n - \theta_0) + \gamma\xi_n\\ \nu_n &= \theta_n + \delta(\theta_n - \theta_{n-1}),\end{aligned}$$

starting from $\theta_0 = \nu_0 \in \mathcal{H}$. We may rewrite it for a quadratic function $f : \theta \mapsto \frac{1}{2}\langle\theta - \theta_*, \Sigma(\theta - \theta_*)\rangle$ for $n \geq 2$ as

$$\theta_n = \big[I - \gamma\Sigma - \gamma\lambda I\big]\Big[\theta_{n-1} + \delta(\theta_{n-1} - \theta_{n-2})\Big] + \gamma\xi_n + \gamma\lambda\theta_0 + \gamma\Sigma\theta_*,$$

with $\theta_0 \in \mathcal{H}$ and $\theta_1 = \big[I - \gamma\Sigma - \gamma\lambda I\big]\theta_0 + \gamma\xi_1 + \gamma\lambda\theta_0 + \gamma\Sigma\theta_*$.

And by centering around the optimum, we get:

$$\theta_n - \theta_* = \big[I - \gamma\Sigma - \gamma\lambda I\big]\big[\theta_{n-1} - \theta_* + \delta(\theta_{n-1} - \theta_* - \theta_{n-2} + \theta_*)\big] + \gamma\xi_n + \lambda\gamma(\theta_0 - \theta_*).$$

Thus this is a second order iterative system which is standard to cast in a linear form

$$\Theta_n = F\Theta_{n-1} + \gamma\Xi_n + \gamma\lambda\Theta_\lambda, \tag{24}$$

with $T = I - \gamma\Sigma - \gamma\lambda I$, $F = \begin{pmatrix}(1+\delta)T & -\delta T\\ I & 0\end{pmatrix}$, $\Theta_n = \begin{pmatrix}\theta_n - \theta_*\\ \theta_{n-1} - \theta_*\end{pmatrix}$, $\Theta_0 = \begin{pmatrix}\theta_0 - \theta_*\\ \theta_0 - \theta_*\end{pmatrix}$, $\Xi_n = \begin{pmatrix}\xi_n\\ 0\end{pmatrix}$ and $\Theta_\lambda = \begin{pmatrix}\theta_0 - \theta_*\\ 0\end{pmatrix}$.

We are interested in the behavior of the average $\bar{\Theta}_n = \frac{1}{n+1}\sum_{k=0}^{n}\Theta_k$ for which we have the following general convergence result:

Lemma 9 *For all $\lambda \in \mathbb{R}_+$ and γ such that $\gamma(\Sigma + \lambda I) \preccurlyeq I$ and any matrix C the average of the iterates Θ_n defined by Eq. (24) satisfy for $P_k \overset{(def)}{=} C^{1/2}(I - F^k)(I - F)^{-1}$, with*

$\tilde{\Theta}_0 = \Theta_0 - \gamma\lambda(I-F)^{-1}\Theta_\lambda$,

$$\begin{aligned}\mathbb{E}\langle \bar{\Theta}_n, C\bar{\Theta}_n\rangle &\leq 2\,(\gamma\lambda)^2\,\|C^{1/2}(I-F)^{-1}\Theta_\lambda\|^2 + \frac{2}{(n+1)^2}\|P_{n+1}\tilde{\Theta}_0\|^2 \\ &\quad + \frac{\gamma^2}{(n+1)^2}\sum_{j=1}^n \operatorname{tr} P_j V P_j^\top.\end{aligned}$$

The error thus decomposes as the sum of three main terms:

- the two first ones are bias terms, one arising from the regularization (the first one), and one arising computation (the second one),
- a variance term. which is the last one.

We remark that as we have assumed that Σ is invertible, the matrix $I-F$ can be shown to be invertible for all the considered δ.

The regularization-based term will be studied directly whereas the two others will be studied in two stages. First a heuristic will lead to an asymptotic bound then an exact computation will give a non-asymptotic bound. Then using $C = H = \begin{pmatrix}\Sigma & 0\\ 0 & 0\end{pmatrix}$ would give a convergence result on the function value and $C = \begin{pmatrix}I & 0\\ 0 & 0\end{pmatrix}$ a result on the iterate. The end of the section is devoted to the proof of this lemma.

Proof The sequence Θ_n satisfies a linear recursion, from which we get, for all $n \geq 1$:

$$\begin{aligned}\Theta_n &= F^n\Theta_0 + \gamma\sum_{k=1}^n F^{n-k}\Xi_k + \gamma\lambda\sum_{k=1}^n F^{n-k}\Theta_\lambda \\ &= F^n\Theta_0 + \gamma\sum_{k=1}^n F^{n-k}\Xi_k + \gamma\lambda(I-F^n)(I-F)^{-1}\Theta_\lambda.\end{aligned}$$

We study the averaged sequence: $\bar{\Theta}_n = \frac{1}{n+1}\sum_{k=0}^n \Theta_k$. Using the identity $\sum_{k=0}^{n-1} F^k = (I-F^n)(I-F)^{-1}$, we get

$$\bar{\Theta}_n = \frac{1}{n+1}\sum_{k=0}^n F^k\Theta_0 + \frac{\gamma}{n+1}\sum_{k=1}^n\sum_{j=1}^k F^{k-j}\Xi_j + \frac{\gamma\lambda}{n+1}\sum_{k=1}^n (I-F^k)(I-F)^{-1}\Theta_\lambda.$$

With

$$\tilde{\Theta}_0 = \Theta_0 - \gamma\lambda(I-F)^{-1}\Theta_\lambda,$$

and $\sum_{k=1}^n (I-F^k) = \sum_{k=0}^n (I-F^k) = [n+1-(I-F^{n+1})(I-F)^{-1}]$.

Using summation formulas for geometric series, we derive:

$$\begin{aligned}\bar{\Theta}_n &= \frac{1}{n+1}(I-F^{n+1})(I-F)^{-1}\tilde{\Theta}_0 + \frac{\gamma}{n+1}\sum_{k=1}^n\sum_{j=1}^k F^{k-j}\Xi_j + \gamma\lambda(I-F)^{-1}\Theta_\lambda \\ &= \frac{1}{n+1}(I-F^{n+1})(I-F)^{-1}\tilde{\Theta}_0 + \frac{\gamma}{n+1}\sum_{j=1}^n\Big(\sum_{k=j}^n F^{k-j}\Big)\Xi_j + \gamma\lambda(I-F)^{-1}\Theta_\lambda \\ &= \frac{1}{n+1}(I-F^{n+1})(I-F)^{-1}\tilde{\Theta}_0 + \frac{\gamma}{n+1}\sum_{j=1}^n\Big(\sum_{k=0}^{n-j} F^{k}\Big)\Xi_j + \gamma\lambda(I-F)^{-1}\Theta_\lambda \\ &= \frac{1}{n+1}(I-F^{n+1})(I-F)^{-1}\tilde{\Theta}_0 + \frac{\gamma}{n+1}\sum_{j=1}^n(I-F^{n+1-j})(I-F)^{-1}\Xi_j + \gamma\lambda(I-F)^{-1}\Theta_\lambda \\ &= \frac{1}{n+1}(I-F^{n+1})(I-F)^{-1}\tilde{\Theta}_0 + \frac{\gamma}{n+1}\sum_{j=1}^n(I-F^{j})(I-F)^{-1}\Xi_{n+1-j} + \gamma\lambda(I-F)^{-1}\Theta_\lambda.\end{aligned}$$

Using martingale square moment inequalities which amount to consider $\Xi_i, i = 1, ..., n$ independent, so that the variance of the sum is the sum of variances, and denoting by $V = \mathbb{E}[\Xi_n \otimes \Xi_n]$ we have for any positive semi-definite C,

$$\begin{aligned}\mathbb{E}\langle \bar{\Theta}_n, C\bar{\Theta}_n\rangle &= \Big\|C^{1/2}\Big(\frac{1}{n+1}(I-F^{n+1})(I-F)^{-1}\tilde{\Theta}_0 + \gamma\lambda(I-F)^{-1}\Theta_\lambda\Big)\Big\|^2 \\ &\quad + \frac{\gamma^2}{(n+1)^2}\sum_{j=1}^n \operatorname{tr}(I-F^j)(I-F)^{-1}V(I-F^\top)^{-1}(I-F^j)^\top C,\end{aligned}$$

where $C^{1/2}$ denotes a symmetric square root of C. Define $P_k \overset{(def)}{=} C^{1/2}(I-F^k)(I-F)^{-1}$, we have, Using Minkowski's inequality and inequality $(a+b)^2 \leq 2(a^2+b^2)$ for any $a, b \in \mathbb{R}$,

$$\begin{aligned}\mathbb{E}\langle \bar{\Theta}_n, C\bar{\Theta}_n\rangle &= \Big\|\frac{1}{n+1}P_{n+1}\tilde{\Theta}_0 + \gamma\lambda C^{1/2}(I-F)^{-1}\Theta_\lambda\Big\|^2 + \frac{\gamma^2}{(n+1)^2}\sum_{j=1}^n \operatorname{tr} P_j V P_j^\top \\ &\leq 2\,(\gamma\lambda)^2\,\|C^{1/2}(I-F)^{-1}\Theta_\lambda\|^2 + \frac{2\|P_{n+1}\tilde{\Theta}_0\|^2}{(n+1)^2} + \frac{\gamma^2}{(n+1)^2}\sum_{j=1}^n \operatorname{tr} P_j V P_j^\top.\end{aligned}$$

This concludes proof of Lemma 9. ■

C.2 Asymptotic Expansion

To give the main terms that we expect, we first provide an asymptotic analysis, which shall only be understood as an insight and is not necessary for the proof. Operator F will have only eigenvalues smaller than 1, thus $\|\|F^j\|\|$ will decrease exponentially to 0 as $j \to \infty$ (even if $\|\|F\|\|$[5] might be bigger than 1). The asymptotic analysis relies on ignoring all terms in

5. $\|\|F\|\|$ denotes the operator norm of F, i.e., $\sup_{\|x\|\leq 1}\|Fx\|$.

which F^j appears. We thus approximately have:

$$\begin{aligned}\mathbb{E}\langle\bar{\Theta}_n, C\bar{\Theta}_n\rangle &\leq 2(\gamma\lambda)^2\|C^{1/2}(I-F)^{-1}\Theta_\lambda\|^2 + 2\Big\|C^{1/2}\frac{1}{n+1}(I-F^{n+1})(I-F)^{-1}\tilde{\Theta}_0\Big\|^2 \\ &\quad + \frac{\gamma^2}{(n+1)^2}\sum_{j=1}^n \operatorname{tr}(I-F^j)(I-F)^{-1}V(I-F^\top)^{-1}(I-F^j)^\top C \\ &\approx 2(\gamma\lambda)^2\|C^{1/2}(I-F)^{-1}\Theta_\lambda\|^2 + 2\Big\|C^{1/2}\frac{1}{n+1}(I-F)^{-1}\tilde{\Theta}_0\Big\|^2 \\ &\quad + \frac{\gamma^2}{(n+1)^2}\sum_{j=1}^n \operatorname{tr}(I-F)^{-1}V(I-F^\top)^{-1}C,\end{aligned}$$

where, as it has been explained $\approx$ stands for an equality up to terms that will decay exponentially. However, these terms have to be studied very carefully, what will be done in the Section C.3.

Using the matrix inversion lemma we have for $C = \begin{pmatrix} c & 0 \\ 0 & 0\end{pmatrix}$,

$$\begin{aligned} I-F &= \begin{pmatrix}(1+\delta)(\gamma\Sigma+\gamma\lambda I) - \delta I & \delta(I-(\gamma\Sigma+\gamma\lambda I)) \\ -I & I\end{pmatrix} \\ (I-F)^{-1} &= \begin{pmatrix}(\gamma\Sigma+\gamma\lambda I)^{-1} & \delta\big(I-(\gamma\Sigma+\gamma\lambda I)^{-1}\big) \\ (\gamma\Sigma+\gamma\lambda I)^{-1} & (1+\delta)I - \delta(\gamma\Sigma+\gamma\lambda I)^{-1}\end{pmatrix} \\ C^{1/2}(I-F)^{-1} &= \begin{pmatrix}c^{1/2}(\gamma\Sigma+\gamma\lambda I)^{-1} & \delta c^{1/2}\big(I-(\gamma\Sigma+\gamma\lambda I)^{-1}\big) \\ 0 & 0\end{pmatrix}.\end{aligned} \tag{25}$$

Regularization based term. This gives for the regularization based term

$$\begin{aligned}\Big\|C^{1/2}(I-F)^{-1}\Theta_\lambda\Big\|^2 &= \left\|\begin{pmatrix}c^{1/2}(\gamma\Sigma+\gamma\lambda I)^{-1} & \delta c^{1/2}\big(I-(\gamma\Sigma+\gamma\lambda I)^{-1}\big) \\ 0 & 0\end{pmatrix}\begin{pmatrix}\theta_0-\theta_* \\ 0\end{pmatrix}\right\|^2 \\ &= \left(\frac{1}{\gamma}\right)^2\|(c^{1/2}(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*))\|^2.\end{aligned} \tag{26}$$

The computation of this term is exact (not asymptotic).

Bias term. For the bias term we have

$$\begin{aligned}\tilde{\Theta}_0 &= \Theta_0 - \gamma\lambda(I-F)^{-1}\Theta_\lambda \\ &= \begin{pmatrix}\theta_0-\theta_* \\ \theta_0-\theta_*\end{pmatrix} - \gamma\lambda\begin{pmatrix}(\gamma\Sigma+\gamma\lambda I)^{-1} & \delta\big(I-(\gamma\Sigma+\gamma\lambda I)^{-1}\big) \\ (\gamma\Sigma+\gamma\lambda I)^{-1} & (1+\delta)I-\delta(\gamma\Sigma+\gamma\lambda I)^{-1}\end{pmatrix}\begin{pmatrix}\theta_0-\theta_* \\ 0\end{pmatrix} \\ &= \begin{pmatrix}\theta_0-\theta_* \\ \theta_0-\theta_*\end{pmatrix} - \gamma\lambda\begin{pmatrix}(\gamma\Sigma+\gamma\lambda I)^{-1}(\theta_0-\theta_*) \\ (\gamma\Sigma+\gamma\lambda I)^{-1}(\theta_0-\theta_*)\end{pmatrix} \\ &= \begin{pmatrix}[I-\lambda(\Sigma+\lambda I)^{-1}](\theta_0-\theta_*) \\ [I-\lambda(\Sigma+\lambda I)^{-1}](\theta_0-\theta_*)\end{pmatrix}.\end{aligned}$$

Thus this gives for the dominant term

$$\begin{aligned}\Big\|C^{1/2}(I-F)^{-1}\tilde{\Theta}_0\Big\|^2 &= \left\|\begin{pmatrix}c^{1/2}(\gamma\Sigma+\gamma\lambda I)^{-1} & \delta c^{1/2}\big(I-(\gamma\Sigma+\gamma\lambda I)^{-1}\big) \\ 0 & 0\end{pmatrix}\tilde{\Theta}_0\right\|^2 \\ &= \|(c^{1/2}[(1-\delta)(\gamma\Sigma+\gamma\lambda I)^{-1}+\delta I][I-\lambda(\Sigma+\lambda I)^{-1}](\theta_0-\theta_*)\|^2.\end{aligned}$$

And if c commutes with Σ we have the bound for $\delta \in [\frac{1-\sqrt{\gamma\lambda}}{1+\sqrt{\gamma\lambda}}, 1]$

$$\begin{aligned}\Big\|C^{1/2}(I-F)^{-1}\tilde{\Theta}_0\Big\|^2 &\leq (\frac{(1-\delta)}{\gamma\lambda}+\delta)\|(c^{1/2}[I-\lambda(\Sigma+\lambda I)^{-1}](\theta_0-\theta_*)\|^2 \\ &\leq (\frac{2}{\sqrt{\gamma\lambda}}+1)\|(c^{1/2}[I-\lambda(\Sigma+\lambda I)^{-1}](\theta_0-\theta_*)\|^2.\end{aligned}$$

Variance term. And for the variance term with $V = \begin{pmatrix} v & 0 \\ 0 & 0\end{pmatrix}$, we have $C^{1/2}(I-F)^{-1}V^{1/2} = \begin{pmatrix}c^{1/2}(\gamma\Sigma+\gamma\lambda I)^{-1}v^{1/2} & 0 \\ 0 & 0\end{pmatrix}$, and

$$\operatorname{tr} C^{1/2}(I-F)^{-1}V(I-F^\top)^{-1}C^{1/2} = \operatorname{tr} c(\gamma\Sigma+\gamma\lambda I)^{-1}v(\gamma\Sigma+\gamma\lambda I)^{-1}.$$

This gives the three dominant terms. However in order to control the remainders we have to compute the eigenvalues more carefully, as done in the next section.

C.3 Direct Computation without the Regularization Based Term

We derive now direct computation both the bias and variance terms. This is not required for the regularization based term whose previous expression in Eq. (26) is already non-asymptotic. Following O'Donoghue and Candès (2013) we consider an eigen-decomposition of the matrix F, in order to study independently the recursion on eigenspaces. We assume Σ has eigenvalues (s_i) and we decompose vectors in an eigenvector basis of Σ we denote by (p_i), with $\theta_n^i = p_i^\top\theta_n$ and $\xi_n^i = p_i^\top\xi_n$ and we have the reduced equation:

$$\Theta_{n+1}^i = F_i\Theta_n^i + \gamma\Xi_{n+1}^i.$$

with $\Theta_0^i = \tilde{\Theta}_0^i$, $F_i = \begin{pmatrix}(1+\delta)T_i & -\delta T_i \\ 1 & 0\end{pmatrix}$, with $T_i = 1-\gamma s_i - \gamma\lambda$.

Computing initial point $\tilde{\Theta}_0^i$. $\tilde{\Theta}_0^i = \Theta_0^i - \gamma\lambda(I-F_i)^{-1}\Theta_\lambda^i$, with $\Theta_0^i = \begin{pmatrix}\theta_0^i-\theta_*^i \\ \theta_0^i-\theta_*^i\end{pmatrix}$, $\Theta_\lambda^i = \begin{pmatrix}\theta_0^i-\theta_*^i \\ 0\end{pmatrix}$ and $(I-F_i)^{-1}$ given in Eq. (25). Thus

$$\begin{aligned}\tilde{\Theta}_0^i &= \begin{pmatrix}\theta_0^i-\theta_*^i \\ \theta_0^i-\theta_*^i\end{pmatrix} - \frac{\gamma\lambda}{(\gamma s_i+\gamma\lambda)}\begin{pmatrix}1 & \delta((\gamma s_i+\gamma\lambda)-1) \\ 1 & (1+\delta)(\gamma s_i+\gamma\lambda)-\delta\end{pmatrix}\begin{pmatrix}\theta_0^i-\theta_*^i \\ 0\end{pmatrix} \\ &= \begin{pmatrix}(1-\frac{\lambda}{\lambda+s_i})(\theta_0^i-\theta_*^i) \\ (1-\frac{\lambda}{\lambda+s_i})(\theta_0^i-\theta_*^i)\end{pmatrix}.\end{aligned} \tag{27}$$

Study of spectrum of F_i. Depending on δ, F_i may have two distinct complex eigenvalues of same modulus, only one (double) eigenvalue, or two real eigenvalues. We only consider the two former cases, which we detail below.

Indeed, the characteristic polynomial

$$\chi_{F_i}(X) \stackrel{def}{=} \det(XI - F_i) = X^2 - (1+\delta)(1-\gamma(s_i+\lambda))X + \delta(1-\gamma(s_i+\lambda))$$

has discriminant $\Delta_i = (1-\gamma(s_i+\lambda))((1+\delta)^2(1-\gamma(s_i+\lambda)) - 4\delta)$ which is non positive as far as $\delta \in [\delta_-;\delta_+]$, with $\delta_- = \frac{1-\sqrt{\gamma(s_i+\lambda)}}{1+\sqrt{\gamma(s_i+\lambda)}}$, $\delta_+ = \frac{1+\sqrt{\gamma(s_i+\lambda)}}{1-\sqrt{\gamma(s_i+\lambda)}}$.

C.3.1 Two Distinct Eigenvalues

We first assume that F_i has two distinct complex eigenvalues $r_\pm = \frac{(1+\delta)(1-\gamma(s_i+\lambda))\pm\sqrt{-1}\sqrt{-\Delta_i}}{2}$ which are conjugate. Thus the roots are of the form $\rho_i e^{\pm i\omega_i}$ with $\rho_i = \sqrt{\delta(1-\gamma(s_i+\lambda))}$, $\cos(\omega_i) = \frac{(1+\delta)(1-\gamma(s_i+\lambda))}{2\rho_i}$, $\omega_i \in [-\pi/2;\pi/2]$ and $\sin(\omega_i) = \frac{\sqrt{-\Delta_i}}{2\rho_i}$.

Let $Q_i = \begin{pmatrix} r_i^- & r_i^+ \\ 1 & 1 \end{pmatrix}$ be the transfer matrix into an eigenbasis of F_i, i.e., $F_i = Q_i D_i Q_i^{-1}$ with $D_i = \begin{pmatrix} r_i^- & 0 \\ 0 & r_i^+ \end{pmatrix}$ and $Q_i^{-1} = \frac{1}{r_i^- - r_i^+}\begin{pmatrix} 1 & -r_i^+ \\ -1 & r_i^- \end{pmatrix}$.

Computing $P_{i,k}$. We first compute the matrix $P_{i,k}$: With

$$C_i^{1/2} = \begin{pmatrix} \sqrt{c_i} & 0 \\ 0 & 0 \end{pmatrix}, C_i^{1/2} Q_i = \begin{pmatrix} r_i^-\sqrt{c_i} & r_i^+\sqrt{c_i} \\ 0 & 0 \end{pmatrix}$$

we have

$$C_i^{1/2} Q_i (I - D_i^k)(I - D_i)^{-1} = \sqrt{c_i}\begin{pmatrix} \frac{1-(r_i^-)^k}{1-r_i^-} r_i^- & \frac{1-(r_i^+)^k}{1-r_i^+} r_i^+ \\ 0 & 0 \end{pmatrix},$$

and, when developing and regrouping terms which depend on k, we get :

$$\begin{aligned} P_{i,k} &= C_i^{1/2} Q_i (I - D_i^k)(I - D_i)^{-1} Q_i^{-1} \\ &= \frac{\sqrt{c_i}}{r_i^- - r_i^+}\begin{pmatrix} \frac{1-(r_i^-)^k}{1-r_i^-} r_i^- - \frac{1-(r_i^+)^k}{1-r_i^+} r_i^+ & \frac{1-(r_i^+)^k}{1-r_i^+} r_i^- r_i^+ - \frac{1-(r_i^-)^k}{1-r_i^-} r_i^+ r_i^- \\ 0 & 0 \end{pmatrix} \\ &= \sqrt{c_i}\begin{pmatrix} \frac{1}{(1-r_i^-)(1-r_i^+)} & \frac{-r_i^+ r_i^-}{(1-r_i^-)(1-r_i^+)} \\ 0 & 0 \end{pmatrix} \\ &\quad - \frac{\sqrt{c_i}}{r_i^- - r_i^+}\begin{pmatrix} \frac{(r_i^-)^{k+1}}{1-r_i^-} - \frac{(r_i^+)^{k+1}}{1-r_i^+} & \frac{(r_i^+)^{k+1}}{1-r_i^+} r_i^- - \frac{(r_i^-)^{k+1}}{1-r_i^-} r_i^+ \\ 0 & 0 \end{pmatrix}. \end{aligned}$$

We also have $P_{i,k} = C_i^{1/2} Q_i (I - D_i^k)(I - D_i)^{-1} Q_i^{-1} = \sum_{j=0}^{k-1} R_{i,j}$ with

$$\begin{aligned} R_{i,j} &= C_i^{1/2} Q_i D_i^j Q_i^{-1} \\ &= \sqrt{c_i}\begin{pmatrix} (r_i^-)^{j+1} & (r_i^+)^{j+1} \\ 0 & 0 \end{pmatrix} Q_i^{-1} \\ &= \frac{\sqrt{s_i}}{r_i^- - r_i^+}\begin{pmatrix} (r_i^-)^{j+1} - (r_i^+)^{j+1} & -r_i^+(r_i^-)^{j+1} + r_i^-(r_i^+)^{j+1} \\ 0 & 0 \end{pmatrix}, \end{aligned}$$

but computing error terms based in $R_{i,j}$ before summing these errors gives a looser error bound than a tight calculation using $P_{i,k}$. More precisely, if we use $P_{i,k}\Theta_0^i = \sum_{j=0}^{k-1} R_{i,j}\Theta_0^i$ to upper bound $\|P_{i,k}\Theta_0^i\| \leq \sum_{j=0}^{k-1}\|R_{i,j}\Theta_0^i\|$, we end up with a worse bound.

Bias term. Thus, for the bias term:

$$\begin{aligned} P_{i,k}\Theta_0^i &= \sqrt{c_i}\theta_0^i \frac{1 - r_i^+ r_i^-}{(1-r_i^-)(1-r_i^+)} - \frac{\sqrt{c_i}\theta_0^i}{r_i^- - r_i^+}\begin{pmatrix} \left[(r_i^-)^{k+1}\frac{1-r_i^+}{1-r_i^-} - (r_i^+)^{k+1}\frac{1-r_i^-}{1-r_i^+}\right] \\ 0 \end{pmatrix} \\ &= \frac{\sqrt{c_i}\theta_0^i}{\sqrt{(1-r_i^-)(1-r_i^+)}}\begin{pmatrix} \frac{\left[(1-r_i^+r_i^-) - \rho_i^k A_1\right]}{\sqrt{(1-r_i^-)(1-r_i^+)}} \\ 0 \end{pmatrix}, \end{aligned}$$

where

$$\rho_i^k A_1 = \frac{(r_i^-)^{k+1}(1-r_i^+)^2 - (r_i^+)^{k+1}(1-r_i^-)^2}{r_i^- - r_i^+}.$$

This can be bound with the following lemma

Lemma 10 *For all $\rho \in (0,1)$ and $\omega \in [-\pi/2;\pi/2]$ and $r^\pm = \rho(\cos(\omega) \pm \sqrt{-1}\sin(\omega))$ we have:*

$$\left|\frac{1 - r^+r^- - \rho^k|A_1|}{|1-r^+|}\right| \leq 3 + 3\rho^k \leq 6 \tag{28}$$

We note that the exact constant seems empirically to be 2. This lemma is proved as Lemma 16 in Appendix E. This gives for the bias term

$$\begin{aligned} \|P_{i,k}\Theta_0^i\| &= \frac{\sqrt{c_i}(\theta_0^i)}{\sqrt{(1-r_i^-)(1-r_i^+)}}\Big[\frac{1}{\sqrt{(1-r_i^-)(1-r_i^+)}}\Big((1-r_i^+r_i^-) - \rho_i^k A_1\Big)\Big] \\ &\leq 6\frac{\sqrt{c_i}(\theta_0^i)}{\sqrt{\gamma(s_i+\lambda)}}, \end{aligned}$$

since:

$$\begin{aligned} (1-r_i^-)(1-r_i^+) &= 1 - 2\mathfrak{Re}\,(r_i^+) + |r_i^+|^2 \\ &= 1 - (1+\delta)(1-\gamma(s_i+\lambda)) + \delta(1-\gamma(s_i+\lambda)) \\ &= \gamma(s_i+\lambda). \end{aligned}$$

We also have a looser bound using $P_{i,k}\Theta_0^i = \sum_{j=0}^{k-1} R_{i,j}\Theta_0^i$.

$$\begin{aligned}
R_{i,j}\Theta_0^i &= \frac{\sqrt{c_i}\theta_0^i}{r_i^- - r_i^+}\big((1-r_i^+)(r_i^-)^{j+1} - (1-r_i^-)(r_i^+)^{j+1}\big) \\
&= \sqrt{c_i}\theta_0^i\bigg(\frac{(r_i^-)^{j+1} - (r_i^+)^{j+1}}{r_i^- - r_i^+} - \frac{r_i^+(r_i^-)^{j+1} - r_i^-(r_i^+)^{j+1}}{r_i^- - r_i^+}\bigg) \text{ using De Moivre's formula,} \\
&= \sqrt{c_i}\theta_0^i\bigg(\frac{\rho_i^{j+1}\sin(\omega_i(j+1))}{\rho_i\sin(\omega_i)} - \frac{\rho_i e^{i\omega_i}\rho_i^{j+1}e^{-i\omega_i(j+1)} - \rho_i e^{-i\omega_i}\rho_i^{j+1}e^{+i\omega_i(j+1)}}{\rho_i e^{-i\omega_i} - \rho_i e^{i\omega_i}}\bigg) \\
&= \sqrt{c_i}\theta_0^i\bigg(\frac{\rho_i^{j+1}\sin(\omega_i(j+1))}{\rho_i\sin(\omega_i)} - \rho_i^{j+1}\frac{e^{-i\omega_i j} - e^{+i\omega_i j}}{e^{-i\omega_i} - e^{i\omega_i}}\bigg) \\
&= \sqrt{c_i}\theta_0^i\bigg(\frac{\rho_i^{j}\sin(\omega_i(j+1))}{\sin(\omega_i)} - \rho_i^{j+1}\frac{\sin(\omega_i j)}{\sin(\omega_i)}\bigg) \\
&\leq (1+e^{-1})\sqrt{c_i}\theta_0^i \quad \text{using Lemma 17 (see proof in Appendix E),}
\end{aligned}$$

which also gives for the bias term

$$\|P_{i,k}\Theta_0^i\| \leq (1+e^{-1})\sqrt{c_i}\theta_0^i k.$$

Thus we have the final bound:

$$\|P_{i,k}\Theta_0^i\|^2 \leq \min\left\{36\frac{c_i(\theta_0^i)^2}{\gamma(s_i+\lambda)}, 6n(1+e^{-1})\frac{c_i(\theta_0^i)^2}{\sqrt{\gamma(s_i+\lambda)}}, n^2(1+e^{-1})^2 c_i(\theta_0^i)^2\right\}. \tag{29}$$

Variance term. As for the variance term, with $V_i = \begin{pmatrix} v_i & 0 \\ 0 & 0\end{pmatrix}$, we have $\operatorname{tr} P_{i,k}V_iP_{i,k} = \left\|P_{i,k}\begin{pmatrix}\sqrt{v_i}\\0\end{pmatrix}\right\|^2$.

$$\begin{aligned}
\left\|P_{i,k}\begin{pmatrix}\sqrt{v_i}\\0\end{pmatrix}\right\| &= \frac{\sqrt{v_i c_i}}{(1-r_i^-)(1-r_i^+)}\left[1 + \frac{(r_i^-)^{k+1}(1-r_i^+) - (r_i^+)^{k+1}(1-r_i^-)}{r_i^+ - r_i^-}\right] \\
&= \frac{\sqrt{v_i c_i}}{\gamma(s_i+\lambda)}\Big[1 - \rho_i^k B_{i,k}\Big],
\end{aligned}$$

where

$$\rho_i^k B_{i,k} = -\frac{(r_i^-)^{k+1}(1-r_i^+) - (r_i^+)^{k+1}(1-r_i^-)}{r_i^+ - r_i^-},$$

which we can bound using the following Lemma:

Lemma 11 *For all $\rho \in (0,1)$ and $\omega \in [-\pi/2;\pi/2]$ and $r^\pm = \rho(\cos(\omega) \pm \sqrt{-1}\sin(\omega))$ we have:*

$$\Big|\rho^k B_k\Big| \leq 1.75.$$

Where we note that the exact majoration seems to be 1.3. This Lemma is proved as Lemma 18 in Appendix E.

We can also have a looser bound using $P_{i,k}\begin{pmatrix}v_i^{1/2}\\0\end{pmatrix} = \sum_{j=0}^{k-1} R_{i,j}\begin{pmatrix}v_i^{1/2}\\0\end{pmatrix}$ and

$$\begin{aligned}
R_{i,j}\begin{pmatrix}v_i^{1/2}\\0\end{pmatrix} &= \frac{\sqrt{c_i v_i}}{r_i^- - r_i^+}\ \big((r_i^-)^{j+1} - (r_i^+)^{j+1}\big) \\
&= \sqrt{c_i v_i}\ \frac{\rho_i^{j+1}\sin(\omega_i(j+1))}{\rho_i\sin(\omega_i)} \\
&\leq (j+1)\sqrt{c_i v_i}, \text{ using the inequality } |\sin(k\omega_i)| \leq k|\sin(\omega_i)|
\end{aligned}$$

and $\left\|P_{i,k}\begin{pmatrix}v_i^{1/2}\\0\end{pmatrix}\right\| \leq \frac{\sqrt{c_i v_i}(k+1)k}{2}$.

This gives for the Variance term

$$\begin{aligned}
\sum_{k=1}^n \operatorname{tr} P_{i,k}V_iP_{i,k} &\leq v_i c_i \sum_{k=1}^n \min\left\{\frac{\big[1-\rho_i^k B_{1,k}\big]^2}{\gamma^2(s_i+\lambda)^2}, \frac{\big[1-\rho_i^k B_{1,k}\big]k(k+1)}{2\gamma(s_i+\lambda)}, \frac{k^2(k+1)^2}{4}\right\} \\
&\leq v_i c_i \min\left\{\frac{8n}{\gamma^2(s_i+\lambda)^2}, \frac{(n+1)^3}{2\gamma(s_i+\lambda)}, \frac{(n+1)^5}{20}\right\}.
\end{aligned} \tag{30}$$

C.3.2 One Coalescent Eigenvalue

We now turn to the case where F has two coalescent eigenvalues, which happens when the discriminant $\Delta = 0$. We assume that F_i has one coalescent eigenvalue $r_i = \frac{(1+\delta)(1-\gamma(s_i+\lambda))}{2}$. Then, with $\delta = \frac{1-\sqrt{\gamma(s_i+\lambda)}}{1+\sqrt{\gamma(s_i+\lambda)}}$, $r_i = \frac{(1+\delta)(1-\gamma(s_i+\lambda))}{2} = 1 - \sqrt{\gamma(s_i+\lambda)}$. Then F_i can be trigonalized as $F_i = Q_i D_i Q_i^{-1}$ with $Q_i = \begin{pmatrix} r_i & 1\\ 1 & 0\end{pmatrix}$, $D_i = \begin{pmatrix} r_i & 1\\ 0 & r_i\end{pmatrix}$ and $Q_i^{-1} = \begin{pmatrix}0 & 1\\ 1 & -r_i\end{pmatrix}$. We note that for all $k \geq 0$, then $D_i^k = r_i^{k-1}\begin{pmatrix} r_i & k\\ 0 & r_i\end{pmatrix}$.

Computing $P_{i,k}$. We first compute $P_{i,k}$:

$$(I_2 - D_i)^{-1} = \begin{pmatrix}\frac{1}{1-r_i} & \frac{1}{(1-r_i)^2}\\ 0 & \frac{1}{1-r_i}\end{pmatrix}$$

and

$$(I_2 - D_i^k)(I_2 - D_i)^{-1} = \begin{pmatrix}\frac{1-r_i^k}{1-r_i} & \frac{1-r_i^k}{(1-r_i)^2} - \frac{kr_i^{k-1}}{1-r_i}\\ 0 & \frac{1-r_i^k}{1-r_i}\end{pmatrix}.$$

Thus with $C_i^{1/2}Q_i = \begin{pmatrix}\sqrt{c_i}r_i & \sqrt{c_i}\\ 0 & 0\end{pmatrix}$ we have

$$C_i^{1/2}Q_i(I_2 - D_i^k)(I_2 - D_i)^{-1} = \sqrt{c_i}\begin{pmatrix}\frac{1-r_i^k}{1-r_i}r_i & \frac{1-r_i^k}{(1-r_i)^2} - \frac{kr_i^k}{1-r_i}\\ 0 & 0\end{pmatrix}.$$

And, computing as previously the matrices products, we derive:

$$\begin{aligned}
P_{i,k} &= C_i^{1/2} Q_i (I_2 - D_i^k)(I_2 - D_i)^{-1} Q_i^{-1} \\
&= \sqrt{c_i} \begin{pmatrix} \frac{1-r_i^k}{(1-r_i)^2} - \frac{kr_i^k}{1-r_i} & \frac{1-r_i^k}{1-r_i} r_i - (\frac{1-r_i^k}{(1-r_i)^2} - \frac{kr_i^k}{1-r_i}) r_i \\ 0 & 0 \end{pmatrix} \\
&= \sqrt{c_i} \begin{pmatrix} \frac{1-r_i^k}{(1-r_i)^2} - \frac{kr_i^k}{1-r_i} & \frac{1-r_i^k}{(1-r_i)^2}(r_i)^2 + \frac{kr_i^{k+1}}{1-r_i} \\ 0 & 0 \end{pmatrix} \\
&= \frac{\sqrt{c_i}}{1-r_i} \begin{pmatrix} \frac{1-r_i^k}{1-r_i} - kr_i^k & -\frac{1-r_i^k}{1-r_i}(r_i)^2 + kr_i^{k+1} \\ 0 & 0 \end{pmatrix}.
\end{aligned}$$

Bias term. We thus have:

$$\begin{aligned}
P_{i,k}\Theta_0^i &= \frac{\sqrt{c_i}}{1-r_i} \begin{pmatrix} \frac{1-r_i^k}{1-r_i} - kr_i^k & -\frac{1-r_i^k}{1-r_i}(r_i)^2 + kr_i^{k+1} \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \theta_0^i \\ \theta_0^i \end{pmatrix} \\
&= \theta_0^i \sqrt{c_i} \begin{pmatrix} (1-r_i^k)\frac{1+r_i}{1-r_i} - kr_i^k \\ 0 \end{pmatrix},
\end{aligned}$$

and this gives for the bias term:

$$\begin{aligned}
&\|P_{i,k}\Theta_0^i\|^2 \\
=&(\theta_0^i)^2 c_i \Big[(1-r_i^k)\frac{1+r_i}{1-r_i} - kr_i^k\Big]^2 \\
=&(\theta_0^i)^2 c_i \Big[\frac{1+r_i}{1-r_i} - \Big(k + \frac{1+r_i}{1-r_i}\Big) r_i^k\Big]^2 \text{ developing the product, then using formulas for } r_i \\
=&(\theta_0^i)^2 c_i \Big[\frac{2-\sqrt{\gamma(s_i+\lambda)}}{\sqrt{\gamma(s_i+\lambda)}} - \Big(k + \frac{2-\sqrt{\gamma(s_i+\lambda)}}{\sqrt{\gamma(c_i+\lambda)}}\Big)(1-\sqrt{\gamma(s_i+\lambda)})^k\Big]^2 \\
=&\frac{(\theta_0^i)^2 c_i}{\gamma(s_i+\lambda)}\Big[2 - \sqrt{\gamma(s_i+\lambda)} - \big(k\sqrt{\gamma(s_i+\lambda)} + 2 - \sqrt{\gamma(s_i+\lambda)}\big)(1-\sqrt{\gamma(s_i+\lambda)})^k\Big]^2 \\
=&\frac{(\theta_0^i)^2 c_i}{\gamma(s_i+\lambda)}\Big[2 - \sqrt{\gamma(s_i+\lambda)} - \big(2 + (k-1)\sqrt{\gamma(s_i+\lambda)}\big)(1-\sqrt{\gamma(s_i+\lambda)})^k\Big]^2 \\
\leq& 4\frac{(\theta_0^i)^2 c_i}{\gamma(s_i+\lambda)}, \text{ using Lemma 19 in Appendix E.}
\end{aligned}$$

Variance term. With $V = \begin{pmatrix} v_i & 0 \\ 0 & 0 \end{pmatrix}$,

$$\begin{aligned}
&\operatorname{tr} P_{i,k} V P_{i,k} \\
=&\frac{s_i}{(1-r_i)^2} \begin{pmatrix} \frac{1-r_i^k}{1-r_i} - kr_i^k & -\frac{1-r_i^k}{1-r_i}(r_i)^2 + kr_i^{k+1} \\ 0 & 0 \end{pmatrix} \begin{pmatrix} v_i & 0 \\ 0 & 0 \end{pmatrix} \begin{pmatrix} \frac{1-r_i^k}{1-r_i} - kr_i^k & -\frac{1-r_i^k}{1-r_i}(r_i)^2 + kr_i^{k+1} \\ 0 & 0 \end{pmatrix}^\top \\
=&\frac{s_i v_i}{(1-r_i)^2}\Big[\frac{1-r_i^k}{1-r_i} - kr_i^k\Big]^2 \\
=&\frac{v_i h_i}{\gamma(s_i+\lambda)}\Big[\frac{1-r_i^k}{1-r_i} - kr_i^k\Big]^2 \\
=&\frac{v_i h_i}{\gamma(s_i+\lambda)(1-r_i)^2}\Big[1 - r_i^k - (1-r_i)kr_i^k\Big]^2 \\
=&\frac{v_i h_i}{\gamma^2(s_i+\lambda)^2}\Big[1 - (1 + k\sqrt{\gamma(s_i+\lambda)})(1-\sqrt{\gamma(s_i+\lambda)})^k\Big]^2,
\end{aligned}$$

and

$$\begin{aligned}
\sum_{k=1}^n \operatorname{tr} P_{i,k} V P_{i,k} &= \frac{v_i s_i}{\gamma^2(s_i+\lambda)^2} \sum_{k=1}^n \Big[1 - (1 + k\sqrt{\gamma(s_i+\lambda)})(1-\sqrt{\gamma(s_i+\lambda)})^k\Big]^2 \\
&\leq n\frac{v_i s_i}{\gamma^2(s_i+\lambda)^2} \text{ using Lemma 19 in Appendix E.} \qquad (31)
\end{aligned}$$

Alternative bounds for the bias and the variance term, as in Equations(26), (29) may be derived as well. Combining all these results, we are now able to state Theorem 3.

C.4 Conclusion

Combining results from Lemma 9, and Equations (26), (29), (30), with $c = \Sigma$, and using the following simple facts:

- For the least squares regression function, with $c = \Sigma$, $\mathbb{E}\langle \bar{\Theta}_n, C\bar{\Theta}_n\rangle = \mathbb{E}f(\bar{\theta}_n) - f(\theta_*)$.
- Under assumption $\mathcal{A}_3$, $\mathcal{A}_4$, we have $V \preccurlyeq \tau^2\Sigma$.
- The squared norm of a vector is the sum of its squared components on the orthonormal eigenbasis. For example $\|P_{n+1}\Theta_0\|^2 = \sum_{i=1}^d \|P_{i,n+1}\Theta_0^i\|^2$.
- For any regularization parameter $\lambda \in \mathbb{R}_+$ and for any constant step-size $\gamma(\Sigma+\lambda I) \preccurlyeq I$, for any $\delta \in \big[\frac{1-\sqrt{\gamma\lambda}}{1+\sqrt{\gamma\lambda}}, 1\big]$, matrix F will have only two distinct complex eigenvalues or two coalescent eigenvalues.

Proposition 12 *Under ($\mathcal{A}_{4,5}$), for any regularization parameter $\lambda \in \mathbb{R}_+$ and for any constant step-size $\gamma(\Sigma+\lambda I) \preccurlyeq I$ we have for any $\delta \in \left[\frac{1-\sqrt{\gamma\lambda}}{1+\sqrt{\gamma\lambda}}, 1\right]$, for the recursion in Eq. (10):*

$$\begin{aligned}\mathbb{E}f(\bar{\theta}_n) - f(\theta_*) \leq\ & 2\lambda\|\lambda^{1/2}\Sigma^{1/2}(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)\|^2 \\ & + \sum_{i=1}^d \frac{2}{(n+1)^2}\min\left\{36\frac{c_i(\tilde{\theta}_0^i)^2}{\gamma(s_i+\lambda)}, 6n(1+e^{-1})\frac{c_i(\tilde{\theta}_0^i)^2}{\sqrt{\gamma(s_i+\lambda)}}, n^2(1+e^{-1})^2 c_i(\tilde{\theta}_0^i)^2\right\} \\ & + \sum_{i=1}^d \frac{\gamma^2}{(n+1)^2} v_i c_i \min\left\{\frac{8n}{\gamma^2(s_i+\lambda)^2}, \frac{(n+1)^3}{2\gamma(s_i+\lambda)}, \frac{(n+1)^5}{20}\right\}.\end{aligned}$$

This implies, using the Equation (27) for the initial point, using $c_i = \sigma_i$ and regrouping sums as traces or norms:

$$\begin{aligned}\mathbb{E}f(\bar{\theta}_n) - f(\theta_*) \ \leq\ & 2\lambda\|\lambda^{1/2}\Sigma^{1/2}(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)\|^2 \\ & + \ 2\min\left\{\frac{36\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)\|^2}{\gamma(n+1)^2}, (1+e^{-1})^2\|\Sigma^{1/2}(\theta_0-\theta_*)\|^2\right\} \\ & + \ \min\left\{\frac{8\operatorname{tr}(V\Sigma(\Sigma+\lambda I)^{-2})}{n+1}, n\gamma\operatorname{tr}(V\Sigma(\Sigma+\lambda I)^{-1})\right\},\end{aligned}$$

which gives exactly Theorem 3 using $V \preccurlyeq \tau^2\Sigma$ in the Variance term, and $\lambda^{1/2}(\Sigma+\lambda I)^{-1/2} \preccurlyeq I$ in the first term.

Appendix D. Tighter Bounds

D.1 Simple Upper-Bounds

In this section, we chow how tighter bounds naturally appear from the regularized quantities appearing in Theorems. It only relies on simple algebraic majorations, even if one has to be careful with the allowed intervals for r, b.

Lemma 13 *For any $\lambda \geq 0$, for any $b \in [0;1]$, if $\operatorname{tr}(\Sigma^b)$ exists, we have :*

$$\begin{aligned}\operatorname{tr}(\Sigma(\Sigma+\lambda I)^{-1}) &\leq \frac{\operatorname{tr}(\Sigma^b)}{\lambda^b} \\ \operatorname{tr}(\Sigma^{-2}(\Sigma+\lambda I)^{-2}) &\leq \frac{\operatorname{tr}(\Sigma^b)}{\lambda^b}.\end{aligned}$$

Proof As all operators can be diagonalized in a same eigenbasis with positive eigenvalues, we have,

$$\begin{aligned}\operatorname{tr}(\Sigma(\Sigma+\lambda I)^{-1}) &\leq \left|\left|\left|\Sigma^{1-b}(\Sigma+\lambda I)^{-1}\right|\right|\right| \operatorname{tr}(\Sigma^b) \\ |||\Sigma^{1-b}(\Sigma+\lambda I)^{-1}||| &\leq \sup_{0\leq x} \frac{x^{1-b}}{(x+\lambda)} \\ &\leq \sup_{0\leq x} x^{1-b}\left(\frac{1}{\lambda}\wedge\frac{1}{x}\right) \\ &\leq \sup_{0\leq x} x^{1-b}\left(\frac{1}{\lambda}\right)^b\left(\frac{1}{x}\right)^{1-b} = \lambda^{-b}.\end{aligned}$$

The calculations are exactly the same for $\operatorname{tr}(\Sigma^{-2}(\Sigma+\lambda I)^{-2}) \leq \frac{\operatorname{tr}(\Sigma^b)}{\lambda^b}$. ■

As for the bias term, we need to bound the following quantities :

Lemma 14 *For any $\lambda \geq 0$, for any $r \in [-1;1]$, we have :*

$$\left\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)\right\|^2 \ \leq\ \lambda^{-(1+r)}\left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\|^2.$$

For any $\lambda \geq 0$, for any $r \in [-1;0]$, we have :

$$\left\|(\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)\right\|^2 \ \leq\ \lambda^{-(1+r)}\left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\|^2.$$

For any $\lambda \geq 0$, for any $r \in [0;1]$, we have :

$$\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)\|^2 \ \leq\ \lambda^{-r}\left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\|^2$$

(No result when $r \leq 0$ because of saturation effect).

Proof Proof relies of simple following calculations:

$$\begin{aligned}\left\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1}(\theta_0-\theta_*)\right\| &\leq \left|\left|\left|\Sigma^{1/2-r/2}(\Sigma+\lambda I)^{-1}\right|\right|\right| \left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\| \\ &\leq \left(\frac{1}{\lambda}\right)^{1-(1/2-r/2)}\left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\| \\ &\leq \lambda^{-\frac{1+r}{2}}\left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\|\end{aligned}$$

$$\begin{aligned}\left\|(\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)\right\| &\leq \left|\left|\left|\Sigma^{-r/2}(\Sigma+\lambda I)^{-1/2}\right|\right|\right| \left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\| \\ &\leq \left(\frac{1}{\lambda}\right)^{\frac{1+r}{2}}\left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\| \\ &\leq \lambda^{-\frac{1+r}{2}}\left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\|\end{aligned}$$

$$\begin{aligned}\|\Sigma^{1/2}(\Sigma+\lambda I)^{-1/2}(\theta_0-\theta_*)\| &\leq \left|\left|\left|\Sigma^{1/2-r/2}(\Sigma+\lambda I)^{-1/2}\right|\right|\right| \left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\| \\ &\leq \left(\frac{1}{\lambda}\right)^{\frac{1-(1-r)}{2}}\left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\| \\ &\leq \lambda^{-\frac{r}{2}}\left\|\Sigma^{r/2}(\theta_0-\theta_*)\right\|.\end{aligned}$$

■

D.2 Theorem 5 and Equation (13)

Theorem 5 and Equation (13) are directly derived from Theorem 2 and Theorem 3, using Lemmas 13 and 14.

To derive corollaries for the optimal γ, one has to find the γ that balances the bias and variance term and to compute the products for such a step size.

D.2.1 Equation (13)

We derive from Theorem 2, when choosing $\gamma = (\lambda n)^{-1}$, and using Lemmas 13 and 14, the following bound, under assumptions of Theorem 2 :

$$\mathbb{E}f(\bar{\theta}_n) - f(\theta_*) \leq \frac{(18 + \mathrm{Res}(n,b,r,\gamma))\|\Sigma^{r/2}(\theta_0 - \theta_*)\|^2}{(\gamma n)^{\frac{1-r}{2}}} + \frac{6\sigma^2 \operatorname{tr}(\Sigma^b)\gamma^b}{n^{1-b}}.$$

Where $\mathrm{Res}(n,b,r,\gamma) := 3\gamma^{1+b}n^b \operatorname{tr}(\Sigma^b)$ if $-1 \leq r \leq 0$ and $\mathrm{Res}(n,b,r,\gamma) := 0$ if $0 \leq r \leq 1$. When choosing the optimal $\gamma \propto n^{\frac{-b+r}{b+1-r}}$, we have that $\gamma^{1+b}n^b = n^{-1+\frac{1+b}{1+b-r}} = n^{\chi}$, with $\chi = \frac{-r}{1+b-r} \geq 0$ if $r \leq 0$. Thus the residual term is always vanishing for $r \leq 0$ and does not exist for $r \geq 0$.

D.2.2 Theorem 5

Theorem 5 directly follows from Lemmas 13 and 14 and the choice of $\gamma \propto n^{\frac{-2b+2r-1}{b+1-r}}$.

Appendix E. Technical Lemmas

The following sequence of Lemmas appear in the proof. They are mostly independent and rely on simple calculations.

Lemma 15 *The operator* $\big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1}$ *is a non-decreasing operator on* $(S_n, \preccurlyeq)$.

Proof Lemma means that for two matrices $M, N \in S_n(\mathbb{R})$ such that $M \preccurlyeq N$, then

$$\big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1} M \preccurlyeq \big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1} N.$$

It is equivalent to show that for any symmetric positive matrix $A \in S_n^+$,

$$\big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1} A \in S_n^+(\mathbb{R}).$$

We consider a matrix $A \in S_n^+(\mathbb{R})$. A can be decomposed as a sum of (at most) n rank one matrices $A = \sum_{i=1}^n \omega_i \omega_i^\top$, with $\omega_i \in \mathbb{R}^n$. We thus just have to prove that for some $\omega \in \mathbb{R}^n$, $\big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1}\omega\omega^\top \in S_n^+(\mathbb{R})$.

Let $\Sigma = \sum_{i\geqslant 0}\mu_i e_i \otimes e_i$ is the eigenvalue decomposition of Σ, then

$$\big[(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)\big]^{-1}\omega\omega^\top = \sum_{i,j\geqslant 0}\frac{\langle\omega,e_i\rangle\langle\omega,e_j\rangle}{\mu_i+\mu_j+2\lambda}e_i\otimes e_j.$$

Thus, in the orthonormal basis of eigenvectors, this is thus Hadamard product between

$$\sum_{i,j\geqslant 0}\langle\omega,e_i\rangle\langle\omega,e_j\rangle e_i\otimes e_j = \omega\omega^\top$$

and the matrix $C = \Big(\big(\frac{1}{\mu_i+\mu_j+2\lambda}\big)_{i,j\geqslant 0}\Big)$. Matrix C is a Cauchy matrix and is thus positive. Moreover the Hadamard product of two positive matrices is positive, which concludes the proof. ■

Remark: surprisingly, the inverse operator $(\Sigma+\lambda I)\otimes I + I\otimes(\Sigma+\lambda I)$ is not non-decreasing. Indeed, $\preccurlyeq$ is not a total order on S_n so we may have that an operator is non-decreasing and its inverse is not.

Lemma 16 *For all* $\rho \in (0,1)$ *and* $\omega \in [-\pi/2;\pi/2]$ *and* $r^\pm = \rho(\cos(\omega) \pm \sqrt{-1}\sin(\omega))$ *we have:*

$$\left|\frac{1 - r^+r^- - \rho^k|A_1|}{|1-r^+|}\right| \leq \min\{1+\rho+e^{-1}+4\rho^k, 2+\rho+\sqrt{5}\rho^{k+1}\} \leq 6. \tag{32}$$

Proof We note that $\rho_i^k A_1$ is a real number as is is a quotient of pure complex numbers, which come from the difference between a complex and its conjugate. We first write A_1 as a combination of sine and cosine functions:

$$\begin{aligned}
\rho_i^k A_1 &= \frac{(r_i^-)^{k+1}(1-r_i^+)^2 - (r_i^+)^{k+1}(1-r_i^-)^2}{r_i^- - r_i^+} \\
&= -\frac{(r_i^-)^{k+1} - (r_i^+)^{k+1} - 2r_i^-r_i^+((r_i^-)^k - (r_i^+)^k) + (r_i^-r_i^+)(r_i^-)^{k-1} - (r_i^+)^{k-1})}{\rho_i \sin\omega_i} \\
&= -\frac{\rho_i^{k+1}\sin((k+1)\omega_i) - 2\rho_i^{k+2}\sin(k\omega_i) + \rho_i^{k+3}\sin((k-1)\omega_i)}{\rho_i\sin\omega_i}.
\end{aligned}$$

This quantity can be simplified when $\rho \to 1$ or $\omega \to 0$. We thus modify the expression of A_1 to make these dependencies clearer:

$$\begin{aligned}
-A_1 &= \frac{\sin((k+1)\omega_i) - 2\rho_i\sin(k\omega_i) + \rho_i^2\sin((k-1)\omega_i)}{\sin\omega_i} \\
&= \frac{(\cos(\omega)-\rho)(\sin(k\omega) - \rho\sin((k-1)\omega)) + \cos(k\omega)\sin(\omega) - \rho\cos((k-1)\omega)\sin(\omega)}{\sin\omega_i} \\
&\text{developing } \sin(a+b) = \sin(a)\cos(b) + \cos(a)\sin(b) \text{ and regrouping terms,} \\
&= \frac{(\cos(\omega)-\rho)^2\sin((k-1)\omega) + (\cos(\omega)-\rho)\sin(\omega)\cos((k-1)\omega) + \cos(k\omega)\sin(\omega)}{\sin\omega_i} \\
&\qquad + \frac{-\rho\cos((k-1)\omega)\sin(\omega)}{\sin\omega_i} \\
&= \frac{(\cos(\omega)-\rho)^2\sin((k-1)\omega)}{\sin\omega_i} + (\cos(\omega)-\rho)\cos((k-1)\omega) + \cos(k\omega) - \rho\cos((k-1)\omega) \\
&\text{simplifying expression, then developing the cosine,} \\
&= \frac{(\cos(\omega)-\rho)^2\sin((k-1)\omega)}{\sin\omega_i} + 2(\cos(\omega)-\rho)\cos((k-1)\omega) + \sin(\omega)\sin((k-1)\omega). \qquad (33)
\end{aligned}$$

So that in that final expression all the terms behave relatively simply when $\rho \to 1$ or $\omega \to 0$. We want to upper bound:

$$\left| \frac{1 - r^+ r^- - \rho^k |A_1|}{|1 - r^+|} \right|.$$

We thus consider separately the first and second term.

$$\frac{1 - r_i^+ r_i^-}{|1 - r_i^+|} = \frac{1 - \rho^2}{|1 - r_i^+|} \leq 1 + \rho \qquad \text{(exact if } \omega = 0\text{)}.$$

Then, using Equation (33):

$$\frac{-\rho_i^k |A_1|}{|1 - r_i^+|} = \rho^k \frac{\frac{(\cos(\omega) - \rho)^2 \sin((k-1)\omega)}{\sin \omega_i} + 2(\cos(\omega) - \rho)\cos((k-1)\omega) + \sin(\omega)\sin((k-1)\omega)}{\sqrt{(1 - \rho\cos\omega)^2 + \rho^2 \sin^2(\omega)}}.$$

Considering separately the three terms in the numerator, using numerous times that for any $a, b \in [0;1]$, $|a - b| \leq 1 - ab$:

$$\begin{aligned}
\left| \frac{\rho^k \frac{(\cos(\omega) - \rho)^2 \sin((k-1)\omega)}{\sin \omega_i}}{\sqrt{(1 - \rho\cos\omega)^2 + \rho^2 \sin^2(\omega)}} \right| &\leq \rho^k \frac{(\cos(\omega) - \rho)\sin((k-1)\omega)}{\sin \omega_i} \\
&\quad \text{as } |(\cos(\omega) - \rho)| \leq 1 - \rho\cos(\omega), \\
&\leq \rho^k \frac{(\cos(\omega) - 1)\sin((k-1)\omega)}{\sin \omega_i} + \rho^k \frac{(1-\rho)\sin((k-1)\omega)}{\sin \omega_i} \\
&\quad \text{writing } \cos(\omega) - \rho = \cos(\omega) - 1 + 1 - \rho \\
&\leq \rho^k (1-\rho)(k-1) + \rho^k \frac{(\cos(\omega) - 1)\sin((k-1)\omega)}{\sin \omega_i} \\
&\quad \text{as } |\sin((k-1)\omega)| \leq |(k-1)\sin(\omega)|, \\
&\leq \rho^k (1-\rho)k - (1-\rho)\rho^k + \rho^k \frac{(\cos(\omega) - 1)\sin((k-1)\omega)}{\sin \omega_i} \\
&\quad \text{writing } \cos(\omega) - 1 = 2\sin^2(\omega/2), \\
&\leq \rho^k (1 + (1-\rho))^k - \rho^k - (1-\rho)\rho^k + \rho^k \frac{2\sin^2(\omega/2)}{\sin \omega_i} \\
&\quad \text{using } 1 + (1-\rho)k \leq (1 + (1-\rho))^k, \\
&\leq \rho^k (1 + (1-\rho))^k - \rho^k - (1-\rho)\rho^k + \rho^k \tan(\omega/2) \\
&\quad \text{and as } \tan(\omega/2) \leq 1 \text{ for } |\omega| \leq \pi/2, \\
&\leq 1 - (1-\rho)\rho^k \\
&\quad \text{using } \rho^k (1 + (1-\rho))^k = (1 - (1-\rho)^2)^k \leq 1,
\end{aligned}$$

And for the second and third term:

$$\begin{aligned}
2\left| \rho^k \frac{(\cos(\omega) - \rho)\cos((k-1)\omega)}{\sqrt{(1 - \rho\cos\omega)^2 + \rho^2 \sin^2(\omega)}} \right| &\leq 2\rho^k, \\
\left| \rho^k \frac{+\sin(\omega)\sin((k-1)\omega)}{\sqrt{(1 - \rho\cos\omega)^2 + \rho^2 \sin^2(\omega)}} \right| &\leq \rho^k.
\end{aligned}$$

Thus:

$$\left| \frac{1 - r_i^+ r_i^- - \rho_i^k |A_1|}{|1 - r_i^+|} \right| \leq 1 + \rho + 1 + 3\rho^k.$$

We also have

$$\begin{aligned}
|\rho^k \frac{\frac{(\cos(\omega) - \rho)^2 \sin((k-1)\omega)}{\sin \omega_i}}{\sqrt{(1 - \rho\cos\omega)^2 + \rho^2 \sin^2(\omega)}}| &\leq \rho^k \frac{(\cos(\omega) - \rho)\sin((k-1)\omega)}{\sin \omega_i} \\
&\leq \rho^k (1-\rho)(k-1) + \rho^k \frac{(\cos(\omega) - 1)\sin((k-1)\omega)}{\sin \omega_i} \\
&\leq (1 - \frac{1}{k+1})^{k+1} - (1-\rho)\rho^k + \rho^k \frac{(\cos(\omega) - 1)\sin((k-1)\omega)}{\sin \omega_i} \\
&\leq e^{-1} - (1-\rho)\rho^k + \rho^k \frac{\sin^2(\omega/2)}{\sin \omega_i}.
\end{aligned}$$

Using that

$$k \sup_{x \in [0;1]} x^k (1-x) = k \frac{1}{k+1}(1 - \frac{1}{k+1})^k = (1 - \frac{1}{k+1})^{k+1} = \exp((k+1)\ln((1 - \frac{1}{k+1})) \leq e^{-1}, \quad (34)$$

we get

$$\left| \frac{1 - r_i^+ r_i^- - \rho_i^k |A_1|}{|1 - r_i^+|} \right| \leq 1 + \rho + e^{-1} + 4\rho^k$$

We can also change $3\rho^k$ into $\sqrt{5}\rho^k$ We have used that $|(\rho - \cos(\omega))| \leq (1 - \rho\cos(\omega))$. ■

Lemma 17 *For any $\rho_i \in (0;1)$, for any $\omega_i \in [-\pi/2; \pi/2]$*

$$\frac{\rho_i^j \sin(\omega_i(j+1))}{\sin(\omega_i)} - \rho_i^{j+1} \frac{\sin(\omega_i j)}{\sin(\omega_i)} \leq 1 + e^{-1}.$$

Proof

$$\begin{aligned}
\frac{\rho_i^j \sin(\omega_i(j+1))}{\sin(\omega_i)} - \rho_i^{j+1} \frac{\sin(\omega_i j)}{\sin(\omega_i)} &= \rho_i^j \left(\frac{\sin(\omega_i(j+1)) - \rho_i \sin(\omega_i j)}{\sin(\omega_i)} \right) \\
&= \rho_i^j \left(\frac{(\cos(\omega_i) - \rho_i)\sin(\omega_i j)}{\sin(\omega_i)} + \cos(j\omega_i) \right) \\
&\leq \rho_i^j \left((1 - \rho_i) j + 1 \right) \\
&\leq 1 + e^{-1} \text{ using (34)}.
\end{aligned}$$

Lemma 18 *For all $\rho \in (0,1)$ and $\omega \in [-\pi/2;\pi/2]$ and $r^{\pm} = \rho(\cos(\omega) \pm \sqrt{-1}\sin(\omega))$ we have:*

$$\left|\rho_i^k B_{1,k}\right| \leq 1.75 \tag{35}$$

Proof Once again, as the considered quantity is real, we first express it as a combination of sine and cosine functions. We then use some simple trigonometric trics to upper bound the quantity.

$$\begin{aligned}
\rho_i^k B_{1,k} &= -\frac{(r_i^-)^{k+1}(1-r_i^+) - (r_i^+)^{k+1}(1-r_i^-)}{r_i^+ - r_i^-} \\
&= -\frac{2\mathfrak{Im}\big[(r_i^-)^{k+1}(1-r_i^+)\big]}{\sqrt{-\Delta_i}} \text{ as it is the difference between a complex and its conjugate,} \\
&= -\frac{\mathfrak{Im}\big[\rho_i^k e^{-(k+1)i\omega_i}(1-\rho_i\cos(\omega_i) - i\rho_i\sin(\omega_i))\big]}{\sin\omega_i\rho_i} \text{ developing the product,} \\
&= \rho_i^k \frac{\cos((k+1)\omega_i)\sin(\omega_i)\rho_i + \sin((k+1)\omega_i)(1-\rho_i\cos(\omega_i))}{\sin\omega_i\rho_i} \\
&= \rho_i^k\Big[\rho_i\cos((k+1)\omega_i) + (1-\rho_i\cos(\omega_i))\frac{\sin((k+1)\omega_i)}{\sin\omega_i}\Big] \text{ and simplifying.}
\end{aligned}$$

Let's turn our interest to the second part of the quantity:

$$\begin{aligned}
\left|\rho_i^k(1-\rho_i\cos(\omega_i))\frac{\sin((k+1)\omega_i)}{\sin\omega_i}\right| &= \left|\rho_i^k(1-\rho_i+\rho_i(1-\cos(\omega_i)))\frac{\sin((k+1)\omega_i)}{\sin\omega_i}\right| \\
&\text{introducing an artificial } +\rho_i - \rho_i, \\
&\leq \rho_i^k\left|(1-\rho_i)\frac{\sin((k+1)\omega_i)}{\sin\omega_i}\right| + \rho_i^k\left|\rho_i(1-\cos(\omega_i))\frac{\sin((k+1)\omega_i)}{\sin\omega_i}\right| \\
&\text{by triangular inequality,} \\
&\leq \rho_i^k\left|(1-\rho_i)(k+1)\right| + \rho_i^k\left|\rho_i\sin^2(\tfrac{\omega}{2})\frac{1}{2\cos(\frac{\omega}{2})\sin(\frac{\omega}{2})}\right| \\
&\text{using } 1-\cos(\omega_i) = 2\sin^2(\frac{\omega}{2}) \\
&\leq \rho_i^k(1-\rho_i)k + \rho_i^k(1-\rho) + \rho_i^k\left|\rho_i\sin^2(\tfrac{\omega}{2})\frac{1}{2\cos(\frac{\omega}{2})\sin(\frac{\omega}{2})}\right| \\
&\leq (1-(1-\rho_i))^k(1+(1-\rho_i))^k - \rho_i^k + \frac{1}{2(k+1)} + \rho_i^k\left|\frac{\rho_i}{2}\tan(\frac{\omega}{2})\right| \\
&\leq (1-(1-\rho_i)^2)^k + \frac{1}{4} + \frac{1}{2} \leq 1 + \frac{1}{4} + \frac{1}{2} - \rho_i^k.
\end{aligned}$$

Thus

$$\left|\rho_i^k B_{1,k}\right| = \rho_i^k + 1 + \frac{1}{4} + \frac{1}{2} - \rho_i^k \leq 1 + \frac{1}{4} + \frac{1}{2} = 1.75.$$

Lemma 19 *For any $s_i, \gamma, \lambda \in \mathbb{R}_+^3$ such that $\gamma(s_i+\lambda) \leq 1$, for any $k \in \mathbb{N}$, we have the two following highly related identities:*

$$\begin{aligned}
0 \leq 2 - \sqrt{\gamma(s_i+\lambda)} - \big(2 + (k-1)\sqrt{\gamma(s_i+\lambda)}\big)(1-\sqrt{\gamma(s_i+\lambda)})^k &\leq 2 \\
0 \leq 1 - (1 + k\sqrt{\gamma(s_i+\lambda)})(1-\sqrt{\gamma(s_i+\lambda)})^k &\leq 1.
\end{aligned}$$

Proof Proof relies on the trick, for any $\alpha \in \mathbb{R}, n \in \mathbb{N}$: $1 + n\alpha \leq (1+\alpha)^n$. For the first one:

$$\begin{aligned}
&\sqrt{\gamma(s_i+\lambda)} + \big(2 + (k-1)\sqrt{\gamma(s_i+\lambda)}\big)(1-\sqrt{\gamma(s_i+\lambda)})^k = \\
=\ &\sqrt{\gamma(s_i+\lambda)} + (1-\sqrt{\gamma(s_i+\lambda)})^k + \big(1 + (k-1)\sqrt{\gamma(s_i+\lambda)}\big)(1-\sqrt{\gamma(s_i+\lambda)})^k \\
\leq\ &\sqrt{\gamma(s_i+\lambda)} + (1-\sqrt{\gamma(s_i+\lambda)}) + \big(1 + (k-1)\sqrt{\gamma(s_i+\lambda)}\big)(1-\sqrt{\gamma(s_i+\lambda)})^{k-1} \\
\leq\ &1 + (1-\gamma(s_i+\lambda))^{k-1} \leq 2.
\end{aligned}$$

For the second one:

$$0 \leq (1 + k\sqrt{\gamma(s_i+\lambda)})(1-\sqrt{\gamma(s_i+\lambda)})^k \leq (1-\gamma(s_i+\lambda))^k \leq 1.$$

Abstract

Multiclass classification problems such as image annotation can involve a large number of classes. In this context, confusion between classes can occur, and single label classification may be misleading. We provide in the present paper a general device that, given an unlabeled dataset and a score function defined as the minimizer of some empirical and convex risk, outputs a set of class labels, instead of a single one. Interestingly, this procedure does not require that the unlabeled dataset explores the whole classes. Even more, the method is calibrated to control the expected size of the output set while minimizing the classification risk. We show the statistical optimality of the procedure and establish rates of convergence under the Tsybakov margin condition. It turns out that these rates are linear on the number of labels. We apply our methodology to convex aggregation of confidence sets based on the V-fold cross validation principle also known as the superlearning principle (van der Laan et al., 2007). We illustrate the numerical performance of the procedure on real data and demonstrate in particular that with moderate expected size, w.r.t. the number of labels, the procedure provides significant improvement of the classification risk.

Keywords: Multiclass Classification, Confidence Sets, Empirical Risk Minimization, Convex Loss, Superlearning

1. Introduction

The advent of high-throughput technology has generated tremendous amounts of large and high-dimensional classification data. This allows classification at unprecedented scales with hundreds or even more classes. The standard approach to classification in the multiclass setting is to use a classification rule for assigning a single label. More specifically, it consists in assigning a single label $Y \in \mathcal{Y}$, with $\mathcal{Y} = \{1, \dots, K\}$, to a given input example $X \in \mathcal{X}$ among a collection of labels. However, while a large number of classes can lead to precise characterizations of data points, similarities among classes also bear the risk of confusion and misclassification. Hence, assigning a single label can lead to wrong or ambiguous results.

In this paper, we address this problem by introducing an approach that yields sets of labels as outputs, namely, confidence sets. A confidence set Γ is a function that maps $\mathcal{X}$ onto $2^{\mathcal{Y}}$. A natural way to obtain a set of labels is to use ranked outputs of the classification rule. For example, one could take the classes that correspond to the top-level conditional probabilities $\mathbb{P}(Y = \cdot | X = x)$. Here, we provide a more general approach where we control the *expected* size of the confidence sets. For a confidence set Γ, the expected size of Γ is defined as $\mathbb{E}[|\Gamma(X)|]$, where $|\cdot|$ stands for the cardinality. For a sample X and given an expected set size β, we provide an algorithm that outputs a set $\hat{\Gamma}(X)$ such that $\mathbb{E}[|\hat{\Gamma}(X)|] \approx \beta$. Furthermore, the procedure aims at minimizing the classification error given by

$$\mathbb{P}\left(Y \notin \hat{\Gamma}(X)\right) \approx \min_{\Gamma\,:\,\mathbb{E}[|\Gamma(X)|]=\beta} \mathbb{P}\left(Y \notin \Gamma(X)\right) = \mathcal{R}^*_\beta.$$

We establish a close formula of the oracle confidence set $\Gamma^* = \operatorname{argmin}_{\Gamma\,:\,\mathbb{E}[|\Gamma(X)|]=\beta} \mathbb{P}\left(Y \notin \Gamma(X)\right)$ that involves the cumulative distribution functions of the conditional probabilities. Besides, we formulate a data-driven counterpart of Γ^* based on the minimization of the empirical risk. However, the natural risk function in the multiclass setting is non convex, and then minimizing it is proving to be a computational issue. As a remedy, convex surrogates are often used in machine learning, and more specifically in classification as reflected by the popularity of methods such as Boosting (Freund and Schapire, 1997), logistic regression (Friedman et al., 2000) and support vector machine (Vapnik, 1998). In our problem this translates by considering some convex surrogate of the 0/1-loss in $\mathbb{P}\left(Y \notin \Gamma(X)\right)$; we introduce a new convex risk function which enables us to emphasize specific aspects of confidence sets. That convex risk function is partly inspired by the works by Zhang (2004), Bartlett et al. (2006) and Yuan and Wegkamp (2010), that deal with binary classification.

Our approach displays two main features. First, our method can be implemented in a semi-supervised way (Vapnik, 1998). More precisely, the method is a two-steps procedure that requires the estimation of score functions (as minimizers of some convex risk function) in a first step and the estimation of the cumulative distribution of these scores in a second one. Hence, the first step requires labeled data whereas the second one involves only unlabeled samples. Notably, the unlabeled sample does not necessary consists of examples coming from the whole classes. This aspects is fondamental when we deal with a large number of classes, some of which been sparsely represented. Second, from the theoretical point of view, we provide an oracle inequality satisfied by $\hat{\Gamma}$, the empirical confidence set that results from the minimization of an empirical convex risk. The obtained oracle inequality shall enable us to derive rates of convergence on a particular class of confidence sets under the Tsybakov noise assumption on the data generating distribution. These rates are linear in the number of classes K and also depend on the regularity of the cumulative distribution functions of the conditional probabilities.

An obvious benefit of considering convex risk minimization is when we deal with aggregation. However, aggregating confidence sets is no simple matter. Another contribution of the present paper is about applying the above methodology to aggregation of confidence sets. More specifically, we provide a generalization of the superlearning algorithm (van der Laan et al., 2007) initially introduced in the context of regression and binary classification. This algorithm relies on the V-fold cross-validation principle. We prove the consistency of this aggregation procedure and illustrate its relevance on real datasets. Let us point out that any arbitrary library of machine learning algorithms may be used in this aggregation procedure; we propose in the present paper to exploit support vector machines, random for-

est procedures or softmax regression since these methods are popular in machine learning and that each of them is associated to a different shape.

We end up this discussion by highlighting in two words what we perceive as being the main contributions of the present paper. We describe an optimal strategy for building confidence sets in multiclass classification setting, and we derive a new aggregation procedure for confidence sets that still allows controlling the expected size of the resulting confidence set.

Related works: The closest learning task to the present work is *classification with reject option* which is a particular setting in binary classification. Several papers fall within the scope of this area (Chow, 1970; Herbei and Wegkamp, 2006; Yuan and Wegkamp, 2010; Wegkamp and Yuan, 2011; Lei, 2014; Denis and Hebiri, 2015) and differ from each other by the goal they consider. Among these references, our procedure is partially inspired by Denis and Hebiri (2015) that also consider a semi-supervised approach to build confidence sets invoking some cumulative distribution functions (of the conditional probabilities themselves in their case). The similarity is however limited to the definition of oracle confidence sets, the oracle confidence in the present paper being an extension of the one defined in the paper by Denis and Hebiri (2015) to the multiclass setting. On the other hand, all the data-driven considerations are completely different (in particular, Denis and Hebiri (2015) focus on plug-in rules) and importantly, we develop here new probabilistic results on sums of cumulative distribution functions of random variables, that are of own interest.

Assigning a set of labels instead of a single one for an input example is not new (Vovk et al., 2005; Wu et al., 2004; del Coz et al., 2009; Lei et al., 2013; Choromanska et al., 2016). One of the most popular methods is based on *Conformal Prediction* approach (Vovk et al., 1999; Vovk, 2002; Vovk et al., 2005). In the multiclass classification framework, the goal of this algorithm is to build the smallest set of labels such that its classification error is below a pre-specified level. Since our procedure aims at minimizing the classification error while keeping under control the size of the set, *Conformal Prediction* can be seen as a dual of our method. It is worth mentioning that conformal predictors approaches need two labeled datasets where we only need one labeled dataset, the second being unlabeled. We refer to the very interesting statistical study of *Conformal Predictors* in the binary case in the paper by Lei (2014).

Notation: First, we state general notation. Let $\mathcal{Y} = \{1, \dots, K\}$, with $K \geq 2$ being an integer. Let (X, Y) be the generic data-structure taking its values in $\mathcal{X} \times \mathcal{Y}$ with distribution $\mathbb{P}$. The goal in classification is to predict the label Y given an observation of X. This is performed based on a classifier (or classification rule) s which is a function mapping $\mathcal{X}$ onto $\mathcal{Y}$. Let $\mathcal{S}$ be the set of all classifiers. The misclassification risk R associated with $s \in \mathcal{S}$ is defined as

$$R(s) = \mathbb{P}(s(X) \neq Y).$$

Moreover, the minimizer of R over $\mathcal{S}$ is the Bayes classifier, denoted by s^*, and is characterized by

$$s^*(\cdot) = \underset{k \in \mathcal{Y}}{\operatorname{argmax}}\, p_k(\cdot),$$

where $p_k(x) = \mathbb{P}(Y = k | X = x)$ for $x \in \mathcal{X}$ and $k \in \mathcal{Y}$.
Let us now consider more specific notation related to the multiclass confidence set setting.

Let a confidence set be any measurable function that maps $\mathcal{X}$ onto $2^{\mathcal{Y}}$. Let Γ be a confidence set. This confidence set is characterized by two attributes. The first one is the risk associated to the confidence set

$$\mathcal{R}(\Gamma) = \mathbb{P}(Y \notin \Gamma(X)), \tag{1}$$

and is related to its accuracy. The second attribute is linked to the information given by the confidence set. It is defined as

$$\mathcal{I}(\Gamma) = \mathbb{E}(|\Gamma(X)|), \tag{2}$$

where $|\cdot|$ stands for the cardinality. Moreover, for some $\beta \in [1, K]$, we say that, for two confidence sets Γ and Γ' such that $\mathcal{I}(\Gamma) = \mathcal{I}(\Gamma') = \beta$, the confidence set Γ is "better" than Γ' if $\mathcal{R}(\Gamma) \leq \mathcal{R}(\Gamma')$.

Organization of the paper: The rest of the paper is organized as follows. Next section is devoted to the definition and the main properties of the oracle confidence set for multiclass classification. The empirical risk minimization procedure is provided in Section 3. Rates of convergence for the confidence set that results from this minimization can also be found in this section. We present an application of our procedure to aggregation of confidence sets in Section 4. We finally draw some conclusions and present perspectives of our work in Section 5. Proofs of our results are postponed to the Appendix.

2. Confidence set for multiclass classification

In the present section, we define a class of confidence sets that are suitable for multiclass classification and referred as *Oracle β-sets*. For some $\beta \in (0, K)$, these sets are shown to be optimal according to the risk (1) with an information (2) equal to β. Moreover, basic but fondamental properties of Oracle β-sets can be found in Proposition 1, while Proposition 7 provides another interpretation of these sets.

2.1 Notation and definition

First of all, we introduce in this section a class of confidence sets that specifies oracle confidence sets. Let $\beta \in (0, K)$ be a desired information level. The so-called *Oracle β-sets* are optimal according to the risk (1) among all the confidence sets Γ such that $\mathcal{I}(\Gamma) = \beta$. Throughout the paper we make the following assumption

(A1) *For all $k \in \{1, \dots, K\}$, the cumulative distribution function F_{p_k} of $p_k(X)$ is continuous.*

The definition of the *Oracle β-set* relies on the continuous and decreasing function G defined for any $t \in [0, 1]$ by

$$G(t) = \sum_{k=1}^{K} \bar{F}_{p_k}(t),$$

where for any $k \in \{1, \dots, K\}$, we denote by $\bar{F}_{p_k}$ the tail distribution function of $p_k(X)$, that is, $\bar{F}_{p_k} = 1 - F_{p_k}$ with F_{p_k} being the cumulative distribution function (c.d.f.) of $p_k(X)$. The generalized inverse G^{-1} of G is given by (see (van der Vaart, 1998)):

$$G^{-1}(\beta) = \inf\{t \in [0, 1] : \; G(t) \leq \beta\}, \;\; \forall \beta \in (0, K).$$

The functions G and G^{-1} are central in the construction of the Oracle β-sets. We then provide some of their useful properties in the following proposition.

Proposition 1 *The following properties on G hold*

i) For every $t \in (0,1)$ and $\beta \in (0,K)$, $G^{-1}(\beta) \leq t \Leftrightarrow \beta \geq G(t)$.

ii) For every $\beta \in (0,K)$, $G(G^{-1}(\beta)) = \beta$.

iii) Let ε be a random variable, independent of X, and distributed from a uniform distribution on $\{1,\dots,K\}$ and let U be uniformly distributed on $[0,K]$. Define

$$Z = \sum_{k=1}^{K} p_k(X)\mathbf{1}_{\{\varepsilon=k\}}.$$

If the function G is continuous, then $G(Z) \overset{\mathcal{L}}{=} U$ and $G^{-1}(U) \overset{\mathcal{L}}{=} Z$.

The proof of Proposition 1 relies on Lemma 1 in the Appendix. Now, we are able to defined the Oracle β-set:

Definition 2 *Let $\beta \in (0,K)$, the Oracle β-set is given by*

$$\begin{aligned}\Gamma^*_\beta(X) &= \{k \in \{1,\dots,K\} :\ G(p_k(X)) \leq \beta\} \\ &= \left\{k \in \{1,\dots,K\} :\ p_k(X) \geq G^{-1}(\beta)\right\}.\end{aligned}$$

This definition of the Oracle β-set is intuitive and can be related to the binary classification with reject option setting (Chow, 1970; Herbei and Wegkamp, 2006; Denis and Hebiri, 2015) in the following way: a label k is assigned to the Oracle β-set if the probability $p_k(X)$ is large enough. It is worth noting that the function G plays the same role as the c.d.f. of the score function used by Denis and Hebiri (2015). As emphasized by Proposition 1, their introduction allows to control exactly the information (2). Indeed, it follows from the definition of the Oracle β-set that for each $\beta \in (0,K)$

$$|\Gamma^*_\beta(X)| = \sum_{k=1}^{K} \mathbf{1}_{\{p_k(X) \geq G^{-1}(\beta)\}},$$

and then $\mathcal{I}(\Gamma^*_\beta) = \mathbb{E}\left[|\Gamma^*_\beta(X)|\right] = G(G^{-1}(\beta))$. Therefore, Proposition 1 ensures that

$$\mathcal{I}(\Gamma^*_\beta) = \beta.$$

This last display points out that the Oracle β-sets are indeed β-level (that is, its information equals β). In the next section, we focus on the study of the risk of these oracle confidence sets.

Remark 3 *Naturally, the definition of Oracle β-sets can be extended to any $\beta \in [0,K]$. However, the limit cases $\beta = 0$ and $\beta = K$ are of limited interest and are completely trivial. We then exclude these two limit cases from the present study.*

2.2 Properties of the oracle confidence sets

Let us first state the optimality of the Oracle β-set:

Proposition 4 *Let Assumption (A1) be satisfied. For any $\beta \in (0,K)$, we have both:*

1. *The Oracle β-set Γ^*_β satisfies the following property:*

$$\mathcal{R}\left(\Gamma^*_\beta\right) = \inf_{\Gamma} \mathcal{R}\left(\Gamma\right),$$

where the infimum is taken over all β-level confidence sets.

2. *For any β-level confidence set Γ, the following holds*

$$0 \leq \mathcal{R}\left(\Gamma\right) - \mathcal{R}\left(\Gamma^*_\beta\right) = \mathbb{E}\left[\sum_{k \in (\Gamma^*_\beta(X)\,\Delta\,\Gamma(X))} \left|p_k(X) - G^{-1}(\beta)\right|\right], \tag{3}$$

where the symbol Δ stands for the symmetric difference of two sets, that is, for two subsets A and B of $\{1,\dots,K\}$, we write $A\,\Delta\,B = (A \setminus B) \cup (B \setminus A)$.

Several remarks can be made from Proposition 4. First, for $\beta \in (0,K)$, the Oracle β-set is optimal for the misclassification risk, over the class of β-level confidence sets. Moreover, the excess risk of any β-level confidence set relies on the behavior of the score functions p_k around the threshold $G^{-1}(\beta)$. Finally, we can note that if $K = 2$ and $\beta = 1$, which implies that $G^{-1}(\beta) = 1/2$, Equation (3) reduces to the misclassification excess risk in binary classification.

Remark 5 *One way to build a confidence set Γ with information β is to set Γ as the β top levels conditional probabilities. In the sequel this method is referred as the* `max` *procedure. This strategy is natural but actually suboptimal as shown by the first point of Proposition 4. As an illustration, we consider a simulation scheme with $K = 10$ classes. We generate (X,Y) according to a mixture model. More precisely,*

i) the label Y is distributed from a uniform distribution on $\{1,\dots,K\}$;

ii) conditional on $Y = k$, the feature X is generated according to a multivariate gaussian distribution with mean parameter $\mu_k \in \mathbb{R}^{10}$ and identity covariance matrix. For each $k = 1,\dots,K$, the vectors μ_k are i.i.d realizations of uniform distribution on $[0,4]$.

For $\beta = 2$ we evaluate the risks of the Oracle β-set and the `max` *procedure and obtain respectively 0.05 and 0.09 (with very small variance).*

Remark 6 *An important motivation behind the introduction of confidence sets and in particular of Oracle β-sets is that they might outperform the Bayes rule which can be seen as the Oracle β-set associated to $\beta = 1$. This gap in performance is even larger when the number of classes K is large and there is a big confusion between classes. Such improvement will be illustrated in the numerical study (see Section 4.3).*

We end up this section by providing another characterization of the Oracle β-set.

Proposition 7 *For $t \in [0,1]$, and Γ a confidence set, we define*

$$L_t(\Gamma) = \mathbb{P}\left(Y \notin \Gamma(X)\right) + t\mathcal{I}(\Gamma).$$

For $\beta \in [0,K]$, the following equality holds:

$$L_{G^{-1}(\beta)}(\Gamma^*_\beta) = \min_{\Gamma} L_{G^{-1}(\beta)}(\Gamma).$$

The proof of this proposition relies on the same arguments as those of Proposition 4. It is then omitted. Proposition 7 states that the Oracle β-set is defined as the minimizer, over all confidence sets Γ, of the risk function L_t when the tuning parameter t is set equal to $G^{-1}(\beta)$. Note moreover that the risk function L_t is a trade-off, controlled by the parameter t, between the risk of a confidence set on the one hand, and the information provided by this confidence set on the other hand. Hence, the risk function L_t can be viewed as a generalization to the multiclass case of the risk function provided by Chow (1970) and Herbei and Wegkamp (2006) for binary classification with reject option setting.

3. Empirical risk minimization

In this section we introduce and study confidence sets which rely on the minimization of convex risks. Their definitions and main properties are given in Sections 3.1-3.2. As a consequence, we deduce a data-driven procedure described in Section 3.3 with several theoretical properties, such as rates of convergence, that we demonstrate in Section 3.4.

3.1 ϕ-risk

Let $f = (f_1, \ldots, f_K) : \mathcal{X} \to \mathbb{R}^K$ be a score function and $G_f(.) = \sum_{k=1}^K \bar{F}_{f_k}(.)$. Assuming that the function G_f is continuous and given an information level $\beta \in (0,K)$, there exists $\delta \in \mathbb{R}$, such that $G_f(-\delta) = \beta$. Given this simple but important fact, we define the confidence set $\Gamma_{f,\delta}$ associated to f and δ as

$$\Gamma_{f,\delta}(X) = \{k \,:\, f_k(X) \geq -\delta\}. \tag{4}$$

In this way, the confidence set $\Gamma_{f,\delta}$ consists of top scores, and the threshold δ is fixed so that $\mathcal{I}\left(\Gamma_{f,\delta}\right) = \beta$. As a consequence, we naturally aim at solving the problem

$$\min_{f \in \mathcal{F}} \mathcal{R}(\Gamma_{f,\delta}),$$

where $\mathcal{F}$ is a class of functions. Due to computational issues, it is convenient to focus on a convex surrogate of the previous minimization problem. To this end, let $\phi : \mathbb{R} \to \mathbb{R}$ be a convex function. We define the ϕ-risk of f by

$$R_\phi\left(f\right) = \mathbb{E}\left[\sum_{k=1}^K \phi(Z_k f_k(X))\right], \tag{5}$$

where $Z_k = 2\,\mathbf{1}_{\{Y=k\}} - 1$ for all $k = 1, \ldots, K$. Therefore, our target score becomes

$$\bar{f} \in \operatorname*{argmin}_{f \in \mathcal{F}} R_\phi\left(f\right),$$

for the purpose of building the confidence $\Gamma_{\bar{f},\delta}$. In the sequel, we also introduce f^*, the minimizer over the class of all measurable functions, of the ϕ-risk. The notation suppresses the dependence on ϕ. It is worth mentioning at this point that the definition of the risk function R_ϕ is dictated by Equation (3) and suits for confidence sets. Moreover, this function differs from the classical risk function used in the multiclass setting (see (Tewari and Bartlett, 2007)). The reason behind this is that building a confidence set is closer to K binary classification problems.

3.2 Classification calibration for confidence sets

Convexification of the risk in classification is a standard technique. In this section we adapt classical results and tools to confidence sets in the multiclass setting. We refer the reader to earlier papers for interesting developments (Zhang, 2004; Bartlett et al., 2006; Yuan and Wegkamp, 2010).

One of the main important concept when we deal with convexification of the risk is the notion of calibration of the loss function ϕ. This property permits to connect confidence sets deduced from the convex risk and from the classification risk.

Definition 8 *We say that the function ϕ is confidence set calibrated if for all $\beta > 0$, there exists $\delta^* \in \mathbb{R}$ such that*

$$\Gamma_{f^*,\delta^*} = \Gamma^*_\beta,$$

with f^* being the minimizer of the ϕ-risk

$$f^* \in \operatorname*{argmin}_f R_\phi\left(f\right),$$

where the infimum is taken over the class of all measurable functions. Hence, the confidence set based on f^* coincides with the Bayes confidence set.

Given this, we can state the following proposition that gives a characterization of the confidence set calibration property in terms of the function G.

Proposition 9 *The function ϕ is confidence set calibrated if and only if for all $\beta \in (0,K)$, there exists $\delta^* \in \mathbb{R}$ such that $\phi'(\delta^*)$ and $\phi'(-\delta^*)$ both exists, $\phi'(\delta^*) < 0$, $\phi'(-\delta^*) < 0$ and*

$$G^{-1}(\beta) = \frac{\phi'(\delta^*)}{\phi'(\delta^*) + \phi'(-\delta^*)}\,,$$

where ϕ' denotes the derivative of ϕ.

The proof of the proposition follows the lines of Theorem 1 in the paper by Yuan and Wegkamp (2010) with minor modifications. These characterizations of calibration for confidence sets generalize the notion of calibration in the classification setting as well as the necessary and sufficient condition for the minimizer of the ϕ-risk to be calibrated. Indeed, if we pick $\delta = 0$ in Definition 8 and Proposition 9 we exactly come back to the calibration property in the classical classification setting (see (Bartlett et al., 2006)). Note that commonly used loss functions as boosting ($x \mapsto \exp(-x)$), least squares ($x \mapsto (x-1)^2$) and logistic ($x \mapsto \log(1+\exp(-x))$) are examples of calibrated losses (see for instance (Bartlett

et al., 2006; Wegkamp and Yuan, 2011)). Now, for some score function f and some real number δ such that $G_f(-\delta) = \beta$, we define the excess risk

$$\Delta\mathcal{R}(\Gamma_{f,\delta}) = \mathcal{R}(\Gamma_{f,\delta}) - \mathcal{R}(\Gamma^*_\beta),$$

and the excess ϕ-risk

$$\Delta R_\phi(f) = R_\phi(f) - R_\phi(f^*).$$

We also introduce the marginal conditional excess ϕ-risk on $f = (f_1, \ldots, f_K)$ as

$$\Delta R^k_\phi(f(X)) = p_k(X)(\phi(f_k(X)) - \phi(f^*_k(X))) + (1 - p_k(X))(\phi(-f_k(X)) - \phi(-f^*_k(X))),$$

for $k = 1, \ldots, K$. The following theorem shows that the consistency in terms of ϕ-risk implies the consistency in terms of classification risk $\mathcal{R}$.

Theorem 10 *Assume that ϕ is confidence set calibrated and assume that there exists constants $C > 0$ and $s \geq 1$ such that*[1]

$$|p_k(X) - G^{-1}(\beta)|^s \leq C\Delta R^k_\phi(-\delta^*). \tag{6}$$

Let $\hat{f}_n$ be a sequence of scores. We assume that for each n, the function $G_{\hat{f}_n}$ is continuous. Let $\delta_n \in \mathbb{R}$ be such that $G_{\hat{f}_n}(-\delta_n) = \beta$, then

$$\Delta R_\phi(\hat{f}_n) \xrightarrow{P} 0 \qquad \Rightarrow \qquad \Delta\mathcal{R}(\Gamma_{\hat{f}_n,\delta_n}) \xrightarrow{P} 0.$$

The theorem ensures that the convergence in terms of ϕ risk implies the convergence in terms of risk $\mathcal{R}$. This convergence is made possible since we manage, in the proof, to bound the excess risk by (a power of) the excess ϕ-risk. The assumption needed in this theorem is also standard and is for instance satisfied for the boosting, least square and logistic losses with the parameter s being equal to 2 (see (Bartlett et al., 2006)).

3.3 Data-driven procedure

In this section we provide the steps of the construction of our empirical confidence set that is deduced from the empirical risk minimization. Before going into further details, let us first mention that our procedure is semi-supervised in the sense that it requires two datasets, one of which being unlabeled. Hence we introduce a first data set $\mathcal{D}_n = \{(X_i, Y_i),\ i = 1, \ldots, n\}$, which consists of independent copies of (X, Y). We define the empirical ϕ-risk associated to a score function f (which is the empirical counterpart of R_ϕ given in (5)):

$$\hat{R}_\phi(f) = \frac{1}{n}\sum_{i=1}^{n}\sum_{k=1}^{K}\phi(Z^i_k f_k(X_i)), \tag{7}$$

where $Z^i_k = 2\,\mathbf{1}_{\{Y_i=k\}} - 1$ for all $k = 1, \ldots, K$. We also define the empirical risk minimizer over $\mathcal{F}$, a convex set of score functions, as

$$\hat{f} = \arg\min_{f\in\mathcal{F}} \hat{R}_\phi(f).$$

1. With abuse of notation, we write $\Delta R^k_\phi(-\delta^*)$ instead of $\Delta R^k_\phi((-\delta^*, \ldots, -\delta^*))$ since no confusion can occur.

At this point, we have in hands the optimal score function $\hat{f}$ and need to build the corresponding confidence set with the right expected size. However, let us before introduce an intermediate confidence set that would help comprehension since it mimics the oracle β-set Γ^* with regard to its construction using $\hat{f}$ instead of f^*. For this purpose, we define

$$F_{\hat{f}_k}(t) = \mathbb{P}_X\left(\hat{f}_k(X) \leq t | \mathcal{D}_n\right),$$

for $t \in \mathbb{R}$, where $\mathbb{P}_X$ is the marginal distribution of X. As for the c.d.f. of p_k and f_k, we make the following assumption:

(A2) *The cumulative distribution functions $F_{\hat{f}_k}$ with $k = 1, \ldots, K$ are continuous.*

At this point, we are able to define an empirical approximation of the Oracle β-set for $\beta \in (0, K)$:

$$\widetilde{\Gamma}_\beta(X) = \left\{k \in \{1, \ldots, K\} :\ \widetilde{G}(\hat{f}_k(X)) \leq \beta\right\}, \tag{8}$$

where for $t \in \mathbb{R}$

$$\widetilde{G}(t) = \sum_{k=1}^{K} \bar{F}_{\hat{f}_k}(t), \tag{9}$$

with $\bar{F}_{\hat{f}_k} = 1 - F_{\hat{f}_k}$. Since the function $\widetilde{G}$ depends on the unknown distribution of X, we consider a second but interestingly *unlabeled* dataset $\mathcal{D}_N = \{X_i, i = 1, \ldots, N\}$, independent of $\mathcal{D}_n$ in order to compute the empirical versions of the $\bar{F}_{\hat{f}_k}$'s. By now, we can define the empirical β-set based on $\hat{f}$:

Definition 11 *Let $\hat{f}$ be the minimizer of the empirical ϕ-risk given in (7) based on $\mathcal{D}_n$, and consider the unlabeled dataset $\mathcal{D}_N$. Let $\beta \in (0, K)$. The empirical β-set is given by*

$$\hat{\Gamma}_\beta(X) = \left\{k \in \{1, \ldots, K\} :\ \hat{G}(\hat{f}_k(X)) \leq \beta\right\}, \tag{10}$$

where

$$\hat{G}(.) = \frac{1}{N}\sum_{i=1}^{N}\sum_{k=1}^{K}\mathbf{1}_{\{\hat{f}_k(X_i)\geq .\}}.$$

The most important remark about the construction of this data-driven confidence set is that it is made in a semi-supervised way. Indeed, the estimation of the tail distribution functions of $\hat{f}_k$ requires only a set of *unlabeled* observations. This is particularly attractive in applications where the number of label observations is small (because labelling examples is time consuming or may be costly) and where one has in hand several unlabeled features that can be used to make prediction more accurate. As an important consequence is that the estimation of the tail distribution functions of $\hat{f}_k$ does not depend on the number of observations in each class label. That is to say, this unlabeled dataset can be unbalanced with respect to the classes, that can often occur in multiclass classification settings where the number of classes K is quite large. Next section deals with the theoretical performance of the empirical β-sets.

3.4 Rates of convergence

In this Section, we provide rates of convergence for the empirical confidence sets defined in Section 3.3. First, we state some additional notation. In the sequel, the symbols $\mathbf{P}$ and $\mathbf{E}$ stand for generic probability and expectation, respectively. Moreover, given the empirical β-set $\hat{\Gamma}_\beta$ from Definition 11, we consider the risk $\mathbf{R}\left(\hat{\Gamma}_\beta\right) = \mathbf{P}\left(Y \notin \hat{\Gamma}_\beta(X)\right)$ and the information $\mathbf{I}\left(\hat{\Gamma}_\beta\right) = \mathbf{E}\left[|\hat{\Gamma}_\beta(X)|\right]$. Our first result ensures that $\hat{\Gamma}_\beta$ is of level β up to a term of order $K/\sqrt{N}$.

Proposition 12 *For each $\beta \in (0, K)$, the following equality holds*

$$\mathbf{I}\left(\hat{\Gamma}_\beta\right) = \beta + O\left(\frac{K}{\sqrt{N}}\right).$$

In order to precise rates of convergence for the risk, we need to formulate several assumptions. First, we consider loss functions ϕ which have in common that the modulus of convexity of their underlying risk function R_ϕ, defined by

$$\delta(\varepsilon) = \inf\left\{\frac{R_\phi(f) + R_\phi(g)}{2} - R_\phi\left(\frac{f+g}{2}\right),\ \sum_{k=1}^{K}\mathbb{E}_X\left[(f_k - g_k)^2(X)\right] \geq \varepsilon^2\right\}, \qquad (11)$$

satisfies $\delta(\varepsilon) \geq c_1\epsilon^2$ for some $c_1 > 0$ (we refer to (Bartlett et al., 2006; Bartlett and Mendelson, 2006) for more details on modulus of convexity for classification risk). Moreover, we assume that ϕ is classification calibrated and L-Lipschitz for $L > 0$. On the other hand, for $\alpha > 0$, we assume a margin condition $\mathrm{M}_\alpha^{\mathrm{k}}$ on each $p_k, k = 1, \ldots, K$ (Tsybakov, 2004).

$\mathrm{M}_\alpha^{\mathrm{k}}$: $\mathbb{P}_X\left(0 < |p_k(X) - G^{-1}(\beta)| \leq t\right) \leq c_2 t^\alpha$, for some constant $c_2 > 0$ and for all $t > 0$.

It is important to note that since we assume that the distribution functions of $p_k(X)$ are continuous for each k, we have $\mathbb{P}_X\left(0 < |p_k(X) - G^{-1}(\beta)| \leq t\right) \to 0$ with $t \to 0$. Therefore, the margin condition only precise the rate of this decay to 0. Now, we provide the rate of convergence that we can expect for the empirical confidence sets defined by Equation (10).

Theorem 13 *Assume that $\|f\|_\infty \leq B$ for all $f \in \mathcal{F}$. Let $M_n = \mathcal{N}(1/n, L_\infty, \mathcal{F})$ be the cardinality of the set of closed balls with radius $1/n$ in L_∞-norm needed to cover $\mathcal{F}$. Under the assumptions of Theorem 10, with the modulos of convexity $\delta(\varepsilon) \geq c_1\epsilon^2$ with $c_1 > 0$, if ϕ is L-Lipschitz and if the margin assumptions $\mathrm{M}_\alpha^{\mathrm{k}}$ are satisfied with $\alpha > 0$, then*

$$\mathbf{E}\left[|\Delta\mathcal{R}(\hat{\Gamma}_\beta)|\right] \leq C(B, L, s, \alpha)K^{1-\alpha/(\alpha+s)}\left\{\inf_{f\in\mathcal{F}}\Delta R_\phi(f) + \frac{K\log(M_n)}{n}\right\}^{\alpha/(\alpha+s)} + C'\frac{K}{\sqrt{N}},$$

where $C' > 0$ is an absolute constant and $C(B, L, s, \alpha) > 0$ is a constant that depends only on L, B, s and α.

From this theorem we obtain the following rate of convergence: $K\left(\frac{\log(M_n)}{n}\right)^{\alpha/(\alpha+s)} + \frac{K}{\sqrt{N}}$. This is the first bound for confidence sets in multiclass setting. The regularity parameter α plays a crucial role and governs the rate; larger values of α lead to faster rates. Moreover,

this rate is linear in K, the number of classes, that seems to be the characteristic of multiclass classification as compared to binary classification. Note that the exponent $\alpha/(\alpha+s)$ is not classical and is due to the estimation of quantiles. The second part of the rates which is of order $K/\sqrt{N}$ relies on the estimation of the function $\tilde{G}$ given in (9). This part of the estimation is established under the mild Assumptions (A1) and (A2). For this term the proof of the linearity on K is tricky and is obtained thanks to a new technical probabilistic results on sums of cumulative distribution functions (see Lemma 1). Let us conclude this paragraph by mentioning that Theorem 13 applies for instance for $\mathcal{F}$ being the convex hull of a finite family of a score functions which is the scope of the next section.

4. Application to confidence sets aggregation

This Section is devoted to an aggregation procedure which relies on the superlearning principle. The specifics of our superlearning procedure is given in Section 4.1. In Section 4.2, we show the consistency of our procedure and finally we provide a numerical illustration in Section 4.3 of our algorithm.

4.1 Description of the procedure: superlearning

In this section, we describe the superlearning procedure for confidence sets. The superlearning procedure is based on the V-fold cross-validation procedure (see (van der Laan et al., 2007)). Initially, this aggregation procedure has been introduced in the context of regression and binary classification. Let $V \geq 2$ be an integer and let $(B_v)_{1\leq v\leq V}$ be a regular partition of $\{1, \ldots, n\}$, *i.e.*, a partition such that, for each $v = 1, \ldots, V$, $\mathrm{card}(B_v) \in \{\lfloor n/V\rfloor, \lfloor n/V\rfloor + 1\}$, where we write $\lfloor x\rfloor$ for the floor of any real number x (that is, $x - 1 \leq \lfloor x\rfloor \leq x$). For each $v \in \{1, \ldots, V\}$, we denote by $D_n^{(v)}$ (respectively $D_n^{(-v)}$) the dataset $\{(X_i, Y_i), i \in B_v\}$ (respectively $\{(X_i, Y_i), i \notin B_v\}$), and define the corresponding empirical measures

$$\begin{aligned} P_n^{(v)} &= \frac{1}{\mathrm{card}(B_v)}\sum_{i\in B_v}\mathrm{Dirac}(X_i, Y_i), \quad \text{and} \\ P_n^{(-v)} &= \frac{1}{n - \mathrm{card}(B_v)}\sum_{i\notin B_v}\mathrm{Dirac}(X_i, Y_i). \end{aligned}$$

For a score algorithm f, that is to say a function which maps the empirical distribution to a score function. We define the cross-validated risk of f as

$$\widehat{R}_\phi^n(f) = \frac{1}{V}\sum_{v=1}^{V} R_\phi^{(P_n^{(v)})}\left(f(P_n^{(-v)})\right), \qquad (12)$$

where for each $v \in \{1, \ldots, V\}$, $R_\phi^{(P_n^{(v)})}(f(P_n^{(-v)}))$ is the empirical estimator of $R_\phi(f(P_n^{(-v)})$, based on $D_n^{(v)}$ and conditionally on $D_n^{(-v)}$:

$$R_\phi^{(P_n^{(v)})}\left(f(P_n^{(-v)})\right) = \frac{1}{\mathrm{card}(B_v)}\sum_{i\in I_v}\sum_{k=1}^{K}\phi(Z_k^i f_k(P_n^{(-v)})(X_i)).$$

Next, we consider $\mathcal{F} = \left(f^1, \ldots, f^M\right)$ a family of M score algorithms. We define the cross-validated score by

$$\widehat{f} \in \underset{f \in \mathrm{conv}(\mathcal{F})}{\mathrm{argmin}} \ \widehat{R}^n_\phi(f). \tag{13}$$

Finally, we consider the resulting cross-validated confidence set defined by

$$\hat{\Gamma}^{\mathrm{CV}}_\beta(X) = \left\{k \in \{1, \ldots, K\} : \ \hat{G}(\hat{f}_k(X)) \leq \beta\right\},$$

that we analyse in the next section.

4.2 Consistency of the algorithm

In this Section, we show some results that illustrate the consistency of the superlearning procedure described above. To this end, we introduce the oracle counterpart of the cross-validated risk defined in (12). For a score f, we define

$$\tilde{R}^n_\phi(f) = \frac{1}{V}\sum_{v=1}^{V} R_\phi(f(P_n^{(-v)}),$$

that yields to the oracle counterpart of the cross-validated score defined in (13)

$$\tilde{f} \in \underset{f \in \mathrm{conv}(\mathcal{F})}{\mathrm{argmin}} \ \tilde{R}^n_\phi(f).$$

Here again, we assume that the loss function ϕ satisfies the properties described in Section 3.4 so that we can state the following result:

Proposition 14 *We assume that for each $f \in \mathrm{conv}(\mathcal{F})$ and $v \in \{1, \ldots, V\}$ we have $\|f(P_n^{(-v)})\|_\infty \leq B$. Then the following holds*

$$\mathbf{E}\left[\tilde{R}^n_\phi(\hat{f}) - \tilde{R}^n_\phi(\tilde{f})\right] \leq C(B, L)\frac{KM\log(n)}{\lfloor n/V \rfloor},$$

where $C(B, L) > 0$ is a constant that depends only on B and L.

As usual when one deals with cross-validated estimators, the theorem compares $\hat{f}$ to the oracle counterpart $\tilde{f}$ in terms of the oracle cross-validated ϕ-risk. The theorem teaches us that, for sufficiently large n, $\hat{f}$ perform as well as $\tilde{f}$. However our main goal remains confidence sets. Therefore the next step consists in showing that the confidence set associated to the cross-validated score $\hat{f}$ has good properties in terms of the classification risk. Let $\Gamma_{f,\delta}$ be the confidence set that results from a choice of $\beta \in (0, K)$ and a score function $f \in \mathrm{conv}(\mathcal{F})$. We introduce the following excess risks

$$\begin{aligned}
\Delta\tilde{\mathcal{R}}^n(\Gamma_{f,\delta}) &= \frac{1}{V}\sum_{v=1}^{V} \mathcal{R}\left(\Gamma_{f\left(P_n^{(-v)}\right),\delta}\right) - \mathcal{R}^*, \\
\Delta\tilde{R}^n_\phi(f) &= \frac{1}{V}\sum_{v=1}^{V} R_\phi(f(P_n^{(-v)})) - R_\phi(f^*).
\end{aligned}$$

These quantities can be view as cross-validated counterparts of the excess risks introduced in Section 3.2. Hereafter, we provide a result which can be view as the cross-validation counterpart of Theorem 13. It is interpreted in a same way.

`Forest` ($K = 4$)

		β-set				
β		`rforest`	`softmax reg`	`svm`	`kknn`	`CV`
2	**R**	0.02 (0.02)	0.06 (0.02)	0.02 (0.01)	0.05 (0.03)	0.02 (0.01)
	I	2.00 (0.09)	2.00 (0.08)	2.00 (0.09)	2.00 (0.08)	2.00 (0.08)

`Plant` ($K = 100$)

		β-set				
β		`rforest`	`softmax reg`	`svm`	`kknn`	`CV`
2	**R**	0.18 (0.03)	0.77 (0.02)	0.32 (0.04)	0.20 (0.03)	0.17 (0.03)
	I	2.00 (0.09)	2.02 (0.18)	1.99 (0.10)	2.00 (0.08)	2.00 (0.08)
10	**R**	0.02 (0.01)	0.42 (0.04)	0.03 (0.02)	0.08 (0.03)	0.02 (0.01)
	I	9.95 (0.38)	10.06 (0.58)	9.98 (0.22)	9.98 (0.23)	9.96 (0.37)

Table 1: For each of the $B = 100$ repetitions and for each dataset, we derive the estimated risks **R** and information **I** of the different β-sets w.r.t. β. We compute the means and standard deviations (between parentheses) over the $B = 100$ repetitions. For each β, the β-sets are based on, from left to right, `rforest`, `softmax reg` and `svm`, `kknn` and `CV` which are respectively the random forest, the softmax regression, support vector machines, k nearest neighbors and the superlearning procedure. Top: the dataset is the `Forest` – the dataset is the `Plant`.

Proposition 15 *We assume that for each $v \in \{1, \ldots, V\}$, $t \mapsto \mathbb{P}_X\left(\hat{f}\left(P_n^{(-v)}\right) \leq t | \mathcal{D}_n\right)$ is continuous. Under the assumptions of Proposition 14 and if the margin assumptions $\mathrm{M}^{\mathrm{k}}_\alpha$ are satisfied with $\alpha > 0$,*

$$\mathbf{E}\left[|\Delta\tilde{\mathcal{R}}^n(\hat{\Gamma}^{\mathrm{CV}}_\beta)|\right] \leq C(B, L, \alpha, s)K^{1-\alpha/(\alpha+s)}\left\{\mathbf{E}\left[\Delta\tilde{R}^n_\phi(\tilde{f})\right] + \frac{KM\log(n)}{\lfloor n/V \rfloor}\right\}^{\alpha/(\alpha+s)} + C'\frac{K}{\sqrt{N}}.$$

The proof of Proposition 15 relies on Proposition 14 and similar arguments as in Theorem 13.

4.3 Application to real datasets

In this section, we provide an application of our aggregation procedure described in Section 4.1. For the numerical experiment we focus on the boosting loss and consider the library of algorithms constituted by the random forest, the softmax regression, the support vector machines and the k nearest neighbors (with $k = 11$) procedures. To be more specifics, we respectively exploit the `R` packages `randomForest`, `polspline`, `e1071` and `kknn`. All the `R` functions are used with standard tuning parameters. Finally the parameter V of the aggregation procedure is fixed to 5.

We evaluate the performance of the procedure on two real datasets: the *Forest type mapping* dataset and the *one-hundred plant species leaves* dataset coming from the UCI database. In the sequel we refer to these two datasets as `Forest` and `Plant` respectively. The `Forest` dataset consists of $K = 4$ classes and 523 labeled observations (we gather the train and test sets) with 27 features. Here the classes are unbalanced. In the `Plant` dataset, there are $K = 100$ classes and 1600 labeled observations. This dataset is balanced

so that each class consists of 16 observations. The original dataset contains 3 covariates (each covariate consists of 64 features). In order to make the problem more challenging, we drop 2 covariates.

To get an indication of the statistical significance, it makes sense to compare our aggregated confidence set (referred as `CV`) to the confidence sets that result from each component of the library. Roughly speaking, we evaluate risks (and informations) of these confidence sets on each dataset. To do so, we use the *cross validation* principle. In particular, we run $B = 100$ times the procedure where we split the data each time in three: a sample of size n to build the scores $\hat{f}$; a sample of size N to estimate the function G and to get the confidence sets; and a sample of size M to evaluate the risk and the information. For both datasets, we make sure that in the sample of size n, there is the same number of observations in each class. As a benchmark, we notify that the misclassification risks of the best classifier from the library in the `Forest` dataset is evaluated at 0.15 , whereas in the `Plant` dataset, it is evaluated at 0.40. As planned, the performance of the classical methods are quite bad in this last dataset.

We set the sizes of the samples as $n = 200$, $N = 100$ and $M = 223$ for the `Forest` dataset, and $n = 1000$, $N = 200$ and $M = 400$ for the `Plant` one. The results are reported in Table 1, and confirm our expectations. In particular, our main observation is that the aggregated confidence set (`CV`) outperforms all components of the library in the sense that it is at least as good as the best component in all of the experiments. Second, let us state some remarks that hold for all of the confidence sets and in particular our aggregated confidence set. First, we note that the information $\mathbf{I}(\Gamma)$ has the good level β which is supported by our theory. Moreover, we see that the risk gets drastically better with moderate β as compared to the *best* misclassification risk. For instance, for the `Plant`, the error rate of the confidence set with $\beta = 2$ based on random forests is 0.18 whereas the misclassification error rate of the best component is 0.40.

5. Conclusion

In multiclass classification setting, the present paper propose a new procedure that assigns a set of labels instead of a single label to each instance. This set has a controlled expected size (or information) and its construction relies on cumulative distribution functions and on an empirical risk minimization procedure. Theoretical guarantees, especially rates of convergence are also provided and rely on the regularity of these cumulative distribution functions. The obtained rates of convergence highlight a linear dependence w.r.t the number of classes K. The procedure described in Section 3 is defined as a two steps algorithm whose second step consists in the estimation of the function G (which is a sum of tail distribution functions). Interestingly, this step does not require a set of labeled data and neither to explore the whole classes, that is suitable for semi-supervised learning. Moreover, we apply our methodology to derive an aggregation algorithm which is based on the V-fold cross-validation principle. Future works will focus on the optimality in the minimax sense with respect to the classification error. In particular, we will investigate whether the rates of convergence are optimal in terms of their dependence on K. We believe that this dependence (linearity on K) is the correct one. However we will instigate whether this dependence can be reduced under some sparsity assumption.

This section gathers the proofs of our results. Let us first add a notation that will be used throughout the Appendix: for any random variable (or vector) Z, we denote by $\mathbb{P}_Z$ the probability w.r.t. Z and by $\mathbb{E}_Z$, the corresponding expectation.

Appendix A. Technical Lemmas

We first lay out key lemmata, which are crucial to establish the main theory. We consider $K \geq 2$ be an integer, and $Z_1, \ldots, Z_K$, K random variables. Moreover we define function H by:

$$H(t) = \frac{1}{K} \sum_{k=1}^{K} F_k(t), \quad \forall t \in [0,1],$$

where for all $k = 1, \ldots, K$, F_k is the cumulative distribution function of Z_k. Finally, let us define the generalized inverse H^{-1} of H:

$$H^{-1}(p) = \inf\{t : H(t) \geq p\}, \quad \forall p \in (0,1).$$

Lemma 1 *Let ε distributed from a uniform distribution on $\{1, \ldots, K\}$ and independent of Z_k, $k = 1, \ldots, K$. Let U distributed from a uniform distribution on $[0,1]$. We consider*

$$Z = \sum_{k=1}^{K} Z_k \mathbf{1}_{\{\varepsilon = k\}}.$$

If H is continuous then

$$H(Z) \overset{\mathcal{L}}{=} U \quad \text{and} \quad H^{-1}(U) \overset{\mathcal{L}}{=} Z$$

Proof First we note that for every $t \in [0,1]$, $\mathbb{P}\left(H(Z) \leq t\right) = \mathbb{P}\left(Z \leq H^{-1}(t)\right)$. Moreover, we have

$$\begin{aligned}
\mathbb{P}\left(H(Z) \leq t\right) &= \sum_{k=1}^{K} \mathbb{P}(Z \leq H^{-1}(t), \varepsilon = k) \\
&= \frac{1}{K} \sum_{k=1}^{K} \mathbb{P}(Z_k \leq H^{-1}(t)) \text{ with } \varepsilon \text{ independent of } X \\
&= H(H^{-1}(t)) \\
&= t \text{ with } H \text{ continuous.}
\end{aligned}$$

To conclude the proof, we observe that

$$\begin{aligned}
\mathbb{P}\left(H^{-1}(U) \leq t\right) &= \mathbb{P}\left(U \leq H(t)\right) \\
&= \frac{1}{K} \sum_{k=1}^{K} F_k(t) \\
&= \sum_{k=1}^{K} \mathbb{P}(Z_k \leq t, \varepsilon = k) \\
&= \mathbb{P}(Z \leq t).
\end{aligned}$$

■

Lemma 2 *There exists an absolute constant $C' > 0$ such that*

$$\sum_{k=1}^{K} \mathbf{P}\left(|\hat{G}(\hat{f}_k(X) - \widetilde{G}(\hat{f}_k(X))| \geq |\widetilde{G}(\hat{f}_k(X)) - \beta|\right) \leq \frac{C'K}{\sqrt{N}}.$$

Proof We define, for $\gamma > 0$ and $k \in \{1, \dots K\}$

$$\begin{aligned} A_0^k &= \left\{\left|\widetilde{G}(\hat{f}_k(X)) - \beta\right| \leq \gamma\right\} \\ A_j^k &= \left\{2^{j-1}\gamma < |\widetilde{G}(\hat{f}_k(X)) - \beta| \leq 2^j\gamma\right\}, \ \ j \geq 1. \end{aligned}$$

Since, for every k, the events $(A_j^k)_{j\geq 0}$ are mutually exclusive, we deduce

$$\sum_{k=1}^{K} \mathbf{P}\left(|\hat{G}(\hat{f}_k(X) - \widetilde{G}(\hat{f}_k(X))| \geq |\widetilde{G}(\hat{f}_k(X)) - \beta|\right) = \sum_{k=1}^{K}\sum_{j\geq 0} \mathbf{P}\left(|\hat{G}(\hat{f}_k(X) - \widetilde{G}(\hat{f}_k(X))| \geq |\widetilde{G}(\hat{f}_k(X)) - \beta|, A_j^k\right). \quad (14)$$

Now, we consider a random variable ε uniformly distributed on $\{1, \dots, K\}$ and independent of $\mathcal{D}_n$ and X. Conditional on $\mathcal{D}_n$ and under Assumption $(A2)$, we apply Lemma 1 with $Z_k = \hat{f}_k(X)$, $Z = \sum_{k=1}^K Z_k \mathbf{1}_{\{\varepsilon=k\}}$ and then obtain that $\widetilde{G}(Z)$ is uniformly distributed on $[0, K]$. Therefore, for all $j \geq 0$ and $\gamma > 0$, we deduce

$$\begin{aligned} \frac{1}{K}\sum_{k=1}^{K} \mathbb{P}_X\left(|\widetilde{G}(\hat{f}_k(X)) - \beta| \leq 2^j\gamma|\mathcal{D}_n\right) &= \mathbb{P}_X\left(|\widetilde{G}(Z) - \beta| \leq 2^j\gamma|\mathcal{D}_n\right) \\ &\leq \frac{2^{j+1}\gamma}{K}. \end{aligned}$$

Hence, for all $j \geq 0$, we obtain

$$\sum_{k=1}^{K} \mathbf{P}(A_j^k) \leq 2^{j+1}\gamma. \quad (15)$$

Next, we observe that for all $j \geq 1$

$$\sum_{k=1}^{K} \mathbf{P}\left(|\hat{G}(\hat{f}_k(X) - \widetilde{G}(\hat{f}_k(X))| \geq |\widetilde{G}(\hat{f}_k(X)) - \beta|, A_j^k\right) \leq \sum_{k=1}^{K} \mathbb{E}_{(\mathcal{D}_n,X)}\left[\mathbb{P}_{\mathcal{D}_N}\left(|\hat{G}(\hat{f}_k(X)) - \widetilde{G}(\hat{f}_k(X))| \geq 2^{j-1}\gamma|\mathcal{D}_n, X\right)\mathbf{1}_{A_j^k}\right]. \quad (16)$$

Now, since conditional on $(\mathcal{D}_n, X)$, $\hat{G}(\hat{f}_k(X))$ is an empirical mean of i.i.d random variables of common mean $\widetilde{G}(\hat{f}_k(X)) \in [0, K]$, we deduce from Hoeffding's inequality that

$$\mathbb{P}_{\mathcal{D}_N}\left(|\hat{G}(\hat{f}_k(X)) - \widetilde{G}(\hat{f}_k(X))| \geq 2^{j-1}\gamma|\mathcal{D}_n, X\right) \leq 2\exp\left(-\frac{N\gamma^2 2^{2j-1}}{K^2}\right).$$

Therefore, from Inequalities (14), (15) and (16), we get

$$\begin{aligned} &\sum_{k=1}^{K} \mathbf{P}\left(|\hat{G}(\hat{f}_k(X) - \widetilde{G}(\hat{f}_k(X))| \geq |\widetilde{G}(\hat{f}_k(X)) - \beta|\right) \\ &\qquad \leq \sum_{k=1}^{K} \mathbf{P}\left(A_0^k\right) + \sum_{j\geq 1} 2\exp\left(-\frac{N\gamma^2 2^{2j-1}}{K^2}\right)\left(\sum_{k=1}^{K}\mathbf{P}\left(A_j^k\right)\right) \\ &\qquad \leq 2\gamma + \gamma\sum_{j\geq 1} 2^{j+2}\exp\left(-\frac{N\gamma^2 2^{2j-1}}{K^2}\right). \end{aligned}$$

Finally, choosing $\gamma = \dfrac{K}{\sqrt{N}}$ in the above inequality, we finish the proof of the lemma. ■

Appendix B. Proof of Proposition 4

Let $\beta > 0$ and Γ be a confidence set such that $\mathcal{I}(\Gamma) = \beta$. First, we note that the following decomposition holds

$$\begin{aligned} \mathcal{R}(\Gamma) - \mathcal{R}(\Gamma_\beta^*) &= \sum_{j=1}^{K}\sum_{k=1}^{K}\mathbb{E}\left[\sum_{l=1}^{K}(\mathbf{1}_{\{Y\notin\Gamma(X)\}} - \mathbf{1}_{\{Y\notin\Gamma_\beta^*(X)\}})\mathbf{1}_{\{Y=l\}}\mathbf{1}_{\{|\Gamma(X)|=k\}}\mathbf{1}_{\{|\Gamma_\beta^*(X)|=j\}}\right] \\ &= \sum_{j=1}^{K}\sum_{k=1}^{K}\mathbb{E}\left[\sum_{l=1}^{K}(\mathbf{1}_{\{l\notin\Gamma(X)\}} - \mathbf{1}_{\{l\notin\Gamma_\beta^*(X)\}})p_l(X)\mathbf{1}_{\{|\Gamma(X)|=k\}}\mathbf{1}_{\{|\Gamma_\beta^*(X)|=j\}}\right] \\ &= \sum_{j=1}^{K}\sum_{k=1}^{K}\mathbb{E}\left[\sum_{l=1}^{K}(\mathbf{1}_{\{l\in\Gamma_\beta^*(X)\setminus\Gamma(X)\}} - \mathbf{1}_{\{l\in\Gamma(X)\setminus\Gamma_\beta^*(X)\}})p_l(X)\mathbf{1}_{\{|\Gamma(X)|=k,|\Gamma_\beta^*(X)|=j\}}\right], \end{aligned}$$

where we conditioned by X to get the second equality. From the last decomposition and with

$$\begin{aligned} \mathbb{E}\left[|\Gamma(X)|\right] &= \mathbb{E}\left[|\Gamma_\beta^*(X)|\right] \\ &= \mathbb{E}\left[\sum_{j=1}^{K}\sum_{k=1}^{K} k\mathbf{1}_{\{|\Gamma(X)|=k\}}\mathbf{1}_{\{|\Gamma_\beta^*(X)|=j\}}\right] \\ &= \mathbb{E}\left[\sum_{j=1}^{K}\sum_{k=1}^{K} j\mathbf{1}_{\{|\Gamma(X)|=k\}}\mathbf{1}_{\{|\Gamma_\beta^*(X)|=j\}}\right], \end{aligned}$$

we can express the excess risk as the sum of two terms:

$$\mathcal{R}(\Gamma)-\mathcal{R}(\Gamma^*_\beta) = \sum_{j=1}^K\sum_{k=1}^K \mathbb{E}\left[\left(\sum_{l=1}^K \mathbf{1}_{\{l\in\Gamma^*_\beta(X)\setminus\Gamma(X)\}} p_l(X) - jG^{-1}(\beta)\right)\mathbf{1}_{\{|\Gamma(X)|=k\}}\mathbf{1}_{\{|\Gamma^*_\beta(X)|=j\}}\right] + \sum_{j=1}^K\sum_{k=1}^K \mathbb{E}\left[\left(kG^{-1}(\beta) - \sum_{l=1}^K \mathbf{1}_{\{l\in\Gamma(X)\setminus\Gamma^*_\beta(X)\}} p_l(X)\right)\mathbf{1}_{\{|\Gamma(X)|=k\}}\mathbf{1}_{\{|\Gamma^*_\beta(X)|=j\}}\right]. \quad (17)$$

Now, for $j,k\in\{1,\dots,K\}$ on the event $\{|\Gamma(X)|=k, |\Gamma^*_\beta(X)|=j\}$, we have

$$k = \sum_{l=1}^K \mathbf{1}_{\{l\in\Gamma(X)\setminus\Gamma^*_\beta(X)\}} + \sum_{l=1}^K \mathbf{1}_{\{l\in\Gamma(X)\cap\Gamma^*_\beta(X)\}},$$

and

$$j = \sum_{l=1}^K \mathbf{1}_{\{l\in\Gamma^*_\beta(X)\setminus\Gamma(X)\}} + \sum_{l=1}^K \mathbf{1}_{\{l\in\Gamma(X)\cap\Gamma^*_\beta(X)\}}.$$

Therefore, since

$$l\in\Gamma^*_\beta \Leftrightarrow p_l(X)\geq G^{-1}(\beta),$$

Equality (17) yields the result.

Appendix C. Proof of Theorem 10

First we recall that $\hat{f}_n = (\hat{f}_{n,1},\dots,\hat{f}_{n,K})$ is a sequence of score functions and $\delta_n\in\mathbb{R}$ is such that $G_{\hat{f}_n}(-\delta_n)=\beta$. We suppress the dependence on n to simplify notation and write $\hat{f}=(\hat{f}_1,\dots,\hat{f}_K)$ and δ for $\hat{f}$ and δ_n respectively. Moreover, since there is no doubt, we also suppress everywhere the dependence on X. We also define the events

$$B_k = \{\hat{f}_k\in(-\delta,-\delta^*) \text{ or } \hat{f}_k\in(-\delta^*,-\delta)\}, \quad (18)$$

for $k=1,\dots,K$. We aim at controlling the excess risk $\Delta\mathcal{R}(\Gamma_{\hat{f},\delta})$. Since the risk $\mathcal{R}$ is decomposable, it is convenient to introduce "marginal excess risks":

$$\Delta\mathcal{R}^k(\Gamma_{f,\delta}) = \mathbf{1}_{\{k\in(\Gamma_{\hat{f},\delta}\,\Delta\,\Gamma^*_\beta)\}}|p_k - G^{-1}(\beta)|.$$

Recall also that by convexity of the loss function ϕ, we have that for all $x,y\in\mathbb{R}$,

$$\phi(y)-\phi(x)\geq\phi'(x)(y-x). \quad (19)$$

Assume that $\hat{f}_k\leq-\delta$ and $\hat{f}_k\leq-\delta^*\leq f^*_k$, which translates as $p_k - G^{-1}(\beta)\geq 0$, we get thanks to (19)

$$p_k(\phi(\hat{f}_k)-\phi(-\delta)) - (1-p_k)(\phi(-\hat{f}_k)-\phi(\delta)) \geq (\phi'(\delta^*)-\phi'(-\delta^*))(p_k-G^{-1}(\beta))(\hat{f}_k+\delta^*)\geq 0.$$

Similarly, if $\hat{f}_k\geq-\delta$ and $\hat{f}_k\geq-\delta^*\geq f^*_k$, that is, $p_k - G^{-1}(\beta)\leq 0$ we have

$$p_k(\phi(\hat{f}_k)-\phi(-\delta)) - (1-p_k)(\phi(-\hat{f}_k)-\phi(\delta))\geq 0.$$

Note that in the following two cases

- $\hat{f}_k\leq -\delta$ and $f^*_k\leq-\delta^*$;
- $\hat{f}_k\geq -\delta$ and $f^*_k\geq-\delta^*$,

we have $\Delta\mathcal{R}^k(\Gamma_{\hat{f},\delta})=0$. Therefore, from the above inequalities, on B^c_k and by assumption (6) we get

$$\mathbf{1}_{B^c_k}\mathbf{1}_{\{k\in(\Gamma_{\hat{f},\delta}\,\Delta\,\Gamma^*_\beta)\}}|p_k - G^{-1}(\beta)|^s \leq C(\Delta R^k_\phi(\hat{f})). \quad (20)$$

Therefore, since $s\geq 1$, we have

$$\left(\mathbb{E}\left[\sum_{k=1}^K \mathbf{1}_{B^c_k\cap\{k\in(\Gamma_{\hat{f},\delta}\,\Delta\,\Gamma^*_\beta)\}}|p_k-G^{-1}(\beta)|\right]\right)^s \leq \frac{1}{K}\sum_{k=1}^K \mathbb{E}\left[\mathbf{1}_{B^c_k\cap\{k\in\Gamma_{\hat{f},\delta}\Delta\Gamma^*_\beta\}}K^s|p_k-G^{-1}(\beta)|^s\right] \leq CK^{s-1}\Delta R_\phi(\hat{f}).$$

Moreover

$$\mathbb{E}\left[\sum_{k=1}^K \mathbf{1}_{B_k}\mathbf{1}_{\{k\in(\Gamma_{\hat{f},\delta}\,\Delta\,\Gamma^*_\beta)\}}|p_k-G^{-1}(\beta)|\right] \leq \sum_{k=1}^K\mathbb{P}(B_k) \leq \mathbb{E}\left[|G_{\hat{f}}(-\delta)-G_{\hat{f}}(-\delta^*)|\right] \leq \mathbb{E}\left[|G_{f^*}(-\delta^*)-G_{\hat{f}}(-\delta^*)|\right].$$

Finally, we get the following bound

$$\Delta\mathcal{R}(\Gamma_{\hat{f},\delta}) \leq K^{\frac{s-1}{s}}\Delta R_\phi(\hat{f})^{1/s} + \mathbb{E}\left[|G_{f^*}(-\delta^*)-G_{\hat{f}}(-\delta^*)|\right].$$

Now we observe that

$$|\mathbf{1}_{\{\hat{f}_k\geq-\delta^*\}} - \mathbf{1}_{\{f^*_k\geq-\delta^*\}}| \leq \mathbf{1}_{\{|p_k-G^{-1}(\beta)|^s\leq C\Delta R^k_\phi(\hat{f})\}}. \quad (21)$$

Therefore, for each $\gamma>0$, we have

$$\mathbb{E}_X\left[|G_{f^*}(-\delta^*)-G_{\hat{f}}(-\delta^*)|\right] \leq \sum_{k=1}^K \mathbb{P}_X\left(|p_k(X)-G^{-1}(\beta)|^s\leq C\Delta R^k_\phi(\hat{f})\right) \leq \sum_{k=1}^K \mathbb{P}_X\left(|p_k(X)-G^{-1}(\beta)|\leq\gamma^{1/s}\right) + \mathbb{P}_X\left(\gamma\leq C\Delta R^k_\phi(\hat{f})\right).$$

Now using Markov Inequality, we have that

$$\sum_{k=1}^K \mathbb{P}_X\left(\gamma\leq C\Delta R^k_\phi(\hat{f})\right) \leq \frac{C}{\gamma}\sum_{k=1}^K\mathbb{E}_X\left[\Delta R^k_\phi(\hat{f})\right] \leq \frac{C\Delta R_\phi(\hat{f})}{\gamma}.$$

The above inequality yields

$$\mathbb{E}_X\left[|G_{f^*}(-\delta^*) - G_{\hat{f}}(-\delta^*)|\right] \leq \frac{C\Delta R_\phi(\hat{f})}{\gamma} + \sum_{k=1}^{K} \mathbb{P}_X\left(|p_k(X) - G^{-1}(\beta)| \leq \gamma^{1/s}\right). \quad (22)$$

Hence, with Equation (21), we get

$$\Delta\mathcal{R}(\Gamma_{\hat{f},\delta}) \leq K^{\frac{s-1}{s}} \Delta R_\phi(\hat{f})^{1/s} + \frac{C\Delta R_\phi(\hat{f})}{\gamma} + \sum_{k=1}^{K} \mathbb{P}_X\left(|p_k(X) - G^{-1}(\beta)| \leq \gamma^{1/s}\right).$$

The term $\sum_{k=1}^{K} \mathbb{P}_X\left(|p_k(X) - G^{-1}(\beta)| \leq \gamma^{1/s}\right) \to 0$ when $\gamma \to 0$, given that the distribution function of the $p_k's$ are continuous. Then using the convergence in distribution of $\Delta R_\phi(\hat{f})$ to zero, the last inequality ensures the desired result.

Appendix D. Proof of Proposition 12

For any $\beta \in (0, K)$, and conditional on $\mathcal{D}_n$ we define

$$\widetilde{G}^{-1}(\beta) = \inf\{t \in \mathbb{R} : \ \widetilde{G}(t) \leq \beta\}. \quad (23)$$

We note that Assumption $(A2)$ ensures that $t \mapsto \widetilde{G}(t)$ is continuous and then

$$\widetilde{G}(\widetilde{G}^{-1}(\beta)) = \beta.$$

Now, we have

$$\begin{aligned} |\widetilde{\Gamma}_\beta(X)| &= \sum_{k=1}^{K} \mathbf{1}_{\{\widetilde{G}(\hat{f}_k(X)) \leq \beta\}} \\ &= \sum_{k=1}^{K} \mathbf{1}_{\{\hat{f}_k(X) \geq \widetilde{G}^{-1}(\beta)\}}. \end{aligned}$$

Hence, the last equation implies that

$$\mathbb{E}_X\left[|\widetilde{\Gamma}_\beta(X)||\mathcal{D}_n\right] = \sum_{k=1}^{K} \mathbb{P}_X\left(\hat{f}_k(X) \geq \widetilde{G}^{-1}(\beta)|\mathcal{D}_n\right) = \widetilde{G}(\widetilde{G}^{-1}(\beta)) = \beta. \quad (24)$$

Therefore, we obtain $\mathbf{E}\left[|\widetilde{\Gamma}_\beta(X)|\right] = \beta$. Also, we can write

$$\begin{aligned} \left|\mathbf{E}\left[\left|\hat{\Gamma}_\beta(X)\right|\right] - \beta\right| &\leq \left|\mathbf{E}\left[|\hat{\Gamma}_\beta(X)| - |\widetilde{\Gamma}_\beta(X)|\right]\right| \\ &\leq \left|\mathbf{E}\left[\sum_{k=1}^{K}\left(\mathbf{1}_{\{\hat{G}(\hat{f}_k(X)) \leq \beta\}} - \mathbf{1}_{\{\widetilde{G}(\hat{f}_k(X)) \leq \beta\}}\right)\right]\right| \\ &\leq \mathbf{E}\left[|\hat{\Gamma}_\beta(X) \,\Delta\, \widetilde{\Gamma}_\beta(X)|\right] \\ &\leq \sum_{k=1}^{K} \mathbf{E}\left[|\mathbf{1}_{\{\hat{G}(\hat{f}_k(X)) \leq \beta\}} - \mathbf{1}_{\{\widetilde{G}(\hat{f}_k(X)) \leq \beta\}}|\right] \\ &\leq \sum_{k=1}^{K} \mathbf{P}\left(|\hat{G}(\hat{f}_k(X) - \widetilde{G}(\hat{f}_k(X))| \geq |\widetilde{G}(\hat{f}_k(X)) - \beta|\right). \end{aligned}$$

Hence, applying Lemma 2 in the above inequality, we obtain the desired result.

Appendix E. Proof of Theorem 13

When there is no doubt, we suppress the dependence on X. First, let us state a intermediate result that is also needed to prove the theorem.

Lemma 3 *Consider $\Gamma_{\hat{f},\delta}$ the confidence set based on the score function $\hat{f}$ with information β (that is, $G_{\hat{f}}(-\delta) = \beta$). Under assumptions M_α^k, the following holds*

$$\Delta\mathcal{R}(\Gamma_{\hat{f},\delta}) \leq C(\alpha, s)\left\{K^{1-1/(s+\lambda-\lambda s)}\Delta R_\phi(\hat{f})^{1/(s+\lambda-\lambda s)} + K^{1-\lambda/(s+\lambda-\lambda s)}\Delta R_\phi(\hat{f})^{\lambda/(s+\lambda-\lambda s)}\right\},$$

where $\lambda = \frac{\alpha}{\alpha+1}$ and $C(\alpha, s)$ is non negative constant which depends only on α and s.

Proof For each $k = 1, \ldots, K$, we define the following events $S_k = B_k^c \cap \{k \in (\Gamma_{\hat{f},\delta} \,\Delta\, \Gamma_\beta^*)\}$ and $T_k = B_k \cap \{k \in (\Gamma_{\hat{f},\delta} \,\Delta\, \Gamma_\beta^*)\}$, where the B_k's are the events given in Eq. (18). Now we observe that

$$\Delta\mathcal{R}(\Gamma_{\hat{f},\delta}) = \mathbb{E}\left[\sum_{k=1}^{K} \mathbf{1}_{S_k}|p_k - G^{-1}(\beta)|\right] + \mathbb{E}\left[\sum_{k=1}^{K} \mathbf{1}_{T_k}|p_k - G^{-1}(\beta)|\right] = \Delta\mathcal{R}_1(\Gamma_{\hat{f},\delta}) + \Delta\mathcal{R}_2(\Gamma_{\hat{f},\delta}),$$

where

$$\begin{aligned} \Delta\mathcal{R}_1(\Gamma_{\hat{f},\delta}) &= \mathbb{E}\left[\sum_{k=1}^{K} \mathbf{1}_{S_k}|p_k - G^{-1}(\beta)|\right], \\ \Delta\mathcal{R}_2(\Gamma_{\hat{f},\delta}) &= \mathbb{E}\left[\sum_{k=1}^{K} \mathbf{1}_{T_k}|p_k - G^{-1}(\beta)|\right]. \end{aligned}$$

The end of the proof consists in controlling each of these two terms. Let us first consider $\Delta\mathcal{R}_1(\Gamma_{\hat{f},\delta})$. For $\varepsilon > 0$, we have

$$\begin{aligned} \Delta\mathcal{R}_1(\Gamma_{\hat{f},\delta}) &= \mathbb{E}\left[\sum_{k=1}^{K} \mathbf{1}_{S_k}|p_k - G^{-1}(\beta)|\left(\mathbf{1}_{\{|p_k - G^{-1}(\beta)| \geq \varepsilon\}} + \mathbf{1}_{\{|p_k - G^{-1}(\beta)| \leq \varepsilon\}}\right)\right] \\ &\leq \mathbb{E}\left[\sum_{k=1}^{K} \mathbf{1}_{S_k}\varepsilon^{1-s}|p_k - G^{-1}(\beta)|^s\right] + \varepsilon\sum_{k=1}^{K}\mathbb{P}(S_k) \\ &\leq C\varepsilon^{1-s}\Delta R_\phi(\hat{f}) + \varepsilon\sum_{k=1}^{K}\mathbb{P}(S_k), \end{aligned} \quad (25)$$

where we used the assumption (6) and more precisely (20) to deduce the last inequality. To control $\sum_{k=1}^{K}\mathbb{P}(S_k)$, we require the following result that is a direct application of Lemma 5 in (Bartlett et al., 2006).

Lemma 4 *Under the assumptions M_α^k we have*

$$\sum_{k=1}^{K} \mathbb{P}(S_k) \leq C(\alpha) \left(K^{1/\alpha} \Delta\mathcal{R}_1(\Gamma_{\hat{f},\delta}) \right)^{\frac{\alpha}{\alpha+1}},$$

where $C(\alpha) > 0$ is a constant that depends only on α.

Proof The proof of this result relies on the following simple fact: for all $\varepsilon > 0$

$$\begin{aligned} \mathbb{E}\left[\mathbf{1}_{S_k} |p_k - G^{-1}(\beta)|\right] &\geq \varepsilon \mathbb{E}\left[\mathbf{1}_{S_k} \mathbf{1}_{\{|p_k - G^{-1}(\beta)| \geq \varepsilon\}}\right] \\ &\geq \varepsilon \left[\mathbb{P}(S_k) - c_2 \varepsilon^\alpha\right]. \end{aligned}$$

Choosing $\varepsilon = \left(\frac{1}{c_2 K(\alpha+1)} \sum_{k=1}^{K} \mathbb{P}(S_k) \right)^{1/\alpha}$ we get the lemma. ■

We go back to the proof of Lemma 3. Applying Lemma 4 to (25), we get

$$\Delta\mathcal{R}_1(\Gamma_{\hat{f},\delta}) \leq C\varepsilon^{1-s} \Delta R_\phi(\hat{f}) + \varepsilon C(\alpha) \left(K^{1/\alpha} \Delta\mathcal{R}_1(\Gamma_{\hat{f},\delta}) \right)^{\frac{\alpha}{\alpha+1}}.$$

Choosing $\varepsilon = \frac{s-1}{sC(\alpha)} K^{(\lambda-1)} \Delta\mathcal{R}_1(\Gamma_{\hat{f},\delta})^{(1-\lambda)}$, we obtain

$$\Delta\mathcal{R}_1(\Gamma_{\hat{f},\delta}) \leq C_1(\alpha, s) K^{1-1/(s-\lambda s+\lambda)} \Delta R_\phi(\hat{f})^{1/(s+\lambda-\lambda s)}, \tag{26}$$

for a non negative constant $C_1(\alpha, s)$ that depends only on α and s.

Let us now focus on the second term, $\Delta\mathcal{R}_2(\Gamma_{\hat{f},\delta})$. Since the assumptions of Theorem 10 are satisfied, we can use Equation (22) for any $\gamma > 0$. Combined with the Margin assumptions M_α^k, we obtain

$$\begin{aligned} \Delta\mathcal{R}_2(\Gamma_{\hat{f},\delta}) &\leq \mathbb{E}_X\left[|G_{f^*}(-\delta^*) - G_{\hat{f}}(-\delta^*)| \right] \\ &\leq \frac{C\Delta R_\phi(\hat{f})}{\gamma} + c_2 K \gamma^{\alpha/s}. \end{aligned}$$

Therefore, optimizing in γ, we have

$$\Delta\mathcal{R}_2(\Gamma_{\hat{f},\delta}) \leq C_2(\alpha, s) K^{1-\lambda/(s+\lambda-\lambda s)} \Delta R_\phi(\hat{f})^{\lambda/(s+\lambda-\lambda s)},$$

for a non negative constant $C_2(\alpha, s)$ that depends only on α and s. The result stated in the lemma is deduced by combining the last equation with Equation (26) and by setting $C(\alpha, s) = \max\{C_1(\alpha, s); C_2(\alpha, s)\}$. ■

We now state another important lemma that describes the behavior of the empirical minimizer of the ϕ-risk on the class $\mathcal{F}$:

Lemma 5 *Let $\bar{f} \in \mathcal{F}$ be the minimizer of $R_\phi(f)$ over $\mathcal{F}$. Under the assumptions of Theorem 13, we have that*

$$\mathbf{E}\left[R_\phi(\hat{f}_n) - R_\phi(\bar{f}) \right] \leq \frac{3KL}{n} + \frac{KC(B, L) \log(N_n)}{n},$$

where $C(B, L) > 0$ is a constant that only depends on the constant B given in the Proposition 14 and on the Lipschitz constant L.

Proof First, according to Eq. (11), for each $f \in \mathcal{F}$, we can write

$$\frac{R_\phi(f) + R_\phi(\bar{f})}{2} - R_\phi\left(\frac{f + \bar{f}}{2} \right) \geq \delta \left(\sqrt{\sum_{k=1}^{K} \mathbb{E}_X\left[(f_k - \bar{f}_k)^2(X) \right]} \right),$$

Hence, by assumption on the modulus of convexity, we deduce

$$\frac{R_\phi(f) + R_\phi(\bar{f})}{2} - R_\phi\left(\frac{f + \bar{f}}{2} \right) \geq c_1 \sum_{k=1}^{K} \mathbb{E}_X\left[(f_k - \bar{f}_k)^2(X) \right].$$

Since $R_\phi\left(\frac{f+\bar{f}}{2}\right) \geq R_\phi(\bar{f})$, we obtain

$$\sum_{k=1}^{K} \mathbb{E}_X\left[(f_k - \bar{f}_k)^2(X) \right] \leq \frac{1}{2c_1} R_\phi(f) - R_\phi(\bar{f}).$$

Now, denoting by $h(z, f(x)) = \sum_{k=1}^{K} \phi(z_k f_k(x)) - \phi(z_k \bar{f}_k(x))$, we get the following bound

$$\begin{aligned} \mathbb{E}_X\left[h^2(Zf(X)) \right] &\leq KL^2 \sum_{k=1}^{K} \mathbb{E}_X\left[(f_k - \bar{f}_k)^2(X) \right] \\ &\leq \frac{KL^2}{2c_1} \mathbb{E}_X\left[h(Zf(X)) \right], \end{aligned} \tag{27}$$

where L is the Lipschitz constant L for ϕ. On the other hand, we have the following decomposition

$$R_\phi(\hat{f}) - R_\phi(\bar{f}) = R_\phi(\hat{f}) + 2(\hat{R}_\phi(\hat{f}) - \hat{R}_\phi(\bar{f})) - 2(\hat{R}_\phi(\hat{f}) - \hat{R}_\phi(\bar{f})) - R_\phi(\bar{f}).$$

Also, since $\hat{R}_\phi(\hat{f}) - \hat{R}_\phi(\bar{f}) \leq 0$, we get

$$\begin{aligned} R_\phi(\hat{f}) - R_\phi(\bar{f}) &\leq (R_\phi(\hat{f}) - R_\phi(\bar{f})) - 2(\hat{R}_\phi(\hat{f}) - \hat{R}_\phi(\bar{f})) \\ &\leq \frac{3KL}{n} + \sup_{f \in \mathcal{F}_n} (R_\phi(f) - R_\phi(\bar{f})) - 2(\hat{R}_\phi(f) - \hat{R}_\phi(\bar{f})), \end{aligned}$$

where $\mathcal{F}_n$ is the ϵ-net of $\mathcal{F}$ w.r.t the L_∞-norm and with $\epsilon = 1/n$. Now, using Bernstein's Inequality, we have that for all $f \in \mathcal{F}_n$ and $t > 0$

$$\begin{aligned} &\mathbf{P}\left((R_\phi(f) - R_\phi(\bar{f})) - 2(\hat{R}_\phi(f) - \hat{R}_\phi(\bar{f})) \geq t \right) \leq \\ &\quad \mathbf{P}\left(2((R_\phi(f) - R_\phi(\bar{f})) - (\hat{R}_\phi(f) - \hat{R}_\phi(\bar{f})) \geq t + R_\phi(f) - R_\phi(\bar{f}) \right) \\ &\quad \leq \exp\left(- \frac{n(t + \mathbb{E}[h(Z, f(X))])^2/8}{\mathbb{E}[h^2(Z, f(X))]) + (2KLB/3)(t + \mathbb{E}[h(Z, f(X))]))} \right). \end{aligned}$$

Using Eq. (27), we get for all $f \in \mathcal{F}_n$

$$\mathbf{P}\left((R_\phi(f) - R_\phi(\bar{f})) - 2(\hat{R}_\phi(f) - \hat{R}_\phi(\bar{f})) \geq t \right) \leq \exp\left(- \frac{nt}{8(KL^2/(2c_1) + KLB/3)} \right),$$

Therefore, using a union bound argument, and then integrating we deduce that

$$\begin{aligned}\mathbf{E}\left[R_\phi(\hat{f}) - R_\phi(\bar{f})\right] &\leq \frac{3KL}{n} + \mathbf{E}\left[\sup_{f\in\mathcal{F}_n}(R_\phi(f) - R_\phi(\bar{f})) - 2(\hat{R}_\phi(f) - \hat{R}_\phi(\bar{f}))\right] \\ &\leq \frac{3KL}{n} + \frac{KC(B,L)\log(M_n)}{n}.\end{aligned}$$

■

We are now ready to conclude the proof of the theorem. We have the following inequality

$$|\mathcal{R}(\hat{\Gamma}_\beta) - \mathcal{R}^*_\beta| \leq \Delta\mathcal{R}(\widetilde{\Gamma}_\beta) + |\mathcal{R}(\hat{\Gamma}_\beta) - \mathcal{R}(\widetilde{\Gamma}_\beta)|. \tag{28}$$

We deal which each terms in the r.h.s separately. First, we have from Jensen's Inequality that

$$\left(\mathbf{E}\left[\Delta\mathcal{R}(\widetilde{\Gamma}_\beta)\right]\right)^{\frac{s+\lambda-\lambda s}{\lambda}} \leq \mathbf{E}\left[\Delta\mathcal{R}(\widetilde{\Gamma}_\beta)^{\frac{s+\lambda-\lambda s}{\lambda}}\right].$$

Hence, from Lemma 3, we deduce

$$\left(\mathbf{E}\left[\Delta\mathcal{R}(\widetilde{\Gamma}_\beta)\right]\right)^{\frac{s+\lambda-\lambda s}{\lambda}} \leq C(\alpha,s)^{\frac{s+\lambda-\lambda s}{\lambda}} K^{\frac{s+\lambda-\lambda s}{\lambda}-1}\mathbf{E}\left[\Delta R_\phi(\hat{f})\right].$$

Moreover, from Lemma 5, we have that

$$\mathbf{E}\left[\Delta R_\phi(\hat{f})\right] \leq \inf_{f\in\mathcal{F}}\Delta R_\phi(f) + \frac{3KL}{n} + \frac{KC(B,L)\log(M_n)}{n}.$$

Therefore, we can write

$$\mathbf{E}\left[\Delta\mathcal{R}(\widetilde{\Gamma}_\beta)\right] \leq C(\alpha,s)K^{1-\lambda/(s+\lambda-\lambda s)}\left\{\inf_{f\in\mathcal{F}}\Delta R_\phi(f) + \frac{3KL}{n} + \frac{KC(B,L)\log(N_n)}{n}\right\}^{\lambda/(s+\lambda-\lambda s)}. \tag{29}$$

For the second term $|\mathcal{R}(\hat{\Gamma}_\beta) - \mathcal{R}(\widetilde{\Gamma}_\beta)|$ in (28), we observe that

$$\mathbf{1}_{\{Y\notin\hat{\Gamma}_\beta(X)\}} - \mathbf{1}_{\{Y\notin\widetilde{\Gamma}_\beta(X)\}} = \sum_{k=1}^K \mathbf{1}_{\{Y=k\}}\mathbf{1}_{\left\{k\notin\hat{\Gamma}_\beta(X)\right\}} - \sum_{k=1}^K \mathbf{1}_{\{Y=k\}}\mathbf{1}_{\left\{k\notin\widetilde{\Gamma}_\beta(X)\right\}}.$$

Therefore, we can write

$$\begin{aligned}\mathbf{E}\left[\mathbf{1}_{Y\notin\hat{\Gamma}_\beta(X)\}} - \mathbf{1}_{\{Y\notin\widetilde{\Gamma}_\beta(X)\}}\right] &= \sum_{k=1}^K \mathbf{E}\left[p_k(X)\left(\mathbf{1}_{\left\{k\notin\hat{\Gamma}_\beta(X)\right\}} - \mathbf{1}_{\left\{k\notin\widetilde{\Gamma}_\beta(X)\right\}}\right)\right] \\ &= \sum_{k=1}^K \mathbf{E}\left[p_k(X)\left(\mathbf{1}_{\left\{\hat{G}(\hat{f}_k(X))>\beta\right\}} - \mathbf{1}_{\left\{\tilde{G}(\hat{f}_k(X))>\beta\right\}}\right)\right].\end{aligned}$$

Since $0 \leq p_k(X) \leq 1$ for all $k \in \{1,\ldots,K\}$, the last equality implies

$$\begin{aligned}\left|\mathbf{R}\left(\hat{\Gamma}_\beta\right) - \mathbf{R}\left(\tilde{\Gamma}_\beta\right)\right| &= \left|\mathbf{E}\left[\mathbf{1}_{Y\notin\hat{\Gamma}_\beta(X)\}} - \mathbf{1}_{\{Y\notin\widetilde{\Gamma}_\beta(X)\}}\right]\right| \\ &\leq \sum_{k=1}^K \mathbf{E}\left[\left|\mathbf{1}_{\left\{\hat{G}(\hat{f}_k(X))>\beta\right\}} - \mathbf{1}_{\left\{\tilde{G}(\hat{f}_k(X))>\beta\right\}}\right|\right] \\ &\leq \sum_{k=1}^K \mathbf{P}\left(|\hat{G}(\hat{f}_k(X) - \widetilde{G}(\hat{f}_k(X))| \geq |\widetilde{G}(\hat{f}_k(X)) - \beta|\right).\end{aligned}$$

Therefore, Lemma 2 implies

$$\left|\mathbf{R}\left(\hat{\Gamma}_\beta\right) - \mathbf{R}\left(\tilde{\Gamma}_\beta\right)\right| \leq \frac{C'K}{\sqrt{N}}. \tag{30}$$

Injecting Equations (29) and (30) to Equation (28) we conclude the proof of the theorem.

Appendix F. Proof of Proposition 14

We begin with the following decomposition

$$\tilde{R}^n_\phi(\hat{f}) - \tilde{R}^n_\phi(\tilde{f}) = \tilde{R}^n_\phi(\hat{f}) + 2(\hat{R}^n_\phi(\hat{f}) - \hat{R}^n_\phi(\tilde{f})) - 2(\hat{R}^n_\phi(\hat{f}) - \hat{R}^n_\phi(\tilde{f})) - \tilde{R}^n_\phi(\tilde{f}),$$

since $\hat{R}^n_\phi(\hat{f}) - \hat{R}^n_\phi(\tilde{f}) \leq 0$, we get

$$\tilde{R}^n_\phi(\hat{f}) - \tilde{R}^n_\phi(\tilde{f}) \leq (\tilde{R}^n_\phi(\hat{f}) - \tilde{R}^n_\phi(\tilde{f})) - 2(\hat{R}^n_\phi(\hat{f}) - \hat{R}^n_\phi(\tilde{f})). \tag{31}$$

Now, we denote by $\mathcal{C}_n = \{(i_1/n,\ldots,i_M/n),(i_1,\ldots,i_M)\in\{0,\ldots,n\}\}\cap\mathcal{C}_M$,
and $\mathcal{F}_n = \{f = \sum_{i=1}^M m_i f_i,\ \ m_1,\ldots m_M)\in\mathcal{C}_n\}$. For each $f\in\mathrm{conv}(\mathcal{F})$, there exists $f_n\in\mathcal{F}_n$ such that

$$\begin{aligned}|\tilde{R}^n_\phi(f) - \tilde{R}^n_\phi(f_n)| &\leq \frac{2KLBM}{n} \\ |\hat{R}^n_\phi(f) - \hat{R}^n_\phi(f_n)| &\leq \frac{2KLBM}{n}.\end{aligned}$$

Therefore, with Equation (31), we obtain

$$\tilde{R}^n_\phi(\hat{f}) - \tilde{R}^n_\phi(\tilde{f}) \leq \frac{6LKB}{n} + \sup_{f\in\mathcal{F}_n}(\tilde{R}^n_\phi(f) - \tilde{R}^n_\phi(\bar{f})) - 2(\hat{R}^n_\phi(f) - \hat{R}^n_\phi(\bar{f})).$$

Now, Similar arguments as in the paper by Dudoit and van der Laan (2005) and Lemma 5 yield the proposition.

Abstract

We consider two settings of online learning to rank where feedback is restricted to top ranked items. The problem is cast as an online game between a learner and sequence of users, over T rounds. In both settings, the learners objective is to present ranked list of items to the users. The learner's performance is judged on the entire ranked list and true relevances of the items. However, the learner receives highly restricted feedback at end of each round, in form of relevances of only the top k ranked items, where $k \ll m$. The first setting is *non-contextual*, where the list of items to be ranked is fixed. The second setting is *contextual*, where lists of items vary, in form of traditional query-document lists. No stochastic assumption is made on the generation process of relevances of items and contexts. We provide efficient ranking strategies for both the settings. The strategies achieve $O(T^{2/3})$ regret, where regret is based on popular ranking measures in first setting and ranking surrogates in second setting. We also provide impossibility results for certain ranking measures and a certain class of surrogates, when feedback is restricted to the top ranked item, i.e. $k = 1$. We empirically demonstrate the performance of our algorithms on simulated and real world data sets.

Keywords: Learning to Rank, Online Learning, Partial Monitoring, Online Bandits, Learning Theory

1. Introduction

Learning to rank (Liu, 2011) is a supervised machine learning problem, where the output space consists of *rankings* of objects. Most learning to rank methods are based on supervised *batch* learning, i.e., rankers are trained on batch data in an offline setting. The accuracy of a ranked list, in comparison to the actual relevance of the documents, is measured by various ranking measures, such as Discounted Cumulative Gain (DCG) (Järvelin and Kekäläinen, 2000), Average Precision (AP) (Baeza-Yates and Ribeiro-Neto, 1999) and others.

Collecting reliable training data can be expensive and time consuming. In certain applications, such as deploying a new web app or developing a custom search engine, collecting large amount of high quality labeled data might be infeasible (Sanderson, 2010). Moreover, a ranker trained from batch data might not be able to satisfy rapidly changing user needs and preferences. Thus, a promising direction of research is development of online ranking systems, where a ranker is updated on the fly. One type of online ranking models learns from implicit feedback inferred from user clicks on ranked lists (Hofmann et al., 2013). However, there are some potential drawbacks in learning from user clicks. It is possible that the system is designed for explicit ratings but not clicks. Moreover, a clicked item might not actually be relevant to the user and there is also the problem of bias towards top ranked items in inferring feedback from user clicks (Joachims, 2002).

We develop models for online learning of ranking systems, from explicit but *highly restricted* feedback. At a high level, we consider a ranking system which interacts with users over a time horizon, in a sequential manner. At each round, the system presents a ranked list of m items to the user, with the quality of the ranked list judged by the relevance of the items to the user. The relevance of the items, reflecting varying user preferences, is encoded as relevance vectors. The system's objective is to learn from the feedback it receives and update its ranker over time, to satisfy as many users as possible. However, the feedback that the system receives at end of each round is not the full relevance vector, but relevance of only the top k ranked items, where $k \ll m$ (typically, $k = 1$ or 2). We consider two problem settings under the general framework: *non-contextual* and *contextual*. In the first setting, we assume that the set of items to be ranked are fixed (i.e., there are no context on items), with the relevance vectors varying according to users' preferences. In the second setting, we assume that set of items vary, as traditional query-document lists. We highlight two motivating examples for such feedback model, encompassing *privacy* concerns and *economic and user-burden* constraints.

Privacy Concerns: Assume that a medical company wants to build an app to suggest activities (take a walk, meditate, watch relaxing videos, etc.) that can lead to reduction of stress in a certain highly stressed segment of the population. The activities do not have contextual representation and are fixed over time. Not all activities are likely to be equally suitable for everyone under all conditions since the effects of the activities vary depending on the user attributes like age & gender and on the context such as time of day & day of week. The user has liberty to browse through all the suggested activities, and the company would like the user to rate every activity (may be on an $1-5$ scale), reflecting the relevances, so that it can keep refining its ranking strategy. However, in practice, though the user may scan through all suggested activities and have a rough idea about how relevant each one is to her; she is unlikely to give feedback on the usefulness (relevance) of every activity due to privacy concerns and cognitive burden. Hence, in exchange of the user using the app, the company only asks for careful rating of the top 1 or 2 ranked activities. The apps performance would still be based on the full ranked list, compared to the implicit relevance vector that the user generates, but it gets feedback on the relevances of only top 1 or 2 ranked activities.

Economic Constraints: Assume that a small retail company wants to build an app that produces a ranked list of suggestions to a user query, for categories of different products. The app develops features representing the categories, and thus, the interaction with the users happens in a traditional query-documents lists framework (user query and retrieved activities are jointly represented through a feature matrix). Different categories are likely to have varying relevance to different users, depending on user characteristics such as age, gender, etc. Like in the first example, the user has liberty to browse through all the suggestions but she will likely feel too burdened to give carefully considered rating on

each suggestion, unless the company provides some economic incentives to do so. Though the company needs high quality feedback on each suggestion to keep refining the ranking strategy, it cannot afford to give incentives due to budget constraints. Similar to the first example, the company only asks, and possibly pays, for rating on the top 1 or 2 ranked suggestions, in lieu of using the app, but its performance is judged on the full ranked list and implicit relevance vector.

We cast the online learning to rank problem as an online game between a learner and an adversary, played over time horizon T. That is, we do not make any *stochastic* assumption on the relevance vector generation process or the context (features) generation process (in the second problem setting). The adversary is considered to be *oblivious*, i.e., an adversary who generates moves without knowledge of the learner's algorithm. We separately discuss the two problem settings, and our contributions in each, in greater details.

1.1 Non-contextual setting

Existing work loosely related to ranking of a fixed set of items to satisfy diverse user preferences (Radlinski et al., 2008, 2009; Agrawal et al., 2009; Wen et al., 2014) has focused on learning an optimal ranking of a subset of items, to be presented to an user, with performance judged by a simple 0-1 loss. The loss in a round is 0 if among the top k (out of m) items presented to a user, the user finds at least one relevant item. All of the work falls under the framework of *online bandit* learning. In contrast, our model focuses on optimal ranking of the entire list of items, where the performance of the system is judged by practical ranking measures like DCG and AP. The challenge is to decide when and how efficient learning is possible with the highly restricted feedback model. Theoretically, the top k feedback model is neither full-feedback nor bandit-feedback since not even the loss (quantified by some ranking measure) at each round is revealed to the learner. The appropriate framework to study the problem is that of *partial monitoring* (Cesa-Bianchi et al., 2006). A very recent paper shows another practical application of partial monitoring in the stochastic setting (Lin et al., 2014). Recent advances in the classification of partial monitoring games tell us that the minimax regret, in an adversarial setting, is governed by a (two-class) property of the loss and feedback functions, called *global observability* and *local observability* (Bartok et al., 2014; Foster and Rakhlin, 2012).

Our contributions: We instantiate these general observability notions for our problem with top 1 ($k = 1$) feedback. We prove that, for some ranking measures, namely PairwiseLoss (Duchi et al., 2010), DCG and Precision@n (Liu et al., 2007), global observability holds. This immediately shows that the upper bound on regret scales as $O(T^{2/3})$. Specifically for PairwiseLoss and DCG, we further prove that local observability fails, when restricted to the top 1 feedback case, illustrating that their *minimax* regret scales as $\Theta(T^{2/3})$. However, the generic algorithm that enjoys $O(T^{2/3})$ regret for globally observable games necessarily maintains explicit weights on each action in learner's action set. It is impractical in our case to do so, since the learner's action set is the exponentially large set of $m!$ rankings over m objects. We propose a generic algorithm for learning with top k feedback, which uses blocking and a black-box full information algorithm. Specifically, we instantiate the black box algorithm with Follow The Perturbed Leader (FTPL) strategy, which leads to an efficient algorithm achieving $O(T^{2/3})$ regret bound for PairwiseLoss, DCG and

Precision@n, with $O(m \log m)$ time spent per step. Moreover, the regret of our efficient algorithm has a logarithmic dependence on number of learner's actions (i.e., polynomial dependence on m), whereas the generic algorithm has a linear dependence on number of actions (i.e., exponential dependence on m).

For several measures, their *normalized* versions are also considered. For example, the normalized versions of PairwiseLoss, DCG and Precision@n are called AUC (Cortes and Mohri, 2004), NDCG (Järvelin and Kekäläinen, 2002) and AP respectively. We show an unexpected result for the normalized versions: *they do not* admit sub-linear regret algorithms with top 1 feedback. This is despite the fact that the opposite is true for their unnormalized counterparts. Intuitively, the normalization makes it hard to construct an unbiased estimator of the (unobserved) relevance vectors. We are able to translate this intuitive hurdle into a provable impossibility.

We also present some preliminary experiments on simulated data sets to explore the performance of our efficient algorithm and compare its regret to its full information counterpart.

1.2 Contextual Setting

The requirement of having a fixed set of items to rank, in the first part of our work, somewhat limits practical applicability. In fact, in the classic multi-armed bandit problem, while non-contextual bandits have received a lot of attention, the authors Langford and Zhang (2008) mention that "settings with no context information are rare in practice". The second part of our work introduces context, by combining query-level ranking with the explicit but restricted feedback model. At each round, the adversary generates a document list of length m, pertaining to a query. The learner sees the list and produces a real valued score vector to rank the documents. We assume that the ranking is generated by sorting the score vector in descending order of its entries. The adversary then generates a relevance vector but, like in the non-contextual setting, the learner gets to see the relevance of only the top k items of the ranked list. The learner's loss in each round, based on the learner's score vector and the *full* relevance vector, is measured by some continuous ranking surrogates. We focus on continuous surrogates, e.g., the cross entropy surrogate in ListNet (Cao et al., 2007) and hinge surrogate in RankSVM (Joachims, 2002), instead of discontinuous ranking measures like DCG, or AP, because the latter lead to intractable optimization problems in the query-documents setting. Just like in the non-contextual setting, we note that the top k feedback model is neither full feedback nor bandit feedback models. The problem is an instance of partial monitoring, *extended to a setting with side information* (documents list) and an *infinite set of learner's moves* (all real valued score vectors). For such an extension of partial monitoring there exists no generic theoretical or algorithmic framework to the best of our knowledge.

Our contributions: In this setting, first, we propose a general, efficient algorithm for online learning to rank with top k feedback and show that it works in conjunction with a number of ranking surrogates. We characterize the minimum feedback required, i.e., the value of k, for the algorithm to work with a particular surrogate by formally relating the feedback mechanism with the structure of the surrogates. We then apply our general techniques to three convex ranking surrogates and one non-convex surrogate. The

convex surrogates considered are from three major learning to ranking methods: squared loss from a *pointwise* method (Cossock and Zhang, 2008), hinge loss used in the *pairwise* RankSVM (Joachims, 2002) method, and (modified) cross-entropy surrogate used in the *listwise* ListNet (Cao et al., 2007) method. The non-convex surrogate considered is the SmoothDCG surrogate (Chapelle and Wu, 2010). For the three convex surrogates, we establish an $O(T^{2/3})$ regret bound.

The convex surrogates we mentioned above are widely used but are known to fail to be calibrated with respect to NDCG (Ravikumar et al., 2011). Our second contribution is to show that for the entire class of NDCG calibrated surrogates, no online algorithm can have sub-linear (in T) regret with top 1 feedback, i.e., the minimax regret of an online game for any NDCG calibrated surrogate is $\Omega(T)$. The proof for this result relies on exploiting a connection between the construction of optimal adversary strategies for hopeless *finite action* partial monitoring games (Piccolboni and Schindelhauer, 2001) and the structure of NDCG calibrated surrogates. We only focus on NDCG calibrated surrogates for the *impossibility* results since no (convex) surrogate can be calibrated for AP and ERR (Calauzenes et al., 2012). This impossibility result is the first of its kind for a natural partial monitoring problem with side information when the learner's action space is infinite. Note, however, that there does exist work on partial monitoring problems with continuous learner actions, but without side information (Kleinberg and Leighton, 2003; Cesa-Bianchi et al., 2006), and vice versa (Bartók and Szepesvári, 2012; Gentile and Orabona, 2014).

We apply our algorithms on benchmark ranking data sets, demonstrating the ability to efficiently learn a ranking function in an online fashion, from highly restricted feedback.

The rest of the paper is divided into the following sections. Section 2 and its subsections detail the notations, definitions and technicalities associated with online ranking with restricted feedback in the non-contextual setting. Section 3 and its subsections detail the notations, definitions and technicalities associated with online ranking with restricted feedback in the contextual setting. Section 4 demonstrates the performance of our algorithms on simulated and commercial data sets. Section 5 discusses open questions and future directions of research.

2. Online Ranking with Restricted Feedback- Non Contextual Setting

All proofs not in main text are in Appendix A.

2.1 Notation and Preliminaries

The fixed m items to be ranked are numbered $\{1, 2, \ldots, m\}$. A permutation σ gives a mapping from ranks to items and its inverse σ^{-1} gives a mapping from items to ranks. Thus, $\sigma^{-1}(i) = j$ means item i is placed at position j while $\sigma(i) = j$ means item j is placed at position i. The supervision is in form of a relevance vector $R = \{0, 1, \ldots, n\}^m$, representing relevance of each document to the query. If $n = 1$, the relevance vector is binary graded. For $n > 1$, relevance vector is multi-graded. $R(i)$ denotes ith component of R, i.e., relevance of item i. The subscript t is exclusively used to denote time t. We denote $\{1, \ldots, n\}$ by $[n]$. The learner can choose from $m!$ actions (permutations) whereas nature/adversary can choose from $(n+1)^m$ outcomes (when there are n relevance levels, $n \geq 1$). We sometimes refer to the learner's ith action (in some fixed ordering of $m!$ available

actions) as σ_i (resp. adversary's ith action as R_i). Note that σ_i^{-1} simply means that we are viewing permutation σ_i as mapping from items to ranks. Also, a vector can be row or column vector depending on context.

At round t, the learner outputs a permutation (ranking) σ_t of the objects (possibly using some internal randomization, based on feedback history so far), and simultaneously, adversary generates relevance vector R_t. The quality of σ_t is judged against R_t by some ranking measure RL. *Crucially, only the relevance of the top k ranked objects are revealed to the learner at end of round t.* Thus, the learner gets to know neither R_t (full information problem) nor $RL(\sigma_t, R_t)$ (bandit problem). The objective of the learner is to minimize the expected regret with respect to best permutation in hindsight:

$$\mathbb{E}_{\sigma_1,\ldots,\sigma_T}\left[\sum_{t=1}^{T} RL(\sigma_t, R_t)\right] - \min_{\sigma} \sum_{t=1}^{T} RL(\sigma, R_t). \tag{1}$$

When RL is a gain, not loss, we need to negate the quantity above. The worst-case regret of a learner strategy is its maximal regret over all possible choices of $R_1, \ldots, R_T$. The **minimax regret** is the minimal worst-case regret over all learner strategies.

2.2 Ranking Measures

We consider ranking measures which can be expressed in the form $f(\sigma) \cdot R$, where the function $f : \mathbb{R}^m \to \mathbb{R}^m$ is composed of m copies of a univariate, monotonic, scalar valued function. Thus, $f(\sigma) = [f^s(\sigma^{-1}(1)), f^s(\sigma^{-1}(2)), \ldots, f^s(\sigma^{-1}(m))]$, where $f^s : \mathbb{R} \to \mathbb{R}$. Monotonic (increasing) means $f^s(\sigma^{-1}(i)) \geq f^s(\sigma^{-1}(j))$, whenever $\sigma^{-1}(i) > \sigma^{-1}(j)$. Monotonic (decreasing) is defined similarly. The following popular ranking measures can be expressed in the form $f(\sigma) \cdot R$.

PairwiseLoss & SumLoss: PairwiseLoss is restricted to binary relevance vectors and defined as:

$$PL(\sigma, R) = \sum_{i=1}^{m}\sum_{j=1}^{m} I(\sigma^{-1}(i) < \sigma^{-1}(j))I(R(i) < R(j))$$

PairwiseLoss cannot be directly expressed in the form of $f(\sigma) \cdot R$. Instead, we consider **SumLoss**, defined as:

$$SumLoss(\sigma, R) = \sum_{i=1}^{m} \sigma^{-1}(i)\ R(i)$$

SumLoss has the form $f(\sigma) \cdot R$, where $f(\sigma) = \sigma^{-1}$. It has been shown by Ailon (2014) that regret under the two measures are equal:

$$\sum_{t=1}^{T} PL(\sigma_t, R_t) - \sum_{t=1}^{T} PL(\sigma, R_t) = \sum_{t=1}^{T} SumLoss(\sigma_t, R_t) - \sum_{t=1}^{T} SumLoss(\sigma, R_t). \tag{2}$$

Discounted Cumulative Gain: DCG is a gain function which admits non-binary relevance vectors and is defined as:

$$DCG(\sigma, R) = \sum_{i=1}^{m} \frac{2^{R(i)} - 1}{\log_2(1 + \sigma^{-1}(i))}$$

and becomes $\sum_{i=1}^{m} \frac{R(i)}{\log_2(1+\sigma^{-1}(i))}$ for $R(i) \in \{0,1\}$. Thus, for binary relevance, $DCG(\sigma, R)$ has the form $f(\sigma) \cdot R$, where $f(\sigma) = [\frac{1}{\log_2(1+\sigma^{-1}(1))}, \frac{1}{\log_2(1+\sigma^{-1}(2))}, \ldots, \frac{1}{\log_2(1+\sigma^{-1}(m))}]$.

Precision@n Gain: Precision@n is a gain function restricted to binary relevance and is defined as

$$Precision@n(\sigma, R) = \sum_{i=1}^{m} I(\sigma^{-1}(i) \leq n)\ R(i)$$

Precision@n can be written as $f(\sigma) \cdot R$ where $f(\sigma) = [I(\sigma^{-1}(1) < n), \ldots, I(\sigma^{-1}(m) < n)]$. It should be noted that for $n = k$ (i.e., when feedback is on top n items), feedback is actually the same as full information feedback, for which efficient algorithms already exist (Kalai and Vempala, 2005).

Normalized measures are not of the form $\mathbf{f(\sigma) \cdot R}$: PairwiseLoss, DCG and Precision@n are unnormalized versions of popular ranking measures, namely, Area Under Curve (AUC), Normalized Discounted Cumulative Gain (NDCG) and Average Precision (AP) respectively. None of these can be expressed in the form $f(\sigma) \cdot R$.

NDCG: NDCG is a gain function, admits non-binary relevance and is defined as:

$$NDCG(\sigma, R) = \frac{1}{Z(R)} \sum_{i=1}^{m} \frac{2^{R(i)} - 1}{\log_2(1 + \sigma^{-1}(i))}$$

and becomes $\frac{1}{Z(R)} \sum_{i=1}^{m} \frac{R(i)}{\log_2(1+\sigma^{-1}(i))}$ for $R(i) \in \{0,1\}$. Here $Z(R) = \max_{\sigma} \sum_{i=1}^{m} \frac{2^{R(i)}-1}{\log_2(1+\sigma^{-1}(i))}$ is the normalizing factor ($Z(R) = \max_{\sigma} \sum_{i=1}^{m} \frac{R(i)}{\log_2(1+\sigma^{-1}(i))}$ for binary relevance). It can be clearly seen that $NDCG(\sigma, R) = f(\sigma) \cdot g(R)$, where $f(\sigma)$ is same as in DCG but $g(R) = \frac{R}{Z(R)}$ is non-linear in R.

AP: Average Precision is a gain function, restricted to binary relevance and is defined as:

$$AP(\sigma, R) = \frac{1}{\|R\|_1} \sum_{i=1}^{m} \frac{\sum_{j \leq i} I(R(\sigma(j)) = 1)}{i} I(R(\sigma(i) = 1))$$

It can be clearly seen that AP cannot be expressed in the form $f(\sigma) \cdot R$.

AUC: AUC is a loss function, restricted to binary relevance and is defined as:

$$AUC(\sigma, R) = \frac{1}{N(R)} \sum_{i=1}^{m} \sum_{j=1}^{m} I(\sigma^{-1}(i) < \sigma^{-1}(j)) I(R(i) < R(j))$$

where $N(R) = (\sum_{i=1}^{m} I(R(i) = 1)) \cdot (m - \sum_{i=1}^{m} I(R(i) = 1))$. It can be clearly seen that AUC cannot be expressed in the form $f(\sigma) \cdot R$.

Note: We will develop our subsequent theory and algorithms for binary valued relevance vectors, and show how they can be extended to multi-graded vectors when ranking measure is DCG/NDCG.

2.3 Relevant Definitions from Partial Monitoring

We develop all results in context of SumLoss, with binary relevance vector. We then extend the results to other ranking measures. Our main results on regret bounds build on some

Table 1: Loss matrix L for $m = 3$

Objects	R_1	R_2	R_3	R_4	R_5	R_6	R_7	R_8
123	000	001	010	011	100	101	110	111
$\sigma_1 = 123$	0	3	2	5	1	4	3	6
$\sigma_2 = 132$	0	2	3	5	1	3	4	6
$\sigma_3 = 213$	0	3	1	4	2	5	3	6
$\sigma_4 = 231$	0	1	3	4	2	3	5	6
$\sigma_5 = 312$	0	2	1	3	3	5	4	6
$\sigma_6 = 321$	0	1	2	3	3	4	5	6

Table 2: Feedback matrix H for $m = 3$

Objects	R_1	R_2	R_3	R_4	R_5	R_6	R_7	R_8
123	000	001	010	011	100	101	110	111
$\sigma_1 = 123$	0	0	0	0	1	1	1	1

$\sigma_5 = 312$	0	0	1	1	0	0	1	1
$\sigma_6 = 321$	0	1	0	1	0	1	0	1

of the theory for abstract partial monitoring games developed by Bartok et al. (2014) and Foster and Rakhlin (2012). For ease of understanding, we reproduce the relevant notations and definitions in context of SumLoss. *We will specifically mention when we derive results for top k feedback, with general k, and when we restrict to top 1 feedback.*

Loss and Feedback Matrices: The online learning game with the SumLoss measure and top 1 feedback can be expressed in form of a pair of *loss matrix* and *feedback matrix*. The *loss matrix* L is an $m! \times 2^m$ dimensional matrix, with rows indicating the learner's actions (permutations) and columns representing adversary's actions (relevance vectors). The entry in cell (i, j) of L indicates loss suffered when learner plays action i (i.e., σ_i) and adversary plays action j (i.e., R_j), that is, $L_{i,j} = \sigma_i^{-1} \cdot R_j = \sum_{k=1}^{m} \sigma_i^{-1}(k) R_j(k)$. The *feedback matrix* H has same dimension as *loss matrix*, with (i, j) entry being the relevance of top ranked object, i.e., $H_{i,j} = R_j(\sigma_i(1))$. When the learner plays action σ_i and adversary plays action R_j, the true loss is $L_{i,j}$, while the feedback received is $H_{i,j}$.

Table 1 and 2 illustrate the matrices, with number of objects $m = 3$. In both the tables, the permutations indicate rank of each object and relevance vector indicates relevance of each object. For example, $\sigma_5 = 312$ means object 1 is ranked 3, object 2 is ranked 1 and object 3 is ranked 2. $R_5 = 100$ means object 1 has relevance level 1 and other two objects have relevance level 0. Also, $L_{3,4} = \sigma_3 \cdot R_4 = \sum_{i=1}^{3} \sigma_3^{-1}(i) R_4(i) = 2 \cdot 0 + 1 \cdot 1 + 3 \cdot 1 = 4$; $H_{3,4} = R_4(\sigma_3(1)) = R_4(2) = 1$. Other entries are computed similarly.

Let $\ell_i \in \mathbb{R}^{2^m}$ denote row i of L. Let Δ be the probability simplex in $\mathbb{R}^{2^m}$, i.e., $\Delta = \{p \in \mathbb{R}^{2^m} : \forall\ 1 \le i \le 2^m,\ p_i \ge 0,\ \sum p_i = 1\}$. The following definitions, given for abstract problems by Bartok et al. (2014), has been refined to fit our problem context.

Definition 1: Learner action i is called optimal under distribution $p \in \Delta$, if $\ell_i \cdot p \le \ell_j \cdot p$, for all other learner actions $1 \le j \le m!,\ j \ne i$. For every action $i \in [m!]$, probability cell of i is defined as $C_i = \{p \in \Delta : \text{action } i \text{ is optimal under } p\}$. If a non-empty cell C_i is $2^m - 1$ dimensional (i.e, elements in C_i are defined by only 1 equality constraint), then associated action i is called *Pareto-optimal*.

Note that since entries in H are relevance levels of objects, there can be maximum of 2 distinct elements in each row of H, i.e., 0 or 1 (assuming binary relevance).

Definition 2: The *signal matrix* S_i, associated with learner's action σ_i, is a matrix with 2 rows and 2^m columns, with each entry 0 or 1, i.e., $S_i \in \{0,1\}^{2 \times 2^m}$. The entries of ℓth column of S_i are respectively: $(S_i)_{1,\ell} = I(H_{i,\ell} = 0)$ and $(S_i)_{2,\ell} = I(H_{i,\ell} = 1)$.

Note that by definitions of signal and feedback matrices, the 2nd row of S_i (2nd column of $S_i^\top$)) is precisely the ith row of H. The 1st row of S_i (1st column of $S_i^\top$)) is the (boolean) complement of ith row of H.

2.4 Minimax Regret for SumLoss

The minimax regret for SumLoss, restricted to top 1 feedback, will be established by showing that: a) SumLoss satisfies *global observability*, and b) it does not satisfy *local observability*.

2.4.1 Global Observability

Definition 3: The condition of *global observability* holds, w.r.t. loss matrix L and feedback matrix H, if for every pair of learner's actions $\{\sigma_i, \sigma_j\}$, it is true that $\ell_i - \ell_j \in \oplus_{k \in [m!]} Col(S_k^\top)$, where Col refers to column space (i.e., the vector difference belongs in the column span).

The global observability condition states that the (vector) loss difference between any pair of learner's actions has to belong to the vector space spanned by columns of (transposed) signal matrices corresponding to all possible learner's actions. We derive the following theorem on global observability for *SumLoss*.

Theorem 1. *The global observability condition, as per Definition 3, holds w.r.t. loss matrix L and feedback matrix H defined for SumLoss, for any $m \ge 1$.*

Proof. For any σ_a (learner's action) and R_b (adversary's action), we have (please see the end of the proof for explanation of notations and equalities):

$$L_{a,b} = \sigma_a^{-1} \cdot R_b = \sum_{i=1}^{m} \sigma_a^{-1}(i) R_b(i) \overset{1}{=} \sum_{j=1}^{m} j\ R_b(\sigma_a(j)) \overset{2}{=} \sum_{j=1}^{m} j\ R_b(\tilde{\sigma}_{j(a)}(1)) \overset{3}{=} \sum_{j=1}^{m} j\ (S^\top_{\tilde{\sigma}_{j(a)}})_{R_b,2}.$$

Thus, we have

$$\ell_a = [L_{a,1}, L_{a,2}, \ldots, L_{a,2^m}] =$$
$$[\sum_{j=1}^{m} j\ (S^\top_{\tilde{\sigma}_{j(a)}})_{R_1,2}, \sum_{j=1}^{m} j\ (S^\top_{\tilde{\sigma}_{j(a)}})_{R_2,2}, .., \sum_{j=1}^{m} j\ (S^\top_{\tilde{\sigma}_{j(a)}})_{R_{2^m},2}] \overset{4}{=} \sum_{j=1}^{m} j\ (S^\top_{\tilde{\sigma}_{j(a)}})_{:,2}\ (:,2 \text{ indicates 2nd column}).$$

Equality 4 shows that ℓ_a is in the column span of m of the $m!$ possible (transposed) signal matrices, specifically in the span of the 2nd columns of those (transposed) m matrices. Hence, for all actions σ_a, it holds that $\ell_a \in \oplus_{k \in [m!]} Col(S_k^\top)$. This implies that $\ell_a - \ell_b \in \oplus_{k \in [m!]} Col(S_k^\top),\ \forall\ \sigma_a, \sigma_b$.

1. Equality 1 holds because $\sigma_a^{-1}(i) = j \Rightarrow i = \sigma_a(j)$.
2. Equality 2 holds because of the following reason. For any permutation σ_a and for every $j \in [m]$, $\exists$ a permutation $\tilde{\sigma}_{j(a)}$, s.t. the object which is assigned rank j by σ_a is the same object assigned rank 1 by $\tilde{\sigma}_{j(a)}$, i.e., $\sigma_a(j) = \tilde{\sigma}_{j(a)}(1)$.
3. In Equality 3, $(S^\top_{\tilde{\sigma}^{-1}_{j(a)}})_{R_b,2}$ indicates the R_bth row and 2nd column of (transposed) signal matrix $S_{\tilde{\sigma}_{j(a)}}$, corresponding to learner action $\tilde{\sigma}_{j(a)}$. Equality 3 holds because $R_b(\tilde{\sigma}_{j(a)}(1))$ is the entry in the row corresponding to action $\tilde{\sigma}_{j(a)}$ and column corresponding to action R_b of H (see Definition 2).
4. Equality 4 holds from the observation that for a particular j, $[(S^\top_{\tilde{\sigma}_{j(a)}})_{R_1,2}, (S^\top_{\tilde{\sigma}_{j(a)}})_{R_2,2}, \ldots, (S^\top_{\tilde{\sigma}_{j(a)}})_{R_{2^m},2}]$ forms the 2nd column of $(S^\top_{\tilde{\sigma}_{j(a)}})$, i.e., $(S^\top_{\tilde{\sigma}_{j(a)}})_{:,2}$. □

2.4.2 Local Observability

Definition 4: Two Pareto-optimal (learner's) actions i and j are called *neighboring actions* if $C_i \cap C_j$ is a $(2^m - 2)$ dimensional polytope (where C_i is probability cell of action σ_i). The *neighborhood action set* of two neighboring (learner's) actions i and j is defined as $N^+_{i,j} = \{k \in [m!] : C_i \cap C_j \subseteq C_k\}$.

Definition 5: A pair of neighboring (learner's) actions i and j is said to be locally observable if $\ell_i - \ell_j \in \oplus_{k \in N^+_{i,j}} Col(S_k^\top)$. The condition of *local observability* holds if every pair of neighboring (learner's) actions is locally observable.

We now show that local observability condition fails for L, H under SumLoss. First, we present the following two lemmas characterizing Pareto-optimal actions and neighboring actions for SumLoss.

Lemma 2. *For SumLoss, each of learner's action σ_i is Pareto-optimal, where Pareto-optimality has been defined in Definition 1.*

Proof. For any $p \in \Delta$, we have $\ell_i \cdot p = \sum_{j=1}^{2^m} p_j\ (\sigma_i^{-1} \cdot R_j) = \sigma_i^{-1} \cdot (\sum_{j=1}^{2^m} p_j R_j) = \sigma_i^{-1} \cdot \mathbb{E}[R]$, where the expectation is taken w.r.t. p. $l_i \cdot p$ is minimized when ranking of objects according to σ_i and expected relevance of objects are in opposite order. That is, the object with highest expected relevance is ranked 1 and so on. Formally, $l_i \cdot p$ is minimized when $\mathbb{E}[R(\sigma_i(1))] \ge \mathbb{E}[R(\sigma_i(2))] \ge \ldots \ge \mathbb{E}[R(\sigma_i(m))]$.

Thus, for action σ_i, probability cell is defined as $C_i = \{p \in \Delta : \sum_{j=1}^{2^m} p_j = 1,\ \mathbb{E}[R(\sigma_i(1))] \ge \mathbb{E}[R(\sigma_i(2))] \ge \ldots \ge \mathbb{E}[R(\sigma_i(m))]\}$. Note that, $p \in C_i$ iff action i is optimal w.r.t. p. Since C_i is obviously non-empty and it has only 1 equality constraint (hence $2^m - 1$ dimensional), action i is Pareto optimal.

The above holds true for all learner's actions σ_i. □

Lemma 3. *A pair of learner's actions $\{\sigma_i,\ \sigma_j\}$ is a neighboring actions pair, if there is exactly one pair of objects, numbered $\{a, b\}$, whose positions differ in σ_i and σ_j. Moreover, a needs to be placed just before b in σ_i and b needs to placed just before a in σ_j.*

Proof. From Lemma 2, we know that every one of learner's actions is Pareto-optimal and C_i, associated with action σ_i, has structure $C_i = \{p \in \Delta : \sum_{j=1}^{2^m} p_j = 1,\ \mathbb{E}[R(\sigma_i(1))] \geq \mathbb{E}[R(\sigma_i(2))] \geq \ldots \geq \mathbb{E}[R(\sigma_i(m))]\}$.

Let $\sigma_i(k) = a,\ \sigma_i(k+1) = b$. Let it also be true that $\sigma_j(k) = b,\ \sigma_j(k+1) = a$ and $\sigma_i(n) = \sigma_j(n),\ \forall n \neq \{k,\ k+1\}$. Thus, objects in $\{\sigma_i, \sigma_j\}$ are same in all places except in a pair of consecutive places where the objects are interchanged.

Then, $C_i \cap C_j = \{p \in \Delta : \sum_{j=1}^{2^m} p_j = 1,\ \mathbb{E}[R(\sigma_i(1)] \geq \ldots \geq \mathbb{E}[R(\sigma_i(k)] = \mathbb{E}[R(\sigma_i(k+1)] \geq \ldots \geq \mathbb{E}[R(\sigma_i(m)]\}$. Hence, there are two equalities in the non-empty set $C_i \cap C_j$ and it is an $(2^m - 2)$ dimensional polytope. Hence condition of Definition 4 holds true and $\{\sigma_i, \sigma_j\}$ are neighboring actions pair.

□

Lemma 2 and 3 are used to establish the following result:

Theorem 4. *The local observability condition, as per Definition 5, fails w.r.t. loss matrix L and feedback matrix H defined for SumLoss, already at $m = 3$.*

Proof. We will explicitly show that local observability condition fails by considering the case when number of objects is $m = 3$. Specifically, action pair $\{\sigma_1,\ \sigma_2\}$, in Table 1 are neighboring actions, using Lemma 3 . Now every other action $\{\sigma_3, \sigma_4, \sigma_5, \sigma_6\}$ either places object 2 at top or object 3 at top. It is obvious that the set of probabilities for which $E[R(1)] \geq E[R(2)] = E[R(3)]$ cannot be a subset of any C_3, C_4, C_5, C_6. From Def. 4, the neighborhood action set of actions $\{\sigma_1, \sigma_2\}$ is precisely σ_1 and σ_2 and contains no other actions. By definition of signal matrices $S_{\sigma_1},\ S_{\sigma_2}$ and entries $\ell_1,\ \ell_2$ in Table 1 and 2, we have,

$$S_{\sigma_1} = S_{\sigma_2} = \begin{bmatrix} 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{bmatrix}$$
$$\ell_1 - \ell_2 = \begin{bmatrix} 0 & 1 & -1 & 0 & 0 & 1 & -1 & 0 \end{bmatrix}. \tag{3}$$

It is clear that $\ell_1 - \ell_2 \notin Col(S_{\sigma_1}^\top)$. Hence, Definition 5 fails to hold. □

2.5 Minimax Regret Bound

We establish the minimax regret for SumLoss by combining results on global and local observability. First, we get a lower bound by combining our Theorem 4 with Theorem 4 of Bartok et al. (2014).

Corollary 5. *Consider the online game for SumLoss with top-1 feedback and $m = 3$. Then, for every learner's algorithm, there is an adversary strategy generating relevance vectors, such that the expected regret of the learner is $\Omega(T^{2/3})$.*

The fact that the game is globally observable (Theorem 1), combined with Theorem 3.1 in Cesa-Bianchi et al. (2006), gives an algorithm (inspired by the algorithm originally given in Piccolboni and Schindelhauer (2001)) obtaining $O(T^{2/3})$ regret.

Corollary 6. *The algorithm in Figure 1 of Cesa-Bianchi et al. (2006) achieves $O(T^{2/3})$ regret bound for SumLoss.*

However, the algorithm in Cesa-Bianchi et al. (2006) is intractable in our setting since the algorithm necessarily enumerates all the actions of the learner in each round, which is exponential in m in our case ($m!$ to be exact). Moreover, the regret bound of the algorithm also has a linear dependence on the number of actions, which renders the bound useless.

Discussion: The results above establish that the minimax regret for SumLoss, *restricted to top-1 feedback*, is $\Theta(T^{2/3})$. Theorem 4 of Bartok et al. (2014) says the following: A partial monitoring game which is both globally and locally observable has minimax regret $\Theta(T^{1/2})$, while a game which is globally observable but *not* locally observable has minimax regret $\Theta(T^{2/3})$. In Theorem 1, we proved global observability, when feedback is restricted to relevance of top ranked item. The global observability result automatically extends to feedback on top k items, for $k > 1$. This is because for top k feedback, with $k > 1$, the learner receives strictly greater information at end of each round than top 1 feedback (for example, the learner can just throw away relevance feedback on items ranked 2nd onwards). So, with top k feedback, for general k, the game will remain at least globally observable. In fact, our algorithm in the next section will achieve $O(T^{2/3})$ regret bound for SumLoss with top k feedback, $k \geq 1$. However, the same is not true for failure of local observability. Feedback on more than top ranked item can make the game strictly easier for the learner and may make local observability condition hold, for some $k > 1$. In fact, for $k = m$ (full feedback), the game will be a simple full information game (disregarding computational complexity), and hence locally observable.

2.6 Algorithm for Obtaining Minimax Regret under SumLoss with Top k Feedback

We first provide a general algorithmic framework for getting an $O(T^{2/3})$ regret bound for SumLoss, with feedback on top k ranked items per round, for $k \geq 1$. We then instantiate a specific algorithm, which spends $O(m \log m)$ time per round (thus, highly efficient) and obtains a regret of rate $O(poly(m)\ T^{2/3})$.

2.6.1 General Algorithmic Framework

Our algorithm combines *blocking* with a randomized *full information* algorithm. We first divide time horizon T into blocks (referred to as blocking). Within each block, we allot a small number of rounds for pure *exploration*, which allows us to estimate the average of the full relevance vectors generated by the adversary in that block. The estimated average vector is cumulated over blocks and then fed to a full information algorithm for the next block. The randomized full information algorithm *exploits* the information received at the beginning of the block to maintain distribution over permutations (learner's actions). In each round in the new block, actions are chosen according to the distribution and presented to the user.

The *key property* of the randomized full information algorithm is this: the algorithm should have an expected regret rate of $O(C\sqrt{T})$, where the regret is the difference between cumulative loss of the algorithm and cumulative loss of best action in hindsight, over T rounds, and C is a parameter specific to the full information algorithm.

Our algorithm is motivated by the reduction from bandit-feedback to full feedback scheme given in Blum and Mansour (2007). However, the reduction *cannot be directly applied to our problem*, because we are not in the bandit setting and hence do not know loss of any action. Further, the algorithm of Blum and Mansour (2007) necessarily spends N rounds per block to try out *each* of the N available actions — this is impractical in our setting since $N = m!$.

Algorithm 1 describes our approach. A key aspect is the formation of estimate of average relevance vector of a block (line 16), for which we have the following lemma:

Lemma 7. *Let the average of (full) relevance vectors over the time period $\{1, 2, \ldots, t\}$ be denoted as $R^{avg}_{1:t}$, that is, $R^{avg}_{1:t} = \sum_{n=1}^{t} \frac{R_n}{t} \in \mathbb{R}^m$. Let $\{i_1, i_2, \ldots, i_{\lceil m/k \rceil}\}$ be $\lceil m/k \rceil$ arbitrary time points, chosen uniformly at random, without replacement, from $\{1, \ldots, t\}$. At time point i_j, only k distinct components of relevance vector R_{i_j}, i.e., $\{R_{i_j}(k \cdot (j-1)+1), R_{i_j}(k \cdot (j-1)+2), \ldots, R_{i_j}(k \cdot j)\}$, become known, $\forall j \in \{1, \ldots, \lceil m/k \rceil\}$ (for $j = \lceil m/k \rceil$, there might be less than k components available). Then the vector formed from the m revealed components, i.e. $\hat{R}_t = [R_{i_j}(k \cdot (j-1)+1), R_{i_j}(k \cdot (j-1)+2), \ldots, R_{i_j}(k \cdot j)]_{\{j=1,2,\ldots,\lceil m/k \rceil\}}$ is an unbiased estimator of $R^{avg}_{1:t}$.*

Proof. We can write $\hat{R}_t = \sum_{j=1}^{\lceil m/k \rceil} \sum_{\ell=1}^{k} R_{i_j}(k \cdot (j-1)+\ell) e_{k \cdot (j-1)+\ell}$, where e_i is the m dimensional standard basis vector along coordinate j. Then, taking expectation over the randomly chosen time points, we have: $E_{i_1,\ldots,i_{\lceil m/k \rceil}}(\hat{R}_t) = \sum_{j=1}^{\lceil m/k \rceil} E_{i_j}[\sum_{\ell=1}^{k} R_{i_j}(k \cdot (j-1)+\ell) e_{k \cdot (j-1)+\ell}] = \sum_{j=1}^{m} \sum_{\ell=1}^{k} \sum_{n=1}^{t} \frac{R_n(k \cdot (j-1)+\ell) e_{k \cdot (j-1)+\ell}}{t} = R^{avg}_{1:t}$. □

Suppose we have a full information algorithm whose regret in T rounds is upper bounded by $C\sqrt{T}$ for some constant C and let C^I be the maximum loss that the learner can suffer in a round. Note that C^I depends on the loss used and on the range of the relevance scores. We have the following regret bound, obtained from application of Algorithm 1 on SumLoss with top k feedback.

Theorem 8. *Let C, C^I be the constants defined above. The expected regret under SumLoss, obtained by applying Algorithm 1, with relevance feedback on top k ranked items per round ($k \geq 1$), and the expectation being taken over randomized learner's actions σ_t, is*

$$\mathbb{E}\left[\sum_{t=1}^{T} SumLoss(\sigma_t, R_t)\right] - \min_{\sigma} \sum_{t=1}^{T} SumLoss(\sigma_t, R_t) \leq C^I \lceil m/k \rceil K + C\frac{T}{\sqrt{K}}. \quad (4)$$

Optimizing over block size K, the final regret bound is:

$$\mathbb{E}\left[\sum_{t=1}^{T} SumLoss(\sigma_t, R_t)\right] - \min_{\sigma} \sum_{t=1}^{T} SumLoss(\sigma_t, R_t) \leq 2(C^I)^{1/3} C^{2/3} \lceil m/k \rceil^{1/3} T^{2/3}. \quad (5)$$

2.6.2 Computationally Efficient Algorithm with FTPL

We instantiate our general algorithm with *Follow The Perturbed Leader* (FTPL) full information algorithm (Kalai and Vempala, 2005). The following choices need to be made in Algorithm 1 to implement FTPL as the full information algorithm:

Algorithm 1 RankingwithTop-kFeedback(RTop-kF)- Non Contextual

1: T = Time horizon, K = No. of (equal sized) blocks, FI= randomized full information algorithm.
2: Time horizon divided into equal sized blocks $\{B_1, \ldots, B_K\}$, where $B_i = \{(i-1)(T/K)+1, \ldots, i(T/K)\}$.
3: Initialize $\hat{s}_0 = \mathbf{0} \in \mathbb{R}^m$. Initialize any other parameter specific to FI.
4: **For** $i = 1, \ldots, K$
5: Select $\lceil m/k \rceil$ time points $\{i_1, \ldots, i_{\lceil m/k \rceil}\}$ from block B_i, uniformly at random, without replacement.
6: Divide the m items into $\lceil m/k \rceil$ cells, with k distinct items in each cell.[1]
7: **For** $t \in B_i$
8: **If** $t = i_j \in \{i_1, \ldots, i_{\lceil m/k \rceil}\}$
9: **Exploration round**:
10: Output any permutation σ_t which places items of jth cell in top k positions (in any order).
11: Receive feedback as relevance of top k items of σ_t (i.e., items of jth cell).
12: **Else**
13: **Exploitation round**:
14: Feed $\hat{s}_{i-1}$ to the randomized full information algorithm FI and output σ_t according to FI.
15: **end for**
16: Set $\hat{R}_i \in \mathbb{R}^m$ as vector of relevances of the m items collected during exploration rounds.
17: Update $\hat{s}_i = \hat{s}_{i-1} + \hat{R}_i$.
18: **end for**

Initialization of parameters: In line 3 of the algorithm, the parameter specific to FTPL is randomization parameter $\epsilon \in \mathbb{R}$.

Exploitation round: σ_t, during exploitation, is sampled by FTPL as follows: sample $p_t \in [0, 1/\epsilon]^m$ from the product of uniform distribution in each dimension. Output permutation $\sigma_t = M(\hat{s}_{i-1} + p_t)$ where $M(y) = \operatorname{argmin}_{\sigma} \sigma^{-1} \cdot y$.

Discussion: The key reason for using FTPL as the full information algorithm is that the structure of our problem allows the permutation σ_t to be chosen during exploitation round via a simple sorting operation on m objects. This leads to an easily implementable algorithm which spends only $O(m \log m)$ time per round (sorting is in fact the most expensive step in the algorithm). The reason that the simple sorting operation does the trick is the following: FTPL only *implicitly* maintains a distribution over $m!$ actions (permutations) at beginning of each round. Instead of having an explicit probability distribution over each action and sampling from it, FTPL mimics sampling from a distribution over actions by randomly perturbing the information vector received so far (say $\hat{s}_{i-1}$ in block B_i) and then sorting the items by perturbed score. The random perturbation puts an implicit weight on each of the $m!$ actions and sorting is basically sampling according to the weights. This is an advantage over general full information algorithms based on exponential weights, which maintain explicit weight on actions and samples from it. We also note that we are using FTPL with uniform distribution over a hypercube as our perturbation distribution. Other choices, such as the Gaussian distribution, can lead to slightly better dependence on the dimension m (see the discussion following the proof of Corollary 9 in the appendix). Our bounds, therefore, do not necessarily yield the optimal dependence on m.

[1] For example, assume $m = 7$ and $k = 2$. Then place items $(1, 2)$ in cell 1, items $(3, 4)$ in cell 2, items $(5, 6)$ in cell 3 and item 7 in cell 4.

We have the following corollary:

Corollary 9. *The expected regret of SumLoss, obtained by applying Algorithm 1, with FTPL full information algorithm and feedback on top k ranked items at end of each round ($k \geq 1$), and* $K = O\left(\frac{m^{1/3}T^{2/3}}{\lceil m/k \rceil^{2/3}}\right)$, $\epsilon = O(\frac{1}{\sqrt{mK}})$, *is:*

$$\mathbb{E}\left[\sum_{t=1}^{T} SumLoss(\sigma_t, R_t)\right] - \min_{\sigma} \sum_{t=1}^{T} SumLoss(\sigma, R_t) \leq O(m^{7/3}\lceil m/k \rceil^{1/3} T^{2/3}). \quad (6)$$

where $O(\cdot)$ hides some numeric constants.

Assuming that $\lceil m/k \rceil \sim m/k$, the regret rate in Corollary 9 is $O\left(\frac{m^{8/3}T^{2/3}}{k^{1/3}}\right)$

2.7 Regret Bounds for PairwiseLoss, DCG and Precision@n

PairwiseLoss: As we saw in Eq. 2, the regret of SumLoss is same as regret of PairwiseLoss. Thus, SumLoss in Corollary 9 can be replaced by PairwiseLoss to get exactly same result.

DCG: All the results of SumLoss can be extended to DCG (see Appendix A). Moreover, the results can be extended even for multi-graded relevance vectors. Thus, the minimax regret under DCG, *restricted to feedback on top ranked item*, even when the adversary can play multi-graded relevance vectors, is $\Theta(T^{2/3})$.

The main differences between SumLoss and DCG are the following. The former is a loss function; the latter is a gain function. Also, for DCG, $f(\sigma) \neq \sigma^{-1}$ (see definition in Sec.2.2) and when relevance is multi-graded, DCG cannot be expressed as $f(\sigma) \cdot R$, as clear from definition. Nevertheless, DCG can be expressed as $f(\sigma) \cdot g(R)$, , where $g(R) = [g^s(R(1)), g^s(R(2)), \ldots, g^s(R(m))]$, $g^s(i) = 2^i - 1$ is constructed from univariate, monotonic, scalar valued functions ($g(R) = R$ for binary graded relevance vectors). Thus, Algorithm 1 can be applied (with slight variation), with FTPL full information algorithm and top k feedback, to achieve regret of $O(T^{2/3})$ [2]. The slight variation is that during *exploration* rounds, when relevance feedback is collected to form the estimator at end of the block, the relevances should be transformed by function $g^s(\cdot)$.. The estimate is then constructed in the transformed space and fed to the full information algorithm. In the *exploitation* round, the selection of σ_t remains exactly same as in SumLoss, i.e., $\sigma_t = M(\hat{s}_{i-1} + p_t)$ where $M(y) = \operatorname{argmin}_{\sigma} \sigma^{-1} \cdot y$. This is because $\operatorname{argmax}_{\sigma} f(\sigma) \cdot y = \operatorname{argmin}_{\sigma} \sigma^{-1} \cdot y$, by definition of $f(\sigma)$ in DCG.

Let relevance vectors chosen by adversary have $n+1$ grades, i.e., $R \in \{0, 1, \ldots, n\}^m$. In practice, n is almost always less than 5. We have the following corollary:

Corollary 10. *The expected regret of DCG, obtained by applying Algorithm 1, with FTPL full information algorithm and feedback on top k ranked items at end of each round ($k \geq 1$), and* $K = O\left(\frac{m^{1/3}T^{2/3}}{\lceil m/k \rceil^{2/3}}\right)$, $\epsilon = O(\frac{1}{(2^n-1)^2\sqrt{mK}})$, *is:*

$$\max_{\sigma} \sum_{t=1}^{T} DCG(\sigma_t, R_t) - \mathbb{E}\left[\sum_{t=1}^{T} DCG(\sigma_t, R_t)\right] \leq O((2^n - 1)m^{4/3}\lceil m/k \rceil^{1/3} T^{2/3}). \quad (7)$$

Assuming that $\lceil m/k \rceil \sim m/k$, the regret rate in Corollary 10 is $O\left(\frac{(2^n-1)m^{5/3}T^{2/3}}{k^{1/3}}\right)$.

Precision@n: Since Precision@$n = f(\sigma) \cdot R$, the global observability property of SumLoss can be easily extended to it and Algorithm 1 can be applied, with FTPL full information algorithm and top k feedback, to achieve regret of $O(T^{2/3})$. In the *exploitation* round, the selection of σ_t remains exactly same as in SumLoss, i.e., $\sigma_t = M(\hat{s}_{i-1} + p_t)$ where $M(y) = \operatorname{argmin}_{\sigma} \sigma^{-1} \cdot y$.

However, the local observability property of SumLoss does not extend to Precision@n. The reason is that while $f(\cdot)$ of SumLoss is strictly monotonic, $f(\cdot)$ of Precision@n is monotonic but not strict. Precision@n depends only on the objects in the top n positions of the ranked list, *irrespective of the order*. A careful review shows that Lemma 3 fails to extend to the case of Precision@n, due to lack of strict monotonicity. Thus, we cannot define the neighboring action set of the Pareto optimal action pairs, and hence cannot prove or disprove local observability.

We have the following corollary:

Corollary 11. *The expected regret of Precision@n, obtained by applying Algorithm 1, with FTPL full information algorithm and feedback on top k ranked items at end of each round ($k \geq 1$), and* $K = O\left(\frac{m^{1/3}T^{2/3}}{\lceil m/k \rceil^{2/3}}\right)$, $\epsilon = O(\frac{1}{\sqrt{mK}})$, *is:*

$$\max_{\sigma} \sum_{t=1}^{T} Precision@n(\sigma_t, R_t) - \mathbb{E}\left[\sum_{t=1}^{T} Precision@n(\sigma_t, R_t)\right] \leq O(n\ m^{1/3}\lceil m/k \rceil^{1/3} T^{2/3}). \quad (8)$$

Assuming that $\lceil m/k \rceil \sim m/k$, the regret rate in Corollary 11 is $O\left(\frac{n\ m^{2/3}T^{2/3}}{k^{1/3}}\right)$.

2.8 Non-Existence of Sublinear Regret Bounds for NDCG, AP and AUC

As stated in Sec. 2.2, NDCG, AP and AUC are normalized versions of measures DCG, Precision@n and PairwiseLoss. We have the following lemma for all these normalized ranking measures.

Lemma 12. *The global observability condition, as per Definition 1, fails for NDCG, AP and AUC, when feedback is restricted to top ranked item.*

Combining the above lemma with Theorem 2 of Bartok et al. (2014), we conclude that there *cannot exist any algorithm which has sub-linear regret for any of the following measures: NDCG, AP or AUC, when restricted to top* 1 *feedback.*

[2] Note that there is no problem in applying Lemma 7 to DCG. This is because we are trying to estimate $\sum_{n=1}^{t} \frac{g(R_n)}{t}$, which can be estimated by considering the relevance feedbacks themselves transformed by $g(\cdot)$

Theorem 13. *There exists an online game, for NDCG with top-1 feedback, such that for every learner's algorithm, there is an adversary strategy generating relevance vectors, such that the expected regret of the learner is $\Omega(T)$. Furthermore, the same lower bound holds if NDCG is replaced by AP or AUC.*

3. Online Ranking with Restricted Feedback- Contextual Setting

All proofs not in the main text are in Appendix B.

3.1 Problem Setting and Learning to Rank Algorithm

First, we introduce some additional notations to Section 2.1. In the contextual setting, each query and associated items (documents) are represented jointly as a feature matrix. Each feature matrix, $X \in \mathbb{R}^{m\times d}$, consists of a list of m documents, each represented as a feature vector in $\mathbb{R}^d$. The feature matrices are considered side-information (context) and represents varying items, as opposed to the fixed set of items in the first part of our work. $X_{i:}$ denotes ith row of X. We assume feature vectors representing documents are bounded by R_D in ℓ_2 norm. The relevance vectors are same as before.

As per traditional learning to rank setting with query-document matrices, documents are ranked by a ranking function. The prevalent technique is to represent a ranking function as a scoring function and get ranking by sorting scores in descending order. A linear scoring function produces score vector as $f_w(X) = Xw = s^w \in \mathbb{R}^m$, with $w \in \mathbb{R}^d$. Here, $s^w(i)$ represents score of ith document (s^w points to score s being generated by using parameter w). We assume that ranking parameter space is bounded in ℓ_2 norm, i.e, $\|w\|_2 \le U$, $\forall\ w$. $\pi_s = \text{argsort}(s)$ is the permutation induced by sorting score vector s in descending order. As a reminder, a permutation π gives a mapping from ranks to documents and π^{-1} gives a mapping from documents to ranks.

Performance of ranking functions are judged, based on the rankings obtained from score vectors, by ranking measures like DCG, AP and others. However, the measures themselves are discontinuous in the score vector produced by the ranking function, leading to intractable optimization problems. Thus, most learning to rank methods are based on minimizing *surrogate* losses, which can be optimized efficiently. A surrogate ϕ takes in a score vector s and relevance vector R and produces a real number, i.e., $\phi : \mathbb{R}^m \times \{0, 1, \ldots, n\}^m \mapsto \mathbb{R}$. $\phi(\cdot, \cdot)$ is said to be convex if it is convex in its first argument, for any value of the second argument. Ranking surrogates are designed in such a way that the ranking function learnt by optimizing the surrogates has good performance with respect to ranking measures.

Formal problem setting: We formalize the problem as a game being played between a learner and an adversary over T rounds. The learner's action set is the uncountably infinite set of score vectors in $\mathbb{R}^m$ and the adversary's action set is all possible relevance vectors, i.e., $(n+1)^m$ possible vectors. At round t, the adversary generates a list of documents, represented by a matrix $X_t \in \mathbb{R}^{m\times d}$, pertaining to a query (the document list is considered as side information). The learner receives X_t, produces a score vector $\tilde{s}_t \in \mathbb{R}^m$ and ranks the documents by sorting according to score vector. The adversary then generates a relevance vector R_t but only reveals the relevances of top k ranked documents to the learner. The learner uses the feedback to choose its action for the next round (updates an internal scoring function). The learner suffers a loss as measured in terms of a surrogate ϕ, i.e, $\phi(\tilde{s}_t, R_t)$.

As is standard in online learning setting, the learner's performance is measured in terms of its expected regret:

$$\mathbb{E}\left[\sum_{t=1}^{T}\phi(\tilde{s}_t, R_t)\right] - \min_{\|w\|_2\le U}\sum_{t=1}^{T}\phi(X_t w, R_t),$$

where the expectation is taken w.r.t. to randomization of learner's strategy and $X_t w = s_t^w$ is the score produced by the linear function parameterized by w.

Algorithm 2 Ranking with Top-k Feedback (RTop-kF)- Contextual

1: Exploration parameter $\gamma \in (0, \frac{1}{2})$, learning parameter $\eta > 0$, ranking parameter $w_1 = \mathbf{0} \in \mathbb{R}^d$
2: **For** $t = 1$ to T
3: Receive X_t (document list pertaining to query q_t)
4: Construct score vector $s_t^{w_t} = X_t w_t$ and get permutation $\sigma_t = \text{argsort}(s_t^{w_t})$
5: $\mathbb{Q}_t(s) = (1-\gamma)\delta(s - s_t^{w_t}) + \gamma\text{Uniform}([0,1]^m)$ (δ is the Dirac Delta function).
6: Sample $\tilde{s}_t \sim \mathbb{Q}_t$ and output the ranked list $\tilde{\sigma}_t = \text{argsort}(\tilde{s}_t)$
(Effectively[3], it means $\tilde{\sigma}_t$ is drawn from $\mathbb{P}_t(\sigma) = (1-\gamma)I(\sigma = \sigma_t) + \frac{\gamma}{m!}$)
7: Receive relevance feedback on top-k items, i.e., $(R_t(\tilde{\sigma}_t(1)), \ldots, R_t(\tilde{\sigma}_t(k)))$
8: Suffer loss $\phi(\tilde{s}_t, R_t)$ (Neither loss nor R_t revealed to learner)
9: Construct $\tilde{z}_t$, an unbiased estimator of gradient $\nabla_{w=w_t}\phi(X_t w, R_t)$, from top-$k$ feedback.
10: Update $w = w_t - \eta\tilde{z}_t$
11: $w_{t+1} = \min\{1, \frac{U}{\|w\|_2}\}w$ (Projection onto Euclidean ball of radius U).
12: **End For**

Relation between feedback and structure of surrogates: Algorithm 2 is our general algorithm for learning a ranking function, online, from partial feedback. The key step in Algorithm 2 is the construction of the unbiased estimator $\tilde{z}_t$ of the surrogate gradient $\nabla_{w=w_t}\phi(X_t w, R_t)$. The information present for the construction process, at end of round t, is the random score vector $\tilde{s}_t$ (and associated permutation $\tilde{\sigma}_t$) and relevance of top-k items of $\tilde{\sigma}_t$, i.e., $\{R_t(\tilde{\sigma}_t(1)), \ldots, R_t(\tilde{\sigma}_t(k)\}$. Let $\mathbb{E}_t[\cdot]$ be the expectation operator w.r.t. to randomization at round t, conditioned on $(w_1, \ldots, w_t)$. Then $\tilde{z}_t$ being an unbiased estimator of gradient of surrogate, w.r.t w_t, means the following: $\mathbb{E}_t[\tilde{z}_t] = \nabla_{w=w_t}\phi(X_t w, R_t)$. We note that conditioned on the past, the score vector $s_t^{w_t} = X_t w_t$ is deterministic. We start with a general result relating feedback to the construction of unbiased estimator of a vector valued function. Let S_m be the set of $m!$ permutations of $[m]$. Let $\mathbb{P}$ denote a probability distribution on S_m, i.e, $\sum_{\sigma\in S_m}\mathbb{P}(\sigma) = 1$. For a distinct set of indices $(j_1, j_2, \ldots, j_k) \subseteq [m]$, we denote $p(j_i, j_2, \ldots, j_k)$ as the the sum of probability of permutations whose first k objects match objects $(j_1, \ldots, j_k)$, in order. Formally,

$$p(j_1, \ldots, j_k) = \sum_{\pi\in S_m}\mathbb{P}(\pi)I(\pi(1) = j_1, \ldots, \pi(k) = j_k). \tag{9}$$

We have the following lemma relating feedback and structure of surrogates:

[3] $\tilde{s}_t \sim s_t^{w_t} \implies \tilde{\sigma}_t \sim \sigma_t$; otherwise $\tilde{\sigma}_t$ is any other permutation.

Lemma 14. *Let $F : \mathbb{R}^m \mapsto \mathbb{R}^a$ be a vector valued function, where $m \geq 1$, $a \geq 1$. For a fixed $x \in \mathbb{R}^m$, let k entries of x be observed at random. That is, for a fixed probability distribution $\mathbb{P}$ and some random $\sigma \sim \mathbb{P}(S_m)$, observed tuple is $\{\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)}\}$. A necessary condition for existence of an unbiased estimator of $F(x)$, that can be constructed from $\{\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)}\}$, is that it should be possible to decompose $F(x)$ over k (or less) coordinates of x at a time. That is, $F(x)$ should have the structure:*

$$F(x) = \sum_{(i_1, i_2, \ldots, i_\ell) \in \ {}^mP_\ell} h_{i_1, i_2, \ldots, i_\ell}(x_{i_1}, x_{i_2}, \ldots, x_{i_\ell}) \tag{10}$$

where $\ell \leq k$, ${}^mP_\ell$ is ℓ permutations of m and $h : \mathbb{R}^\ell \mapsto \mathbb{R}^a$ (the subscripts in h are used to denote possibly different functions in the decomposition structure). Moreover, when $F(x)$ can be written in form of Eq 10 , with $\ell = k$, an unbiased estimator of $F(x)$, based on $\{\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)}\}$, is,

$$g(\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)}) = \frac{\sum_{(j_1, j_2, \ldots, j_k) \in S_k} h_{\sigma(j_1), \ldots, \sigma(j_k)}(x_{\sigma(j_1)}, \ldots, x_{\sigma(j_k)})}{\sum_{(j_1, \ldots, j_k) \in S_k} p(\sigma(j_1), \ldots, \sigma(j_k))} \tag{11}$$

where S_k is the set of $k!$ permutations of $[k]$ and $p(\sigma(1), \ldots, \sigma(k))$ is as in Eq 9 .

Illustrative Examples: We provide simple examples to concretely illustrate the abstract functions in Lemma 14. Let $F(\cdot)$ be the identity function, and $x \in \mathbb{R}^m$. Thus, $F(x) = x$ and the function decomposes over $k = 1$ coordinate of x as follows: $F(x) = \sum_{i=1}^m x_i e_i$, where $e_i \in \mathbb{R}^m$ is the standard basis vector along coordinate i. Hence, $h_i(x_i) = x_i e_i$. Based on top-1 feedback, following is an unbiased estimator of $F(x)$: $g(\sigma, x_{\sigma(1)}) = \frac{x_{\sigma(1)} e_{\sigma(1)}}{p(\sigma(1))}$, where $p(\sigma(1)) = \sum_{\pi \in S_m} \mathbb{P}(\pi) I(\pi(1) = \sigma(1))$. In another example, let $F : \mathbb{R}^3 \mapsto \mathbb{R}^2$ and $x \in \mathbb{R}^3$. Let $F(x) = [x_1 + x_2; x_2 + x_3]^\top$. Then the function decomposes over $k = 1$ coordinate of x as $F(x) = x_1 e_1 + x_2(e_1 + e_2) + x_3 e_2$, where $e_i \in \mathbb{R}^2$. Hence, $h_1(x_1) = x_1 e_1$, $h_2(x_2) = x_2(e_1 + e_2)$ and $h_3(x_3) = x_3 e_2$. An unbiased estimator based on top-1 feedback is: $g(\sigma, x_{\sigma(1)}) = \frac{h_{\sigma(1)}(x_{\sigma(1)})}{p(\sigma(1))}$.

3.2 Unbiased Estimators of Gradients of Surrogates

Algorithm 2 can be implemented for any ranking surrogate as long as an unbiased estimator of the gradient can be constructed from the random feedback. We will use techniques from *online convex optimization* to obtain formal regret guarantees. We will thus construct the unbiased estimator of four major ranking surrogates. Three of them are popular *convex* surrogates, one each from the three major learning to rank methods, i.e., *pointwise*, *pairwise* and *listwise* methods. The fourth one is a popular *non-convex* surrogate.

Shorthand notations: We note that by chain rule, $\nabla_{w=w_t} \phi(X_t w, R_t) = X_t^\top \nabla_{s_t^{w_t}} \phi(s_t^{w_t}, R_t)$, where $s_t^{w_t} = X_t w_t$. Since X_t is deterministic in our setting, we focus on unbiased estimators of $\nabla_{s_t^{w_t}} \phi(s_t^{w_t}, R_t)$ and take a matrix-vector product with X_t. To reduce notational clutter

in our derivations, we drop w from s^w and the subscript t throughout. Thus, in our derivations, $\tilde{z} = \tilde{z}_t$, $X = X_t$, $s = s_t^{w_t}$ (and not $\tilde{s}_t$), $\sigma = \tilde{\sigma}_t$ (and not σ_t), $R = R_t$, e_i is standard basis vector in $\mathbb{R}^m$ along coordinate i and $p(\cdot)$ as in Eq. 9 with $\mathbb{P} = \mathbb{P}_t$ where $\mathbb{P}_t$ is the distribution in round t in Algorithm 2.

3.2.1 Convex Surrogates

Pointwise Method: We will construct the unbiased estimator of the gradient of squared loss (Cossock and Zhang, 2006): $\phi_{sq}(s, R) = \|s - R\|_2^2$. The gradient $\nabla_s \phi_{sq}(s, R)$ is $2(s - R) \in \mathbb{R}^m$. As we have already demonstrated in the example following Lemma 14, *we can construct unbiased estimator of R from top-1 feedback* ($\{\sigma, R(\sigma(1))\}$). Concretely, the unbiased estimator is:

$$\tilde{z} = X^\top \left(2 \left(s - \frac{R(\sigma(1)) e_{\sigma(1)}}{p(\sigma(1))} \right) \right).$$

Pairwise Method: We will construct the unbiased estimator of the gradient of hinge-like surrogate in RankSVM (Joachims, 2002): $\phi_{svm}(s, R) = \sum_{i \neq j = 1} I(R(i) > R(j)) \max(0, 1 + s(j) - s(i))$. The gradient is given by:

$$\nabla_s \phi_{svm}(s, R) = \sum_{i=1}^m \sum_{j=1, j \neq i}^m I(R(i) > R(j)) I(1 + s(j) > s(i))(e_j - e_i) \in \mathbb{R}^m.$$

Since s is a known quantity, from Lemma 14, we can construct $F(R)$ as follows:

$$F(R) = F_s(R) = \sum_{i=1}^m \sum_{j=1, j \neq i}^m h_{s,i,j}(R(i), R(j)), \ \ h_{s,i,j}(R(i), R(j)) = I(R(i) > R(j)) I(1 + s(j) > s(i))(e_j - e_i).$$

Since $F_s(R)$ is decomposable over 2 coordinates of R at a time, *we can construct an unbiased estimator from top-2 feedback* ($\{\sigma, R(\sigma(1)), R(\sigma(2))\}$). The unbiased estimator is:

$$\tilde{z} = X^\top \left(\frac{h_{s,\sigma(1),\sigma(2)}(R(\sigma(1)), R(\sigma(2))) + h_{s,\sigma(2),\sigma(1)}(R(\sigma(2)), R(\sigma(1)))}{p(\sigma(1), \sigma(2)) + p(\sigma(2), \sigma(1))} \right).$$

We note that the unbiased estimator was constructed from top-2 feedback. The following lemma, in conjunction with the necessary condition of Lemma 14 shows that it is the minimum information required to construct the unbiased estimator.

Lemma 15. *The gradient of RankSVM surrogate, i.e., $\phi_{svm}(s, R)$ cannot be decomposed over 1 coordinate of R at a time.*

Listwise Method: Convex surrogates developed for listwise methods of learning to rank are defined over the entire score vector and relevance vector. Gradients of such surrogates cannot usually be decomposed over coordinates of the relevance vector. We will focus on the cross-entropy surrogate used in the highly cited ListNet (Cao et al., 2007) ranking algorithm and show how a very natural modification to the surrogate makes its gradient estimable in our partial feedback setting.

The authors of the ListNet method use a cross-entropy surrogate on two probability distributions on permutations, induced by score and relevance vector respectively. More

formally, the surrogate is defined as follows[4]. Define m maps from $\mathbb{R}^m$ to $\mathbb{R}$ as: $P_j(v) = \exp(v(j))/\sum_{j=1}^m \exp(v(j))$ for $j \in [m]$. Then, for score vector s and relevance vector R, $\phi_{\text{LN}}(s,R) = -\sum_{i=1}^m P_i(R)\log P_i(s)$ and $\nabla_s \phi_{\text{LN}}(s,R) = \sum_{i=1}^m \left(-\frac{\exp(R(i))}{\sum_{j=1}^m \exp(R(j))} + \frac{\exp(s(i))}{\sum_{j=1}^m \exp(s(j))}\right) e_i$. We have the following lemma about the gradient of ϕ_{LN}.

Lemma 16. *The gradient of ListNet surrogate $\phi_{LN}(s,R)$ cannot be decomposed over k, for $k = 1, 2$, coordinates of R at a time.*

In fact, an examination of the proof of the above lemma reveals that decomposability at any $k < m$ does not hold for the gradient of LisNet surrogate, though we only prove it for $k = 1, 2$ (since feedback for top k items with $k > 2$ does not seem practical). Due to Lemma 14, this means that if we want to run Alg. 2 under top-k feedback, a modification of ListNet is needed. We now make such a modification.

We first note that the cross-entropy surrogate of ListNet can be easily obtained from a standard divergence, viz. Kullback-Liebler divergence. Let $p, q \in \mathbb{R}^m$ be 2 probability distributions ($\sum_{i=1}^m p_i = \sum_{i=1}^m q_i = 1$). Then $KL(p,q) = \sum_{i=1}^m p_i \log(p_i) - \sum_{i=1}^m p_i \log(q_i) - \sum_{i=1}^m p_i + \sum_{i=1}^m q_i$. Taking $p_i = P_i(R)$ and $q_i = P_i(s)$, $\forall\, i \in [m]$ (where $P_i(v)$ is as defined in ϕ_{LN}) and noting that $\phi_{\text{LN}}(s,R)$ needs to be minimized w.r.t. s (thus we can ignore the $\sum_{i=1}^m p_i \log(p_i)$ term in $KL(p,q)$), we get the cross entropy surrogate from KL.

Our natural modification now easily follows by considering KL divergence for *un-normalized* vectors (it should be noted that KL divergence is an instance of a Bregman divergence). Define m maps from $\mathbb{R}^m$ to $\mathbb{R}$ as: $P'_j(v) = \exp(v(j))$ for $j \in [m]$. Now define $p_i = P'_i(R)$ and $q_i = P'_i(s)$. Then, the modified surrogate $\phi_{KL}(s,R)$ is:

$$\sum_{i=1}^m e^{R(i)} \log(e^{R(i)}) - \sum_{i=1}^m e^{R(i)} \log(e^{s(i)}) - \sum_{i=1}^m e^{R(i)} + \sum_{i=1}^m e^{s(i)},$$

and $\sum_{i=1}^m (\exp(s(i)) - \exp(R(i)))\, e_i$ is its gradient w.r.t. s. Note that $\phi_{KL}(s,R)$ is non-negative and convex in s. Equating gradient to $\mathbf{0} \in \mathbb{R}^m$, at the minimum point, $s(i) = R(i)$, $\forall\, i \in [m]$. Thus, the sorted order of optimal score vector agrees with sorted order of relevance vector and it is a valid ranking surrogate.

Now, from Lemma 14, we can construct $F(R)$ as follows: $F(R) = F_s(R) = \sum_{i=1}^m h_{s,i}(R(i))$, where $h_{s,i}(R(i)) = (\exp(s(i)) - \exp(R(i)))\, e_i$. Since $F_s(R)$ is decomposable over 1 coordinate of R at a time, *we can construct an unbiased estimator from top-1 feedback* ($\{\sigma, R(\sigma(1))\}$). The unbiased estimator is:

$$\tilde{\mathbf{z}} = X^\top \left(\frac{(\exp(s(\sigma(1))) - \exp(R(\sigma(1))))e_{\sigma(1)}}{p(\sigma(1))}\right)$$

Other Listwise Methods: As we mentioned before, most listwise convex surrogates will not be suitable for Algorithm 2 with top-k feedback. For example, the class of popular listwise surrogates that are developed from structured prediction perspective (Chapelle et al., 2007; Yue et al., 2007) cannot have unbiased estimator of gradients from top-k feedback since they are based on maps from full relevance vectors to full rankings and thus cannot be decomposed over $k = 1$ or 2 coordinates of R. It does not appear they have any natural modification to make them amenable to our approach.

[4]The ListNet paper actually defines a family of losses based on probability models for top r documents, with $r \leq m$. We use $r = 1$ in our definition since that is the version implemented in their experimental results.

3.2.2 Non-convex Surrogate

We provide an example of a non-convex surrogate for which Alg. 2 is applicable (however it will not have any regret guarantees due to non-convexity). We choose the SmoothDCG surrogate given in (Chapelle and Wu, 2010), which has been shown to have very competitive empirical performance. SmoothDCG, like ListNet, defines a family of surrogates, based on the cut-off point of DCG (see original paper (Chapelle and Wu, 2010) for details). We consider SmoothDCG@1, which is the smooth version of DCG@1 (i.e., DCG which focuses just on the top-ranked document). The surrogate is defined as: $\phi_{SD}(s,R) = \frac{1}{\sum_{j=1}^m \exp(s(j)/\epsilon)} \sum_{i=1}^m G(R(i)) \exp(s(i)/\epsilon)$, where ϵ is a (known) smoothing parameter and $G(a) = 2^a - 1$. The gradient of the surrogate is:

$$[\nabla_s \phi_{\text{SD}}(s,R)] = \sum_{i=1}^m h_{s,i}(R(i)),$$

$$h_{s,i}(R(i)) = G(R_i)\left(\sum_{j=1}^m \frac{1}{\epsilon}\left[\frac{\exp(s(i)/\epsilon)}{\sum_{j'} \exp(s(j')/\epsilon)} I_{(i=j)} - \frac{\exp((s(i)+s(j))/\epsilon)}{(\sum_{j'} \exp(s(j')/\epsilon))^2}\right] e_j\right)$$

Using Lemma 14, we can write $F(R) = F_s(R) = \sum_{i=1}^m h_{s,i}(R(i))$ where $h_{s,i}(R(i))$ is defined above. Since $F_s(R)$ is decomposable over 1 coordinate of R at a time, *we can construct an unbiased estimator from top-1 feedback* ($\{\sigma, R(\sigma(1))\}$), with unbiased estimator being:

$$s(\sigma(1))\tilde{z} = X^\top \left(\frac{G(R(\sigma(1)))}{p(\sigma(1))} \sum_{j=1}^m \frac{1}{\epsilon}\left[\frac{\exp(s(\sigma(1))/\epsilon)}{\sum_{j'} \exp(s(j')/\epsilon)} I_{(\sigma(1)=j)} - \frac{\exp((s(\sigma(1)) + s(j))/\epsilon)}{(\sum_{j'} \exp(s(j')/\epsilon))^2}\right] e_j\right)$$

3.3 Computational Complexity of Algorithm 2

Three of the four key steps governing the complexity of Algorithm 2, i.e., construction of $\tilde{s}_t$, $\tilde{\sigma}_t$ and sorting can all be done in $O(m \log(m))$ time.The only bottleneck could have been calculations of $p(\tilde{\sigma}_t(1))$ in squared loss, (modified) ListNet loss and SmoothDCG loss, and $p(\tilde{\sigma}_t(1), \tilde{\sigma}_t(2))$ in RankSVM loss, since they involve sum over permutations. However, they have a compact representation, i.e., $p(\tilde{\sigma}_t(1)) = (1 - \gamma + \frac{\gamma}{m}) I(\tilde{\sigma}_t(1) = \sigma_t(1)) + \frac{\gamma}{m} I(\tilde{\sigma}_t(1) \neq \sigma_t(1))$ and $p(\tilde{\sigma}_t(1), \tilde{\sigma}_t(2)) = (1 - \gamma + \frac{\gamma}{m(m-1)}) I(\tilde{\sigma}_t(1) = \sigma_t(1), \tilde{\sigma}_t(2) = \sigma_t(2)) + \frac{\gamma}{m(m-1)}[\sim I(\tilde{\sigma}_t(1) = \sigma_t(1), \tilde{\sigma}_t(2) = \sigma_t(2))]$. The calculations follow easily due to the nature of $\mathbb{P}_t$ (step-6 in algorithm) which put equal weights on all permutations other than σ_t.

3.4 Regret Bounds

The underlying deterministic part of our algorithm is online gradient descent (OGD) (Zinkevich, 2003). The regret of OGD, run with unbiased estimator of gradient of a **convex**

function, as given in Theorem 3.1 of (Flaxman et al., 2005), in our problem setting is:

$$\mathbb{E}\left[\sum_{t=1}^{T}\phi(X_t w_t, R_t)\right] \leq \min_{w:\|w\|_2\leq U}\sum_{t=1}^{T}\phi(X_t w, R_t) + \frac{U^2}{2\eta} + \frac{\eta}{2}\mathbb{E}\left[\sum_{t=1}^{T}\|\tilde{z}_t\|_2^2\right] \tag{12}$$

where $\tilde{z}_t$ is unbiased estimator of $\nabla_{w=w_t}\phi(X_t w, R_t)$, conditioned on past events, η is the learning rate and the expectation is taken over all randomness in the algorithm.

However, from the perspective of the loss $\phi(\tilde{s}_t, R_t)$ incurred by Algorithm 2, at each round t, the RHS above is not a valid upper bound. The algorithms plays the score vector suggested by OGD ($\tilde{s}_t = X_t w_t$) with probability $1-\gamma$ (exploitation) and plays a randomly selected score vector (i.e., a draw from the uniform distribution on $[0,1]^m$), with probability γ (exploration). Thus, the expected number of rounds in which the algorithm does not follow the score suggested by OGD is γT, leading to an extra regret of order γT. Thus, we have [5]

$$\mathbb{E}\left[\sum_{t=1}^{T}\phi(\tilde{s}_t, R_t)\right] \leq \mathbb{E}\left[\sum_{t=1}^{T}\phi(X_t w_t, R_t)\right] + O\left(\gamma T\right) \tag{13}$$

We first control $\mathbb{E}_t\|\tilde{z}_t\|_2^2$, for all convex surrogates considered in our problem (we remind that $\tilde{z}_t$ is the estimator of a gradient of a surrogate, calculated at time t. In Sec 3.2.1 , we omitted showing w in s^w and index t). To get bound on $\mathbb{E}_t\|\tilde{z}_t\|_2^2$, we used the following norm relation that holds for any matrix X (Bhaskara and Vijayaraghavan, 2011): $\|X\|_{p\to q} = \sup_{v\neq 0}\frac{\|Xv\|_q}{\|v\|_p}$, where q is the dual exponent of p (i.e., $\frac{1}{q}+\frac{1}{p}=1$), and the following lemma derived from it:

Lemma 17. *For any $1 \leq p \leq \infty$, $\|X^\top\|_{1\to p} = \|X\|_{q\to\infty} = \max_{j=1}^{m}\|X_{j:}\|_p$, where $X_{j:}$ denotes jth row of X and m is the number of rows of matrix.*

We have the following result:

Lemma 18. *For parameter γ in Algorithm 2 , R_D being the bound on ℓ_2 norm of the feature vectors (rows of document matrix X), m being the upper bound on number of documents per query, U being the radius of the Euclidean ball denoting the space of ranking parameters and $R_{\max}$ being the maximum possible relevance value (in practice always ≤ 5), let $C^\phi \in \{C^{sq}, C^{svm}, C^{KL}\}$ be polynomial functions of R_D, m, U, R_{max}, where the degrees of the polynomials depend on the surrogate ($\phi_{sq}, \phi_{svm}, \phi_{KL}$), with no degree ever greater than four. Then we have,*

$$\mathbb{E}_t\left[\|\tilde{z}_t\|_2^2\right] \leq \frac{C^\phi}{\gamma} \tag{14}$$

Plugging Eq. 14 and Eq. 13 in Eq. 12, and optimizing over η and γ, (which gives $\eta = O(T^{-2/3})$ and $\gamma = O(T^{-1/3})$), we get the final regret bound:

[5] The instantaneous loss suffered at each of the exploration round can be maximum of $O(1)$, as long as $\phi(s,R)$ is bounded, $\forall\ s$ and $\forall\ R$. This is true because the score space is ℓ_2 norm bounded, maximum relevance grade is finite in practice and we consider Lipschitz, convex surrogates.

Theorem 19. *For any sequence of instances and labels $(X_t, R_t)_{\{t\in[T]\}}$, applying Algorithm 2 with top-1 feedback for ϕ_{sq} and ϕ_{KL} and top-2 feedback for ϕ_{svm}, will produce the following bound:*

$$\mathbb{E}\left[\sum_{t=1}^{T}\phi(\tilde{s}_t, R_t)\right] - \min_{w:\|w\|_2\leq U}\sum_{t=1}^{T}\phi(X_t w, R_t) \leq C^\phi O\left(T^{2/3}\right) \tag{15}$$

where C^ϕ is a surrogate dependent function, as described in Lemma 18 , and expectation is taken over underlying randomness of the algorithm, over T rounds.

3.5 Impossibility of Sublinear Regret for NDCG Calibrated Surrogates

Learning to rank methods optimize surrogates to learn a ranking function, even though performance is measured by target measures like NDCG. This is done because direct optimization of the measures lead to NP-hard optimization problems. One of the most desirable properties of any surrogate is *calibration*, i.e., the surrogate should be calibrated w.r.t the target (Bartlett et al., 2006). Intuitively, it means that a function with small expected surrogate loss on unseen data should have small expected target loss on unseen data. We focus on NDCG calibrated surrogates (both convex and non-convex) that have been characterized by Ravikumar et al. (2011). We first state the necessary and sufficient condition for a surrogate to be calibrated w.r.t NDCG. For any score vector s and distribution η on relevance space $\mathcal{Y}$, let $\bar{\phi}(s,\eta) = \mathbb{E}_{R\sim\eta}\phi(s,R)$. Moreover, we define $G(\mathbf{R}) = (G(R_1),\ldots,G(R_m))^\top$. $Z(R)$ is defined in Sec 2.2.

Theorem 20. *(Ravikumar et al., 2011, Thm. 6) A surrogate ϕ is NDCG calibrated iff for any distribution η on relevance space $\mathcal{Y}$, there exists an invertible, order preserving map $g:\mathbb{R}^m \mapsto \mathbb{R}^m$ s.t. the unique minimizer $s^*_\phi(\eta)$ can be written as*

$$s^*_\phi(\eta) = g\left(\mathbb{E}_{R\sim\eta}\left[\frac{G(\mathbf{R})}{Z(R)}\right]\right). \tag{16}$$

Informally, Eq. 16 states that $\text{argsort}(s^*_\phi(\eta)) \subseteq \text{argsort}(\mathbb{E}_{R\sim\eta}\left[\frac{G(\mathbf{R})}{Z(R)}\right])$. Ravikumar et al. (2011) give concrete examples of NDCG calibrated surrogates, including how some of the popular surrogates can be converted into NDCG calibrated ones: e.g., the NDCG calibrated version of squared loss is $\|s - \frac{G(\mathbf{R})}{Z(R)}\|_2^2$.

We now state the *impossibility* result for the class of NDCG calibrated surrogates when feedback is restricted to top ranked item.

Theorem 21. *Fix the online learning to rank game with top 1 feedback and any NDCG calibrated surrogate. Then, for every learner's algorithm, there exists an adversary strategy such that the learner's expected regret is $\Omega(T)$.*

We note that the proof of Theorem. 3 of Piccolboni and Schindelhauer (2001) cannot be directly extended to prove the impossibility result because it relies on constructing a connected graph on vertices defined by neighboring actions of learner. In our case, due to the continuous nature of learner's actions, the graph will be an empty graph and proof will break down.

4. Experiments

We conducted experiments on simulated and commercial data sets to demonstrate the performance of our algorithms.

4.1 Non Contextual Setting

Objectives: We had the following objectives while conducting experiments in the non-contextual, online ranking with partial feedback setting:

- Investigate how performance of Algorithm 1 is affected by size of blocks during blocking.
- Investigate how performance of the algorithm is affected by amount of feedback received (i.e., generalizing k in top k feedback).
- Demonstrate the difference between regret rate of our algorithm, which operates in partial feedback setting, with regret rate of a full information algorithm which receives full relevance vector feedback at end of each round.

We applied Algorithm 1 in conjunction with Follow-The-Perturbed-Leader (FTPL) full information algorithm, as described in Sec. 2.6. Note that the online learning to rank problem is not as well studied as the batch problem. This is especially true for the partial feedback setting we have. Therefore benchmark data sets with published baseline performance measures, are not available for comparison, to the best of our knowledge. The generic partial monitoring algorithms that do exist cannot be applied due to computational inefficiency (Sec. 2.5).

Experimental Setting: All our experiments were conducted with respect to the DCG measure, which is quite popular in practice, and binary graded relevance vectors. Our experiments were conducted on the following simulated data set. We fixed number of items to 20 ($m = 20$). We then fixed a "true" relevance vector which had 5 items with relevance level 1 and 15 items with relevance level 0. We then created a total of T=10000 relevance vectors by corrupting the true relevance vector. The corrupted copies were created by independently flipping each relevance level (0 to 1 and vice-versa) with a small probability. The reason for creating adversarial relevance vectors in such a way was to reflect diversity of preferences in practice. In reality, it is likely that most users will have certain similarity in preferences, with small deviations on certain items and certain users. That is, some items are likely to be relevant in general, with most items not relevant to majority of users, with slight deviation from user to user. Moreover, the comparator term in our regret bound (i.e., cumulative loss/gain of the true best ranking in hindsight) makes practical sense if there is a ranking which satisfies most users.

Results: We plotted average regret over time under DCG. Average regret over time means cumulative regret up to time t, divided by t, for $1 \leq t \leq T$. Figure 1 demonstrates the effect of block size on the regret rate under DCG. We fixed feedback to relevance of top ranked item ($k = 1$). As can be seen in Corollary 10, the optimal regret rate is achieved by optimizing over number of blocks (hence block size), which requires prior knowledge of

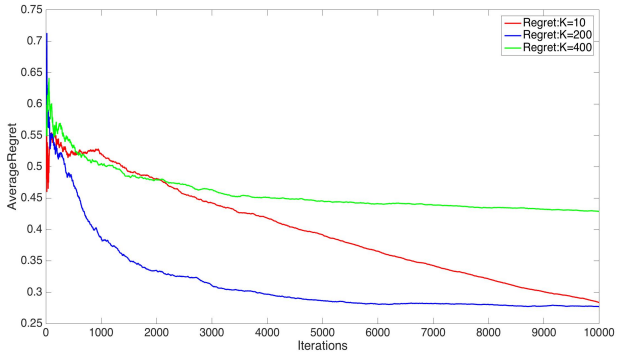

Figure 1: Average regret under DCG, with feedback on top ranked object, for varying block size, where block size is $\lceil T/K \rceil$. *Best viewed in color.*

time horizon T. We wanted to demonstrate how the regret rate (and hence the performance of the algorithm) differs with different block sizes. The optimal number of blocks in our setting is $K \sim 200$, with corresponding block size being $\lceil T/K \rceil = 50$. As can be clearly seen, with optimal block size, the regret drops fastest and becomes steady after a point. $K = 10$ means that block size is 1000. This means over the time horizon, number of exploitation rounds greatly dominates number of exploration rounds, leading to regret dropping at a slower rate initially than than the case with optimal block size. However, the regret drops of pretty sharply later on. This is because the relevance vectors are slightly corrupted copies of a "true" relevance vector and the algorithm gets a good estimate of the true relevance vector quickly and then more exploitation helps. When $K = 400$ (i.e., block size is 25), most of the time, the algorithm is exploring, leading to a substantially worse regret and poor performance.

Figure 2 demonstrates the effect of amount of feedback on the regret rate under DCG. We fixed $K = 200$, and varied feedback as relevance of top k ranked items per round, where $k = 1, 5, 10$. Validating our regret bound, we see that as k increases, the regret decreases.

Figure 3 compares regret of our algorithm, working with top 1 feedback, and FTPL full information algorithm, working with full relevance vector feedback at end of each round. We fixed $K = 200$ and the comparison was done from 1000 iterations onwards, i.e., roughly after the initial learning phase. FTPL full information algorithm has regret rate of $O(T^{1/2})$ (ignoring other parameters). So, as expected, FTPL with full information feedback outperforms our algorithm with highly restricted feedback; yet, we have demonstrated, both theoretically and empirically, that it is possible to have a good ranking strategy with highly restricted feedback.

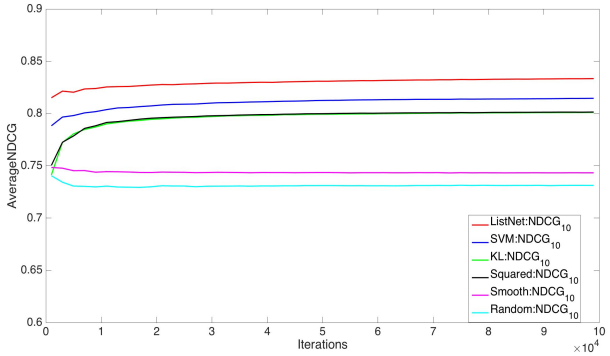

Figure 5: Average NDCG_{10} values of different algorithms, for Yandex data set. ListNet:NDCG_{10} (in cyan) operates on full feedback and Random:NDCG_{10} (in red) does not receive any feedback. *Best viewed in color.*

4.2 Contextual Setting

Objective: Since our contextual, online learning to rank with restricted feedback setting involves query-document matrices, we could conduct experiments on commercial, publicly available ranking data sets. Our objective was to demonstrate that it is possible to learn a good ranking function, even with highly restricted feedback, when standard online learning to rank algorithms would require full feedback at end of each round. As stated before, though our algorithm is designed to minimize surrogate based regret, the surrogate loss is only a proxy for ranking measures like NDCG. The users care about the ranking presented to them, and indeed the algorithm interacts with users by presenting ranked lists and getting feedback on top ranked item(s). We tested the quality of the ranked lists, and hence the performance of the evolving ranking functions, against the full relevance vectors, via ranking measure NDCG, cutoff at the 10th item. NDCG, cutoff at a point n, is defined as follows:

$$NDCG_n(\sigma, R) = \frac{1}{Z_n(R)} \sum_{i=1}^{n} \frac{2^{R(\sigma(i))} - 1}{\log_2(1+i)}$$

where $Z_n(R) = \max_{\sigma \in S_m} \sum_{i=1}^{n} \frac{2^{R(\sigma(i))}-1}{\log_2(1+i)}$. We want to emphasize that the algorithm was in no way affected by the fact that we were measuring its performance with respect to NDCG cutoff at 10. In fact, the cutoff point can be varied, but usually, researchers report performance under NDCG cutoff at 5 or 10.

Baselines: We applied Algorithm 2, with top 1 feedback, on Squared, KL (un-normalized ListNet) and SmoothDCG surrogates, and with top 2 feedback, on the RankSVM surrogate. Based on the objective of our work, we selected two different ranking algorithms as baselines. The first one is the online version of ListNet ranking algorithm (which is essentially OGD on cross-entropy function), with full relevance vector revealed at end of every round. ListNet is not only one of the most cited ranking algorithms (over 700 citations according to Google Scholar), but also one of the most validated algorithms (Tax et al., 2015). We emphasize that some of the ranking algorithms in literature, which have shown better empirical performance than ListNet, are based on non-convex surrogates with complex, non-linear ranking functions. These algorithms cannot usually be converted into online algorithms which learn from streaming data. Our second algorithm is a simple, fully random algorithm , which outputs completely random ranking of documents at each round. This algorithm, in effect, receives no feedback at end of each round. *Thus, we are comparing Algorithm 2, which learns from highly restricted feedback, with an algorithm which learns from full feedback and an algorithm which receives no feedback and learns nothing.*

Data sets: We compared the various ranking functions on two large scale commercial data sets. They were Yahoo's Learning to Rank Challenge data set (Chapelle and Chang, 2011) and a data set published by Russian search engine Yandex (IM-2009). The Yahoo data set had 19944 unique queries with 5 distinct relevance levels, while Yandex had 9126 unique queries with 5 distinct relevance levels.

Experimental Setting: We selected time horizon $T = 200,000$ (Yahoo) and $T = 100,000$ (Yandex) iterations for our experiments (thus, each algorithm went over each data set multiple times). The reason for choosing different time horizons is that there were roughly double the number of queries in Yahoo data set as compared to Yandex data set. All the online algorithms, other than the fully random one, involve learning rate η and exploration parameter γ (full information ListNet does not involve γ and SmoothDCG has an additional smoothing parameter ϵ). While obtaining our regret guarantees, we had established that $\eta = O(T^{-2/3})$ and $\gamma = O(T^{-1/3})$. In our experiments, for each instance of Algorithm 2, we selected a time varying $\eta = \frac{0.01}{t^{2/3}}$ and $\gamma = \frac{0.1}{t^{1/3}}$, for round t . We fixed $\epsilon = 0.01$. For ListNet, we selected $\eta = \frac{0.01}{t^{1/2}}$, since regret guarantee in OGD is established with $\eta = O(T^{-1/2})$. It should be noted that, while we varied the numerators in the parameters between $\{0.001, 0.01, 0.1, 1, 10\}$, and selected the parameters which produced the best (avg.) NDCG value over the entire time horizon, more emphasis could have been given on the issue of parameter tuning. However, better tuning of parameters could have only improved the performance of our algorithm. We plotted average NDCG_{10} against time, where average NDCG_{10} at time t is the cumulative NDCG_{10} up to time t, divided by t. We made an important observation while comparing the performance plots of the algorithms. As we have shown, construction of the unbiased estimators involve division by a probability value (Eq 11). The particular probability value can be $\frac{\gamma}{m}$, which is very small since γ goes to 0, when the top ranked item of the randomly drawn permutation does not match the top ranked item of the permutation given by the deterministic score vector (Sec 3.3). The mismatch happens with very low probability (since the random permutation is actually the deterministic permutation with high probability). While theoretically useful, in practice, dividing by such small value negatively affected the gradient estimation and hence the performance of our algorithm. So, when the mismatch happened, we made the denominator γ, instead of $\frac{\gamma}{m}$, and saw signficantly better performance.

Results: Figure 4 and Figure 5 show that ListNet, with full information feedback at end of each round, has highest average NDCG value throughout, as expected. However, Algorithm 2, with the convex surrogates, produce competitive performance. In fact, in the Yahoo data set, our algorithm, with RankSVM and KL, are very close to the performance of ListNet. RanSVM based algorithm does better than the others, since the estimator of RankSVM gradient is constructed from top 2 feedback, leading to lower variance of the estimator. KL based algorithm does much better than Squared loss based algorithm on Yahoo and equally as well on Yandex data set. *Crucially, our algorithm, based on all three convex surrogates, perform significantly better than the purely random algorithm, and are much closer to ListNet in performance, despite being much closer to the purely random algorithm in terms of feedback.* Our algorithm, with SmoothDCG, on the other hand, produce poor performance. We believe the reason is the non-convexity of the surrogate, which leads to the optimization procedure possibly getting stuck at a local minima. In batch setting, such problem is avoided by an annealing technique that successively reduces ϵ. We are not aware of an analogue in an online setting. Possible algorithms optimizing non-convex surrogates in an online manner, which require gradient of the surrogate, may be adapted to this partial feedback setting. The main purpose for including SmoothDCG in our work was to show that unbiased estimation of gradient, from restricted feedback, is possible even for non-convex surrogates.

5. Conclusion and Future Directions

We studied the problem of online learning to rank with a novel, restricted feedback model. The work is divided into two parts: in the first part, the set of items to be ranked is fixed, with varying user preferences, and in the second part, the items vary, as traditional query-documents matrices. The parts are tied by the feedback model; where the user gives feedback only on top k ranked items at end of each round, though the performance of the learner's ranking strategy is judged against full, *implicit* relevance vectors. In the first part, we gave comprehensive results on learnability with respect to a number of practically important ranking measures. We also gave a generic algorithm, along with an efficient instantiation, which achieves sub-linear regret rate for certain ranking measures. In the second part, we gave an efficient algorithm, which works on a number of popular ranking surrogates, to achieve sub-linear regret rate. We also gave an impossibility result for an entire class of ranking surrogates. Finally, we conducted experiments on simulated and commercial ranking data sets to demonstrate the performance of our algorithms.

We highlight some of the open questions of interest:

- What are the minimax regret rates with top k feedback model, for $k > 1$, for the ranking measures DCG, PairwiseLoss, Precision@n and their normalized versions NDCG, AUC and AP? Specifically, NDCG and AP are very popular in the learning to rank community. We showed that with top 1 feedback model, no algorithm can achieve sub-linear regret for NDCG and AP. Is it possible to get sub-linear regret with $1 < k < m$?

- We used FTPL as the sub-routine in Algorithm 1 to get an efficient algorithm. It might be possible to use other full information algorithms as sub-routine, retaining the efficiency, but getting tighter rates in terms of parameters (other than T) and better empirical performance.

- We applied Algorithm 2 on three convex surrogates and one non-convex surrogates. It would be interesting to investigate what other surrogates the algorithm can be applied on, guided by Lemma 14, and test its empirical performance. Since the algorithm learns a ranking function in the traditional query-documents setting, the question is more of practical interest.

- We saw that Algorithm 2, when applied to SmoothDCG, does not produce competitive empirical performance. It has been shown that a ranking function, learnt by optimizing SmoothDCG in the batch setting, has extremely competitive empirical performance (Qin and Liu, 2006). In the batch setting, simulated annealing is used to prevent the optimization procedure getting stuck in local minima. Any algorithm that optimizes non-convex surrogates in an online manner, by accessing its gradient, can replace the online gradient descent part in our algorithm and tested on SmoothDCG for empirical performance.

- We proved an impossibility result for NDCG calibrated surrogates with top 1 feedback. What is the minimax regret for NDCG calibrated surrogates, with top k feedback, for $k > 1$?

Appendix A. Proofs for Non Contextual Setting

We provide technical details of results of Online Ranking with Restricted Feedback- Non Contextual Setting.

Proof of Theorem 8:

Proof. **Full information feedback**: Instead of top k feedback, assume that at end of each round, after learner reveals its action, the full relevance vector R is revealed to the learner. Since the knowledge of full relevance vector allows the learner to calculate the loss for every action (SumLoss(σ, R), $\forall\ \sigma$), the game is in full information setting, and the learner, using the full information algorithm, will have an $O(C\sqrt{T})$ expected regret for $SumLoss$ (ignoring computational complexity). Here, C denotes parameter specific to the full information algorithm used.

Blocking with full information feedback: We consider a blocked variant of the full information algorithm. We still assume that full relevance vector is revealed at end of each round. Let the time horizon T be divided into K blocks, i.e., $\{B_1, \ldots, B_K\}$, of equal size. Here, $B_i = \{(i-1)(T/K)+1, (i-1)(T/K)+2, (i-1)T/K+3, \ldots, i(T/K)\}$. While operating in a block, the relevance vectors revealed at end of each round are accumulated, but not used to generate learner's actions like in the "without blocking" variant. Assume at the start of block B_i, there was some vector $s_{i-1} \in \mathbb{R}^m$. Then, at each round in the block, the randomized full information algorithm exploits s_{i-1} and outputs a permutation (basically maintains a distribution over actions, using s_{i-1}, and samples from the distribution). At the end of a block, the average of the accumulated relevance vectors (R_i^{avg}) for the block is used to update, as $s_{i-1} + R_i^{avg}$, to get s_i for the next block. The process is repeated for each block.

Formally, the full information algorithm creates distribution ρ_i over the actions, at beginning of block B_i, exploiting information s_{i-1}. Thus, $\rho_i \in \Delta$, where Δ is the probability simplex over $m!$ actions. Note that ρ_i is a deterministic function of $\{R_1^{avg}, \ldots, R_{i-1}^{avg}\}$.

Since action σ_t, for $t \in B_i$, is generated according to distribution ρ_i (we will denote this as $\sigma_t \sim \rho_i$), and in block i, distribution ρ_i is fixed, we have

$$\mathbb{E}_{\sigma_t \sim \rho_i}[\sum_{t \in [B_i]} SumLoss(\sigma_t, R_t)] = \sum_{t \in B_i} \rho_i \cdot [SumLoss(\sigma_1, R_t), \ldots, SumLoss(\sigma_{m!}, R_t)].$$

Thus, the total expected loss of this variant of the full information problem is:

$$\begin{aligned}
\mathbb{E}\sum_{t=1}^{T}[SumLoss(\sigma_t, R_t)] &= \sum_{i=1}^{K} \mathbb{E}_{\sigma_t \sim \rho_i}[\sum_{t \in B_i} SumLoss(\sigma_t, R_t)] \\
&= \sum_{i=1}^{K} \sum_{t \in B_i} \rho_i \cdot [SumLoss(\sigma_1, R_t), \ldots, SumLoss(\sigma_{m!}, R_t)] \\
&= \sum_{i=1}^{K} \sum_{t \in B_i} \rho_i \cdot [\sigma_1^{-1} \cdot R_t, \ldots, \sigma_{m!}^{-1} \cdot R_t)] \quad \text{By defn. of SumLoss} \\
&= \frac{T}{K} \sum_{i=1}^{K} \rho_i \cdot [\sigma_1^{-1} \cdot R_i^{avg}, \ldots, \sigma_{m!}^{-1} \cdot R_i^{avg}]
\end{aligned}$$

$$\begin{aligned}
&= \frac{T}{K} \sum_{i=1}^{K} \mathbb{E}_{\sigma_i \sim \rho_i}[SumLoss(\sigma_i, R_i^{avg})] \\
&= \frac{T}{K} \mathbb{E}_{\sigma_1 \sim \rho_1, \ldots, \sigma_K \sim \rho_K} \sum_{i=1}^{K} SumLoss(\sigma_i, R_i^{avg}) \qquad (17)
\end{aligned}$$

where $R_i^{avg} = \sum_{t \in B_i} \frac{R_t}{T/K}$. Note that, at end of every block $i \in [K]$, ρ_i is updated to ρ_{i+1}. By the regret bound of the full information algorithm, for K rounds of full information problem, we have:

$$\begin{aligned}
\mathbb{E}_{\sigma_1 \sim \rho_1, \ldots, \sigma_K \sim \rho_K} \sum_{i=1}^{K} SumLoss(\sigma_i, R_i^{avg}) &\leq \min_{\sigma} \sum_{i=1}^{K} SumLoss(\sigma, R_i^{avg}) + C\sqrt{K} \\
&= \min_{\sigma} \sum_{i=1}^{K} \sigma^{-1} \cdot R_i^{avg} + C\sqrt{K} \qquad (18) \\
&= \min_{\sigma} \sum_{t=1}^{T} \sigma^{-1} \cdot \frac{R_t}{T/K} + C\sqrt{K}
\end{aligned}$$

Now, since

$$\min_{\sigma} \sum_{t=1}^{T} \sigma^{-1} \cdot \frac{R_t}{T/K} = \min_{\sigma} \frac{1}{T/K} \sum_{t=1}^{T} SumLoss(\sigma, R_t),$$

combining Eq. 17 and Eq. 18, we get:

$$\sum_{t=1}^{T} \mathbb{E}_{\sigma_t \in \rho_i}[SumLoss(\sigma_t, R_t)] \leq \min_{\sigma} \sum_{t=1}^{T} SumLoss(\sigma, R_t) + C\frac{T}{\sqrt{K}}. \qquad (19)$$

Blocking with top k feedback: However, in our top k feedback model, the learner does not get to see the full relevance vector at each end of round. Thus, we form the unbiased estimator $\hat{R}_i$ of R_i^{avg}, using Lemma 7. That is, at start of each block, we choose $\lceil m/k \rceil$ time points uniformly at random, and at those time points, we output a random permutation which places k distinct objects on top (refer to Algorithm 1). At the end of the block, we form the vector $\hat{R}_i$ which is the unbiased estimator of R_i^{avg}. Note that using random vector $\hat{R}_i$ instead of true R_i^{avg} introduces randomness in the distribution ρ_i itself . But significantly, ρ_i is dependent only on information received up to the beginning of block i and is independent of the information collected in the block. We show the exclusive dependence as $\rho_i(\hat{R}_1, \hat{R}_2, .., \hat{R}_{i-1})$. Thus, for block i, we have:

$$\begin{aligned}
&\mathbb{E}_{\sigma_t \sim \rho_i(\hat{R}_1, \hat{R}_2, .., \hat{R}_{i-1})} \sum_{t \in [B_i]} SumLoss(\sigma_t, R_t) \\
&= \frac{T}{K} \mathbb{E}_{\sigma_i \sim \rho_i(\hat{R}_1, \hat{R}_2, .., \hat{R}_{i-1})} SumLoss(\sigma_i, R_i^{avg}) \\
&\quad \text{(From Eq. 17)}
\end{aligned}$$

$$= \frac{T}{K}\mathbb{E}_{\sigma_i\sim\rho_i(\hat{R}_1,\hat{R}_2,..,\hat{R}_{i-1})}\mathbb{E}_{\hat{R}_i}SumLoss(\sigma_i,\hat{R}_i)$$
$$(\because \text{SumLoss is linear in both arguments and } \hat{R}_i \text{ is unbiased})$$
$$= \frac{T}{K}\mathbb{E}_{\hat{R}_i}\mathbb{E}_{\sigma_i\sim\rho_i(\hat{R}_1,\hat{R}_2,..,\hat{R}_{i-1})}SumLoss(\sigma_i,\hat{R}_i).$$

In the last step above, we crucially used the fact that, since random distribution ρ_i is independent of $\hat{R}_i$, the order of expectations is interchangeable. Taking expectation w.r.t. $\hat{R}_1, \hat{R}_2, .., \hat{R}_{i-1}$, we get,

$$\mathbb{E}_{\hat{R}_1,..,\hat{R}_{i-1}}\mathbb{E}_{\sigma_t\sim\rho_i(\hat{R}_1,\hat{R}_2,..,\hat{R}_{i-1})}\sum_{t\in[B_i]}SumLoss(\sigma_t,R_t) = \frac{T}{K}\mathbb{E}_{\hat{R}_1,..,\hat{R}_{i-1},\hat{R}_i}E_{\sigma_i\sim\rho_i(\hat{R}_1,\hat{R}_2,..,\hat{R}_{i-1})}SumLoss(\sigma_i,\hat{R}_i). \tag{20}$$

Thus,

$$\begin{aligned}
\mathbb{E}\sum_{t=1}^{T}SumLoss(\sigma_t,R_t) &= \mathbb{E}\sum_{i=1}^{K}\sum_{t\in[B_i]}SumLoss(\sigma_t,R_t)\\
&= \sum_{i=1}^{K}E_{\hat{R}_1,..,\hat{R}_{i-1}}E_{\sigma_t\sim\rho_i(\hat{R}_1,\hat{R}_2,..,\hat{R}_{i-1})}\sum_{t\in[B_i]}SumLoss(\sigma_t,R_t)\\
&= \frac{T}{K}\sum_{i=1}^{K}\mathbb{E}_{\hat{R}_1,..,\hat{R}_{i-1},\hat{R}_i}\mathbb{E}_{\sigma_i\sim\rho_i(\hat{R}_1,\hat{R}_2,..,\hat{R}_{i-1})}SumLoss(\sigma_i,\hat{R}_i)\\
&\quad\text{(From Eq. 20)}\\
&= \frac{T}{K}\mathbb{E}_{\hat{R}_1,..,\hat{R}_K}\mathbb{E}_{\sigma_i\sim\rho_i(\hat{R}_1,\hat{R}_2,..,\hat{R}_{i-1})}\sum_{i=1}^{K}SumLoss(\sigma_i,\hat{R}_i)
\end{aligned}$$

Now using Eq. 18, we can upper bound the last term above as

$$\begin{aligned}
&\le \frac{T}{K}\{\mathbb{E}_{\hat{R}_1,..,\hat{R}_K}[\min_{\sigma}\sum_{i=1}^{K}\sigma^{-1}\cdot\hat{R}_i] + C\sqrt{K}\}\\
&\le \frac{T}{K}\{\min_{\sigma}\sum_{i=1}^{K}\sigma^{-1}\cdot R_i^{avg} + C\sqrt{K}\}\\
&\quad\text{(Jensen's Inequality)}\\
&\le \min_{\sigma}\sum_{t=1}^{T}\sigma^{-1}\cdot R_t + C\frac{T}{\sqrt{K}}\\
&= \min_{\sigma}\sum_{t=1}^{T}SumLoss(\sigma,R_t) + C\frac{T}{\sqrt{K}}.
\end{aligned}$$

Effect of exploration: Since in each block B_i, $\lceil m/k\rceil$ rounds are reserved for exploration, where we do not draw σ_t from distribution ρ_i, we need to account for it in our

regret bound. Exploration leads to an extra regret of $C^I\lceil m/k\rceil K$, where C^I is a constant depending on the loss under consideration and specific full information algorithm used. The extra regret is because loss in each of the exploration rounds is at most C^I and there are a total of $\lceil m/k\rceil K$ exploration rounds over all K blocks. Thus, overall regret :

$$\mathbb{E}\left[\sum_{t=1}^{T}SumLoss(\sigma_t,R_t)\right] - \min_{\sigma}\sum_{t=1}^{T}SumLoss(\sigma,R_t) \le C^I\lceil m/k\rceil K + C\frac{T}{\sqrt{K}}. \tag{21}$$

Now we optimize over K, to get:

$$\mathbb{E}\left[\sum_{t=1}^{T}SumLoss(\sigma_t,R_t)\right] \le \min_{\sigma}\sum_{t=1}^{T}SumLoss(\sigma,R_t) + 2(C^I)^{1/3}C^{2/3}\lceil m/k\rceil^{1/3}T^{2/3} \tag{22}$$

□

Proof of Corollary 9:

Proof. We only need to instantiate the constants C and C^I from Theorem 8, with respect to SumLoss and FTPL. FTPL has the following parameters in its regret bound, for any online full information linear optimization problem: D is the ℓ_1 diameter of learner's action set, R is upper bound on difference between losses of 2 actions on same information vector and A is the ℓ_1 diameter of the set of information vectors (adversary's action set).

For SumLoss, it can be easily calculated that $R = \sum_{i=1}^{m}\sigma^{-1}(i)R(i) = O(m^2)$, $D = \sum_{i=1}^{m}\sigma^{-1}(i) = O(m^2)$, and $A = \sum_{i=1}^{m}R(i) = O(m)$.

FTPL gets $O(C\sqrt{T})$ regret over T rounds when $\epsilon = \sqrt{\frac{D}{RAT}}$. Here, $C = 2\sqrt{DRA} = O(m^{5/2})$ and $C^I = R$. Substituting the values of D, R, A, we conclude. □

In the proof above, we used the standard FTPL bound from the work of Kalai and Vempala (2005). In particular, we used uniform noise distribution drawn from a hypercube. We could have used other distributions, e.g. Gaussian. For Gaussian perturbations, Theorem 1.7 of Abernethy et al. (2016) gives an FTPL regret bound of $B_1B_2m^{1/4}\sqrt{2T}$ where B_1, B_2 are upper bounds on the maximum ℓ_1 norm of vectors in the learner's and adversary's sets respectively. For us, B_1 is $O(m^{3/2})$ and B_2 is $O(m^{1/2})$ giving a bound of $O(m^{2.25}\sqrt{T})$ which is slightly better than the $O(m^{2.5}\sqrt{T})$ bound used in the proof above.

Extension of results from SumLoss to DCG and Precision@n:

DCG: Due to structural differences, there are minor differences in definitions and proofs of theorems for SumLoss and DCG. We prove that local observability condition fails to hold for DCG, when restricted to top 1 feedback. We can skip the explicit proof of global observability, since the application of Algorithm 1 already establishes that $O(T^{2/3})$ regret can be achieved.

With slight abuse of notations, the loss matrix L implicitly means gain matrix, where entry in cell $\{i,j\}$ of L is $f(\sigma_i)\cdot g(R_j)$. The columns of feedback matrix H are expanded to account for greater number of moves available to adversary (due to multi-graded relevance vectors). In Definition 1, learner action i is optimal if $\ell_i\cdot p \ge \ell_j\cdot p,\ \forall j\ne i$.

In Definition 2, the maximum number of distinct elements that can be in a row of H is $n+1$. The signal matrix now becomes $S_i\in\{0,1\}^{(n+1)\times 2^m}$, where $(S_i)_{j,\ell} = I(H_{i,\ell} = j-1)$.

Local Observability Fails: Since we are trying to establish a lower bound, it is sufficient to show it for binary relevance vectors, since the adversary can only be more powerful otherwise.

In Lemma 2, proved for SumLoss, $\ell_i \cdot p$ equates to $f(\sigma) \cdot \mathbb{E}[R]$. From definition of DCG, and from the structure and properties of $f(\cdot)$, it is clear that $\ell_i \cdot p$ is *maximized* under the same condition, i.e, $\mathbb{E}[R(\sigma_i(1)] \geq \mathbb{E}[R(\sigma_i(2)] \geq \ldots \geq \mathbb{E}[R(\sigma_i(m)]$. Thus, all actions are Pareto-optimal.

Careful observation of Lemma 3 shows that it is directly applicable to DCG, in light of extension of Lemma 2 to DCG.

Finally, just like in SumLoss, simple calculations with $m = 3$ and $n = 1$, in light of Lemma 2 and 3, show that local observability condition fails to hold.

We show the calculations:

$$S_{\sigma_1} = S_{\sigma_2} = \begin{bmatrix} 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{bmatrix}$$

$$\begin{aligned} \ell_{\sigma_1} =& [0, 1/2, 1/\log_2 3, 1/2 + 1/\log_2 3, 1, 3/2, \\ & 1 + 1/\log_2 3, 3/2 + 1/\log_2 3] \\ \ell_{\sigma_2} =& [0, 1/\log_2 3, 1/2, 1/2 + 1/\log_2 3, 1, 1 + 1/\log_2 3, \\ & 3/2, 3/2 + 1/\log_2 3] \end{aligned}$$

It is clear that $\ell_1 - \ell_2 \notin Col(S_{\sigma_1}^\top)$. Hence, Definition 5 fails to hold.

Proof of Corrolary 10

For DCG, the parameters of FTPL are: $R = \sum_{i=1}^m f^s(\sigma^{-1}(i)) g^s(R(i)) = O(m(2^n - 1)), D = \sum_{i=1}^m f^s(\sigma^{-1}(i)) = O(m), A = \sum_{i=1}^m g^s(R(i)) = O(m(2^n - 1))$. Again, $C = 2\sqrt{DRA}$ and $C^I = R$.

Precision@n:

Proof of Corrolary 11

For Precision@n, the parameters of FTPL are: $D = \sum_{i=1}^m f^s(\sigma^{-1}(i)) = O(n), R = \sum_{i=1}^m f^s(\sigma^{-1}(i)) g^s(R(i)) = O(n), A = \sum_{i=1}^m g^s(R(i)) = O(m)$. Again, $C = 2\sqrt{DRA}$ and $C^I = R$.

Non-existence of Sublinear Regret Bounds for NDCG, AP and AUC

We show via simple calculations that for the case $m = 3$, global observability condition fails to hold for NDCG, when feedback is restricted to top ranked item, and relevance vectors are restricted to take binary values. It should be noted that allowing for multi-graded relevance vectors only makes the adversary more powerful; hence proving for binary relevance vectors is enough.

The intuition behind failure to satisfy global observability condition is that the $NDCG(\sigma, R) = f(\sigma) \cdot g(R)$, where where $g(r) = R/Z(R)$ (see Sec.2.2). Thus, $g(\cdot)$ cannot be represented by univariate, scalar valued functions. This makes it impossible to write the difference between two rows of the loss matrix as linear combination of columns of (transposed) signal matrices.

Similar intuitions hold for AP and AUC.

Proof of Lemma 12

Proof. We will first consider NDCG and then, AP and AUC.

NDCG:

The first and last row of Table 1, when calculated for NDCG, are:

$$\begin{aligned} \ell_{\sigma_1} &= [1, 1/2, 1/\log_2 3, (1 + \log_2 3/2))/(1 + \log_2 3), 1, 3/(2(1 + 1/\log_2 3)), 1, 1] \\ \ell_{\sigma_6} &= [1, 1, \log_2 2/\log_2 3, 1, 1/2, 3/(2(1 + 1/\log_2 3)), (1 + (\log_2 3)/2))/(1 + \log_2 3), 1] \end{aligned}$$

We remind once again that NDCG is a gain function, as opposed to SumLoss.

The difference between the two vectors is:

$$\ell_{\sigma_1} - \ell_{\sigma_6} = [0, -1/2, 0, -\log_2 3/(2(1 + \log_2 3)), 1/2, 0, \log_2 3/(2(1 + \log_2 3)), 0].$$

The signal matrices are same as SumLoss:

$$S_{\sigma_1} = S_{\sigma_2} = \begin{bmatrix} 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{bmatrix}$$

$$S_{\sigma_3} = S_{\sigma_5} = \begin{bmatrix} 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \end{bmatrix}$$

$$S_{\sigma_4} = S_{\sigma_6} = \begin{bmatrix} 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \end{bmatrix}$$

It can now be easily checked that $\ell_{\sigma_1} - \ell_{\sigma_6}$ does not lie in the (combined) column span of the (transposed) signal matrices.

We show similar calculations for AP and AUC.

AP:

We once again take $m = 3$. The first and last row of Table 1, when calculated for AP, is:

$$\begin{aligned} \ell_{\sigma_1} &= [1, 1/3, 1/2, 7/12, 1, 5/6, 1, 1] \\ \ell_{\sigma_6} &= [1, 1, 1/2, 1, 1/3, 5/6, 7/12, 1] \end{aligned}$$

Like NDCG, AP is also a gain function.

The difference between the two vectors is:

$$\ell_{\sigma_1} - \ell_{\sigma_6} = [0, -2/3, 0, -5/12, 2/3, 0, 5/12, 0].$$

The signal matrices are same as in the SumLoss case:

$$S_{\sigma_1} = S_{\sigma_2} = \begin{bmatrix} 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{bmatrix}$$

$$S_{\sigma_3} = S_{\sigma_5} = \begin{bmatrix} 1 & 1 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \end{bmatrix}$$

$$S_{\sigma_4} = S_{\sigma_6} = \begin{bmatrix} 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \end{bmatrix}$$

It can now be easily checked that $\ell_{\sigma_1} - \ell_{\sigma_6}$ does not lie in the (combined) column span of the (transposed) signal matrices. □

AUC:

For AUC, we will show the calculations for $m = 4$. This is because global observability does hold with $m = 3$, as the normalizing factors for all relevance vectors with non-trivial mixture of 0 and 1 are same (i.e, when relevance vector has 1 irrelevant and 2 relevant objects, and 1 relevant and 2 irrelevant objects, the normalizing factors are same). The normalizing factor changes from $m = 4$ onwards; hence global observability fails.

Table 1 will be extended since $m = 4$. Instead of illustrating the full table, we point out the important facts about the loss matrix table with $m = 4$ for AUC.

The 2^4 relevance vectors heading the columns are:

$R_1 = 0000,\ R_2 = 0001,\ R_3 = 0010,\ R_4 = 0100,\ R_5 = 1000,\ R_6 = 0011,\ R_7 = 0101,\ R_8 = 1001,\ R_9 = 0110,\ R_{10} = 1010,\ R_{11} = 1100,\ R_{12} = 0111,\ R_{13} = 1011,\ R_{14} = 1101,\ R_{15} = 1110,\ R_{16} = 1111.$

We will calculate the losses of 1st and last (24th) action, where $\sigma_1 = 1234$ and $\sigma_{24} = 4321$.

$$\ell_{\sigma_1} = [0, 1, 2/3, 1/3, 0, 1, 3/4, 1/2, 1/2, 1/4, 0, 1, 2/3, 1/3, 0, 0]$$
$$\ell_{\sigma_{24}} = [0, 0, 1/3, 2/3, 1, 0, 1/4, 1/2, 1/2, 3/4, 1, 0, 1/3, 2/3, 1, 0]$$

AUC, like SumLoss, is a loss function.

The difference between the two vectors is:

$$\ell_{\sigma_1} - \ell_{\sigma_{24}} = [0, 1, 1/3, -1/3, -1, 1, 1/2, 0, 0, -1/2, -1, 1, 1/3, -1/3, -1, 0].$$

The signal matrices for AUC with $m = 4$ will be slightly different. This is because there are 24 signal matrices, corresponding to 24 actions. However, groups of 6 actions will share the same signal matrix. For example, all 6 permutations that place object 1 first will have same signal matrix, all 6 permutations that place object 2 first will have same signal matrix, and so on. For simplicity, we denote the signal matrices as S_1, S_2, S_3, S_4, where S_i corresponds to signal matrix where object i is placed at top. We have:

$$S_1 = \begin{bmatrix} 1 & 1 & 1 & 1 & 0 & 1 & 1 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 1 & 1 & 0 & 1 & 1 & 1 & 1 \end{bmatrix}$$

$$S_2 = \begin{bmatrix} 1 & 1 & 1 & 0 & 1 & 1 & 0 & 1 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 1 & 0 & 1 & 1 & 0 & 1 & 1 & 1 \end{bmatrix}$$

$$S_3 = \begin{bmatrix} 1 & 1 & 0 & 1 & 1 & 0 & 1 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 1 & 0 & 1 & 1 & 0 & 1 & 1 \end{bmatrix}$$

$$S_4 = \begin{bmatrix} 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 1 \end{bmatrix}$$

It can now be easily checked that $\ell_{\sigma_1} - \ell_{\sigma_{24}}$ does not lie in the (combined) column span of transposes of S_1, S_2, S_3, S_4.

Appendix B. Proofs for Contextual Setting

We provide technical details of results of Online Ranking with Restricted Feedback- Contextual Setting.

Proof of Lemma 14: We restate the lemma before giving the proof, for ease of reading:

Lemma 14: Let $F : \mathbb{R}^m \mapsto \mathbb{R}^a$ be a vector valued function, where $m \geq 1$, $a \geq 1$. For a fixed $x \in \mathbb{R}^m$, let k entries of x be observed at random. That is, for a fixed probability distribution $\mathbb{P}$ and some random $\sigma \sim \mathbb{P}(S_m)$, observed tuple is $\{\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)}\}$. The necessary condition for existence of an unbiased estimator of $F(x)$, that can be constructed from $\{\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)}\}$, is that it should be possible to decompose $F(x)$ over k (or less) coordinates of x at a time. That is, $F(x)$ should have the following structure:

$$F(x) = \sum_{(i_1, i_2, \ldots, i_\ell) \in\ {}^mP_\ell} h_{i_1, i_2, \ldots, i_\ell}(x_{i_1}, x_{i_2}, \ldots, x_{i_\ell})$$

where $\ell \leq k$, ${}^mP_\ell$ is ℓ permutations of m and $h : \mathbb{R}^\ell \mapsto \mathbb{R}^a$. Moreover, when $F(x)$ can be written in form of Eq 10 , with $\ell = k$, an unbiased estimator of $F(x)$, based on $\{\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)}\}$, is,

$$g(\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)}) = \frac{\sum_{(j_1, j_2, \ldots, j_k) \in S_k} h_{\sigma(j_1), \ldots, \sigma(j_k)}(x_{\sigma(j_1)}, \ldots, x_{\sigma(j_k)})}{\sum_{(j_1, \ldots, j_k) \in S_k} p(\sigma(j_1), \ldots, \sigma(j_k))}$$

where S_k is the set of $k!$ permutations of [k] and $p(\sigma(1), \ldots, \sigma(k))$ is as in Eq 9 .

Proof. For a fixed $x \in \mathbb{R}^m$ and probability distribution $\mathbb{P}$, let the random permutation be $\sigma \sim \mathbb{P}(S_m)$ and the observed tuple be $\{\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)}\}$. Let $\hat{G} = G(\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)})$ be an unbiased estimator of $F(x)$ based on the random observed tuple. Taking expectation, we get:

$$\begin{aligned} F(x) =& \mathbb{E}_{\sigma \sim \mathbb{P}}\left[\hat{G}\right] = \sum_{\pi \in S_m} \mathbb{P}(\pi) G(\pi, x_{\pi(1)}, \ldots, x_{\pi(k)}) \\ =& \sum_{(i_1, i_2, \ldots, i_k) \in\ {}^mP_k} \sum_{\pi \in S_m} \mathbb{P}(\pi) I(\pi(1) = i_1, \pi(2) = i_2, \ldots, \pi(k) = i_k) G(\pi, x_{i_1}, x_{i_2}, \ldots, x_{i_k}) \end{aligned}$$

We note that $\mathbb{P}(\pi) \in [0, 1]$ is independent of x for all $\pi \in S_m$. Then we can use the following construction of function $h(\cdot)$:

$$h_{i_1, i_2, \ldots, i_k}(x_{i_1}, \ldots, x_{i_k}) = \sum_{\pi \in S_m} \mathbb{P}(\pi) I(\pi(1) = i_1, \pi(2) = i_2, \ldots, \pi(k) = i_k) G(\pi, x_{i_1}, x_{i_2}, \ldots, x_{i_k})$$

and thus,

$$F(x) = \sum_{(i_1, i_2, \ldots, i_k) \in\ {}^mP_k} h_{i_1, i_2, \ldots, i_k}(x_{i_1}, x_{i_2}, \ldots, x_i)$$

Hence, we conclude that for existence of an unbiased estimator based on the random observed tuple, it should be possible to decompose $F(x)$ over k (or less) coordinates of x at a time. The "less than k" coordinates arguement follows simply by noting that if

$F(x)$ can be decomposed over ℓ coordinates at a time ($\ell < k$) and observation tuple is $\{\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)})\}$, then any $k-\ell$ observations can be thrown away and the rest used for construction of the unbiased estimator.

The construction of the unbiased estimator proceeds as follows:

Let $F(x) = \sum_{i=1}^{m} h_i(x_i)$ and feedback is for top-1 item ($k = 1$). The unbiased estimator according to Lemma. 14 is:

$$g(\sigma, x_{\sigma(1)}) = \frac{h_{\sigma(1)}(x_{\sigma(1)})}{p(\sigma(1))} = \frac{h_{\sigma(1)}(x_{\sigma(1)})}{\sum_{\pi} \mathbb{P}(\pi) I(\pi(1) = \sigma(1))}$$

Taking expectation w.r.t. σ, we get:

$$\mathbb{E}_{\sigma}[g(\sigma, x_{\sigma(1)})] = \sum_{i=1}^{m} \frac{h_i(x_i)(\sum_{\pi} \mathbb{P}(\pi) I(\pi(1) = i))}{\sum_{\pi} \mathbb{P}(\pi) I(\pi(1) = i)} = \sum_{i=1}^{m} h_i(x_i) = F(x)$$

Now, let $F(x) = \sum\limits_{i \neq j = 1}^{m} h_{i,j}(x_i, x_j)$ and the feedback is for top-2 item ($k = 2$). The unbiased estimator according to Lemma. 14 is:

$$g(\sigma, x_{\sigma(1)}, x_{\sigma(2)}) = \frac{h_{\sigma(1),\sigma(2)}(x_{\sigma(1)}, x_{\sigma(2)}) + h_{\sigma(2),\sigma(1)}(x_{\sigma(2)}, x_{\sigma(1)})}{p(\sigma(1), \sigma(2)) + p(\sigma(2), \sigma(1))}$$

We will use the fact that for any 2 permutations σ_1, σ_2, which places the same 2 objects in top-2 positions but in opposite order, estimators based on σ_1 (i.e, $g(\sigma_1, x_{\sigma_1(1)}, x_{\sigma_1(2)})$) and σ_2 (i.e, $g(\sigma_2, x_{\sigma_2(1)}, x_{\sigma_2(2)})$) have same numerator and denominator. For eg., let $\sigma_1(1) = i, \sigma_1(2) = j$. Numerator and denominator for $g(\sigma_1, x_{\sigma_1(1)}, x_{\sigma_1(2)})$ are $h_{i,j}(x_i, x_j) + h_{j,i}(x_j, x_i)$ and $p(i,j) + p(j,i)$ respectively. Now let $\sigma_2(1) = j, \sigma_2(2) = i$. Then numerator and denominator for $g(\sigma_2, x_{\sigma_2(1)}, x_{\sigma_2(2)})$ are $h_{j,i}(x_j, x_i) + h_{i,j}(x_i, x_j)$ and $p(j,i) + p(i,j)$ respectively.

Then, taking expectation w.r.t. σ, we get:

$$\begin{aligned}
\mathbb{E}_{\sigma} g(\sigma, x_{\sigma(1)}, x_{\sigma(2)}) &= \sum_{i \neq j = 1}^{m} \frac{(h_{i,j}(x_i, x_j) + h_{j,i}(x_j, x_i)) p(i,j)}{p(i,j) + p(j,i)} \\
&= \sum_{i > j = 1}^{m} \frac{(h_{i,j}(x_i, x_j) + h_{j,i}(x_j, x_i))(p(i,j) + p(j,i))}{p(i,j) + p(j,i)} \\
&= \sum_{i > j = 1}^{m} (h_{i,j}(x_i, x_j) + h_{j,i}(x_j, x_i)) = \sum_{i \neq j = 1}^{m} h_{i,j}(x_i, x_j) = F(x)
\end{aligned}$$

This chain of logic can be extended for any $k \geq 3$. Explicitly, for general $k \leq m$, let $\mathbb{S}(i_1, i_2, \ldots, i_k)$ denote all permutations of the set $\{i_1, \ldots, i_k\}$. Then, taking expectation of the unbiased estimator will give:

$$\begin{aligned}
&\mathbb{E}_{\sigma} g(\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(k)}) \\
&= \sum_{(i_1, i_2, \ldots, i_k) \in {}^{m}P_k} \frac{\left(\sum\limits_{(j_1, \ldots, j_k) \in \mathbb{S}(i_1, \ldots, i_k)} h_{j_1, \ldots, j_k}(x_{j_1}, \ldots, x_{j_k}) \right) p(i_1, \ldots, i_k)}{\sum\limits_{(j_1, \ldots, j_k) \in \mathbb{S}(i_1, \ldots, i_k)} p(j_1, \ldots, j_k)} \\
&= \sum_{i_1 > i_2 > \ldots > i_k = 1}^{m} \frac{\left(\sum\limits_{(j_1, \ldots, j_k) \in \mathbb{S}(i_1, \ldots, i_k)} h_{j_1, \ldots, j_k}(x_{j_1}, \ldots, x_{j_k}) \right) \left(\sum\limits_{(j_1, \ldots, j_k) \in \mathbb{S}(i_1, \ldots, i_k)} p(j_1, \ldots, j_k) \right)}{\sum\limits_{(j_1, \ldots, j_k) \in \mathbb{S}(i_1, \ldots, i_k)} p(j_1, \ldots, j_k)} \\
&= \sum_{i_1 > i_2 > \ldots > i_k = 1}^{m} \left(\sum_{(j_1, \ldots, j_k) \in \mathbb{S}(i_1, \ldots, i_k)} h_{j_1, \ldots, j_k}(x_{j_1}, \ldots, x_{j_k}) \right) \\
&= \sum_{(i_1, i_2, \ldots, i_k) \in {}^{m}P_k} h_{i_1, i_2, \ldots, i_k}(x_{i_1}, x_{i_2}, \ldots, x_{i_k}) = F(x)
\end{aligned}$$

Note: For $k = m$, i.e., when the full feedback is received, the unbiased estimator is:

$$\begin{aligned}
g(\sigma, x_{\sigma(1)}, \ldots, x_{\sigma(m)}) &= \frac{\sum\limits_{(j_1, j_2, \ldots, j_m) \in S_m} h_{\sigma(j_1), \ldots, \sigma(j_m)}(x_{\sigma(j_1)}, \ldots, x_{\sigma(j_m)})}{\sum\limits_{(j_1, \ldots, j_m) \in S_m} p(\sigma(j_1), \ldots, \sigma(j_m))} \\
&= \frac{\sum\limits_{(i_1, i_2, \ldots, i_m) \in {}^{m}P_m} h_{i_1, \ldots, i_m}(x_{i_1}, \ldots, x_{i_m})}{1} = F(x)
\end{aligned}$$

Hence, with full information, the unbiased estimator of $F(x)$ is actually $F(x)$ itself, which is consistent with the theory of unbiased estimator.

□

Proof of Lemma 18 :

Proof. All our unbiased estimators are of the form $X^{\top} f(s, R, \sigma)$. We will actually get a bound on $f(s, R, \sigma)$ by using Lemma 17 and $p \to q$ norm relation, to equate out X:

$$\|\tilde{z}\|_2 = \|X^{\top} f(s, R, \sigma)\|_2 \leq \|X^{\top}\|_{1 \to 2} \|f(s, R, \sigma)\|_1 \leq R_D \|f(s, R, \sigma)\|_1$$

since $R_D \geq \max_{j=1}^{m} \|X_{j:}\|_2$.

Squared Loss: The unbiased estimator of gradient of squared loss, as given in the main text, is:

$$\tilde{z} = X^{\top}(2(s - \frac{R(\sigma(1)) e_{\sigma(1)}}{p(\sigma(1))}))$$

where $p(\sigma(1)) = \sum_{\pi \in S_m} \mathbb{P}(\pi) I(\pi(1) = \sigma(1))$ ($\mathbb{P} = \mathbb{P}_t$ is the distribution at round t as in Algorithm 2)

Now we have:

$$\|s - \frac{R(\sigma(1))e_{\sigma(1)}}{p(\sigma(1))}\|_1 \leq mR_DU + \frac{R_{max}}{p(\sigma(1))} \leq \frac{mR_DUR_{max}}{p(\sigma(1)}$$

Thus, taking expectation w.r.t σ, we get:

$$\mathbb{E}_\sigma\|\tilde{z}\|_2^2 \leq m^2R_D^4U^2R_{max}^2\mathbb{E}_\sigma\frac{1}{p(\sigma(1))^2} = m^2R_D^4U^2R_{max}^2\sum_{i=1}^{m}\frac{p(i)}{p^2(i)}$$

Now, since $p(i) \geq \frac{\gamma}{m}$, $\forall\ i$, we get: $\mathbb{E}_\sigma\|\tilde{z}\|_2^2 \leq \frac{C^{sq}}{\gamma}$, where $C^{sq} = m^4R_D^4U^2R_{max}^2$.

RankSVM Surrogate: The unbiased estimator of gradient of the RankSVM surrogate, as given in the main text, is:

$$\tilde{z} = X^\top\left(\frac{h_{s,\sigma(1),\sigma(2)}(R(\sigma(1)),R(\sigma(2))) + h_{s,\sigma(2),\sigma(1)}(R(\sigma(2)),R(\sigma(1)))}{p(\sigma(1),\sigma(2)) + p(\sigma(2),\sigma(1))}\right)$$

where $h_{s,i,j}(R(i),R(j)) = I(R(i) > R(j))I(1 + s(j) > s(i))(e_j - e_i)$ and $p(\sigma(1),\sigma(2)) = \sum_{\pi\in S_m}\mathbb{P}(\pi)I(\pi(1) = \sigma(1),\pi(2) = \sigma(2))$ ($\mathbb{P} = \mathbb{P}_t$ as in Algorithm 2)).

Now we have:

$$\|\frac{h_{s,\sigma(1),\sigma(2)}(R_{\sigma(1)},R_{\sigma(2)}) + h_{s,\sigma(2),\sigma(1)}(R_{\sigma(2)},R_{\sigma(1)})}{p(\sigma(1),\sigma(2)) + p(\sigma(2),\sigma(1))}\|_1 \leq \frac{2}{p(\sigma(1),\sigma(2)) + p(\sigma(2),\sigma(1))}$$

Thus, taking expectation w.r.t σ, we get:

$$\mathbb{E}_\sigma\|\tilde{z}\|_2^2 \leq 4R_D^2\mathbb{E}_\sigma\frac{1}{(p(\sigma(1),\sigma(2)) + p(\sigma(2),\sigma(1)))^2} \leq 4R_D^2\sum_{i>j}^{m}\frac{p(i,j) + p(j,i)}{(p(i,j) + p(j,i))^2}$$

Now, since $p(i,j) \geq \frac{\gamma}{m^2}$, $\forall\ i,j$, we get: $\mathbb{E}_\sigma\|\tilde{z}\|_2^2 \leq \frac{C^{svm}}{\gamma}$, where $C^{svm} = O(m^4R_D^2)$.

KL based Surrogate: The unbiased estimator of gradient of the KL based surrogate, as given in the main text, is:

$$\tilde{z} = X^\top\left(\frac{(\exp(s(\sigma(1))) - \exp(R(\sigma(1))))e_{\sigma(1)}}{p(\sigma(1))}\right)$$

where $p(\sigma(1)) = \sum_{\pi\in S_m}\mathbb{P}(\pi)I(\pi(1) = \sigma(1))$ ($\mathbb{P} = \mathbb{P}_t$ as in Alg. 2)).

Now we have:

$$\|\frac{(\exp(s(\sigma(1))) - \exp(R(\sigma(1))))e_{\sigma(1)}}{p(\sigma(1))}\|_1 \leq \frac{\exp(R_DU)}{p(\sigma(1))}$$

Thus, taking expectation w.r.t σ, we get:

$$\mathbb{E}_\sigma\|\tilde{z}\|_2^2 \leq R_D^2\exp(2R_DU)\mathbb{E}_\sigma\frac{1}{p(\sigma(1))^2}$$

Following the same arguement as in squared loss, we get: $\mathbb{E}_\sigma\|\tilde{z}\|_2^2 \leq \frac{C^{KL}}{\gamma}$, where $C^{KL} = m^2R_D^2\exp(2R_DU)$.

□

Proof of Lemma 15 :

Proof. Let $m = 3$. Collection of all terms which are functions of 1st coordinate of R, i.e, $R(1)$, in the gradient of RankSVM is:

$$I(R(1) > R(2))I(1 + s(2) > s(1))(e_2 - e_1) + I(R(2) > R(1))I(1 + s(1) > s(2))(e_1 - e_2)$$
$$+ I(R(1) > R(3))I(1 + s(3) > s(1))(e_3 - e_1) + I(R(3) > R(1))I(1 + s(1) > s(3))(e_1 - e_3).$$

Now let $s(1) = 1, s(2) = 0, s(3) = 0$. Then the collection becomes:

$$I(R(2) > R(1))(e_1 - e_2) + I(R(3) > R(1))(e_1 - e_3) =$$
$$(I(R(2) > R(1)) + I(R(3) > R(1)))e_1 - I(R(2) > R(1))e_2 - I(R(3) > R(1))e_3$$

Now, if the gradient can be decomposed over each coordinate of R, then the collection of terms associated with $R(1)$ should *only and only be a function* of $R(1)$. Specifically, $(I(R(2) > R(1)) + I(R(3) > R(1)))$ (the non-zero coefficient of e_1) should be a function of only $R(1)$ (similarly for e_2 and e_3).

Now assume that the $(I(R(2) > R(1)) + I(R(3) > R(1)))$ can be expressed as a function of $R(1)$ only. Then the difference between the coefficient's values, for the following two cases: $R(1) = 0, R(2) = 0, R(3) = 0$ and $R(1) = 1, R(2) = 0, R(3) = 0$, would be same as the difference between the coefficient's values, for the following two cases: $R(1) = 0, R(2) = 1, R(3) = 1$ and $R(1) = 1, R(2) = 1, R(3) = 1$ (Since the difference would be affected only by change in $R(1)$ value). It can be clearly seen that the change in value between the first two cases is: $0 - 0 = 0$, while the change in value between the second two cases is: $2 - 0 = 2$. Thus, we reach a contradiction. □

Proof of Lemma 16 :

Proof. The term associated with the 1st coordinate of R, i.e, $R(1)$, in the gradient of ListNet is $= \sum_{i=1}^{m}\left(\frac{-\exp(R(i))}{\sum_{j=1}^{m}\exp(R(j))} + \frac{\exp(s(i))}{\sum_{j=1}^{m}\exp(s(j))}\right)e_i$ (in fact, the same term is associated with every coordinate of R).

Specifically, $f(R) = \left(\frac{-\exp(R(1))}{\sum_{j=1}^{m}\exp(R(j))} + \frac{\exp(s_1)}{\sum_{j=1}^{m}\exp(s(j))}\right)$ is the non-zero coefficient of e_1, associated with $R(1)$. Now, if $f(R)$ would have only been a function of $R(1)$, then $\frac{\partial^2 f(R)}{\partial R(1)\partial R(j)}$, $\forall\ j \neq 1$ would have been zero. It can be clearly seen this is not the case.

Now, the term associated jointly with $R(1)$ and $R(2)$, in the gradient of ListNet is same as before, i.e, $\sum_{i=1}^{m}\left(\frac{-\exp(R(i))}{\sum_{j=1}^{m}\exp(R(j))} + \frac{\exp(s(i))}{\sum_{j=1}^{m}\exp(s(j))}\right)e_i$ (since $R(1)$ and $R(2)$ are present in all the summation terms of the gradient).

Specifically, $f(R) = \left(\frac{-\exp(R(i))}{\sum_{j=1}^{m}\exp(R(j))} + \frac{\exp(s(i))}{\sum_{j=1}^{m}\exp(s(j))}\right)$ is the non-zero coefficient of e_1. Now, if $f(R)$ would have only been a function of $R(1)$ and $R(2)$, then $\frac{\partial^3 f(R)}{\partial R(1)\partial R(2)\partial R(j)}$, $\forall j \neq 1, j \neq 2$ would have been zero. It can be clearly seen this is not the case.

The same argument can be extended for any $k < m$.

□

Proof of Theorem. 21:

Proof. (*Sketch*) The proof builds on the proof of hopeless finite action partial monitoring games given by Piccolboni and Schindelhauer (2001). An examination of their proof of Theorem. 3 indicates that for hopeless games, there have to exist two probability distributions (over adversary's actions), which are indistinguishable in terms of feedback but the optimal learner's actions for the distributions are different. We first provide a mathematical explanation as to why such existence lead to hopeless games. Then, we provide a characterization of indistinguishable probability distributions in our problem setting, and then exploit the characterization of optimal actions for NDCG calibrated surrogates (Theorem 20) to explicitly construct two such probability distributions. This proves the result. Full proof is given below. □

Proof. We will first fix the setting of the online game. We consider $m = 3$ and fixed the document matrix $X \in \mathbb{R}^{3\times 3}$ to be the identity. At each round of the game, the adversary generates the fixed X and the learner chooses a score vector $s \in \mathbb{R}^3$. Making the matrix X identity makes the distinction between weight vectors w and scores s irrelevant since $s = Xw = w$. We note that allowing the adversary to vary X over the rounds only makes him more powerful, which can only increase the regret. We also restrict the adversary to choose binary relevance vectors. Once again, allowing adversary to choose multi-graded relevance vectors only makes it more powerful. Thus, in this setting, the adversary can now choose among $2^3 = 8$ possible relevance vectors. The learner's action set is infinite, i.e., the learner can choose any score vector $s = Xw = \mathbb{R}^m$. The loss function $\phi(s, R)$ is any NDCG calibrated surrogate and feedback is the relevance of top-ranked item at each round, where ranking is induced by sorted order (descending) of score vector. We will use p to denote randomized adversary one-short strategies, i.e. distributions over the 8 possible relevance score vectors. Let $s^*_p = \text{argmin}_s \mathbb{E}_{R\sim p}\phi(s, R)$. We note that in the definition of NDCG calibrated surrogates, Ravikumar et al. (2011) assume that the optimal score vector for each distribution over relevance vectors is unique and we subscribe to that assumption. The assumption was taken to avoid some boundary conditions.

It remains to specify the choice of U, a bound on the Euclidean norm of the weight vectors (same as score vectors for us right now) that is used to define the best loss in hindsight. It never makes sense for the learner to play anything outside the set $\cup_p s^*_p$ so that we can set $U = \max\{\|s\|_2 : s \in \cup_p s^*_p\}$.

The paragraph following Lemma 6 of Thm. 3 in Piccolboni and Schindelhauer (2001) gives the main intuition behind the argument the authors developed to prove hopelessness of finite action partial monitoring games. To make our proof self contained, we will explain the intuition in a rigorous way.

Key insight: Two adversary strategies $p, \tilde{p}$ are said to be indistinguishable from the learner's feedback perspective, if for every action of the learner, the probability distribution over the feedbacks received by learner is the same for p and $\tilde{p}$. Now assume that adversary always selects actions according to one of the two such indistinguishable strategies. Thus, the learner will always play one of s^*_p and $s^*_{\tilde{p}}$. By uniqueness, $s^*_p \neq s^*_{\tilde{p}}$. Then, the learner

incurs a constant (non-zero) regret on any round where adversary plays according to p and learner plays $s^*_{\tilde{p}}$, or if the adversary plays according to $\tilde{p}$ and learner plays s^*_p. We show that in such a setting, adversary can simply play according to $(p + \tilde{p})/2$ and the learner suffers an expected regret of $\Omega(T)$.

Assume that the adversary selects $\{R_1, \ldots, R_T\}$ from product distribution $\otimes p$. Let the number of times the learner plays s^*_p and $s^*_{\tilde{p}}$ be denoted by random variables N^p_1 and N^p_2 respectively, where N^p shows the exclusive dependence on p. It is always true that $N^p_1 + N^p_2 = T$. Moreover, let the expected per round regret be ϵ_p when learner plays $s^*_{\tilde{p}}$, where the expectation is taken over the randomization of adversary. Now, assume that adversary selects $\{R_1, \ldots, R_T\}$ from product distribution $\otimes\tilde{p}$. The corresponding notations become $N^{\tilde{p}}_1$ and $N^{\tilde{p}}_2$ and $\epsilon_{\tilde{p}}$. Then,

$$\mathbb{E}_{(R_1,\ldots,R_T)\sim\otimes p}\mathbb{E}_{(s_1,\ldots,s_T)}[\text{Regret}((s_1,\ldots,s_T),(R_1,\ldots,R_T))] = 0\cdot\mathbb{E}[N^p_1] + \epsilon_p\cdot\mathbb{E}[N^p_2]$$

and

$$\mathbb{E}_{(R_1,\ldots,R_T)\sim\otimes\tilde{p}}\mathbb{E}_{(s_1,\ldots,s_T)}[\text{Regret}((s_1,\ldots,s_T),(R_1,\ldots,R_T))] = \epsilon_{\tilde{p}}\cdot\mathbb{E}[N^{\tilde{p}}_1] + 0\cdot\mathbb{E}[N^{\tilde{p}}_2]$$

Since p and $\tilde{p}$ are indistinguishable from perspective of learner, $\mathbb{E}[N^p_1] = \mathbb{E}[N^{\tilde{p}}_1] = \mathbb{E}[N_1]$ and $\mathbb{E}[N^p_2] = \mathbb{E}[N^{\tilde{p}}_2] = \mathbb{E}[N_2]$. That is, the random variable denoting number of times s^*_p is played by learner does not depend on adversary distribution (same for $s^*_{\tilde{p}}$.). Using this fact and averaging the two expectations, we get:

$$\begin{aligned}\mathbb{E}_{(R_1,\ldots,R_T)\sim\frac{\otimes p+\otimes\tilde{p}}{2}}\mathbb{E}_{(s_1,\ldots,s_T)}[\text{Regret}((s_1,\ldots,s_T),(R_1,\ldots,R_T))] &= \frac{\epsilon_{\tilde{p}}}{2}\cdot\mathbb{E}[N_1] + \frac{\epsilon_p}{2}\cdot\mathbb{E}[N_2]\\ &\geq \min(\frac{\epsilon_p}{2},\frac{\epsilon_{\tilde{p}}}{2})\cdot\mathbb{E}[N_1+N_2] = \epsilon\cdot T\end{aligned}$$

Since

$$\sup_{R_1,\ldots,R_T}\mathbb{E}[\text{Regret}((s_1,\ldots,s_T),(R_1,\ldots,R_T))] \geq \mathbb{E}_{(R_1,\ldots,R_T)\sim\frac{\otimes p+\otimes\tilde{p}}{2}}\mathbb{E}_{(s_1,\ldots,s_T)}[\text{Regret}((s_1,\ldots,s_T),(R_1,\ldots,R_T))]$$

we conclude that for every learner algorithm, adversary has a strategy, s.t. learner suffers an expected regret of $\Omega(T)$.

Now, the thing left to be shown is the existence of two indistinguishable distributions p and $\tilde{p}$, s.t. $s^*_p \neq s^*_{\tilde{p}}$.

Characterization of indistinguishable strategies in our problem setting: Two adversary's strategies p and $\tilde{p}$ will be indistinguishable, in our problem setting, if for every score vector s, the relevances of the top-ranked item, according to s, are same for relevance vector drawn from p and $\tilde{p}$. Since relevance vectors are restricted to be binary, mathematically, it means that $\forall s$, $\mathbb{P}_{R\sim p}(R(\pi_s(1)) = 1) = \mathbb{P}_{R\sim\tilde{p}}(R(\pi_s(1)) = 1)$ (actually, we also need $\forall s$, $\mathbb{P}_{R\sim p}(R(\pi_s(1)) = 0) = \mathbb{P}_{R\sim\tilde{p}}(R(\pi_s(1)) = 0)$, but due to the binary nature, $\mathbb{P}_{R\sim p}(R(\pi_s(1)) = 1) = \mathbb{P}_{R\sim\tilde{p}}(R(\pi_s(1)) = 1) \implies \mathbb{P}_{R\sim p}(R(\pi_s(1)) = 0) = \mathbb{P}_{R\sim\tilde{p}}(R(\pi_s(1)) = 0)$). Since the equality has to hold $\forall s$, this implies $\forall j \in [m]$, $\mathbb{P}_{R\sim p}(R(j) = 1) = \mathbb{P}_{R\sim\tilde{p}}(R(j) = 1)$ (as every item will be ranked at top by some score vector). Hence, $\forall j \in [m]$, $\mathbb{E}_{R\sim p}[R(j)] = \mathbb{E}_{R\sim\tilde{p}}[R(j)] \implies \mathbb{E}_{R\sim p}[R] = \mathbb{E}_{R\sim\tilde{p}}[R]$. It can be

Table 3: Relevance and probability vectors.

p	0.0	0.1	0.15	0.05	0.2	0.3	0.2	0.0
$\tilde{p}$	0.0	0.3	0.0	0.0	0.15	0.15	0.4	0.0
Rel.	R_1	R_2	R_3	R_4	R_5	R_6	R_7	R_8
	0	1	1	0	1	0	0	1
	0	1	0	1	0	1	0	1
	0	0	1	1	0	0	1	1

seen clearly that the chain of implications can be reversed. Hence, $\forall s$, $\mathbb{P}_{R\sim p}(R(\pi_s(1)) = 1) = \mathbb{P}_{R\sim\tilde{p}}(R(\pi_s(1)) = 1) \iff \mathbb{E}_{R\sim p}[R] = \mathbb{E}_{R\sim\tilde{p}}[R]$.

Explicit adversary strategies: Following from the discussion so far and Theorem 20, if we can show existence of two strategies p and $\tilde{p}$ s.t. $\mathbb{E}_{R\sim p}[R] = \mathbb{E}_{R\sim\tilde{p}}[R]$, but argsort $\left(\mathbb{E}_{R\sim p}\left[\frac{G(\mathbf{R})}{Z(R)}\right]\right) \neq$ argsort $\left(\mathbb{E}_{R\sim\tilde{p}}\left[\frac{G(\mathbf{R})}{Z(R)}\right]\right)$, we are done.

The 8 possible relevance vectors (adversary's actions) are $(R_1, R_2, R_3, R_4, R_5, R_6, R_7, R_8) = (000, 110, 101, 011, 100, 010, 001, 111)$. Let the two probability vectors be:

$$p = (0.0, 0.1, 0.15, 0.05, 0.2, 0.3, 0.2, 0.0)$$
$$\tilde{p} = (0.0, 0.3, 0.0, 0.0, 0.15, 0.15, 0.4, 0.0).$$

The data is provided in table format in Table. 3.

Under the two distributions, it can be checked that $\mathbb{E}_{R\sim p}[R] = \mathbb{E}_{R\sim\tilde{p}}[R] = (0.45, 0.45, 0.4)^\top$.

However, $\mathbb{E}_{R\sim p}\left[\frac{G(\mathbf{R})}{Z(R)}\right] = (0.3533, 0.3920, 0.3226)^\top$, but $\mathbb{E}_{R\sim\tilde{p}}\left[\frac{G(\mathbf{R})}{Z(R)}\right] = (0.3339, 0.3339, 0.4000)^\top$.

Hence, argsort $\left(\mathbb{E}_{R\sim p}\left[\frac{G(\mathbf{R})}{Z(R)}\right]\right) = [2, 1, 3]^\top$ but argsort $\left(\mathbb{E}_{R\sim\tilde{p}}\left[\frac{G(\mathbf{R})}{Z(R)}\right]\right) \in \{[3, 1, 2]^\top, [3, 2, 1]^\top\}$. □

Abstract

Gaussian processes (GPs) are flexible distributions over functions that enable high-level assumptions about unknown functions to be encoded in a parsimonious, flexible and general way. Although elegant, the application of GPs is limited by computational and analytical intractabilities that arise when data are sufficiently numerous or when employing non-Gaussian models. Consequently, a wealth of GP approximation schemes have been developed over the last 15 years to address these key limitations. Many of these schemes employ a small set of pseudo data points to summarise the actual data. In this paper we develop a new pseudo-point approximation framework using Power Expectation Propagation (Power EP) that unifies a large number of these pseudo-point approximations. Unlike much of the previous venerable work in this area, the new framework is built on standard methods for approximate inference (variational free-energy, EP and Power EP methods) rather than employing approximations to the probabilistic generative model itself. In this way all of the approximation is performed at 'inference time' rather than at 'modelling time', resolving awkward philosophical and empirical questions that trouble previous approaches. Crucially, we demonstrate that the new framework includes new pseudo-point approximation methods that outperform current approaches on regression and classification tasks.

Keywords: Gaussian process, expectation propagation, variational inference, sparse approximation

1. Introduction

Gaussian Processes (GPs) are powerful nonparametric distributions over continuous functions that are routinely deployed in probabilistic modelling for applications including regression and classification (Rasmussen and Williams, 2005), representation learning (Lawrence, 2005), state space modelling (Wang et al., 2005), active learning (Houlsby et al., 2011), reinforcement learning (Deisenroth, 2010), black-box optimisation (Snoek et al., 2012), and numerical methods (Mahsereci and Hennig, 2015). GPs have many elegant theoretical properties, but their use in probabilistic modelling is greatly hindered by analytic and computational intractabilities. A large research effort has been directed at this fundamental problem resulting in the development of a plethora of sparse approximation methods that can sidestep these intractabilities (Csató, 2002; Csató and Opper, 2002; Schwaighofer and Tresp, 2002; Seeger et al., 2003; Quiñonero-Candela and Rasmussen, 2005; Snelson and Ghahramani, 2006; Snelson, 2007; Naish-Guzman and Holden, 2007; Titsias, 2009; Figueiras-Vidal and Lázaro-Gredilla, 2009; Álvarez et al., 2010; Qi et al., 2010; Bui and Turner, 2014; Frigola et al., 2014; McHutchon, 2014; Hensman et al., 2015; Hernández-Lobato and Hernández-Lobato, 2016; Matthews et al., 2016)

This paper develops a general sparse approximate inference framework based upon Power Expectation Propagation (PEP) (Minka, 2004) that unifies many of these approximations, extends them significantly, and provides improvements in practical settings. In this way, the paper provides a complementary perspective to the seminal review of Quiñonero-Candela and Rasmussen (2005) viewing sparse approximations through the lens of approximate *inference*, rather than approximate *generative models*.

The paper begins by reviewing several frameworks for sparse approximation focussing on the GP regression and classification setting (Section 2). It then lays out the new unifying framework and the relationship to existing techniques (Section 3). Readers whose focus is to understand the new framework might want to move directly to this section. Finally, a thorough experimental evaluation is presented in Section 4.

2. Pseudo-point Approximations for GP Regression and Classification

This section provides a concise introduction to GP regression and classification and then reviews several pseudo-point based sparse approximation schemes for these models. For simplicity, we first consider a supervised learning setting in which the training set comprises N D-dimensional input and scalar output pairs $\{\mathbf{x}_n, y_n\}_{n=1}^N$ and the goal is to produce probabilistic predictions for the outputs corresponding to novel inputs. A non-linear function, $f(\mathbf{x})$, can be used to parameterise the probabilistic mapping between inputs and outputs, $p(y_n|f, \mathbf{x}_n, \theta)$ which may also depend on hyperparameters θ. Typical choices for the probabilistic mapping are Gaussian $p(y_n|f, \mathbf{x}_n, \theta) = \mathcal{N}(y_n; f(\mathbf{x}_n), \sigma_y^2)$ for the regression setting ($y_n \in \mathbb{R}$) and Bernoulli $p(y_n|f, \mathbf{x}_n, \theta) = \mathcal{B}(y_n; \Phi(f(\mathbf{x}_n)))$ with a sigmoidal link function $\Phi(f)$ for the binary classification setting ($y_n \in \{0, 1\}$). Whilst it is possible to specify the non-linear function f via an explicit parametric form, a more flexible and elegant approach employs a GP prior over the functions directly, $p(f|\theta) = \mathcal{GP}(f; 0, k_\theta(\cdot, \cdot))$, here assumed without loss of generality to have a zero mean-function and a covariance function $k_\theta(\mathbf{x}, \mathbf{x}')$. This class of probabilistic models has a joint distribution

$$p(f, \mathbf{y}|\theta) = p(f|\theta) \prod_{n=1}^{N} p(y_n|f(\mathbf{x}_n), \theta)$$

where we have collected the observations into the vector $\mathbf{y}$ and suppressed the inputs on the left hand side to lighten the notation.

This model class contains two potential sources of intractability. First, the possibly non-linear likelihood function can introduce analytic intractabilities that require approximation. Second, the GP prior entails an $\mathcal{O}(N^3)$ complexity that is computationally intractable for many practical problems. These two types of intractability can be handled by combining standard approximate inference methods with pseudo-point approximations that summarise the full Gaussian process via M pseudo data points leading to an $\mathcal{O}(NM^2)$ cost. The main

approaches of this sort can be characterised in terms of two parallel frameworks that are described in the following sections.

2.1 Sparse GP Approximation via Approximate Generative Models

The first framework begins by constructing a new generative model that is similar to the original, so that inference in the new model might be expected to produce similar results, but which has a special structure that supports efficient computation. Typically this approach involves approximating the Gaussian process prior as it is the origin of the cubic cost. If there are analytic intractabilities in the approximate model, as will be the case in e.g. classification or state-space models, then these will require approximate inference to be performed in the approximate model.

The seminal review by Quiñonero-Candela and Rasmussen (Quiñonero-Candela and Rasmussen, 2005) reinterprets a family of approximations in terms of this unifying framework. The GP prior is approximated by identifying a small set of $M \leq N$ pseudo-points $\mathbf{u}$, here assumed to be disjoint from the training function values $\mathbf{f}$ so that $f = \{\mathbf{u}, \mathbf{f}, f_{\neq \mathbf{u},\mathbf{f}}\}$. Here $f_{\neq \mathbf{u},\mathbf{f}}$ denotes the function values which are not at the training inputs or pseudo-inputs. The GP prior is then decomposed using the product rule

$$p(f|\theta) = p(\mathbf{u}|\theta)p(\mathbf{f}|\mathbf{u},\theta)p(f_{\neq \mathbf{u},\mathbf{f}}|\mathbf{f},\mathbf{u},\theta).$$

Of central interest is the relationship between the pseudo-points and the training function values $p(\mathbf{f}|\mathbf{u},\theta) = \mathcal{N}(\mathbf{f}; \mathbf{K_{fu}}\mathbf{K_{uu}^{-1}}\mathbf{u}, \mathbf{D_{ff}})$ where $\mathbf{D_{ff}} = \mathbf{K_{ff}} - \mathbf{Q_{ff}}$ and $\mathbf{Q_{ff}} = \mathbf{K_{fu}}\mathbf{K_{uu}^{-1}}\mathbf{K_{uf}}$. Here we have introduced matrices corresponding to the covariance function's evaluation at the pseudo-input locations $\{\mathbf{z}_m\}_{m=1}^M$, so that $[\mathbf{K_{uu}}]_{mm'} = k_\theta(\mathbf{z}_m, \mathbf{z}_{m'})$ and similarly for the covariance between the pseudo-input and data locations $[\mathbf{K_{uf}}]_{mn} = k_\theta(\mathbf{z}_m, \mathbf{x}_n)$. Importantly, this term saddles inference and learning with a complexity cost that is cubic in the number of data points. Computationally efficient approximations can be constructed by simplifying these dependencies between the pseudo-points and the data function values $q(\mathbf{f}|\mathbf{u},\theta) \approx p(\mathbf{f}|\mathbf{u},\theta)$. In order to benefit from these efficiencies at prediction time as well, a second approximation is made whereby the pseudo-points form a bottleneck between the data function values and test function values $p(f_{\neq \mathbf{u},\mathbf{f}}|\mathbf{u},\theta) \approx p(f_{\neq \mathbf{u},\mathbf{f}}|\mathbf{f},\mathbf{u},\theta)$. Together, the two approximations result in an approximate prior process,

$$q(f|\theta) = p(\mathbf{u}|\theta)q(\mathbf{f}|\mathbf{u},\theta)p(f_{\neq \mathbf{u},\mathbf{f}}|\mathbf{u},\theta).$$

We can now compactly summarise a number of previous approaches to GP approximation as special cases of the choice

$$q(\mathbf{f}|\mathbf{u},\theta) = \prod_{b=1}^{B} \mathcal{N}(\mathbf{f}_b; \mathbf{K}_{\mathbf{f}_b,\mathbf{u}}\mathbf{K_{uu}^{-1}}\mathbf{u}, \alpha\mathbf{D}_{\mathbf{f}_b,\mathbf{f}_b})$$

where b indexes B disjoint blocks of data-function values. The Deterministic Training Conditional (DTC) approximation uses $\alpha \to 0$; the Fully Independent Training Conditional (FITC) approximation uses $\alpha = 1$ and $B = N$; the Partially Independent Training Conditional (PITC) approximation uses $\alpha = 1$ (Quiñonero-Candela and Rasmussen, 2005; Schwaighofer and Tresp, 2002).

Before considering inference in the modified models, note that it is possible to construct more flexible modified prior processes using the inter-domain approach that places the pseudo-points in a different domain from the data, defined by a linear integral transform $g(z) = \int w(z,z')f(z')\mathrm{d}z'$. Here the window $w(z,z')$ might be a Gaussian blur or a wavelet transform. The pseudo-points are now placed in the new domain $g = \{\mathbf{u}, \mathbf{g}_{\neq \mathbf{u}}\}$ where they induce a potentially more flexible Gaussian process in the old domain f through the linear transform (see Figueiras-Vidal and Lázaro-Gredilla, 2009, for FITC). The expressions in this section still hold, but the covariance matrices involving pseudo-points are modified to take account of the transform,

$$[\mathbf{K_{uu}}]_{mm'} = \int w(\mathbf{z}_m,\mathbf{z})k_\theta(\mathbf{z},\mathbf{z}')w(\mathbf{z}',\mathbf{z}_{m'})\mathbf{dzdz}', \quad [\mathbf{K_{uf}}]_{mn} = \int w(\mathbf{z}_m,\mathbf{z})k_\theta(\mathbf{z},\mathbf{x}_n)\mathbf{dz}.$$

Having specified modified prior processes, these can be combined with the original likelihood function to produce a new generative model. In the case of point-wise likelihoods we have

$$q(\mathbf{y}, f|\theta) = q(f|\theta)\prod_{n=1}^{N} p(y_n|f(\mathbf{x}_n),\theta).$$

Inference and learning can now be performed using the modified model using standard techniques. Due to the form of the new prior process, the computational complexity is $\mathcal{O}(NM^2)$ (for testing, N becomes the number of test data points, assuming dependencies between the test-points are not computed).[1] For example, in the case of regression, the posterior distribution over function values f (necessary for inference and prediction) has a simple analytic form

$$q(f|\mathbf{y},\theta) = \mathcal{GP}(f; \mu_{f|\mathbf{y}}, \Sigma_{f|\mathbf{y}}), \quad \mu_{f|\mathbf{y}} = \mathbf{Q}_{f\mathbf{f}}\overline{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{y}, \quad \Sigma_{f|\mathbf{y}} = \mathbf{K}_{ff} - \mathbf{Q}_{f\mathbf{f}}\overline{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{Q}_{\mathbf{f}f}, \qquad (1)$$

where $\overline{\mathbf{K}}_{\mathbf{ff}} = \mathbf{Q_{ff}} + \mathrm{blkdiag}(\{\alpha_b\mathbf{D}_{\mathbf{f}_b\mathbf{f}_b}\}_{b=1}^B) + \sigma_y^2\mathrm{I}$ and blkdiag builds a block-diagonal matrix from its inputs. One way of understanding the origin of the computational gains is that the new generative model corresponds to a form of factor analysis in which the M pseudo-points determine the N function values at the observed data (as well as at potential test locations) via a linear Gaussian relationship. This results in low rank (sparse) structure in $\overline{\mathbf{K}}_{\mathbf{ff}}$ that can be exploited through the matrix inversion and determinant lemmas. In the case of regression, the new model's marginal likelihood also has an analytic form that allows the hyperparameters, θ, to be learned via optimisation

$$\log q(\mathbf{y}|\theta) = -\frac{N}{2}\log(2\pi) - \frac{1}{2}\log|\overline{\mathbf{K}}_{\mathbf{ff}}| - \frac{1}{2}\mathbf{y}^\intercal\overline{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{y}. \qquad (2)$$

The approximate generative model framework has attractive properties. The cost of inference, learning, and prediction has been reduced from $\mathcal{O}(N^3)$ to $\mathcal{O}(NM^2)$ and in many cases accuracy can be maintained with a relatively small number of pseudo-points. The pseudo-point input locations can be optimised by maximising the new model's marginal

1. It is assumed that the maximum size of the blocks is not greater than the number of pseudo-points $\dim(\mathbf{f}_b) \leq M$.

likelihood (Snelson and Ghahramani, 2006). When $M = N$ and the pseudo-points and observed data inputs coincide, then FITC and PITC are exact which appears reassuring. However, the framework is philosophically challenging as the elegant separation of model and (approximate) inference has been lost. Are we allowed in an online inference setting, for example, to add new pseudo-points as more data are acquired and the complexity of the underlying function is revealed? This seems sensible, but effectively changes the modelling assumptions as more data are seen. Devout Bayesians might then demand that we perform model averaging for coherence. Similarly, if the pseudo-input locations are optimised, the principled non-parametric model has suddenly acquired MD parameters and with them all of the concomitant issues of parametric models including overfitting and optimisation difficulties (Bauer et al., 2016). As the pseudo-inputs are considered part of the model, the Bayesians might then suggest that we place priors over the pseudo-inputs and perform full-blown probabilistic inference over them.

These awkward questions arise because the generative modelling interpretation of pseudo-data entangles the assumptions made about the data with the approximations required to perform inference. Instead, the modelling assumptions (which encapsulate prior understanding of the data) should remain decoupled from inferential assumptions (which leverage structure in the posterior for tractability). In this way pseudo-data should be introduced when we seek to perform computationally efficient approximate inference, leaving the modelling assumptions unchanged as we refine and improve approximate inference. Indeed, even under the generative modelling perspective, for analytically intractable likelihood functions an additional approximate inference step is required, begging the question: why not handle computational and analytic intractabilities together at inference time?

2.2 Sparse GP Approximation via Approximate Inference: VFE

The approximate generative model framework for constructing sparse approximations is philosophically troubling. In addition, learning pseudo-point input locations via optimisation of the model likelihood can perform poorly e.g. for DTC it is prone to overfitting even for $M \ll N$ (Titsias, 2009). This motivates a more direct approach that commits to the true generative model and performs all of the necessary approximation at inference time.

Perhaps the most well known approach in this vein is Titsias's beautiful sparse variational free energy (VFE) method (Titsias, 2009). The original presentation of this work employs finite variable sets and an augmentation trick that arguably obscures its full elegance. Here instead we follow the presentation in Matthews et al. (2016) and lower bound the marginal likelihood using a distribution $q(f)$ over the entire infinite-dimensional function,

$$\log p(\mathbf{y}|\theta) = \log \int p(\mathbf{y}, f|\theta) \mathrm{d}f \geq \int q(f) \log \frac{p(\mathbf{y}, f|\theta)}{q(f)} \mathrm{d}f = \mathbb{E}_{q(f)}\left[\log \frac{p(\mathbf{y}, f|\theta)}{q(f)}\right] = \mathcal{F}(q, \theta).$$

The VFE bound can be written as the difference between the model log-marginal likelihood and the KL divergence between the variational distribution and the true posterior $\mathcal{F}(q, \theta) = \log p(\mathbf{y}|\theta) - \mathrm{KL}[q(f)||p(f|\mathbf{y}, \theta)]$. The bound is therefore saturated when $q(f) = p(f|\mathbf{y}, \theta)$, but this is intractable. Instead, pseudo-points are made explicit, $f = \{\mathbf{u}, f_{\neq \mathbf{u}}\}$, and an approximate posterior distribution used of the following form $q(f) = q(\mathbf{u}, f_{\neq \mathbf{u}}|\theta) = p(f_{\neq \mathbf{u}}|\mathbf{u}, \theta)q(\mathbf{u})$. Under this approximation, the set of variables $f_{\neq \mathbf{u}}$ do not experience the data directly, but

rather only through the pseudo-points, as can be seen by comparison to the true posterior $p(f|\mathbf{y}, \theta) = p(f_{\neq \mathbf{u}}|\mathbf{y}, \mathbf{u}, \theta)p(\mathbf{u}|\mathbf{y}, \theta)$. Importantly, the form of the approximate posterior causes a cancellation of the prior conditional term, which gives rise to a bound with $\mathcal{O}(NM^2)$ complexity,

$$\begin{aligned}\mathcal{F}(q, \theta) &= \mathbb{E}_{q(f|\theta)}\left[\log \frac{p(\mathbf{y}|f, \theta)\cancel{p(f_{\neq \mathbf{u}}|\mathbf{u}, \theta)}p(\mathbf{u}|\theta)}{\cancel{p(f_{\neq \mathbf{u}}|\mathbf{u}, \theta)}q(\mathbf{u})}\right] \\ &= \sum_n \mathbb{E}_{q(f|\theta)}\left[\log p(y_n|\mathrm{f}_n, \theta)\right] - \mathrm{KL}[q(\mathbf{u})||p(\mathbf{u}|\theta)].\end{aligned}$$

For regression with Gaussian observation noise, the calculus of variations can be used to find the optimal approximate posterior Gaussian process over pseudo-data $q^{\mathrm{opt}}(f|\theta) = p(f_{\neq \mathbf{u}}|\mathbf{u}, \theta)q^{\mathrm{opt}}(\mathbf{u})$ which has the form

$$q^{\mathrm{opt}}(f|\theta) = \mathcal{GP}(f; \mu_{f|\mathbf{y}}, \Sigma_{f|\mathbf{y}}), \;\; \mu_{f|\mathbf{y}} = \mathbf{Q}_{f\mathbf{f}}\tilde{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{y}, \;\; \Sigma_{f|\mathbf{y}} = \mathbf{K}_{ff} - \mathbf{Q}_{f\mathbf{f}}\tilde{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{Q}_{\mathbf{f}f}, \qquad (3)$$

where $\tilde{\mathbf{K}}_{\mathbf{ff}} = \mathbf{Q}_{\mathbf{ff}} + \sigma_y^2\mathrm{I}$. This process is identical to that recovered when performing exact inference under the DTC approximate regression generative model (Titsias, 2009) (see Equation (1) as $\alpha \to 0$). In fact, DTC was originally derived using a related KL argument (Csató, 2002; Seeger et al., 2003). The optimised free-energy is

$$\mathcal{F}(q^{\mathrm{opt}}, \theta) = -\frac{N}{2}\log(2\pi) - \frac{1}{2}\log|\tilde{\mathbf{K}}_{\mathbf{ff}}| - \frac{1}{2}\mathbf{y}^\intercal\tilde{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{y} - \frac{1}{2\sigma_y^2}\mathrm{trace}(\mathbf{K}_{\mathbf{ff}} - \mathbf{Q}_{\mathbf{ff}}). \qquad (4)$$

Notice that the free-energy has an additional trace term as compared to the marginal likelihood obtained from the DTC generative model approach (see Equation (2) as $\alpha \to 0$). The trace term is proportional to the sum of the variances of the training function values given the pseudo-points, $p(\mathbf{f}|\mathbf{u})$, it thereby encourages pseudo-input locations that explain the observed data well. This term acts as a regulariser that prevents overfitting which plagues the generative model formulation of DTC.

The VFE approach can be extended to non-linear models including classification (Hensman et al., 2015), latent variable models (Titsias and Lawrence, 2010) and state space models (Frigola et al., 2014; McHutchon, 2014) by restricting $q(\mathbf{u})$ to be Gaussian and optimising its parameters. Indeed, this uncollapsed form of the bound can be beneficial in the context of regression too as it is amenable to stochastic optimisation (Hensman et al., 2013). Additional approximation is sometimes required to compute any remaining intractable non-linear integrals, but these are often low-dimensional. For example, when the likelihood depends on only one latent function value, as is typically the case for regression and classification, the bound requires only 1D integrals $\mathbb{E}_{q(f_n)}\left[\log p(y_n|\mathrm{f}_n, \theta)\right]$ which may be evaluated using quadrature (Hensman et al., 2015).

The VFE approach can also be extended to employ inter-domain variables (Álvarez et al., 2010; Tobar et al., 2015; Matthews et al., 2016). The approach considers the augmented generative model $p(f, g|\theta)$ where to remind the reader the auxiliary process is defined by a linear integral transformation, $g(z) = \int w(z, z')f(z')\mathrm{d}z'$. Variational inference is now performed over both latent processes $q(f, g) = q(f, \mathbf{u}, g_{\neq \mathbf{u}}|\theta) = p(f, g_{\neq \mathbf{u}}|\mathbf{u}, \theta)q(\mathbf{u})$. Here the pseudo-data have been placed into the auxiliary process with the idea being that they can

induce richer dependencies in the original domain that model the true posterior more accurately. In fact, if the linear integral transformation is parameterised then the transformation can be learned so that it approximates the posterior more accurately.

A key concept underpinning the VFE framework is that the pseudo-input locations (and the parameters of the inter-domain transformation, if employed) are purely parameters of the approximate posterior, hence the name 'variational parameters'. This distinction is important as it means, for example, that we are free to add pseudo-data as more structure of the underlying function is revealed, without altering the modelling assumptions (e.g. see Bui et al. (2017) for an example in online inference). Moreover, since the pseudo-input locations are variational parameters, placing priors over them is unnecessary in this framework. Unlike the model parameters, optimisation of variational parameters is automatically protected from overfitting as the optimisation is minimising the KL divergence between the approximate posterior and the true posterior. Indeed, although the DTC posterior is recovered in the regression setting, as we have seen the free-energy is *not* equal to the log-marginal likelihood of the DTC generative model, containing an additional term that substantially improves the quality of the optimised pseudo-point input locations.

The facts that the form of the DTC approximation can be recovered from a direct approximate inference approach and that this new perspective leads to superior pseudo-input optimisation, raises the question: can this also be done for FITC and PITC?

2.3 Sparse GP Approximation via Approximate Inference: EP

Expectation Propagation (EP) is a deterministic inference method (Minka, 2001) that is known to outperform VFE methods in GP classification when non-sparse fully-factored approximations $q(\mathbf{f}) = \prod_n q_n(\mathrm{f}_n)$ are used (Nickisch and Rasmussen, 2008). Motivated by this observation, EP has been combined with the approximate generative modelling approach to handle non-linear likelihoods (Naish-Guzman and Holden, 2007; Hernández-Lobato and Hernández-Lobato, 2016). This begs the question: can the sparsification and the non-linear approximation be handled in a single EP inference stage, as for VFE? Astonishingly Csató and Opper not only developed such a method in 2002 (Csató and Opper, 2002), predating much of the work mentioned above, they showed that it is equivalent to applying the FITC approximation and running EP if further approximation is required. In our view, this is a central result, but it appears to have been largely overlooked by the field. Snelson was made aware of it when writing his thesis (Snelson, 2007), briefly acknowledging Csató and Opper's contribution. Qi et al. (2010) extended Csató and Opper's work to utilise inter-domain pseudo-points and they additionally recognised that the EP energy function at convergence is equal to the FITC log-marginal likelihood approximation. Interestingly, no additional term arises as it does when the VFE approach generalised the DTC generative model approach. We are unaware of other work in this vein.

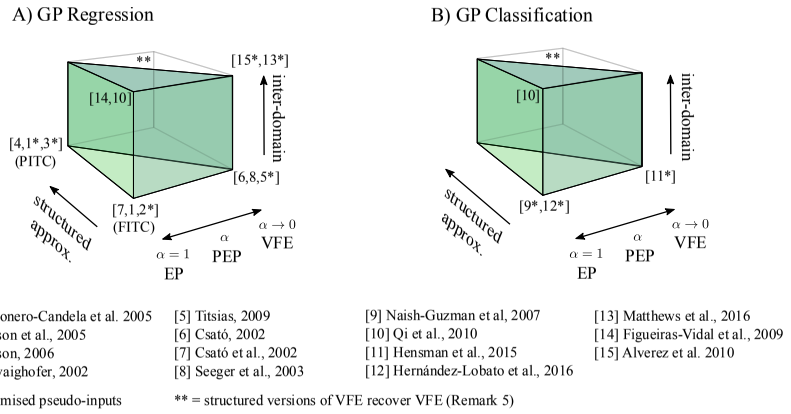
It is hard to know for certain why these important results are not widely known, but a contributing factor is that the exposition in these papers is largely at Marr's algorithmic level (Dawson, 1998), and does not focus on the computational level, making them challenging to understand. Moreover, Csató and Opper's paper was written before EP was formulated in a general way and the presentation, therefore, does not follow what has become the standard

approach. In fact, as the focus was online inference, Assumed Density Filtering (Kushner and Budhiraja, 2000; Ito and Xiong, 2000) was employed rather than full-blown EP.

2.4 Contributions

One of the primary contributions of this paper is to provide a clear computational exposition of Csató and Opper's EP procedure including an explicit form of the approximating distribution and full details about each step. In addition to bringing clarity we make the following novel contributions:

- We show that a generalisation of EP called Power EP can subsume the EP and VFE approaches (and therefore FITC and DTC) into a single unified framework. More precisely, the fixed points of Power EP yield the FITC and VFE posterior distribution under different limits and the Power EP marginal likelihood estimate (the negative 'Power EP energy') recovers the FITC marginal likelihood and the VFE too. Critically, the connection to the VFE method leans on the new interpretation of Titsias's approach (Matthews et al., 2016) outlined in the previous section that directly employs the approximate posterior over function values (rather than augmenting the model with pseudo-points). The connection therefore also requires a formulation of Power EP that involves KL divergence minimisation between stochastic processes.



- We show how versions of PEP that are intermediate between the existing VFE and EP approaches can be derived, as well as mixed approaches that treat some data variationally and others using EP. We also show how PITC emerges from the same framework and how to incorporate inter-domain transforms. For regression with Gaussian observation noise, we obtain analytical expressions for the fixed points of Power EP in a general case that includes all of these extensions as well as the form of the Power EP marginal likelihood estimate at convergence that is useful for hyperparameter and pseudo-input optimisation.

- We consider (Gaussian) regression and probit classification as canonical models on which to test the new framework and demonstrate through exhaustive testing that versions of PEP intermediate between VFE and EP perform substantially better on average. The experiments also shed light on situations where VFE is to be preferred to EP and vice versa, an important open area of research.

Many of the new theoretical contributions described above are summarised in Figure 1 along with their relationship to previous work.

3. A New Unifying View using Power Expectation Propagation

In this section, we provide a new unifying view of sparse approximation using Power Expectation Propagation (PEP or Power EP) (Minka, 2004). We review Power EP, describe how to apply it for sparse GP regression and classification, and then discuss its relationship to existing methods.

Previous algorithms correspond to labelled vertices. The new Power EP framework encompasses the three polygons, including their interior.

3.1 The Joint-Distribution View of Approximate Inference and Learning

One way of understanding the goal of distributional inference approximations, including the VFE method, EP and Power EP, is that they return an approximation of a tractable form to the model *joint-distribution* evaluated on the observed data. In the case of GP regression and classification, this means $q^*(f) \approx p(f, \mathbf{y}|\theta)$ where $*$ is used to denote an unnormalised process. Why is the model joint-distribution a sensible object of approximation? The joint distribution can be decomposed into the product of the posterior distribution and the marginal likelihood, $p(f, \mathbf{y}|\theta) = p^*(f|\mathbf{y}, \theta) = p(f|\mathbf{y}, \theta)p(\mathbf{y}|\theta)$, the two inferential objects of interest. A tractable approximation to the joint can therefore be similarly decomposed $q^*(f) = Zq(f)$ into a normalised component that approximates the posterior $q(f) \approx p(f|\mathbf{y}, \theta)$ and the normalisation constant which approximates the marginal likelihood $Z \approx p(\mathbf{y}|\theta)$. In other words, the approximation of the joint simultaneously returns approximations to the posterior and marginal likelihood. In the current context, tractability of the approximating family means that it is analytically integrable and that this integration can be performed with an appropriate computational complexity. We consider the approximating family comprising unnormalised GPs, $q^*(f) = Z\ \mathcal{GP}(f; m_{\mathrm{f}}, V_{\mathrm{ff}'})$.

The VFE approach can be reformulated in the new context using the unnormalised KL divergence (Zhu and Rohwer, 1997) to measure the similarity between the approximation

and the joint distribution

$$\overline{\mathrm{KL}}[q^*(f)||p(f, \mathbf{y}|\theta)] = \int q^*(f) \log \frac{q^*(f)}{p(f, \mathbf{y}|\theta)} \mathrm{d}f + \int \left(p(f, \mathbf{y}|\theta) - q^*(f)\right) \mathrm{d}f. \tag{5}$$

The unnormalised KL divergence generalises the KL divergence to accommodate unnormalised densities. It is always non-negative and collapses back to the standard form when its arguments are normalised. Minimising the unnormalised KL with respect to $q^*(f) = Z_{\mathrm{VFE}}\, q(f)$ encourages the approximation to match both the posterior and marginal-likelihood, and it yields analytic solutions

$$q^{\mathrm{opt}}(f) = \operatorname*{argmin}_{q(f)\in\mathcal{Q}} \mathrm{KL}[q(f)||p(f|\mathbf{y}, \theta)], \quad \text{and} \quad Z^{\mathrm{opt}}_{\mathrm{VFE}} = \exp(\mathcal{F}(q^{\mathrm{opt}}(f), \theta)).$$

That is, the standard variational free-energy approximation to the posterior and marginal likelihood is recovered. One of the pedagogical advantages of framing VFE in this way is that approximation of the posterior and marginal likelihood are committed to upfront, in contrast to the traditional derivation which begins by targeting approximation of the marginal likelihood, but shows that approximation of the posterior emerges as an essential part of this scheme (see Section 2.2). A disadvantage is that optimisation of hyperparameters must logically proceed by optimising the marginal likelihood approximation, $Z^{\mathrm{opt}}_{\mathrm{VFE}}$, and at first sight therefore appears to necessitate different objective functions for $q^*(f|\theta)$ and θ (unlike the standard view which uses a single objective from the beginning). However, it is easy to show that maximising the single objective $p(\mathbf{y}|\theta) - \overline{\mathrm{KL}}[q^*(f|\theta)||p(f, \mathbf{y}|\theta)]$ directly for both $q^*(f|\theta)$ and θ is equivalent and that this also recovers the standard VFE method (see Appendix A).

3.2 The Approximating Distribution Employed by Power EP

Power EP also approximates the joint-distribution, employing an approximating family whose form mirrors that of the target,

$$p^*(f|\mathbf{y}, \theta) = p(f|\mathbf{y}, \theta)p(\mathbf{y}|\theta) = p(f|\theta) \prod_n p(y_n|f, \theta) \approx p(f|\theta) \prod_n t_n(\mathbf{u}) = q^*(f|\theta). \tag{6}$$

Here, the approximation retains the exact prior, but each likelihood term in the exact posterior, $p(y_n|\mathrm{f}_n, \theta)$, is approximated by a simple factor $t_n(\mathbf{u})$ that is assumed Gaussian. These simple factors will be iteratively refined by the PEP algorithm such that they will capture the effect that each true likelihood has on the posterior. As the approximation retains the exact prior it explicitly depends on the hyperparameters θ. However, we will suppress this dependence to lighten the notation.

Before describing the details of the PEP algorithm, it is illuminating to consider an alternative interpretation of the approximation. Together, the approximate likelihood functions specify an unnormalised Gaussian over the pseudo-points that can be written $\prod_n t_n(\mathbf{u}) = \mathcal{N}(\tilde{\mathbf{y}}; \tilde{\mathbf{W}}\mathbf{u}, \tilde{\Sigma})$ (assuming that the product of these factors is normalisable which may not be the case for heavy tailed likelihoods, for example). The approximate posterior above can therefore be thought of as the (exact) GP posterior resulting from a surrogate regression problem with surrogate observations $\tilde{\mathbf{y}}$ that are generated from linear combinations of the pseudo-points and additive surrogate noise $\tilde{\mathbf{y}} = \tilde{\mathbf{W}}\mathbf{u} + \tilde{\Sigma}^{1/2}\epsilon$. We note that the

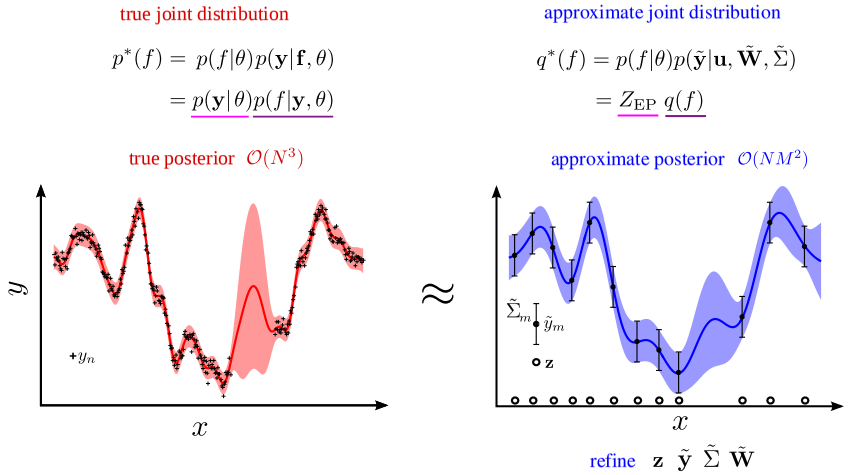

Figure 2: Perspectives on the approximating family. The true joint distribution over the unknown function f and the N data points $\mathbf{y}$ (top left) comprises the GP prior and an intractable likelihood function. This is approximated by a surrogate regression model with a joint distribution over the function f and M surrogate data points $\tilde{\mathbf{y}}$ (top right). The surrogate regression model employs the same GP prior, but uses a Gaussian likelihood function $p(\tilde{\mathbf{y}}|\mathbf{u},\tilde{\mathbf{W}},\tilde{\Sigma}) = \mathcal{N}(\tilde{\mathbf{y}};\tilde{\mathbf{W}}\mathbf{u},\tilde{\Sigma})$. The intractable true posterior (bottom left) is approximated by refining the surrogate data $\tilde{\mathbf{y}}$, their input locations $\mathbf{z}$ and the parameters of the surrogate model $\tilde{\mathbf{W}}$ and $\tilde{\Sigma}$.

pseudo-points $\mathbf{u}$ live on the latent function (or an inter-domain transformation thereof) and the surrogate observations $\tilde{\mathbf{y}}$ will not generally lie on the latent function. The surrogate observations and the pseudo-points are therefore analogous to the data $\mathbf{y}$ and the function values $\mathbf{f}$ in a normal Gaussian Process regression problem, respectively. To make the paper more specific on this point, we have defined parameters for the surrogate regression problem explicitly in Appendix H. The PEP algorithm will implicitly iteratively refine $\{\tilde{\mathbf{y}},\tilde{\mathbf{W}},\tilde{\Sigma}\}$ such that exact inference in the simple surrogate regression model returns a posterior and marginal likelihood estimate that is 'close' to that returned by performing exact inference in the intractable complex model (see Figure 2).

3.3 The EP Algorithm

One method for updating the approximate likelihood factors $t_n(\mathbf{u})$ would be to minimise the unnormalised KL divergence between the joint distribution and each of the distributions formed by replacing one of the likelihoods by the corresponding approximating factor (Li et al., 2015),

$$\underset{t_n(\mathbf{u})}{\operatorname{argmin}}\ \overline{\mathrm{KL}}\left[p(f,\mathbf{y}|\theta)\middle|\middle|\frac{p(f,\mathbf{y}|\theta)t_n(\mathbf{u})}{p(y_n|\mathrm{f}_n,\theta)}\right] = \underset{t_n(\mathbf{u})}{\operatorname{argmin}}\ \overline{\mathrm{KL}}[p^*_{\backslash n}(f)p(y_n|\mathrm{f}_n,\theta)||p^*_{\backslash n}(f)t_n(\mathbf{u})].$$

Here we have introduced the leave-one-out joint $p^*_{\backslash n}(f) = p(f,\mathbf{y}|\theta)/p(y_n|\mathrm{f}_n,\theta)$ which makes clear that the minimisation will cause the approximate factors to approximate the likelihoods in the context of the leave-one-out joint. Unfortunately, such an update is still intractable. Instead, EP approximates this idealised procedure by replacing the exact leave-one-out joint on both sides of the KL by the approximate leave-one-out joint (called the cavity) $p^*_{\backslash n}(f) \approx q^*_{\backslash n}(f) = q^*(f)/t_n(\mathbf{u})$. Not only does this improve tractability, but it also means that the new procedure effectively refines the approximating distribution directly at each stage, rather than setting the component parts in isolation,

$$\overline{\mathrm{KL}}[q^*_{\backslash n}(f)p(y_n|\mathrm{f}_n,\theta)||q^*_{\backslash n}(f)t_n(\mathbf{u})] = \overline{\mathrm{KL}}[q^*_{\backslash n}(f)p(y_n|\mathrm{f}_n,\theta)||q^*(f)].$$

However, the updates for the approximating factors are now coupled and so the updates must now be iterated, unlike in the idealised procedure. In this way, EP iteratively refines the approximate factors or surrogate likelihoods so that the GP posterior of the surrogate regression task 'best' approximates the posterior of the original regression/classification problem.

3.4 The Power EP Algorithm

Power EP is, algorithmically, a mild generalisation of the EP algorithm that instead removes (or includes) a fraction α of the approximate (or true) likelihood functions in the following steps:

1. **Deletion**: compute the cavity distribution by removing a fraction of one approximate factor, $q^*_{\backslash n}(f) \propto q^*(f)/t^\alpha_n(\mathbf{u})$.
2. **Projection**: first, compute the tilted distribution by incorporating a corresponding fraction of the true likelihood into the cavity, $\tilde{p}(f) = q^*_{\backslash n}(f)p^\alpha(y_n|\mathrm{f}_n,\theta)$. Second, project the tilted distribution onto the approximate posterior using the KL divergence for unnormalised densities,

$$q^*(f) \leftarrow \underset{q^*(f)\in\mathcal{Q}}{\operatorname{argmin}}\ \overline{\mathrm{KL}}[\tilde{p}(f)||q^*(f)].$$

   Here $\mathcal{Q}$ is the set of allowed $q^*(f)$ defined by Equation (6).
3. **Update**: compute a new fraction of the approximate factor by dividing the new approximate posterior by the cavity, $t^\alpha_{n,\text{new}}(\mathbf{u}) = q^*(f)/q^*_{\backslash n}(f)$, and incorporate this fraction back in to obtain the updated factor, $t_n(\mathbf{u}) = t^{1-\alpha}_{n,\text{old}}(\mathbf{u})t^\alpha_{n,\text{new}}(\mathbf{u})$.

The above steps are iteratively repeated for each factor that needs to be approximated. Notice that the procedure only involves one likelihood factor to be handled at a time. In the case of analytically intractable likelihood functions, this often requires only low dimensional integrals to be computed. In other words, PEP has transformed a high dimensional intractable integral that is hard to approximate into a set of low dimensional intractable

integrals that are simpler to approximate. The procedure is not guaranteed to converge in general, but we did not observe any convergence issues in our experiments. Furthermore, it can be shown to be numerically stable when the factors are log-concave (as in GP regression and classification without pseudo-data) (Seeger, 2008).

If Power EP converges, the fractional updates are equivalent to running the original EP procedure, but replacing the KL minimisation with an alpha-divergence minimisation (Zhu and Rohwer, 1995; Minka, 2005),

$$\overline{\mathrm{D}}_\alpha[p^*(f)||q^*(f)] = \frac{1}{\alpha(1-\alpha)}\int \left[\alpha p^*(f) + (1-\alpha)q^*(f) - p^*(f)^\alpha q^*(f)^{1-\alpha}\right] \mathrm{d}f.$$

When $\alpha = 1$, the alpha-divergence is the inclusive KL divergence $\overline{\mathrm{D}}_1[p^*(f)||q^*(f)] = \overline{\mathrm{KL}}[p^*(f)||q^*(f)]$ recovering EP as expected from the PEP algorithm. As $\alpha \to 0$ the exclusive KL divergence is recovered, $\overline{\mathrm{D}}_{\to 0}[p^*(f)||q^*(f)] = \overline{\mathrm{KL}}[q^*(f)||p^*(f)]$, and since minimising a set of local exclusive KL divergences is equivalent to minimising a single global exclusive KL divergence (Minka, 2005), the Power EP solution is the minimum of a variational free-energy (see Appendix B for more details). In the current case, we will now show explicitly that these cases of Power EP recover FITC and Titsias's VFE solution respectively.

3.5 General Results for Gaussian Process Power EP

This section describes the Power EP steps in finer detail showing the complexity is $\mathcal{O}(NM^2)$ and laying the ground work for the equivalence relationships. The Appendix F includes a full derivation.

We start by defining the approximate factors to be in natural parameter form, making it simple to combine and delete them, $t_n(\mathbf{u}) = \tilde{\mathcal{N}}(\mathbf{u}; z_n, \mathbf{T}_{1,n}, \mathbf{T}_{2,n}) = z_n \exp(\mathbf{u}^\intercal \mathbf{T}_{1,n} - \frac{1}{2}\mathbf{u}^\intercal \mathbf{T}_{2,n}\mathbf{u})$. We consider full rank $\mathbf{T}_{2,n}$, but will show that the optimal form is rank 1. The parameterisation means the approximate posterior over the pseudo-points has natural parameters $\mathbf{T}_{1,\mathbf{u}} = \sum_n \mathbf{T}_{1,n}$ and $\mathbf{T}_{2,\mathbf{u}} = \mathbf{K}_{\mathbf{uu}}^{-1} + \sum_n \mathbf{T}_{2,n}$ inducing an approximate posterior, $q^*(f|\theta) = \mathcal{Z}_{\mathrm{PEP}}\mathcal{GP}(f; m_{\mathrm{f}}, V_{\mathrm{ff}'})$. The mean and covariance functions of the approximate posterior are

$$m_{\mathrm{f}} = \mathbf{K}_{\mathrm{fu}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{T}_{2,\mathbf{u}}^{-1}\mathbf{T}_{1,\mathbf{u}}; \quad V_{\mathrm{ff}'} = \mathbf{K}_{\mathrm{ff}'} - \mathbf{Q}_{\mathrm{ff}'} + \mathbf{K}_{\mathrm{fu}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{T}_{2,\mathbf{u}}^{-1}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}\mathrm{f}'}.$$

Deletion: The cavity for data point n, $q^*_{\backslash n}(f) \propto q^*(f)/t_n^\alpha(\mathbf{u})$, has a similar form to the posterior, but the natural parameters are modified by the deletion step, $\mathbf{T}_{1,\mathbf{u}}^{\backslash n} = \mathbf{T}_{1,\mathbf{u}} - \alpha\mathbf{T}_{1,n}$ and $\mathbf{T}_{2,\mathbf{u}}^{\backslash n} = \mathbf{T}_{2,\mathbf{u}} - \alpha\mathbf{T}_{2,n}$, yielding the following mean and covariance functions

$$m_{\mathrm{f}}^{\backslash n} = \mathbf{K}_{\mathrm{fu}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{T}_{2,\mathbf{u}}^{\backslash n,-1}\mathbf{T}_{1,\mathbf{u}}^{\backslash n}; \quad V_{\mathrm{ff}'}^{\backslash n} = \mathbf{K}_{\mathrm{ff}'} - \mathbf{Q}_{\mathrm{ff}'} + \mathbf{K}_{\mathrm{fu}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{T}_{2,\mathbf{u}}^{\backslash n,-1}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}\mathrm{f}'}.$$

Projection: The central step in Power EP is the projection. Obtaining the new approximate unnormalised posterior $q^*(f)$ by minimising $\overline{\mathrm{KL}}[\tilde{p}(f)||q^*(f)]$ would naïvely appear intractable. Fortunately,

Remark 1 *Due to the structure of the approximate posterior, $q^*(f) = p(f_{\neq\mathbf{u}}|\mathbf{u})q^*(\mathbf{u})$, the objective, $\overline{\mathrm{KL}}[\tilde{p}(f)||q^*(f)]$ is minimised when $\mathbb{E}_{\tilde{p}(f)}[\phi(\mathbf{u})] = \mathbb{E}_{q^*(\mathbf{u})}[\phi(\mathbf{u})]$, where $\phi(\mathbf{u}) = \{\mathbf{u}, \mathbf{u}\mathbf{u}^\intercal\}$ are the sufficient statistics, that is when the moments at the pseudo-inputs are matched.*

This is the central result from which computational savings are derived. Furthermore, this moment matching condition would appear to necessitate computation of a set of integrals to find the zeroth, first and second moments. However, the technique known as 'differentiation under the integral sign'[2] provides a useful shortcut that only requires one integral to compute the log-normaliser of the tilted distribution, $\log \tilde{Z}_n = \log \mathbb{E}_{q^*_{\backslash n}(f)}[p^\alpha(y_n|\mathrm{f}_n)]$, before differentiating w.r.t. the cavity mean to give

$$\mathbf{m}_{\mathbf{u}} = \mathbf{m}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}\frac{\mathrm{d}\log \tilde{Z}_n}{\mathrm{d}m_{\mathrm{f}_n}^{\backslash n}}; \qquad \mathbf{V}_{\mathbf{u}} = \mathbf{V}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}\frac{\mathrm{d}^2\log \tilde{Z}_n}{\mathrm{d}(m_{\mathrm{f}_n}^{\backslash n})^2}\mathbf{V}_{\mathrm{f}_n\mathbf{u}}^{\backslash n}. \tag{7}$$

Update: Having computed the new approximate posterior, the approximate factor $t_{n,\mathrm{new}}(\mathbf{u}) = q^*(f)/q^*_{\backslash n}(f)$ can be straightforwardly obtained, resulting in,

$$\mathbf{T}_{1,n,\mathrm{new}} = \mathbf{V}_{\mathbf{u}}^{-1}\mathbf{m}_{\mathbf{u}} - (\mathbf{V}_{\mathbf{u}}^{\backslash n})^{-1}\mathbf{m}_{\mathbf{u}}^{\backslash n}, \ \mathbf{T}_{2,n,\mathrm{new}} = \mathbf{V}_{\mathbf{u}}^{-1} - (\mathbf{V}_{\mathbf{u}}^{\backslash n})^{-1}, \ z_n^\alpha = \tilde{Z}_n \mathrm{e}^{\mathcal{G}(q_*^{\backslash n}(\mathbf{u})) - \mathcal{G}(q^*(\mathbf{u}))},$$

where we have defined the log-normaliser as the functional $\mathcal{G}(\tilde{\mathcal{N}}(\mathbf{u}; z, \mathbf{T}_1, \mathbf{T}_2)) = \log \int \tilde{\mathcal{N}}(\mathbf{u}; z, \mathbf{T}_1, \mathbf{T}_2)\mathrm{d}\mathbf{u}$. Remarkably, these results and Equation (7) reveals that $\mathbf{T}_{2,n,new}$ is a rank-1 matrix. As such, the minimal and simplest way to parameterise the approximate factor is $t_n(\mathbf{u}) = z_n\mathcal{N}(\mathbf{K}_{\mathrm{f}_n\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{u}; g_n, v_n)$, where g_n and v_n are scalars, resulting in a significant memory saving and $\mathcal{O}(NM^2)$ cost.

In addition to providing the approximate posterior after convergence, Power EP also provides an approximate log-marginal likelihood for model selection and hyperparameter optimisation,

$$\log \mathcal{Z}_{\mathrm{PEP}} = \log \int p(f)\prod_n t_n(\mathbf{u})\mathrm{d}f = \mathcal{G}(q^*(\mathbf{u})) - \mathcal{G}(p^*(\mathbf{u})) + \sum_n \log z_n. \tag{8}$$

Armed with these general results, we now consider the implications for Gaussian Process regression.

3.6 Gaussian Regression case

When the model contains Gaussian likelihood functions, closed-form expressions for the Power EP approximate factors at convergence can be obtained and hence the approximate posterior:

$$t_n(\mathbf{u}) = \mathcal{N}(\mathbf{K}_{\mathrm{f}_n\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{u}; y_n, \alpha D_{\mathrm{f}_n\mathrm{f}_n} + \sigma_y^2), \ \ q(\mathbf{u}) = \mathcal{N}(\mathbf{u}; \mathbf{K}_{\mathbf{uf}}\overline{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{y}, \mathbf{K}_{\mathbf{uu}} - \mathbf{K}_{\mathbf{uf}}\overline{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{K}_{\mathbf{fu}})$$

where $\overline{\mathbf{K}}_{\mathbf{ff}} = \mathbf{Q}_{\mathbf{ff}} + \alpha\mathrm{diag}(\mathbf{D}_{\mathbf{ff}}) + \sigma_y^2\mathrm{I}$ and $\mathbf{D}_{\mathbf{ff}} = \mathbf{K}_{\mathbf{ff}} - \mathbf{Q}_{\mathbf{ff}}$ as defined in Section 2. These analytic expressions can be rigorously proven to be the stable fixed point of the Power EP procedure using Remark 1. Briefly, assuming the factors take the form above, the natural parameters of the cavity $q^*_{\backslash n}(\mathbf{u})$ become,

$$\mathbf{T}_{1,\mathbf{u}}^{\backslash n} = \mathbf{T}_{1,\mathbf{u}} - \alpha\gamma_n y_n \mathbf{K}_{\mathrm{f}_n\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}, \quad \mathbf{T}_{2,\mathbf{u}}^{\backslash n} = \mathbf{T}_{2,\mathbf{u}} - \alpha\gamma_n \mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}\mathrm{f}_n}\mathbf{K}_{\mathrm{f}_n\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1},$$

2. In this case, the dominated convergence theorem can be used to justify the interchange of integration and differentiation (see e.g. Brown, 1986).

where $\gamma_n^{-1} = \alpha D_{\mathrm{f}_n\mathrm{f}_n} + \sigma_y^2$. The subtracted quantities in the equations above are exactly the contribution the likelihood factor makes to the cavity distribution (see Remark 1) so $\int q^*_{\backslash n}(f) p^\alpha(y_n|\mathrm{f}_n)\mathrm{d}f_{\neq \mathbf{u}} = q^*_{\backslash n}(\mathbf{u}) \int p(\mathrm{f}_n|\mathbf{u}) p^\alpha(y_n|\mathrm{f}_n)\mathrm{d}\mathrm{f}_n \propto q^*(\mathbf{u})$. Therefore, the posterior approximation remains unchanged after an update and the form for the factors above is the fixed point. Moreover, the approximate log-marginal likelihood is also analytically tractable,

$$\log \mathcal{Z}_{\mathrm{PEP}} = -\frac{N}{2}\log(2\pi) - \frac{1}{2}\log|\overline{\mathbf{K}}_{\mathbf{ff}}| - \frac{1}{2}\mathbf{y}^\intercal \overline{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{y} - \frac{1-\alpha}{2\alpha}\sum_n \log\left(1 + \alpha D_{\mathrm{f}_n\mathrm{f}_n}/\sigma_y^2\right).$$

We now look at special cases and the correspondence to the methods discussed in Section 2.

Remark 2 *When $\alpha = 1$ [EP], the Power EP posterior becomes the FITC posterior in Equation* (1) *and the Power EP approximate marginal likelihood becomes the FITC marginal likelihood in Equation* (2)*. In other words, the FITC approximation for GP regression is, surprisingly, equivalent to running an EP algorithm for sparse GP posterior approximation to convergence.*

Remark 3 *As $\alpha \to 0$ the approximate posterior and approximate marginal likelihood are identical to that of the VFE approach in Equations* (3) *and* (4) *(Titsias, 2009). This result uses the limit: $\lim_{x\to 0} x^{-1}\log(1+x) = 1$. So FITC and Titsias's VFE approach employ the same form of pseudo-point approximation, but refine it in different ways.*

Remark 4 *For fixed hyperparameters, a single pass of Power EP is sufficient for convergence in the regression case.*

3.7 Extensions: Structured, Inter-domain and Multi-power Power EP Approximations

The framework can now be generalised in three orthogonal directions:

1. enable structured approximations to be handled that retain more dependencies in the spirit of PITC (see Section 2.1)
2. incorporate inter-domain pseudo-points thereby adding further flexibility to the form of the approximate posterior
3. employ different powers α for each factor (thereby enabling e.g. VFE updates to be used for some data points and EP for others).

Given the groundwork above, these three extensions are straightforward. In order to handle structured approximations, we take inspiration from PITC and partition the data into B disjoint blocks $\mathbf{y}_b = \{y_n\}_{n\in\mathcal{B}_b}$ (see Section 2.1). Each PEP factor update will then approximate an entire block which will contain a set of data points, rather than just a single one. This is related to a form of EP approximation that has recently been used to distribute Monte Carlo algorithms across many machines (Gelman et al., 2014; Xu et al., 2014).

In order to handle inter-domain variables, we define a new domain via a linear transform $g(\mathbf{x}) = \int \mathrm{d}\mathbf{x}' W(\mathbf{x},\mathbf{x}') f(\mathbf{x}')$ which now contains the pseudo-points $g = \{g_{\neq\mathbf{u}}, \mathbf{u}\}$. Choices for

$W(\mathbf{x},\mathbf{x}')$ include Gaussians or wavelets. These two extensions mean that the approximation becomes,

$$p(f,g)\prod_b p(\mathbf{y}_b|f) \approx p(f,g)\prod_b t_b(\mathbf{u}) = q^*(f).$$

Power EP is then performed using private powers α_b for each data block, which is the third generalisation mentioned above. Analytic solutions are again available (covariance matrices now incorporate the inter-domain transform)

$$t_b(\mathbf{u}) = \mathcal{N}(\mathbf{K}_{\mathbf{f}_b\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{u}; \mathbf{y}_b, \alpha_b\mathbf{D}_{\mathbf{f}_b\mathbf{f}_b} + \sigma_y^2\mathrm{I}), \quad q(\mathbf{u}) = \mathcal{N}(\mathbf{u}; \mathbf{K}_{\mathbf{uf}}\overline{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{y}, \mathbf{K}_{\mathbf{uu}} - \mathbf{K}_{\mathbf{uf}}\overline{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{K}_{\mathbf{fu}}),$$

where $\overline{\mathbf{K}}_{\mathbf{ff}} = \mathbf{Q}_{\mathbf{ff}} + \mathrm{blkdiag}(\{\alpha_b\mathbf{D}_{\mathbf{f}_b\mathbf{f}_b}\}_{b=1}^B) + \sigma_y^2\mathrm{I}$ and blkdiag builds a block-diagonal matrix from its inputs. The approximate log-marginal likelihood can also be obtained in closed-form,

$$\log \mathcal{Z}_{\mathrm{PEP}} = -\frac{N}{2}\log(2\pi) - \frac{1}{2}\log|\overline{\mathbf{K}}_{\mathbf{ff}}| - \frac{1}{2}\mathbf{y}^\intercal\overline{\mathbf{K}}_{\mathbf{ff}}^{-1}\mathbf{y} + \sum_b \frac{1-\alpha_b}{2\alpha_b}\log\left(\mathrm{I} + \alpha_b\mathbf{D}_{\mathbf{f}_b\mathbf{f}_b}/\sigma_y^2\right).$$

Remark 5 *When $\alpha_b = 1$ and $W(\mathbf{x},\mathbf{x}') = \delta(\mathbf{x}-\mathbf{x}')$ the structured Power EP posterior becomes the PITC posterior and the Power EP approximate marginal likelihood becomes the PITC marginal likelihood. Additionally, when $B = N$ we recover FITC as discussed in Section 3.6.*

Remark 6 *When $\alpha_b \to 0$ and $W(\mathbf{x},\mathbf{x}') = \delta(\mathbf{x}-\mathbf{x}')$ the structured Power EP posterior and approximate marginal likelihood becomes identical to the VFE approach (Titsias, 2009). This is a result of the equivalence of local and global exclusive KL divergence minimisation. See Appendix B for more details and Figure 1 for more relationships.*

3.8 Classification

For classification, the non-Gaussian likelihood prevents an analytic solution. As such, the iterative Power EP procedure is required to obtain the approximate posterior. The projection step requires computation of the log-normaliser of the tilted distribution, $\log \tilde{Z}_n = \log \mathbb{E}_{q^*_{\backslash n}(f)}[p^\alpha(y_n|f)] = \log \mathbb{E}_{q^*_{\backslash n}(\mathrm{f}_n)}[\Phi^\alpha(y_n\mathrm{f}_n)]$. For general α, this quantity is not available in closed form[3]. However, it involves a one-dimensional expectation of a non-linear function of a normally-distributed random variable and, therefore, can be approximated using numerical methods, e.g. Gauss-Hermite quadrature. This procedure gives an approximation to the expectation, resulting in an approximate update for the posterior mean and covariance. The approximate log-marginal likelihood can also be obtained and used for hyperparameter optimisation. As $\alpha \to 0$, it becomes the variational free-energy used in Hensman et al. (2015) which employs quadrature for the same purpose. These relationships are shown in Figure 1 which also shows that inter-domain transformations and structured approximations have

3. except for special cases, e.g. when $\alpha = 1$ and $\Phi(x)$ is the probit inverse link function, $\Phi(x) = \int_{-\infty}^x \mathcal{N}(a;0,1)\mathrm{d}a$.

not yet been fully explored in the classification setting. In our view, the inter-domain generalisation would be a sensible one to pursue and it is mathematically and algorithmically straightforward. The structured approximation variant is more complicated as it requires multiple non-linear likelihoods to be handled at each step of EP. This will require further approximation such as using Monte Carlo methods (Gelman et al., 2014; Xu et al., 2014). In addition, when $\alpha = 1$, $M = N$ and the pseudo-points are at the training inputs, the standard EP algorithm for GP classification is recovered (Rasmussen and Williams, 2005, sec. 3.6).

Since the proposed Power EP approach is general, an extension to other likelihood functions is as simple as for VFE methods (Dezfouli and Bonilla, 2015). For example, the multinomial probit likelihood can be handled in the same way as the binary case, where the log-normaliser of the tilted distribution can be computed using a C-dimensional Gaussian quadrature [C is the number of classes] (Seeger and Jordan, 2004) or nested EP (Riihimäki et al., 2013).

3.9 Complexity

The computational complexity of all the regression and classification methods described in this section is $\mathcal{O}(NM^2)$ for training, and $\mathcal{O}(M^2)$ per test point for prediction. The training cost can be further reduced to $\mathcal{O}(M^3)$, in a similar vein to the uncollapsed VFE approach (Hensman et al., 2013, 2015), by employing stochastic updates of the posterior and stochastic optimisation of the hyperparameters using minibatches of data points (Hernández-Lobato and Hernández-Lobato, 2016). In particular, the Power EP update steps in Section 3.2 are repeated for only a small subset of training points and for only a small number of iterations. The approximate log-marginal likelihood in Equation (8) is then computed using this minibatch and optimised as if the Power EP procedure has converged. This approach results in a computationally efficient training scheme, at the cost of returning noisy hyperparameter gradients. In practice, we find that the noise can be handled using stochastic optimisers such as Adam (Kingma and Ba, 2015). In summary, given these advances the general PEP framework is as scalable as variational inference.

4. Experiments

The general framework described above lays out a large space of potential inference algorithms suggesting many exciting directions for innovation. The experiments considered in the paper will investigate only one aspect of this space; how do algorithms that are intermediate between VFE ($\alpha = 0$) and EP/FITC ($\alpha = 1$) perform? Specifically, we will investigate how the performance of the inference scheme varies as a function of α and whether this depends on: the type of problem (classification or regression); the data set (synthetic data sets, 8 real world regression data sets and 6 classification data sets); the performance metric (we compare metrics that require point-estimates to those that are uncertainty sensitive). An important by-product of the experiments is that they provide a comprehensive comparison between the VFE and EP approaches which has been an important area of debate in its own right.

The results presented below are compact summaries of a large number of experiments full details of which are included in Appendix I (along with additional experiments). Python

and Matlab implementations are available at `http://github.com/thangbui/sparseGP_powerEP`.

4.1 Regression on Synthetic Data Sets

In the first experiment, we investigate the performance of the proposed Power EP method on toy regression data sets where ground truth is known. We vary α (from 0 VFE to 1 EP/FITC) and the number of pseudo-points (from 5 to 500). We use thirty data sets, each comprising 1000 data points with five input dimensions and one output dimension, that were drawn from a GP with an Automatic Relevance Determination squared exponential kernel. A 50:50 train/test split was used. The hyperparameters and pseudo-inputs were found by optimising the PEP energy using L-BFGS with a maximum of 2000 function evaluations. The performances are compared using two metrics: standardised mean squared error (SMSE) and standardised mean log loss (SMLL) as described in Rasmussen and Williams (2005). The approximate negative log-marginal likelihood (NLML) for each experiment is also computed. The mean performance using Power EP with different α values and full GP regression is shown in Figure 3. The results demonstrate that as M increases, the SMLL and SMSE of the sparse methods approach that of full GP. Power EP with $\alpha = 0.8$ or $\alpha = 1$ (EP) overestimates the log-marginal likelihood when intermediate numbers of pseudo-points are used, but the overestimation is markedly less when $M = N = 500$. Importantly, however, an intermediate value of α in the range 0.5-0.8 seems to be best for prediction on average, outperforming both EP and VFE.

4.2 Regression on Real-world Data Sets

The experiment above was replicated on 8 UCI regression data sets, each with 20 train/test splits. We varied α between 0 and 1, and M was varied between 5 and 200. Full details of the experiments along with extensive additional analysis is presented in the appendices. Here we concentrate on several key aspects. First we consider pairwise comparisons between VFE ($\alpha \to 0$), Power EP with $\alpha = 0.5$ and EP/FITC ($\alpha = 1$) on both the SMSE and SMLL evaluation metrics. Power EP with $\alpha = 0.5$ was chosen because it is the mid-point between VFE and EP and because settings around this value empirically performed the best on average across all data sets, splits, numbers of inducing points, and evaluation metrics.

In Figure 4A we plot (for each data set, each split and each setting of M) the evaluation scores obtained using one inference algorithm (e.g. PEP $\alpha = 0.5$) against the score obtained using another (e.g. VFE $\alpha = 0$). In this way, points falling below the identity line indicate experiments where the method on the y-axis outperformed the method on the x-axis. These results have been collapsed by forming histograms of the difference in the performance of the two algorithms, such that mass to the right of zero indicates the method on the y-axis outperformed that on the x-axis. The proportion of mass on each side of the histogram, also indicated on the plots, shows in what fraction of experiments one method returns a more accurate result than the other. This is a useful summary statistic, linearly related to the average rank, that we will use to unpack the results. The average rank is insensitive to the magnitude of the performance differences and readers might worry that this might give an overly favourable view of a method that performs the best frequently, but only by a tiny margin, and when it fails it does so catastrophically. However, the histograms indicate that

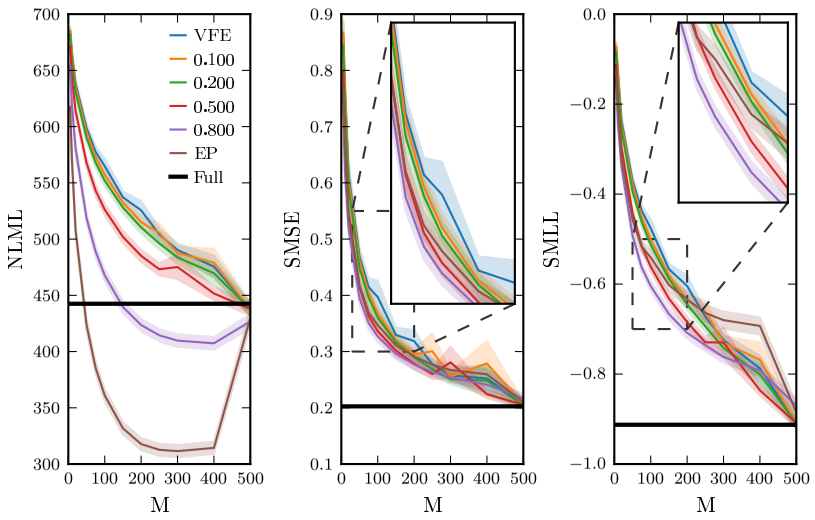

Figure 3: The performance of various α values averaged over 30 trials. See text for more details

the methods that win most frequently tend also to 'win big' and 'lose small', although EP is a possible exception to this trend (see the outliers below the identity line on the bottom right-hand plot).

A clear pattern emerges from these plots. First, PEP $\alpha = 0.5$ is the best performing approach on the SMSE metric, outperforming VFE 67% of the time and EP 78% of the time. VFE is better than EP on the SMSE metric 64% of the time. Second, EP performs the best on the SMLL metric, outperforming VFE 93% of the time and PEP $\alpha = 0.5$ 71% of the time. PEP $\alpha = 0.5$ outperforms VFE in terms of the SMLL metric 93% of the time.

These pairwise rank comparisons have been extended to other values of α in Figure 5A. Here, each row of the figure compares one approximation with all others. Horizontal bars indicate that the methods have equal average rank. Upward sloping bars indicate the method shown on that row has lower average rank (better performance), and downward sloping bars indicate higher average rank (worse performance). The plots show that PEP $\alpha = 0.5$ outperforms all other methods on the SMSE metric, except for PEP $\alpha = 0.6$ which is marginally better. EP is outperformed by all other methods, and VFE only outperforms EP on this metric. On the other hand, EP is the clear winner on the SMLL metric, with performance monotonically decreasing with α so that VFE is the worst.

The same pattern of results is seen when we simultaneously compare all of the methods, rather than considering sets of pairwise comparisons. The average rank plots shown in Figure 4B were produced by sorting the performances of the nine different approximating

methods for each data set, split, and number of pseudo-points M and assigning a rank. These ranks are then averaged over all data sets and their splits, and settings of M. PEP $\alpha = 0.5$ is the best for the SMSE metric, and the two worst methods are EP and VFE. PEP $\alpha = 0.8$ is the best for the SMLL metric, with EP and PEP $\alpha = 0.6$ not far behind (when EP performs poorly it can do so with a large magnitude, explaining the discrepancy with the pairwise ranks).

There is some variability between individual data sets, but the same general trends are clear: For MSE $\alpha = 0.5$ is better than VFE on 6/8 data sets and EP on 8/8 data sets, whilst VFE is better than EP on 3 data sets (the difference on the others being small). For SMLL EP is better than $\alpha = 0.5$ on 5/8 data sets and VFE on 7/8 data sets, whilst $\alpha = 0.5$ is better than VFE on 8/8 data sets. Performance tends to increase for all methods as a function of the number of pseudo-points M. The interaction between the choice of M and the best performing inference method is often complex and variable across data sets making it hard to give precise advice about selecting α in an M dependent way.

In summary, we make the following recommendations based on these results for GP regression problems. For a MSE loss, we recommend using $\alpha = 0.5$. For SMLL we recommend using EP. It is possible that more fine grained recommendations are possible based upon details of the data set and the computational resources available for processing, but further work will be needed to establish this.

4.3 Binary Classification

We also evaluated the Power EP method on 6 UCI classification data sets, each has 20 train/test splits. The details of the data sets are included in Appendix I.3. The data sets are all roughly balanced, and the most imbalanced is `pima` with 500 positive and 267 negative data points. Again α was varied between 0 and 1, and M was varied between 10 and 100. We adopt the experimental protocol discussed in Section 3.9, including: (i) not waiting for Power EP to converge before making hyperparameter updates, (ii) using minibatches of data points for each Power EP sweep, (iii) parallel factor updates. The Adam optimiser was used with default hyperparameters to handle the noisy gradients produced by these approximations (Kingma and Ba, 2015). We also implemented the VFE approach of Hensman et al. (2015) and include this in the comparison to the PEP methods. The VFE approach should be theoretically identical to PEP with small α, however, we note that the results can be slightly different due to differences in the implementation—optimisation for VFE vs. the iterative PEP procedure, and we also note that each step of PEP only gets to see a tiny fraction of each data point when α is small which can slow the learning speed. Similar to the regression experiment, we compare the methods using the pairwise ranking plots on the test error and negative log-likelihood (NLL) evaluation metrics.

In Figure 6, we plot (for each data set, each split and each setting of M) the evaluation scores using one inference algorithm against the score obtained using another [see Section 4.2 for a detailed explanation of the plots]. In contrast to the regression results in Section 4.2, there are no clear-cut winners among the methods. The test error results show that PEP $\alpha = 0.5$ is marginally better than VFE and EP, while VFE edges EP out in this metric. Similarly, all methods perform comparably on the NLL scale, except with PEP $\alpha = 0.5$ outperforming EP by a narrow margin (65% of the time vs. 35%)

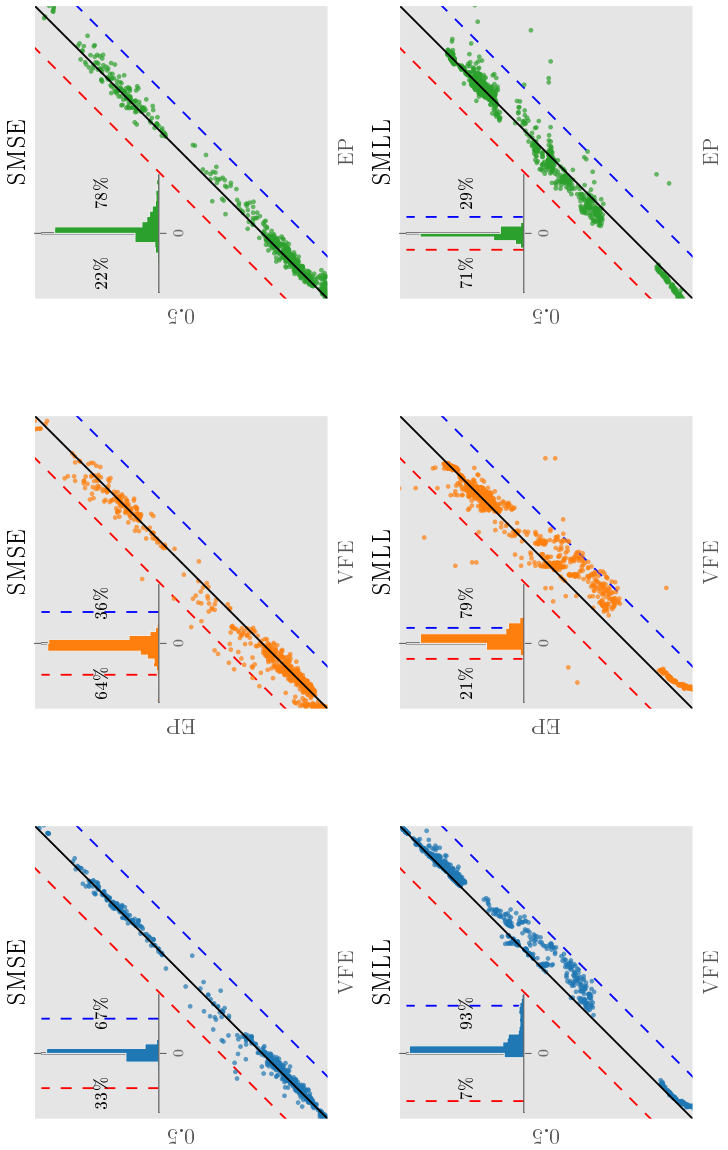

Figure 4: Pair-wise comparisons between Power EP with $\alpha = 0.5$, EP ($\alpha = 1$) and VFE ($\alpha \to 0$), evaluated on several regression data sets and various settings of M. Each coloured point is the result for one split. Points that are below the diagonal line illustrate the method on the y-axis is better than the method on the x-axis. The inset diagrams show the histograms of the difference between methods (x-value $-$ y-value), and the counts of negative and positive differences. Note that this indicates pairwise ranking of the two methods. Positive differences mean the y-axis method is better than the x-axis method and vice versa. For example, the middle, bottom plot shows EP is on average better than VFE.

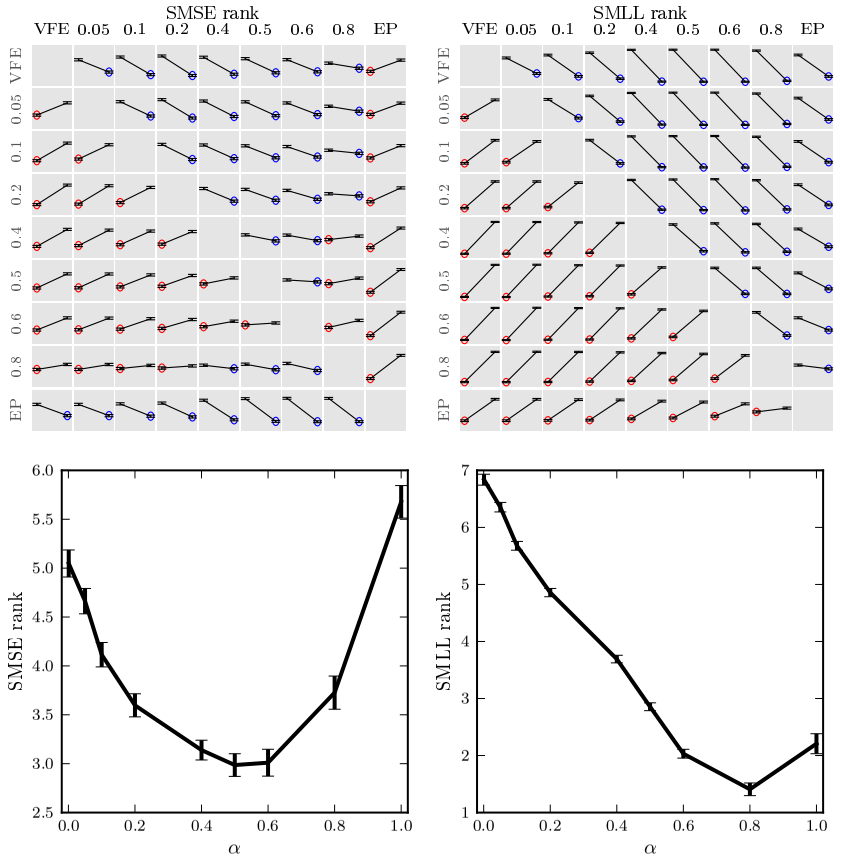

Figure 5: Average ranking of various α values in the regression experiment, lower is better. Top plots show the pairwise comparisons. Red circles denote rows being better than the corresponding columns, and blue circles mean vice versa. Bottom plots show the ranks of all methods when being compared together. Intermediate α values (not EP or VFE) are best on average.

We repeat the pairwise comparison above to all methods and show the results in Figure 7. The plots show that there is no conclusive winner on the test error metric with VFE and PEP $\alpha \leq 0.5$ performing similarly. On the NLL metric VFE, PEP $\alpha = 0.4$ and PEP $\alpha = 0.5$ have a slight edge over other α values. Notably, methods corresponding to bigger α values, such as PEP $\alpha = 0.8$ and EP, are outperformed by all other methods. Similar to the regression experiment, we observe the same pattern of results when all methods are simultaneously compared, as shown in Figure 7. However, the large errorbars suggest the difference between the methods is small in both metrics.

There is some variability between individual data sets, but the general trends are clear and consistent with the pattern noted above. For test error, PEP $\alpha = 0.5$ is better than VFE on 1/6 data set and is better than EP on 3/6 data sets (the differences on the other data sets are small). VFE outperforms EP on 2/6 data sets, while EP beats VFE on only 1/6 data sets. For NLL, PEP $\alpha = 0.5$ only clearly outperforms VFE on 1/6 data set, but is worse compared to VFE on 1 data set (the other 4 data sets have no clear winner). PEP $\alpha = 0.5$ is better than EP on 5/6 data sets and EP is better on the remaining data set). EP is only better than VFE on 2/6 data sets, and is outperformed by VFE on the other 4/6 data sets. The finding that PEP and VFE are slightly better than EP on the NLL metric is surprising as we expected EP perform the best on the uncertainty sensitive metric (just as was discovered in the regression case). The full results are included in the appendices (see figs 25, 26 and 27). Similar to the regression case, we observe that as M increases, the performance tends to be better for all methods and the differences between the methods tend to become smaller, but we have not found evidence for systematic sensitivity to the nature of the approximation.

In summary, we make the following recommendations based on these results for GP classification problems. For a raw test error loss and for NLL, we recommend using $\alpha = 0.5$ (or $\alpha = 0.4$). It is possible that more fine grained recommendations are possible based upon details of the data set and the computational resources available for processing, but further work will be needed to establish this.

5. Discussion

It is difficult to identify precisely where the best approximation methods derive their advantages, but here we will speculate. Since the negative variational free-energy is a lower-bound on the log-marginal likelihood it has the enviable theoretical guarantee that pseudo-input optimisation is always guaranteed to improve the estimate of the log marginal likelihood and the posterior (as measured by the inclusive KL). The negative EP energy, in contrast, is not generally a lower bound which can mean that pseudo-input optimisation drives the solution to the point where the EP energy over-estimates the log marginal likelihood the most, rather than to the point where the marginal likelihood and/or posterior estimate is best. For this reason, we believe that variational methods are likely to be better than EP if the goal is to derive accurate marginal likelihood estimates, or accurate predictive distributions, for fixed hyperparameter settings. For hyperparameter optimisation, things are less clear-cut since variational methods are biased away from the maximal marginal likelihood, towards hyperparameter settings for which the posterior approximation is accurate. Often this bias is severe and also creates local-optima (Turner and Sahani, 2011). So,

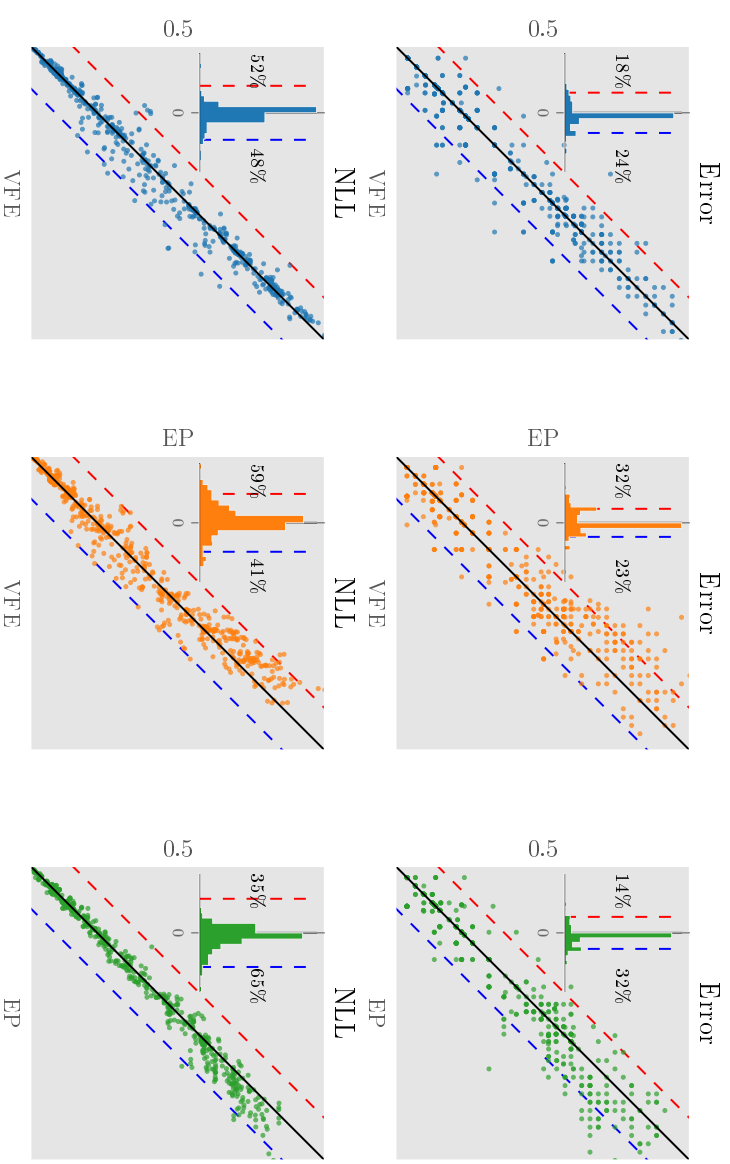

Figure 6: Pair-wise comparisons between Power EP with $\alpha = 0.5$, EP ($\alpha = 1$) and VFE ($\alpha \to 0$), evaluated on several classification data sets and various settings of M. Each coloured point is the result for one split. Points that are below the diagonal line illustrate the method on the y-axis is better than the method on the x-axis. The inset diagrams show the histograms of the difference between methods (x-value $-$ y-value), and the counts of negative and positive differences. Note that this indicates pairwise ranking of the two methods. Positive differences means the y-axis method is better than the x-axis method and vice versa.

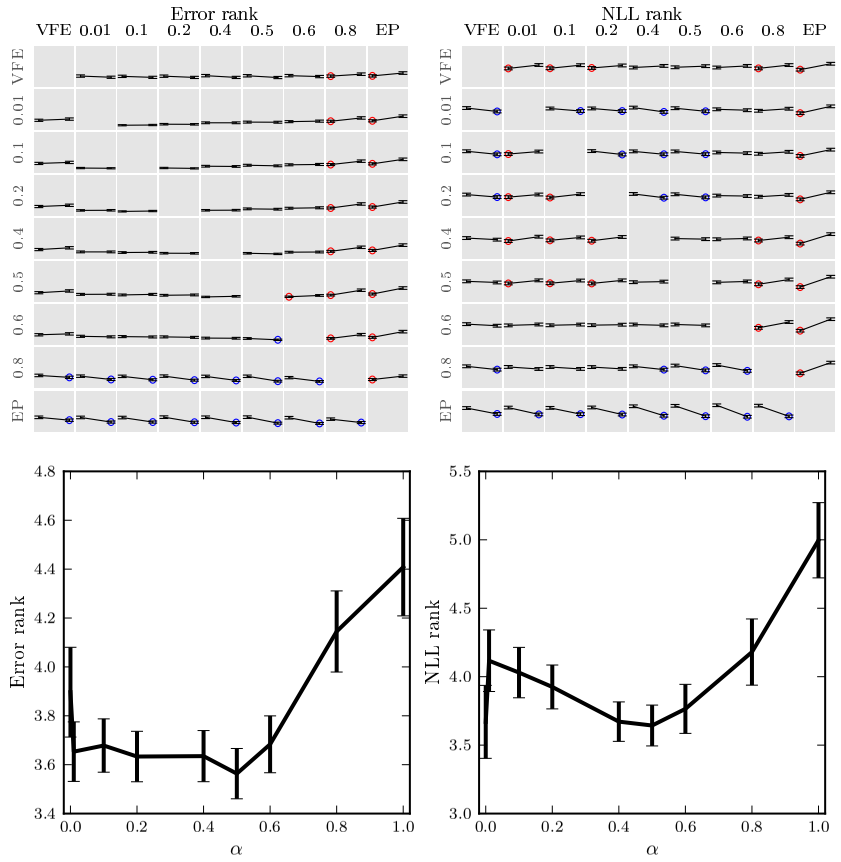

Figure 7: Average ranking of various α values in the classification experiment, lower is better. Top plots show the pairwise comparisons. Red circles denote rows being better than the corresponding columns, and blue circles mean vice versa. Bottom plots show the ranks of all methods when being compared together. Intermediate α values (not EP or VFE) are best on average.

although EP will generally also be biased away from the maximal marginal likelihood and potentially towards areas of over-estimation, it can still outperform variational methods. Superposed onto these factors, is a general trend for variational methods to minimise MSE or classification error-rate and EP methods to minimise negative log-likelihood, due to the form of their respective energies (the variational free-energy includes the average training MSE in the regression case, for example). Intermediate methods will blend the strengths and weaknesses of the two extremes. It is interesting that values of α around a half are arguably the best performing on average. Similar empirical conclusions have been made elsewhere (see e.g. Minka, 2005; Hernández-Lobato et al., 2016; Depeweg et al., 2016). In this case, the alpha-divergence interpretation of Power EP shows that it is minimising the Hellinger distance whose square root is a valid distance metric. Further experimental and theoretical work is required to clarify these issues.

The results presented above employed (approximate) type-II maximum likelihood fitting of the hyperparameters. This estimation method is known in some circumstances to overfit the data. It is therefore conceivable therefore that pseudo-point approximations, which have a tendency to encourage under-fitting due to their limited representational capacity, could be beneficial due to them mitigating overfitting. We do not believe that this is a strong effect in the experiments above. For example, in the synthetic data experiments the NLML, SMSE and SMLL obtained from fitting the unapproximated GP were similar to those obtained using the GP from which the data were generated, indicating that overfitting is not a strong effect (see fig. 9 in the appendix). It is true that EP and $\alpha = 0.8$ over-estimates the marginal likelihood in the synthetic data experiments, but this is a distinct effect from over-fitting which would, for example, result in overconfident predictions on the test data set. The SMSE and SMLL on the training and test sets, for example, are similar which is indicative of a well-fit model. It would be interesting to explore distributional hyperparameter estimates (see e.g. Piironen and Vehtari, 2017) that employ these pseudo-point approximations.

One of the features of the approximate generative models introduced in Section 2.1 for regression, is that they contain input-dependent noise, unlike the original model. Many data sets contain noise of this sort and so approximate models like FITC and PITC, or models in which the observation noise is explicitly modelled are arguably more appropriate than the original unapproximated regression model (Snelson, 2007; Saul et al., 2016). Motivated by this train of reasoning, Titsias (2009) applied the variational free-energy approximation to the FITC generative model, an approach that was later generalised by Hoang et al. (2016) to encompass a more general class of input dependent noise, including Markov structure (Low et al., 2015). Here the insight is that the resulting variational lower bound separates over data points (Hensman et al., 2013) and is, therefore, amenable to stochastic optimisation using minibatches, unlike the marginal likelihood. In a sense, these approaches unify the approximate generative modelling approach, including the FITC and PITC variants, with the variational free-energy methods. Indeed, one approach is to posit the desired form of the optimal variational posterior, and to work backwards from this to construct the generative model implied (Hoang et al., 2016). However, these approaches are quite different from the one described in this paper where FITC and PITC are shown to emerge in the context of approximating the original unapproximated GP regression model using Power EP. Indeed, if the goal really is to model input dependent noise, it is not at all clear that generative models

like FITC are the most sensible. For example, FITC uses a single set of hyperparameters to describe the variation of the underlying function and the input dependent noise.

6. Conclusion

This paper provided a new unifying framework for GP pseudo-point approximations based on Power EP that subsumes many previous approaches including FITC, PITC, DTC, Titsias's VFE method, Qi et al's EP method, and inter-domain variants. It provided a clean computational perspective on the seminal work of Csató and Opper that related FITC to EP, before extending their analysis significantly to include a closed form Power EP marginal likelihood approximation for regression, connections to PITC, and further results on classification and GPSSMs. The new framework was used to devise new algorithms for GP regression and GP classification. Extensive experiments indicate that intermediate values of Power EP with the power parameter set to $\alpha = 0.5$ often outperform the state-of-the-art EP and VFE approaches. The new framework suggests many interesting directions for future work in this area that we have not explored, for example, extensions to online inference, combinations with special structured matrices (e.g. circulant and Kronecker structure), Bayesian hyperparameter learning, and applications to richer models. The current work has only scratched the surface, but we believe that the new framework will form a useful theoretical foundation for the next generation of GP approximation schemes.

Appendix A. A Unified Objective for Unnormalised KL Variational Free-energy Methods

Here we show that performing variational inference by optimising the unnormalised KL naturally leads to a single objective for both the approximation to the joint distribution, $q^*(f|\theta)$ and the hyperparameters θ.

The unnormalised KL is given by

$$\overline{\mathrm{KL}}[q^*(f|\theta)||p(f,\mathbf{y}|\theta)] = \int q^*(f|\theta)\log\frac{q^*(f|\theta)}{p(f,\mathbf{y}|\theta)}\mathrm{d}f + \int \left(p(f,\mathbf{y}|\theta) - q^*(f|\theta)\right)\mathrm{d}f.$$

This is intractable as it includes the marginal likelihood $p(\mathbf{y}|\theta) = \int p(f,\mathbf{y}|\theta)\mathrm{d}f$. However, since we are interested in minimising this objective with respect to $q^*(f|\theta)$ we can ignore the intractable term,

$$\begin{aligned}\operatorname*{argmin}_{q^*(f|\theta)} \overline{\mathrm{KL}}[q^*(f|\theta)||p(f,\mathbf{y}|\theta)] &= \operatorname*{argmax}_{q^*(f|\theta)} \left(p(\mathbf{y}|\theta) - \overline{\mathrm{KL}}[q^*(f|\theta)||p(f,\mathbf{y}|\theta)]\right) \\ &= \operatorname*{argmax}_{q^*(f|\theta)} \left(\int q^*(f|\theta)\log\frac{p(f,\mathbf{y}|\theta)}{q^*(f|\theta)}\mathrm{d}f + \int q^*(f|\theta)\mathrm{d}f\right).\end{aligned}$$

In other words, we have turned the unnormalised KL into a tractable lower-bound of the marginal likelihood $\mathcal{G}(q^*(f|\theta),\theta) = p(\mathbf{y}|\theta) - \overline{\mathrm{KL}}[q^*(f|\theta)||p(f,\mathbf{y}|\theta)]$. The structure of this new lower-bound can be understood by decomposing the approximation to the joint distribution into a normalised posterior approximation $q(f|\theta)$ and an approximation to the marginal likelihood, Z_{VFE}, that is $q^*(f|\theta) = Z_{\mathrm{VFE}}\, q(f|\theta)$:

$$\mathcal{G}(Z_{\mathrm{VFE}}q(f|\theta),\theta) = Z_{\mathrm{VFE}}\left(1 - \log Z_{\mathrm{VFE}} + \int q(f|\theta)\log\frac{p(f,\mathbf{y}|\theta)}{q(f|\theta)}\mathrm{d}f\right).$$

We can see that optimising the lower-bound with respect to θ is equivalent to optimising the standard variational free-energy $\mathcal{F}(q(f|\theta),\theta) = \int q(f|\theta)\log\frac{p(f,\mathbf{y}|\theta)}{q(f|\theta)}\mathrm{d}f$. Moreover, optimising for Z_{VFE} recovers $Z^{\mathrm{opt}}_{\mathrm{VFE}} = \exp(\mathcal{F}(q(f|\theta),\theta))$. Substituting this back into the bound

$$\mathcal{G}(Z^{\mathrm{opt}}_{\mathrm{VFE}}q(f|\theta),\theta) = Z^{\mathrm{opt}}_{\mathrm{VFE}} = \exp(\mathcal{F}(q(f|\theta),\theta)).$$

In other words, the new collapsed bound is just the exponential of the original variational free-energy and optimising the collapsed bound for θ is equivalent to optimising the approximation to the marginal likelihood.

Appendix B. Global and Local Inclusive KL Minimisations

In this section, we will show that optimising a single global inclusive KL divergence, $\mathrm{KL}[q||p]$, is equivalent to optimising a sum of a set of local inclusive KL divergence, $\mathrm{KL}[q||\tilde{p}]$, where p, q and $\tilde{p}$ are the exact posterior, the approximate posterior and the tilted distribution accordingly. Without loss of generality, we assume that $p(\theta) = \prod_n f_n(\theta) \approx \prod_n t_n(\theta) = q(\theta)$, that is the exact posterior is a product of factors, $\{f_n(\theta)\}_n$, each of which is approximated by an approximate factor $t_n(\theta)$. Substituting these distributions into the global KL divergence

gives,

$$\begin{aligned}
\mathrm{KL}[q(\theta)||p(\theta)] &= \int \mathrm{d}\theta q(\theta) \log \frac{q(\theta)}{p(\theta)} \\
&= \int \mathrm{d}\theta q(\theta) \log \frac{\prod_n t_n(\theta)}{\prod_n f_n(\theta)} \\
&= \int \mathrm{d}\theta q(\theta) \log \left[\frac{\prod_n t_n(\theta)}{\prod_n f_n(\theta)} \frac{\prod_n \prod_{i\neq n} t_i(\theta)}{\prod_n \prod_{i\neq n} t_i(\theta)}\right] \\
&= \int \mathrm{d}\theta q(\theta) \log \frac{\prod_n [\prod_i t_i(\theta)]}{\prod_n [f_n(\theta) \prod_{i\neq n} t_i(\theta)]} \\
&= \sum_n \int \mathrm{d}\theta q(\theta) \log \frac{\prod_i t_i(\theta)}{f_n(\theta) \prod_{i\neq n} t_i(\theta)} \\
&= \sum_n \mathrm{KL}[q(\theta)||\tilde{p}_n(\theta)],
\end{aligned}$$

which means running the EP procedure, where we use $\mathrm{KL}[q(\theta)||\tilde{p}_n(\theta)]$ in place of $\mathrm{KL}[\tilde{p}_n(\theta)||q(\theta)]$, is *equivalent* to the VFE approach which optimises a single global KL divergence, $\mathrm{KL}[q(\theta)||p(\theta)]$.

Appendix C. Some Relevant Linear Algebra and Function Expansion Identities

The Woodbury matrix identity or Woodbury formula is:

$$(A + UCV)^{-1} = A^{-1} - A^{-1}U(C^{-1} + VA^{-1}U)^{-1}VA^{-1}. \tag{9}$$

In general, C need not be invertible, we can use the Binomial inverse theorem,

$$(A + UCV)^{-1} = A^{-1} - A^{-1}UC(C + CVA^{-1}UC)^{-1}CVA^{-1}. \tag{10}$$

When C is an identity matrix and U and V are vectors, the Woodbury identity can be shortened and become the Sherman-Morrison formula,

$$(A + uv^\intercal)^{-1} = A^{-1} - \frac{A^{-1}uv^\intercal A^{-1}}{1 + v^\intercal A^{-1}u}. \tag{11}$$

Another useful identity is the matrix determinant lemma,

$$\det(A + uv^\intercal) = (1 + v^\intercal A^{-1}u)\det(A). \tag{12}$$

The above theorem can be extend for matrices U and V,

$$\det(A + UV^\intercal) = \det(\mathrm{I} + V^\intercal A^{-1}U)\det(A). \tag{13}$$

We also make use of the following Maclaurin series,

$$\exp(x) = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \cdots, \tag{14}$$

$$\text{and} \quad \log(1 + x) = x - \frac{x^2}{2} + \frac{x^3}{3} + \cdots. \tag{15}$$

Appendix D. KL Minimisation between Gaussian Processes and Moment Matching

The difficult step of Power-EP is the projection step, that is how to find the posterior approximation $q(f)$ that minimises the KL divergence, $\mathrm{KL}[\tilde{p}(f)||q(f)]$, where $\tilde{p}(f)$ is the tilted distribution. We have chosen the form of the approximate posterior

$$q(f) = p(f_{\neq \mathbf{u}}|\mathbf{u})q(\mathbf{u}) = p(f_{\neq \mathbf{u}}|\mathbf{u})\frac{\exp(\theta_\mathbf{u}^\intercal \phi(\mathbf{u}))}{\mathcal{Z}(\theta_\mathbf{u})},$$

where $\mathcal{Z}(\theta_\mathbf{u}) = \int \exp(\theta_\mathbf{u}^\intercal \phi(\mathbf{u}))\mathrm{d}\mathbf{u}$ to ensure normalisation. We can then write the KL minimisation objective as follows,

$$\begin{aligned}
\mathcal{F}_{\mathrm{KL}} &= \mathrm{KL}[\tilde{p}(f)||q(f)] \\
&= \int \tilde{p}(f) \log \frac{\tilde{p}(f)}{q(f)} \mathrm{d}f \\
&= \langle \log \tilde{p}(f) \rangle_{\tilde{p}(f)} - \langle \log p(f_{\neq \mathbf{u}}|\mathbf{u}) \rangle_{\tilde{p}(f)} - \theta_\mathbf{u}^\intercal \langle \phi(\mathbf{u}) \rangle_{\tilde{p}(f)} + \log \mathcal{Z}(\theta_\mathbf{u}).
\end{aligned}$$

Since $p(f_{\neq \mathbf{u}}|\mathbf{u})$ is the prior conditional distribution, the only free parameter that controls our posterior approximation is $\theta_\mathbf{u}$. As such, to find $\theta_\mathbf{u}$ that minimises F_{KL}, we find the gradient of F_{KL} w.r.t $\theta_\mathbf{u}$ and set it to zero,

$$\begin{aligned}
0 = \frac{\mathrm{d}\mathcal{F}_{\mathrm{KL}}}{\mathrm{d}\theta_\mathbf{u}} &= -\langle \phi(\mathbf{u}) \rangle_{\tilde{p}(f)} + \frac{\mathrm{d} \log \mathcal{Z}(\theta_\mathbf{u})}{\mathrm{d}\theta_\mathbf{u}} \\
&= -\langle \phi(\mathbf{u}) \rangle_{\tilde{p}(f)} + \langle \phi(\mathbf{u}) \rangle_{q(\mathbf{u})},
\end{aligned}$$

therefore, $\langle \phi(\mathbf{u}) \rangle_{\tilde{p}(f)} = \langle \phi(\mathbf{u}) \rangle_{q(\mathbf{u})}$. That is, though we are trying to perform the KL minimisation between two Gaussian processes, due to the special form of the posterior approximation, *it is sufficient to only match the moments at the inducing points* $\mathbf{u}$.[4]

Appendix E. Shortcuts to the Moment Matching Equations

The most crucial step in Power-EP is the moment matching step as discussed above. This step can be done analytically for the Gaussian case, as the mean and covariance of the approximate posterior can be linked to the cavity distribution as follows,

$$\mathbf{m}_\mathbf{u} = \mathbf{m}_\mathbf{u}^{\backslash n} + \mathbf{V}_{\mathbf{u}f}^{\backslash n} \frac{\mathrm{d} \log \mathcal{Z}_{\mathrm{tilted},n}}{\mathrm{d}\mathbf{m}_f^{\backslash n}},$$

$$\mathbf{V}_\mathbf{u} = \mathbf{V}_\mathbf{u}^{\backslash n} + \mathbf{V}_{\mathbf{u}f}^{\backslash n} \frac{\mathrm{d}^2 \log \mathcal{Z}_{\mathrm{tilted},n}}{\mathrm{d}\mathbf{m}_f^{\backslash n,2}} \mathbf{V}_{f\mathbf{u}}^{\backslash n},$$

4. We can show that this condition gives the minimum of $\mathcal{F}_{\mathrm{KL}}$ by computing the second derivative.

where $\mathcal{Z}_{\text{tilted},n}$ is the normaliser of the tilted distribution,

$$\begin{aligned}\mathcal{Z}_{\text{tilted},n} &= \int q^{\backslash n}(f)p(y_n|f)\mathrm{d}f \\ &= \int q^{\backslash n}(f)p(y_n|f_n)\mathrm{d}f \\ &= \int q^{\backslash n}(f_n)p(y_n|f_n)\mathrm{d}f_n.\end{aligned}$$

In words, $\mathcal{Z}_{\text{tilted},n}$ only depends on the marginal distribution of the cavity process, $q^{\backslash n}(f_n)$, simplifying the moment matching equations above,

$$\mathbf{m}_{\mathbf{u}} = \mathbf{m}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}f_n}^{\backslash n}\frac{\mathrm{d}\log\mathcal{Z}_{\text{tilted},n}}{\mathrm{d}m_{f_n}^{\backslash n}}, \tag{16}$$

$$\mathbf{V}_{\mathbf{u}} = \mathbf{V}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}f_n}^{\backslash n}\frac{\mathrm{d}^2\log\mathcal{Z}_{\text{tilted},n}}{\mathrm{d}m_{f_n}^{\backslash n,2}}\mathbf{V}_{f_n\mathbf{u}}^{\backslash n}. \tag{17}$$

We can rewrite the cross-covariance $\mathbf{V}_{\mathbf{u}f_n}^{\backslash n} = \mathbf{V}_{\mathbf{u}}^{\backslash n}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}f_n}$. We also note that, $m_{f_n}^{\backslash n} = \mathbf{K}_{f_n\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{m}_{\mathbf{u}}^{\backslash n}$, resulting in,

$$\begin{aligned}\frac{\mathrm{d}\log\mathcal{Z}_{\text{tilted},n}}{\mathrm{d}\mathbf{m}_{\mathbf{u}}^{\backslash n}} &= \frac{\mathrm{d}\log\mathcal{Z}_{\text{tilted},n}}{\mathrm{d}m_{f_n}^{\backslash n}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}f_n}, \\ \frac{\mathrm{d}\log\mathcal{Z}_{\text{tilted},n}}{\mathrm{d}\mathbf{V}_{\mathbf{u}}^{\backslash n}} &= \mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}f_n}\frac{\mathrm{d}^2\log\mathcal{Z}_{\text{tilted},n}}{\mathrm{d}m_{f_n}^{\backslash n,2}}\mathbf{K}_{f_n\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}.\end{aligned}$$

Substituting these results back in Equations (16) and (17), we obtain

$$\mathbf{m}_{\mathbf{u}} = \mathbf{m}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}}^{\backslash n}\frac{\mathrm{d}\log\mathcal{Z}_{\text{tilted},n}}{\mathrm{d}\mathbf{m}_{\mathbf{u}}^{\backslash n}}, \tag{18}$$

$$\mathbf{V}_{\mathbf{u}} = \mathbf{V}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}}^{\backslash n}\frac{\mathrm{d}^2\log\mathcal{Z}_{\text{tilted},n}}{\mathrm{d}\mathbf{m}_{\mathbf{u}}^{\backslash n,2}}\mathbf{V}_{\mathbf{u}}^{\backslash n}. \tag{19}$$

Therefore, using Equations (16) and (17), or Equations (18) and (19) are equivalent in our approximation settings.

Appendix F. Full Derivation of the Power-EP Procedure

We provide the full derivation of the Power-EP procedure in this section. We follow the derivation in (Qi et al., 2010) closely, but provide a clearer exposition and details how to get to each step used in the implementation, and how to handle powered/fractional deletion and update in Power-EP.

F.1 Optimal Factor Parameterisation

We start by defining the approximate factors to be in natural parameter form as this makes it simple to combine and delete them, $t_n(\mathbf{u}) = \tilde{\mathcal{N}}(\mathbf{u}; z_n, \mathbf{T}_{1,n}, \mathbf{T}_{2,n}) = z_n\exp(\mathbf{u}^\intercal\mathbf{T}_{1,n} - \frac{1}{2}\mathbf{u}^\intercal\mathbf{T}_{2,n}\mathbf{u})$. We initially consider full rank $\mathbf{T}_{2,n}$, but will show that the optimal form is rank 1.

The next goal is to relate these parameters to the approximate GP posterior. The approximate posterior over the pseudo-outputs has natural parameters $\mathbf{T}_{1,\mathbf{u}} = \sum_n \mathbf{T}_{1,n}$ and $\mathbf{T}_{2,\mathbf{u}} = \mathbf{K}_{\mathbf{uu}}^{-1} + \sum_n \mathbf{T}_{2,n}$. This induces an approximate GP posterior with mean and covariance function,

$$\begin{aligned}m_{\mathrm{f}} &= \mathbf{K}_{\mathrm{f}\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{T}_{2,\mathbf{u}}^{-1}\mathbf{T}_{1,\mathbf{u}} = \mathbf{K}_{\mathrm{f}\mathbf{u}}\gamma, \\ V_{\mathrm{ff}'} &= \mathbf{K}_{\mathrm{ff}'} - \mathbf{Q}_{\mathrm{ff}'} + \mathbf{K}_{\mathrm{f}\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{T}_{2,\mathbf{u}}^{-1}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}\mathrm{f}'} = \mathbf{K}_{\mathrm{ff}'} - \mathbf{K}_{\mathrm{f}\mathbf{u}}\beta\mathbf{K}_{\mathbf{u}\mathrm{f}'},\end{aligned}$$

where γ and β are likelihood-dependent terms we wish to store and update using PEP; γ and β fully specify the approximate posterior.

Deletion step: The cavity for data point n, $q^{\backslash n}(f) \propto q^*(f)/t_n^\alpha(\mathbf{u})$, has a similar form to the posterior, but the natural parameters are modified by the deletion, $\mathbf{T}_{1,\mathbf{u}}^{\backslash n} = \mathbf{T}_{1,\mathbf{u}} - \alpha\mathbf{T}_{1,n}$ and $\mathbf{T}_{2,\mathbf{u}}^{\backslash n} = \mathbf{T}_{2,\mathbf{u}} - \alpha\mathbf{T}_{2,n}$, yielding a new mean and covariance function

$$\begin{aligned}m_{\mathrm{f}}^{\backslash n} &= \mathbf{K}_{\mathrm{f}\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{T}_{2,\mathbf{u}}^{\backslash n,-1}\mathbf{T}_{1,\mathbf{u}}^{\backslash n} = \mathbf{K}_{\mathrm{f}\mathbf{u}}\gamma^{\backslash n}, \\ V_{\mathrm{ff}'}^{\backslash n} &= \mathbf{K}_{\mathrm{ff}'} - \mathbf{Q}_{\mathrm{ff}'} + \mathbf{K}_{\mathrm{f}\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{T}\backslash n, -1_{2,\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}\mathrm{f}'} = \mathbf{K}_{\mathrm{ff}'} - \mathbf{K}_{\mathrm{f}\mathbf{u}}\beta^{\backslash n}\mathbf{K}_{\mathbf{u}\mathrm{f}'}.\end{aligned}$$

Projection step: The central step in Power EP is the projection step. Obtaining the new approximate unnormalised posterior $q^*(f)$ such that $\mathrm{KL}[\tilde{p}(f)||q^*(f)]$ is minimised would naïvely appear intractable. Fortunately, as shown in the previous section, because of the structure of the approximate posterior, $q(f) = p(f_{\neq\mathbf{u}}|\mathbf{u})q(\mathbf{u})$, the objective, $\mathrm{KL}[\tilde{p}(f)||q^*(f)]$ is minimised when $\mathbb{E}_{\tilde{p}(f)}[\phi(\mathbf{u})] = \mathbb{E}_{q(u)}[\phi(\mathbf{u})]$, where $\phi(\mathbf{u})$ are the sufficient statistics, that is when the moments at the pseudo-inputs are matched. This is the central result from which computational savings are derived. Furthermore, this moment matching condition would appear to necessitate computation of a set of integrals to find the zeroth, first and second moments. Using results from the previous section simplifies and provides the following shortcuts,

$$\mathbf{m}_{\mathbf{u}} = \mathbf{m}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}\frac{\mathrm{d}\log\tilde{Z}_n}{\mathrm{d}m_{\mathrm{f}_n}^{\backslash n}}, \tag{20}$$

$$\mathbf{V}_{\mathbf{u}} = \mathbf{V}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}\frac{\mathrm{d}^2\log\tilde{Z}_n}{\mathrm{d}(m_{\mathrm{f}_n}^{\backslash n})^2}\mathbf{V}_{\mathrm{f}_n\mathbf{u}}^{\backslash n}, \tag{21}$$

where $\log\tilde{Z}_n = \log\mathbb{E}_{q^{\backslash n}(f)}[p^\alpha(y_n|\mathrm{f}_n)]$ is the log-normaliser of the tilted distribution.

Update step: Having computed the new approximate posterior, the fractional approximate factor $t_{n,\text{new}}(\mathbf{u}) = q^*(f)/q^{\backslash n}(f)$ can be straightforwardly obtained, resulting in,

$$\mathbf{T}_{1,n,\text{new}} = \mathbf{V}_{\mathbf{u}}^{-1}\mathbf{m}_{\mathbf{u}} - \mathbf{V}_{\mathbf{u}}^{\backslash n,-1}\mathbf{m}_{\mathbf{u}}^{\backslash n}, \tag{22}$$

$$\mathbf{T}_{2,n,\text{new}} = \mathbf{V}_{\mathbf{u}}^{-1} - \mathbf{V}_{\mathbf{u}}^{\backslash n,-1}, \tag{23}$$

$$z_n^\alpha = \tilde{Z}_n\exp(\mathcal{G}_{q_*^{\backslash n}(\mathbf{u})} - \mathcal{G}_{q^*(\mathbf{u})}),$$

where $\mathcal{G}_{\tilde{\mathcal{N}}(\mathbf{u};z,\mathbf{T}_1,\mathbf{T}_2)} = \int \tilde{\mathcal{N}}(\mathbf{u}; z, \mathbf{T}_1, \mathbf{T}_2)\mathrm{d}\mathbf{u}$. Let $d_1 = \frac{\mathrm{d}\log \tilde{Z}_n}{\mathrm{d}m_{\mathrm{f}_n}^{\backslash n}}$ and $d_2 = \frac{\mathrm{d}^2\log \tilde{Z}_n}{\mathrm{d}(m_{\mathrm{f}_n}^{\backslash n})^2}$. Using Equation (9) and Equation (21), we have,

$$\mathbf{V}_{\mathbf{u}}^{-1} - \mathbf{V}_{\mathbf{u}}^{\backslash n,-1} = -\mathbf{V}_{\mathbf{u}}^{\backslash n,-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}\left[d_2^{-1} + \mathbf{V}_{\mathrm{f}_n\mathbf{u}}^{\backslash n}\mathbf{V}_{\mathbf{u}}^{\backslash n,-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}\right]^{-1}\mathbf{V}_{\mathrm{f}_n\mathbf{u}}^{\backslash n}\mathbf{V}_{\mathbf{u}}^{\backslash n,-1}. \tag{24}$$

Let $v_n = \alpha(-d_2^{-1} - \mathbf{V}_{\mathrm{f}_n\mathbf{u}}^{\backslash n}\mathbf{V}_{\mathbf{u}}^{\backslash n,-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n})$, and $\mathbf{w}_n = \mathbf{V}_{\mathbf{u}}^{\backslash n,-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}$. Combining Equation (24) and Equation (23) gives

$$\mathbf{T}_{2,n,\mathrm{new}} = \mathbf{w}_n\alpha v_n^{-1}\mathbf{w}_n^\intercal. \tag{25}$$

At convergence, we have $t_n(\mathbf{u})^\alpha = t_{n,\mathrm{new}}(\mathbf{u})$, hence $\mathbf{T}_{2,n} = \mathbf{w}_n v_n^{-1}\mathbf{w}_n^\intercal$. In words, $\mathbf{T}_{2,n}$ is optimally a rank-1 matrix. Note that,

$$\begin{aligned}
\mathbf{w}_n &= \mathbf{V}_{\mathbf{u}}^{\backslash n,-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n} \\
&= (\mathbf{K}_{\mathbf{uu}} - \mathbf{K}_{\mathbf{uu}}\beta^{\backslash n}\mathbf{K}_{\mathbf{uu}})^{-1}(\mathbf{K}_{\mathbf{u}\mathrm{f}_n} - \mathbf{K}_{\mathbf{uu}}\beta^{\backslash n}\mathbf{K}_{\mathbf{u}\mathrm{f}_n}) \\
&= \mathbf{K}_{\mathbf{uu}}^{-1}(\mathrm{I} - \mathbf{K}_{\mathbf{uu}}\beta^{\backslash n})^{-1}(\mathrm{I} - \mathbf{K}_{\mathbf{uu}}\beta^{\backslash n})\mathbf{K}_{\mathbf{u}\mathrm{f}_n} \\
&= \mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}\mathrm{f}_n}.
\end{aligned}$$

Using Equation (20) an Equation (25) gives,

$$\begin{aligned}
\mathbf{V}_{\mathbf{u}}^{-1}\mathbf{m}_{\mathbf{u}} &= (\mathbf{V}_{\mathbf{u}}^{\backslash n,-1} + \mathbf{w}_n\alpha v_n^{-1}\mathbf{w}_n^\intercal)(\mathbf{m}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_1) \\
&= \mathbf{V}_{\mathbf{u}}^{\backslash n,-1}\mathbf{m}_{\mathbf{u}}^{\backslash n} + \mathbf{w}_n\alpha v_n^{-1}\mathbf{w}_n^\intercal\mathbf{m}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}}^{\backslash n,-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_1 + \mathbf{w}_n\alpha v_n^{-1}\mathbf{w}_n^\intercal\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_1.
\end{aligned}$$

Substituting this result into Equation (22),

$$\begin{aligned}
\mathbf{T}_{1,n,\mathrm{new}} &= \mathbf{V}_{\mathbf{u}}^{-1}\mathbf{m}_{\mathbf{u}} - \mathbf{V}_{\mathbf{u}}^{\backslash n,-1}\mathbf{m}_{\mathbf{u}}^{\backslash n} \\
&= \mathbf{w}_n\alpha v_n^{-1}\mathbf{w}_n^\intercal\mathbf{m}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}}^{\backslash n,-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_1 + \mathbf{w}_n\alpha v_n^{-1}\mathbf{w}_n^\intercal\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_1 \\
&= \mathbf{w}_n\alpha v_n^{-1}\left(\mathbf{w}_n^\intercal\mathbf{m}_{\mathbf{u}}^{\backslash n} + d_1 v_n/\alpha + \mathbf{w}_n^\intercal\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_1\right).
\end{aligned}$$

Let $\mathbf{T}_{1,n,\mathrm{new}} = \mathbf{w}_n\alpha v_n^{-1}g_n$, we obtain,

$$g_n = -\frac{d_1}{d_2} + \mathbf{K}_{\mathrm{f}_n\mathbf{u}}\gamma^{\backslash n}.$$

At convergence, $\mathbf{T}_{1,n} = \mathbf{w}_n v_n^{-1}g_n$. Re-writing the form of the approximate factor using $\mathbf{T}_{1,n}$ and $\mathbf{T}_{2,n}$ at convergence,

$$\begin{aligned}
t_n(\mathbf{u}) &= \tilde{\mathcal{N}}(\mathbf{u}; z_n, \mathbf{T}_{1,n}, \mathbf{T}_{2,n}) \\
&= z_n \exp(\mathbf{u}^\intercal\mathbf{T}_{1,n} - \frac{1}{2}\mathbf{u}^\intercal\mathbf{T}_{2,n}\mathbf{u}) \\
&= z_n \exp(\mathbf{u}^\intercal\mathbf{w}_n v_n^{-1}g_n - \frac{1}{2}\mathbf{u}^\intercal\mathbf{w}_n v_n^{-1}\mathbf{w}_n^\intercal\mathbf{u}).
\end{aligned}$$

As a result, the minimal and simplest way to parameterise the approximate factor is $t_n(\mathbf{u}) = \tilde{z}_n\mathcal{N}(\mathbf{w}_n^\intercal\mathbf{u}; g_n, v_n) = \tilde{z}_n\mathcal{N}(\mathbf{K}_{\mathrm{f}_n\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{u}; g_n, v_n)$, where g_n and v_n are scalars, resulting in a significant memory saving compared to the parameterisation using $\mathbf{T}_{1,n}$ and $\mathbf{T}_{2,n}$.

F.2 Projection

We now recall the update equations in the projection step (Equations (20) and (21)):

$$\begin{aligned}
\mathbf{m}_{\mathbf{u}} &= \mathbf{m}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_1, \\
\mathbf{V}_{\mathbf{u}} &= \mathbf{V}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_2\mathbf{V}_{\mathrm{f}_n\mathbf{u}}^{\backslash n}.
\end{aligned}$$

Note that:

$$\begin{aligned}
\mathbf{m}_{\mathbf{u}} &= \mathbf{K}_{\mathbf{uu}}\gamma, \\
\mathbf{V}_{\mathbf{u}} &= \mathbf{K}_{\mathbf{uu}} - \mathbf{K}_{\mathbf{uu}}\beta\mathbf{K}_{\mathbf{uu}},
\end{aligned}$$

and

$$\begin{aligned}
\mathbf{m}_{\mathbf{u}}^{\backslash n} &= \mathbf{K}_{\mathbf{uu}}\gamma^{\backslash n}, \\
\mathbf{V}_{\mathbf{u}}^{\backslash n} &= \mathbf{K}_{\mathbf{uu}} - \mathbf{K}_{\mathbf{uu}}\beta^{\backslash n}\mathbf{K}_{\mathbf{uu}}.
\end{aligned}$$

Using these results, we can convert the update for the mean and covariance, $\mathbf{m}_{\mathbf{u}}$ and $\mathbf{V}_{\mathbf{u}}$, into an update for γ and β,

$$\begin{aligned}
\gamma &= \mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{m}_{\mathbf{u}} \\
&= \mathbf{K}_{\mathbf{uu}}^{-1}(\mathbf{m}_{\mathbf{u}}^{\backslash n} + \mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_1) \\
&= \gamma^{\backslash n} + \mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_1, \text{ and} \qquad (26) \\
\beta &= \mathbf{K}_{\mathbf{uu}}^{-1}(\mathbf{K}_{\mathbf{uu}} - \mathbf{V}_{\mathbf{u}})\mathbf{K}_{\mathbf{uu}}^{-1} \\
&= \mathbf{K}_{\mathbf{uu}}^{-1}(\mathbf{K}_{\mathbf{uu}} - \mathbf{V}_{\mathbf{u}}^{\backslash n} - \mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_2\mathbf{V}_{\mathrm{f}_n\mathbf{u}}^{\backslash n})\mathbf{K}_{\mathbf{uu}}^{-1} \\
&= \beta^{\backslash n} - \mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}d_2\mathbf{V}_{\mathrm{f}_n\mathbf{u}}^{\backslash n}\mathbf{K}_{\mathbf{uu}}^{-1}. \qquad (27)
\end{aligned}$$

F.3 Deletion Step

Finally, we present how deletion might be accomplished. One direct approach to this step is to divide out the cavity from the cavity, that is,

$$q^{\backslash n}(f) \propto \frac{q(f)}{t_n^\alpha(\mathbf{u})} = \frac{p(f_{\neq\mathbf{u}}|\mathbf{u})q(\mathbf{u})}{t_n^\alpha(\mathbf{u})} = p(f_{\neq\mathbf{u}}|\mathbf{u})q^{\backslash n}(\mathbf{u}).$$

Instead, we use an alternative using the KL minimisation as used in (Qi et al., 2010), by realising that doing this will result in an identical outcome as the direct approach since the factor and distributions are Gaussian. Furthermore, we can re-use results from the projection and inclusion steps, by simply swapping the quantities and negating the site approximation variance. In particular, we present projection and deletion side-by-side, to facilitate the comparison,

$$\begin{aligned}
&\text{Projection:} \quad q(f) \approx q^{\backslash n}(f)p(y_n|\mathrm{f}_n), \\
&\text{Deletion:} \quad q^{\backslash n}(f) \propto q(f)\frac{1}{t_n^\alpha(\mathbf{u})}.
\end{aligned}$$

The projection step minimises the KL between the LHS and RHS while moment matching, to get $q(f)$. We would like to do the same for the deletion step to find $q^{\backslash n}(f)$, and thus reuse the same moment matching results for γ and β with some modifications.

Our task will be to reuse Equations (26) and (27), the moment matching equations in γ and β. We have two differences to account for. Firstly, we need to change any uses of the parameters of the cavity distribution to the parameters of the approximate posterior, $\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n}$ to $\mathbf{V}_{\mathbf{u}\mathrm{f}_n}$, $\gamma^{\backslash n}$ to γ and $\beta^{\backslash n}$ to β. This is the equivalent of re-deriving the entire projection operation while swapping the symbols (and quantities) for the cavity and the full distribution. Secondly, the derivatives d_1 and d_2 are different here, as

$$\log \tilde{Z}_n = \log \int q(f) \frac{1}{t_n^{\alpha}(\mathbf{u})} \mathrm{d}f.$$

Now, we note

$$\begin{aligned}
\frac{1}{t_n(\mathbf{u})} &\propto \frac{1}{\mathcal{N}^{\alpha}(\mathbf{w}_n^{\intercal}\mathbf{u}; g_n, v_n)} \\
&\propto \frac{1}{\exp\left(-\frac{\alpha}{2} v_n^{-1} \left(\mathbf{w}_n^{\intercal}\mathbf{u} - g_n\right)^2\right)} \\
&= \exp\left(\frac{1}{2}\alpha v_n^{-1} \left(\mathbf{w}_n^{\intercal}\mathbf{u} - g_n\right)^2\right) \\
&\propto \mathcal{N}(\mathbf{w}_n^{\intercal}\mathbf{u}; g_n, -v_n/\alpha).
\end{aligned}$$

Then we obtain the derivatives of $\log \tilde{Z}_n$

$$\begin{aligned}
\tilde{d}_2 &= \frac{\mathrm{d}^2 \log \tilde{Z}_n}{\mathrm{d}m_{\mathrm{f}_n}^2} = -\left[\mathbf{K}_{\mathrm{f}_n,\mathbf{u}}\mathbf{K}_{\mathbf{u},\mathbf{u}}^{-1}\mathbf{K}_{\mathbf{u},\mathrm{f}_n} - \mathbf{K}_{\mathrm{f}_n,\mathbf{u}}\beta\mathbf{K}_{\mathbf{u},\mathrm{f}_n} - v_n/\alpha\right]^{-1}, \\
\tilde{d}_1 &= \frac{\mathrm{d}\log \tilde{Z}_n}{\mathrm{d}m_{\mathrm{f}_n}} = (\mathbf{K}_{\mathrm{f}_n,\mathbf{u}}\gamma - g_n)\tilde{d}_2.
\end{aligned}$$

Putting the above results together, we obtain,

$$\begin{aligned}
\gamma^{\backslash n} &= \gamma + \mathbf{K}_{\mathbf{u}\mathbf{u}}^{-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}\tilde{d}_1, \text{ and} \\
\beta^{\backslash n} &= \beta - \mathbf{K}_{\mathbf{u}\mathbf{u}}^{-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}\tilde{d}_2\mathbf{V}_{\mathrm{f}_n\mathbf{u}}\mathbf{K}_{\mathbf{u}\mathbf{u}}^{-1}.
\end{aligned}$$

F.4 Summary of the PEP Procedure

We summarise here the key steps and equations that we have obtained, that are used in the implementation:

1. Initialise the parameters: $\{g_n = 0\}_{n=1}^N$, $\{v_n = \infty\}_{n=1}^N$, $\gamma = \mathbf{0}_{M\times 1}$ and $\beta = \mathbf{0}_{M\times M}$
2. Loop through all data points until convergence:

(a) Deletion step: find $\gamma^{\backslash n}$ and $\beta^{\backslash n}$

$$\begin{aligned}
\gamma^{\backslash n} &= \gamma + \mathbf{K}_{\mathbf{u}\mathbf{u}}^{-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}\tilde{d}_1, \text{ and} \\
\beta^{\backslash n} &= \beta - \mathbf{K}_{\mathbf{u}\mathbf{u}}^{-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}\tilde{d}_2\mathbf{V}_{\mathrm{f}_n\mathbf{u}}\mathbf{K}_{\mathbf{u}\mathbf{u}}^{-1}.
\end{aligned}$$

(b) Projection step: find γ and β

$$\begin{aligned}
\gamma &= \gamma^{\backslash n} + \mathbf{K}_{\mathbf{u}\mathbf{u}}^{-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n} d_1, \\
\beta &= \beta^{\backslash n} - \mathbf{K}_{\mathbf{u}\mathbf{u}}^{-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n} d_2\mathbf{V}_{\mathrm{f}_n\mathbf{u}}^{\backslash n}\mathbf{K}_{\mathbf{u}\mathbf{u}}^{-1}.
\end{aligned}$$

(c) Update step: find $g_{n,\text{new}}$ and $v_{n,\text{new}}$

$$\begin{aligned}
g_{n,\text{new}} &= -\frac{d_1}{d_2} + \mathbf{K}_{\mathrm{f}_n\mathbf{u}}\gamma^{\backslash n}, \\
v_{n,\text{new}} &= -d_2^{-1} - \mathbf{V}_{\mathrm{f}_n\mathbf{u}}^{\backslash n}\mathbf{V}_{\mathbf{u}}^{\backslash n,-1}\mathbf{V}_{\mathbf{u}\mathrm{f}_n}^{\backslash n},
\end{aligned}$$

and parameters for the full factor,

$$\begin{aligned}
v_n &\leftarrow (v_{n,\text{new}}^{-1} + (1-\alpha)v_n^{-1})^{-1}, \\
g_n &\leftarrow v_n(g_{n,\text{new}}v_{n,\text{new}}^{-1} + (1-\alpha)g_n v_n^{-1}).
\end{aligned}$$

Appendix G. Power-EP Energy for Sparse GP Regression and Classification

The Power-EP procedure gives an approximate marginal likelihood, which is the negative Power-EP energy, as follows,

$$\mathcal{F} = \mathcal{G}(q_*(\mathbf{u})) - \mathcal{G}(p_*(\mathbf{u})) + \frac{1}{\alpha}\sum_n \left[\log \mathcal{Z}_{\text{tilted},n} + \mathcal{G}(q_*^{\backslash n}(\mathbf{u})) - \mathcal{G}(q_*(\mathbf{u}))\right],$$

where $\mathcal{G}(q_*(\mathbf{u}))$ is the log-normaliser of the approximate posterior, that is,

$$\begin{aligned}
\mathcal{G}(q_*(\mathbf{u})) &= \log \int p(f_{\neq\mathbf{u}}|\mathbf{u}) \exp(\theta_{\mathbf{u}}^{\intercal}\phi(\mathbf{u})) \mathrm{d}f_{\neq\mathbf{u}}\mathrm{d}\mathbf{u} \\
&= \log \int \exp(\theta_{\mathbf{u}}^{\intercal}\phi(\mathbf{u}))\mathrm{d}\mathbf{u} \\
&= \frac{M}{2}\log(2\pi) + \frac{1}{2}\log|\mathbf{V}| + \frac{1}{2}\mathbf{m}^{\intercal}\mathbf{V}^{-1}\mathbf{m},
\end{aligned} \tag{28}$$

where $\mathbf{m}$ and $\mathbf{V}$ are the mean and covariance of the posterior distribution over $\mathbf{u}$, respectively. Similarly,

$$\begin{aligned}
\mathcal{G}(q_*^{\backslash n}(\mathbf{u})) &= \frac{M}{2}\log(2\pi) + \frac{1}{2}\log|\mathbf{V}_{\text{cav},n}| + \frac{1}{2}\mathbf{m}_{\text{cav},n}^{\intercal}\mathbf{V}_{\text{cav},n}^{-1}\mathbf{m}_{\text{cav},n}, \\
\text{and } \mathcal{G}(p_*(\mathbf{u})) &= \frac{M}{2}\log(2\pi) + \frac{1}{2}\log|\mathbf{K}_{\mathbf{u}\mathbf{u}}|.
\end{aligned} \tag{29}$$

Finally, $\log \mathcal{Z}_{\text{tilted},n}$ is the log-normalising constant of the tilted distribution,

$$\begin{aligned}\log \mathcal{Z}_{\text{tilted}} &= \log \int q_{\text{cav}}(f) p^{\alpha}(y_n|f) \mathrm{d}f \\ &= \log \int p(f_{\neq \mathbf{u}}|\mathbf{u}) q_{\text{cav}}(\mathbf{u}) p^{\alpha}(y_n|f) \mathrm{d}f_{\neq \mathbf{u}} \mathrm{d}\mathbf{u} \\ &= \log \int p(f_n|\mathbf{u}) q_{\text{cav}}(\mathbf{u}) p^{\alpha}(y_n|f_n) \mathrm{d}f_n \mathrm{d}\mathbf{u}. \end{aligned} \tag{30}$$

Next, we can write down the form of the natural parameters of the approximate posterior and the cavity distribution, based on the approximate factor's parameters, as follows,

$$\mathbf{V}^{-1} = \mathbf{K}_{\mathbf{uu}}^{-1} + \sum_i \mathbf{w}_i \tau_i \mathbf{w}_i^{\intercal}, \tag{31}$$

$$\mathbf{V}^{-1}\mathbf{m} = \sum_i \mathbf{w}_i \tau_i \tilde{y}_i, \tag{32}$$

$$\mathbf{V}_{\text{cav},n}^{-1} = \mathbf{V}^{-1} - \alpha \mathbf{w}_n \tau_n \mathbf{w}_n^{\intercal}, \tag{33}$$

$$\mathbf{V}_{\text{cav},\mathbf{n}}{}^{-1}\mathbf{m}_{\text{cav},n} = \mathbf{V}^{-1}\mathbf{m} - \alpha \mathbf{w}_n \tau_n g_n. \tag{34}$$

Note that $\tau_i \coloneqq v_i^{-1}$. Using Equation (11) and Equation (33) gives,

$$\mathbf{V}_{\text{cav},n} = \mathbf{V} + \frac{\mathbf{V}\mathbf{w}_n \alpha \tau_n \mathbf{w}_n^{\intercal}\mathbf{V}}{1 - \mathbf{w}_n^{\intercal}\alpha\tau_n \mathbf{V}\mathbf{w}_n}. \tag{35}$$

Using Equation (12) and Equation (33) gives,

$$\log\det(\mathbf{V}_{\text{cav},n}) = \log\det(\mathbf{V}) - \log(1 - \mathbf{w}_n^{\intercal}\alpha\tau_n\mathbf{V}\mathbf{w}_n). \tag{36}$$

Substituting Equation (35) and Equation (36) back to Equation (29) results in,

$$\begin{aligned}\mathcal{G}(q_*^{\setminus n}(\mathbf{u})) = &\frac{M}{2}\log(2\pi) + \frac{1}{2}\log\det(\mathbf{V}) + \frac{1}{2}\mathbf{m}^{\intercal}\mathbf{V}^{-1}\mathbf{m} \\ &- \frac{1}{2}\log(1 - \mathbf{w}_n^{\intercal}\alpha\tau_n\mathbf{V}\mathbf{w}_n) + \frac{1}{2}\frac{\mathbf{m}^{\intercal}\mathbf{w}_n\alpha\tau_n\mathbf{w}_n^{\intercal}\mathbf{m}}{1 - \mathbf{w}_n^{\intercal}\alpha\tau_n\mathbf{V}\mathbf{w}_n} \\ &+ \frac{1}{2}g_n\alpha\tau_n\mathbf{w}_n^{\intercal}\mathbf{V}_{\text{cav},n}\mathbf{w}_n\alpha\tau_n g_n - g_n\alpha\tau_n\mathbf{w}_n^{\intercal}\mathbf{V}_{\text{cav},n}\mathbf{V}^{-1}\mathbf{m}. \end{aligned} \tag{37}$$

We now plug the above result back into the approximate marginal likelihood, yielding,

$$\begin{aligned}\mathcal{F} = &\frac{1}{2}\log|\mathbf{V}| + \frac{1}{2}\mathbf{m}^{\intercal}\mathbf{V}^{-1}\mathbf{m} - \frac{1}{2}\log|\mathbf{K}_{\mathbf{uu}}| + \frac{1}{\alpha}\sum_n \log \mathcal{Z}_{\text{tilted},n} \\ &+ \sum_n \left[-\frac{1}{2\alpha}\log(1 - \mathbf{w}_n^{\intercal}\alpha\tau_n\mathbf{V}\mathbf{w}_n) + \frac{1}{2}\frac{\mathbf{m}^{\intercal}\mathbf{w}_n\tau_n\mathbf{w}_n^{\intercal}\mathbf{m}}{1 - \mathbf{w}_n^{\intercal}\alpha\tau_n\mathbf{V}\mathbf{w}_n} \right. \\ &\left. + \frac{1}{2}g_n\tau_n\mathbf{w}_n^{\intercal}\mathbf{V}_{\text{cav},n}\mathbf{w}_n\alpha\tau_n g_n - g_n\tau_n\mathbf{w}_n^{\intercal}\mathbf{V}_{\text{cav},n}\mathbf{V}^{-1}\mathbf{m} \right]. \end{aligned} \tag{38}$$

G.1 Regression

We have shown in the previous section that the fixed point solution of the Power-EP iterations can be obtained analytically for the regression case, $g_n = y_n$ and $\tau_n^{-1} = d_n = \alpha(K_{f_n f_n} - \mathbf{K}_{f_n\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}f_n}) + \sigma_y^2$. Crucially, we can obtain a closed form expression for $\log \mathcal{Z}_{\text{tilted},n}$,

$$\log \mathcal{Z}_{\text{tilted},n} = -\frac{\alpha}{2}\log(2\pi\sigma_y^2) + \frac{1}{2}\log(\sigma_y^2) - \frac{1}{2}\log(\alpha v_n + \sigma_y^2) - \frac{1}{2}\frac{(y_n - \mu_n)^2}{v_n + \sigma_y^2/\alpha},$$

where $\mu_n = \mathbf{w}_n^{\intercal}\mathbf{m}_{\text{cav}} = \mathbf{w}_n^{\intercal}\mathbf{V}_{\text{cav}}(\mathbf{V}^{-1}\mathbf{m} - \mathbf{w}_n\alpha\tau_n y_n)$ and $v_n = \frac{d_n - \sigma_y^2}{\alpha} + \mathbf{w}_n^{\intercal}\mathbf{V}_{\text{cav}}\mathbf{w}_n$. We can therefore simplify the approximate marginal likelihood F further,

$$\begin{aligned}\mathcal{F} &= \frac{1}{2}\log|\mathbf{V}| + \frac{1}{2}\mathbf{m}^{\intercal}\mathbf{V}^{-1}\mathbf{m} - \frac{1}{2}\log|\mathbf{K}_{\mathbf{uu}}| \\ &\quad + \sum_n \left[-\frac{1}{2}\log(2\pi\sigma_y^2) + \frac{1}{2\alpha}\log\sigma_y^2 - \frac{1}{2\alpha}\log d_n - \frac{y_n^2}{2d_n} \right] \\ &= -\frac{N}{2}\log(2\pi) - \frac{1}{2}\log|\mathbf{D} + \mathbf{Q}_{\mathbf{ff}}| - \frac{1}{2}\mathbf{y}^T(\mathbf{D} + \mathbf{Q}_{\mathbf{ff}})^{-1}\mathbf{y} - \frac{1-\alpha}{2\alpha}\sum_n \log(\frac{d_n}{\sigma_y^2}), \end{aligned}$$

where $\mathbf{Q}_{\mathbf{ff}} = \mathbf{K}_{\mathbf{fu}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{uf}}$ and $\mathbf{D}$ is a diagonal matrix, $\mathbf{D}_{nn} = d_n$.

When $\alpha = 1$, the approximate marginal likelihood takes the same form as the FITC marginal likelihood,

$$\mathcal{F} = -\frac{N}{2}\log(2\pi) - \frac{1}{2}\log|\mathbf{D} + \mathbf{Q}_{\mathbf{ff}}| - \frac{1}{2}\mathbf{y}^T(\mathbf{D} + \mathbf{Q}_{\mathbf{ff}})^{-1}\mathbf{y},$$

where $\mathbf{D}_{nn} = d_n = K_{f_n f_n} - \mathbf{K}_{f_n\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}f_n} + \sigma_y^2$.

When α tends to 0, we have,

$$\lim_{\alpha\to 0}\frac{1-\alpha}{2\alpha}\sum_n \log(\frac{d_n}{\sigma_y^2}) = \frac{1}{2}\sum_n \lim_{\alpha\to 0}\frac{\log(1 + \alpha\frac{g_n}{\sigma_y^2})}{\alpha} = \frac{\sum_n h_n}{2\sigma_y^2},$$

where $h_n = K_{f_n f_n} - \mathbf{K}_{f_n\mathbf{u}}\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{K}_{\mathbf{u}f_n}$. Therefore,

$$\mathcal{F} = -\frac{N}{2}\log(2\pi) - \frac{1}{2}\log|\sigma_y^2\mathbf{I} + \mathbf{Q}_{\mathbf{ff}}| - \frac{1}{2}\mathbf{y}^T(\sigma_y^2\mathbf{I} + \mathbf{Q}_{\mathbf{ff}})^{-1}\mathbf{y} - \frac{\sum_n h_n}{2\sigma_y^2},$$

which is the variational lower bound of Titsias (Titsias, 2009).

G.2 Classification

In contrast to the regression case, the approximate marginal likelihood for classification cannot be simplified due to the non-Gaussian likelihood. Specifically, $\log \mathcal{Z}_{\text{tilted},n}$ is not analytically tractable, except when $\alpha = 1$ and the classification link function is the Gaussian CDF. However, this quantity can be evaluated numerically, using sampling or Gauss-Hermite quadrature, since it only involves a one-dimensional integral.

We now consider the case when α tends to 0 and verify that in such case the approximate marginal likelihood becomes the variational lower bound. We first find the limits of individual terms in Equation (38):

$$\lim_{\alpha\to 0} -\frac{1}{2\alpha}\log(1-\mathbf{w}_n^\intercal\alpha\tau_n\mathbf{V}\mathbf{w}_n) = \frac{1}{2}\mathbf{w}_n^\intercal\tau_n\mathbf{V}\mathbf{w}_n, \tag{39}$$

$$\frac{1}{2}\frac{\mathbf{m}^\intercal\mathbf{w}_n\tau_n\mathbf{w}_n^\intercal\mathbf{m}}{1-\mathbf{w}_n^\intercal\alpha\tau_n\mathbf{V}\mathbf{w}_n}\bigg|_{\alpha=0} = \frac{1}{2}\mathbf{m}^\intercal\mathbf{w}_n\tau_n\mathbf{w}_n^\intercal\mathbf{m}, \tag{40}$$

$$\frac{1}{2}g_n\tau_n\mathbf{w}_n^\intercal\mathbf{V}_{\text{cav},n}\mathbf{w}_n\alpha\tau_n g_n\bigg|_{\alpha=0} = 0, \tag{41}$$

$$-g_n\tau_n\mathbf{w}_n^\intercal\mathbf{V}_{\text{cav},n}\mathbf{V}^{-1}\mathbf{m}\bigg|_{\alpha=0} = -g_n\tau_n\mathbf{w}_n^\intercal\mathbf{m}. \tag{42}$$

We turn our attention to $\log\mathcal{Z}_{\text{tilted},n}$. First, we expand $p^\alpha(y_n|f_n)$ using Equation (14):

$$\begin{aligned} p^\alpha(y_n|f_n) &= \exp(\alpha\log p(y_n|f_n)) \\ &= 1+\alpha\log p(y_n|f_n)+\xi(\alpha^2). \end{aligned}$$

Substituting this result back into $\log\mathcal{Z}\text{tilted}/\alpha$ gives,

$$\begin{aligned} \frac{1}{\alpha}\log\mathcal{Z}_{\text{tilted}} &= \frac{1}{\alpha}\log\int p(f_n|\mathbf{u})q_{\text{cav}}(\mathbf{u})p^\alpha(y_n|f_n)\mathrm{d}f_n\mathrm{d}\mathbf{u} \\ &= \frac{1}{\alpha}\log\int p(f_n|\mathbf{u})q_{\text{cav}}(\mathbf{u})[1+\alpha\log p(y_n|f_n)+\xi(\alpha^2)]\mathrm{d}f_n\mathrm{d}\mathbf{u} \\ &= \frac{1}{\alpha}\log\left[1+\alpha\int p(f_n|\mathbf{u})q_{\text{cav}}(\mathbf{u})\log p(y_n|f_n)\mathrm{d}f_n\mathrm{d}\mathbf{u}+\alpha^2\xi(1)\right] \\ &= \frac{1}{\alpha}\left[\alpha\int p(f_n|\mathbf{u})q_{\text{cav}}(\mathbf{u})\log p(y_n|f_n)\mathrm{d}f_n\mathrm{d}\mathbf{u}+\alpha^2\xi(1)\right] \\ &= \int p(f_n|\mathbf{u})q_{\text{cav}}(\mathbf{u})\log p(y_n|f_n)\mathrm{d}f_n\mathrm{d}\mathbf{u}+\alpha\xi(1). \end{aligned}$$

Therefore,

$$\lim_{\alpha\to 0}\frac{1}{\alpha}\log\mathcal{Z}_{\text{tilted}} = \int p(f_n|\mathbf{u})q(\mathbf{u})\log p(y_n|f_n)\mathrm{d}f_n\mathrm{d}\mathbf{u}. \tag{43}$$

Putting these results into Equation (38), we obtain,

$$\begin{aligned} \mathcal{F} &= \frac{1}{2}\log|\mathbf{V}|+\frac{1}{2}\mathbf{m}^\intercal\mathbf{V}^{-1}\mathbf{m}-\frac{1}{2}\log|\mathbf{K}_{\mathbf{uu}}| \\ &\quad+\sum_n\frac{1}{2}\mathbf{w}_n^\intercal\tau_n\mathbf{V}\mathbf{w}_n+\frac{1}{2}\mathbf{m}^\intercal\mathbf{w}_n\tau_n\mathbf{w}_n^\intercal\mathbf{m}-g_n\tau_n\mathbf{w}_n^\intercal\mathbf{m}+\int p(f_n|\mathbf{u})q(\mathbf{u})\log p(y_n|f_n)\mathrm{d}f_n\mathrm{d}\mathbf{u} \\ &= \frac{1}{2}\log|\mathbf{V}|+\frac{1}{2}\mathbf{m}^\intercal\mathbf{V}^{-1}\mathbf{m}-\frac{1}{2}\log|\mathbf{K}_{\mathbf{uu}}|+\frac{1}{2}\mathbf{m}^\intercal(\mathbf{V}^{-1}-\mathbf{K}_{\mathbf{uu}}^{-1})\mathbf{m}-\mathbf{m}^\intercal\mathbf{V}^{-1}\mathbf{m} \\ &\quad+\sum_n\frac{1}{2}\mathbf{w}_n^\intercal\tau_n\mathbf{V}\mathbf{w}_n+\int p(f_n|\mathbf{u})q(\mathbf{u})\log p(y_n|f_n)\mathrm{d}f_n\mathrm{d}\mathbf{u} \\ &= \frac{1}{2}\log|\mathbf{V}|-\frac{1}{2}\mathbf{m}^\intercal\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{m}-\frac{1}{2}\log|\mathbf{K}_{\mathbf{uu}}|+\sum_n\frac{1}{2}\mathbf{w}_n^\intercal\tau_n\mathbf{V}\mathbf{w}_n \\ &\quad+\sum_n\int p(f_n|\mathbf{u})q(\mathbf{u})\log p(y_n|f_n)\mathrm{d}f_n\mathrm{d}\mathbf{u}. \end{aligned} \tag{44}$$

We now write down the evidence lower bound of the global variational approach of Titsias (Titsias, 2009), as applied to the classification case (Hensman et al., 2015),

$$\mathcal{F}_{\text{VFE}} = -\text{KL}[q(\mathbf{u})||p(\mathbf{u})]+\sum_n\int p(f_n|\mathbf{u})q(\mathbf{u})\log p(y_n|f_n)\mathrm{d}f_n\mathrm{d}\mathbf{u}, \tag{45}$$

where

$$\begin{aligned} -\text{KL}[q(\mathbf{u})||p(\mathbf{u})] &= -\frac{1}{2}\text{trace}(\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{V})-\frac{1}{2}\mathbf{m}^\intercal\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{m}+\frac{M}{2}-\frac{1}{2}\log|\mathbf{K}_{\mathbf{uu}}|+\frac{1}{2}\log|\mathbf{V}| \\ &= -\frac{1}{2}\text{trace}([\mathbf{V}^{-1}-\sum_n\mathbf{w}_n\tau_n\mathbf{w}_n]\mathbf{V})-\frac{1}{2}\mathbf{m}^\intercal\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{m} \\ &\quad+\frac{M}{2}-\frac{1}{2}\log|\mathbf{K}_{\mathbf{uu}}|+\frac{1}{2}\log|\mathbf{V}| \\ &= \frac{1}{2}\text{trace}(\sum_n\mathbf{w}_n\tau_n\mathbf{w}_n\mathbf{V})-\frac{1}{2}\mathbf{m}^\intercal\mathbf{K}_{\mathbf{uu}}^{-1}\mathbf{m}-\frac{1}{2}\log|\mathbf{K}_{\mathbf{uu}}|+\frac{1}{2}\log|\mathbf{V}|. \end{aligned} \tag{46}$$

Therefore, $\mathcal{F}_{\text{VFE}}$ is identical to the limit of the approximate marginal likelihood provided by power-EP as shown in Equation (44).

Appendix H. The Surrogate Regression Viewpoint

It was written in the main text that it is instructive to view the approximation using pseudo-points as forming a surrogate exact Gaussian process regression problem such that the posterior and the marginal likelihood of this surrogate problem are close to that of the original intractable regression/classification problem. This approximation view is useful and could potentially be used for other intractable probabilistic model, despite that we have not used this view in the practical implementation of the algorithms/PEP procedure discussed in this paper. In this section, we detail the surrogate model and how the parameters of this model can be tuned to match the approximate posterior and approximate marginal likelihood.

We consider the exact GP regression problem with M surrogate observations $\tilde{\mathbf{y}}$ that are formed by linear combinations the pseudo-outputs and additive surrogate Gaussian noise, $\tilde{\mathbf{y}} = \tilde{\mathbf{W}}\mathbf{u} + \tilde{\Sigma}^{1/2}\epsilon$. The exact posterior and log marginal likelihood can be obtained for this model as follows,

$$\begin{aligned}\tilde{p}(\mathbf{u}|\mathbf{y}) &= \mathcal{N}^{-1}(\mathbf{u}; \tilde{\mathbf{W}}\tilde{\Sigma}^{-1}\tilde{\mathbf{y}}, \mathbf{K}_{\mathbf{uu}}^{-1} + \tilde{\mathbf{W}}^\intercal\tilde{\Sigma}^{-1}\tilde{\mathbf{W}}),\\ \log p(\tilde{\mathbf{y}}) &= -\frac{M}{2}\log(2\pi) - \frac{1}{2}(\log|\mathbf{K}_{\mathbf{uu}}^{-1} + \tilde{\mathbf{W}}^\intercal\tilde{\Sigma}^{-1}\tilde{\mathbf{W}}| + \log|\mathbf{K}_{\mathbf{uu}}^{-1}| + \log|\tilde{\Sigma}|)\\ &\quad - \frac{1}{2}\tilde{\mathbf{y}}^\intercal\tilde{\Sigma}^{-1}\tilde{\mathbf{y}} - \frac{1}{2}\tilde{\mathbf{y}}^\intercal\tilde{\Sigma}^{-1}\tilde{\mathbf{W}}(\mathbf{K}_{\mathbf{uu}}^{-1} + \tilde{\mathbf{W}}^\intercal\tilde{\Sigma}^{-1}\tilde{\mathbf{W}})^{-1}\tilde{\mathbf{W}}^\intercal\tilde{\Sigma}^{-1}\tilde{\mathbf{y}},\end{aligned}$$

where we have used the matrix inversion lemma and the matrix determinant lemma in the equations above, and that $\mathcal{N}^{-1}$ denotes the Gaussian distribution with natural parameters.

The aim is to show that we can use the above quantities is to match a given approximate posterior $q(\mathbf{u}) = \mathcal{N}^{-1}(\mathbf{u}; \mathbf{S}^{-1}\mathbf{m}, \mathbf{S}^{-1})$ and an approximate marginal likelihood $\mathcal{F}$, that is, $\tilde{p}(\mathbf{u}|\mathbf{y}) = q(\mathbf{u})$ and $\log p(\tilde{\mathbf{y}}) = \mathcal{F}$. Substituting the above results into the constraints leading to the following simplified constraints:

$$\begin{aligned}\tilde{\mathbf{W}}\tilde{\Sigma}^{-1}\tilde{\mathbf{y}} &= \mathbf{m},\\ \tilde{\mathbf{W}}^\intercal\tilde{\Sigma}^{-1}\tilde{\mathbf{W}} &= \mathbf{R} = \mathbf{K}_{\mathbf{uu}}^{-1} - \mathbf{S}^{-1},\\ \tilde{\mathbf{y}}^\intercal\tilde{\Sigma}^{-1}\tilde{\mathbf{y}} + \log|\tilde{\Sigma}| &= c,\end{aligned}$$

where c is a constant. Assume that $\mathbf{R}$ is invertible, we can simplified the above results further,

$$\begin{aligned}\tilde{\Sigma}^{-1/2}\tilde{\mathbf{y}} &= \mathbf{R}^{-1/2}\mathbf{m},\\ \tilde{\Sigma}^{-1/2}\tilde{\mathbf{W}} &= \mathbf{R}^{\intercal/2},\\ \log|\tilde{\Sigma}| &= d,\end{aligned}$$

where d is a constant. We can choose $\tilde{\Sigma}$, e.g. a diagonal matrix, that satisfies the third equality above. Given $\tilde{\Sigma}$, obtaining $\tilde{\mathbf{y}}$ and $\tilde{\mathbf{W}}$ from the first two equalities is trivial.

Appendix I. Extra Experimental Results

I.1 Comparison Between Various α Values on a Toy Regression Problem

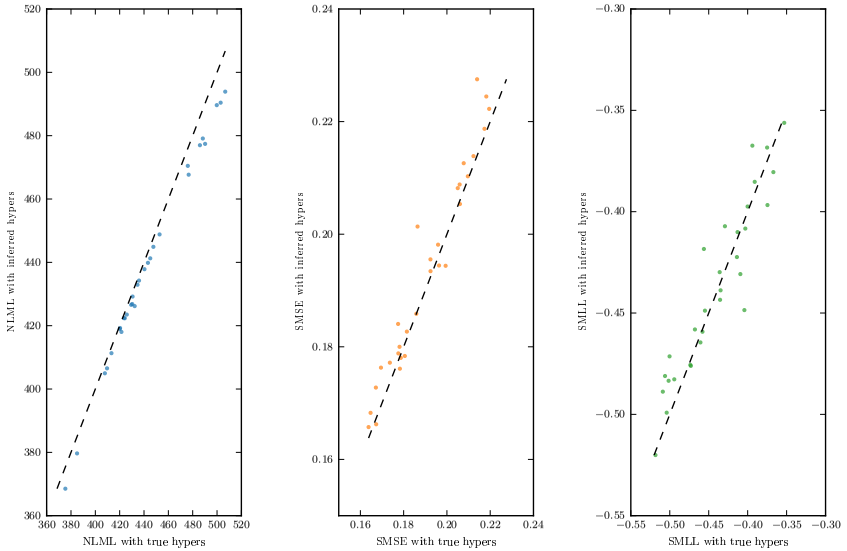

Figure 8: Results on a toy regression problem: Negative log-marginal likelihood, mean squared error and mean log-loss on the test set for full Gaussian process regression on synthetic data sets with *true* hyperparameters and hyperparameters obtained by type-2 ML. Each dot is one trial, i.e. one synthetic data set. The results demonstrate that type-2 maximum likelihood on hyperparameters works well, despite being a little confident on the log-marginal likelihood on the train set.

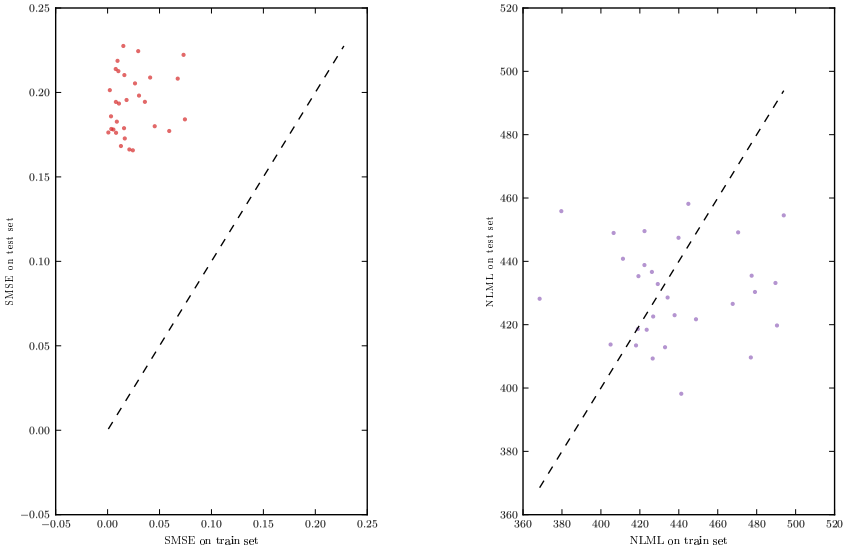

Figure 9: Results on a toy regression problem with 500 training points: Mean squared error and log-likelihood on train and test sets on synthetic data sets with hyperparameters obtained by type-2 ML. In this example, the test error is higher than the training error, as measured by the mean squared error, because the test points and training points are relatively far apart, making the prediction task on the training set easier (interpolation) than on the test set (extrapolation). This is consistent with the results with more training points, shown in Figure 10.

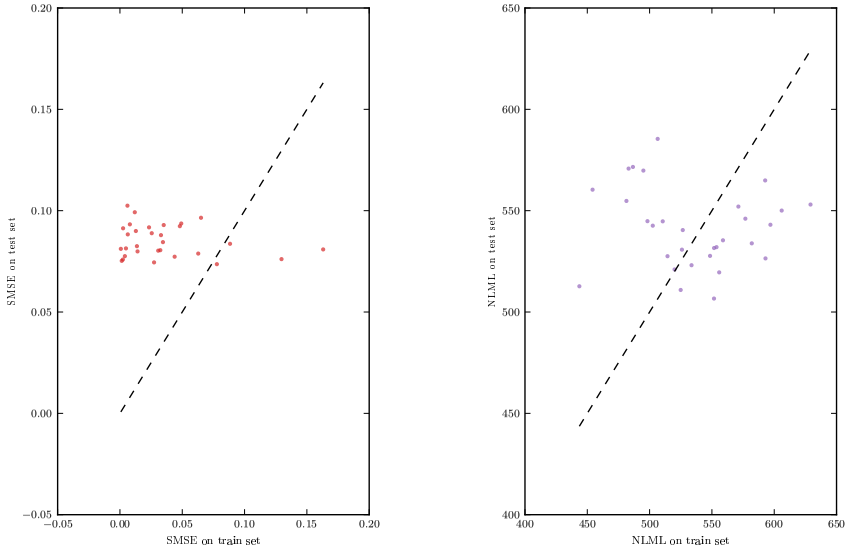

Figure 10: Results on a toy regression problem with 1000 training points: Mean squared error and log-likelihood on train and test sets on synthetic data sets with hyperparameters obtained by type-2 ML. See Figure 9 for a discussion.

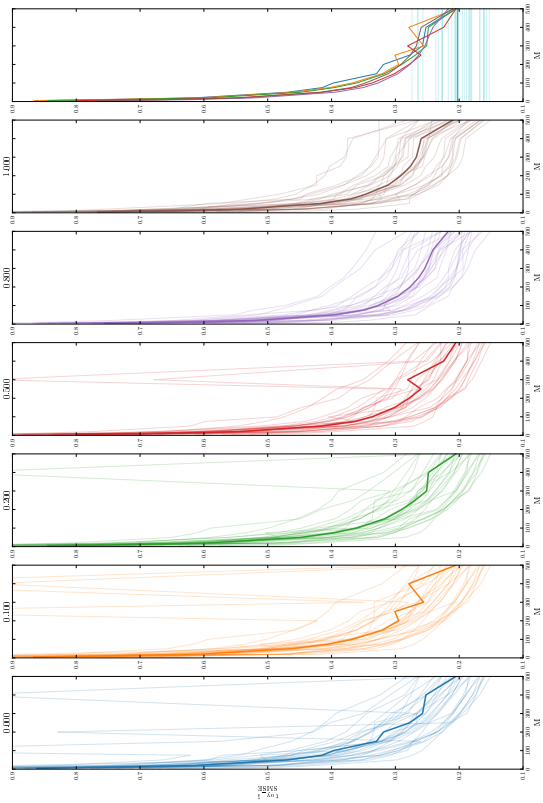

Figure 12: Results on a toy regression problem: Standardsised mean squared error on the test set for various values of α and various number of pseudo-points M. Each trace is for one split, bold line is the mean. The rightmost figure shows the mean for various α, and the results using GP regression.

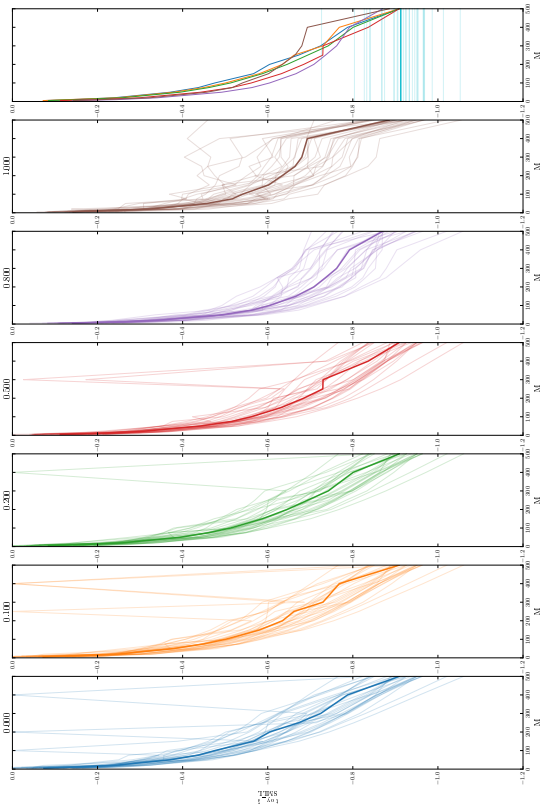

Figure 11: Results on a toy regression problem: Standardsised mean log-loss on the test set for various values of α and various number of pseudo-points M. Each trace is for one split, bold line is the mean. The rightmost figure shows the mean for various α, and the results using GP regression.

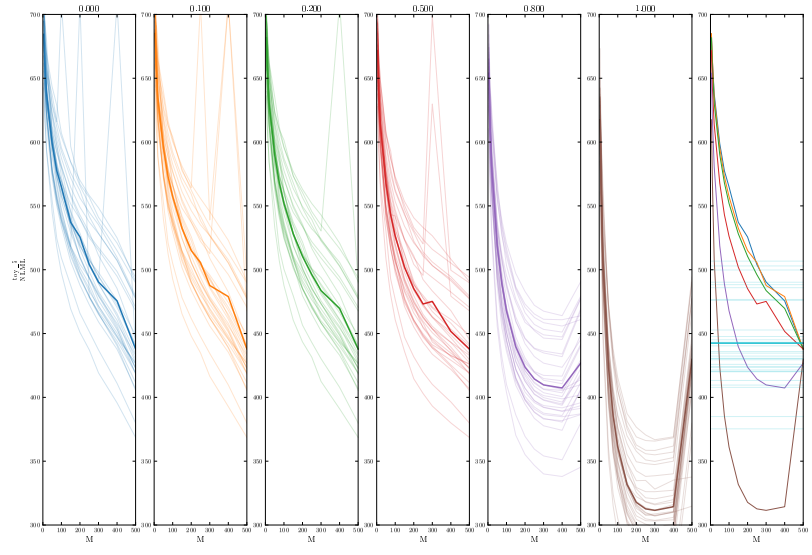

Figure 13: Results on a toy regression problem: The negative log marginal likelihood of the training set after training for various values of α and various number of pseudo-points M. Each trace is for one split, bold line is the mean. The rightmost figure shows the mean for various α, and the results using GP regression. Power EP with α close to 1 over-estimates the marginal-likelihood.

I.2 Real-world Regression

We include the details of the regression data sets in Table 1 and several comparisons of α values in Figures 17 to 22.

data set	N train/test	D
boston	455/51	14
concrete	927/103	9
energy	691/77	9
kin8nm	7373/819	9
naval	10741/1193	18
yacht	277/31	7
power	8611/957	5
red wine	1439/160	12

Table 1: Regression data sets

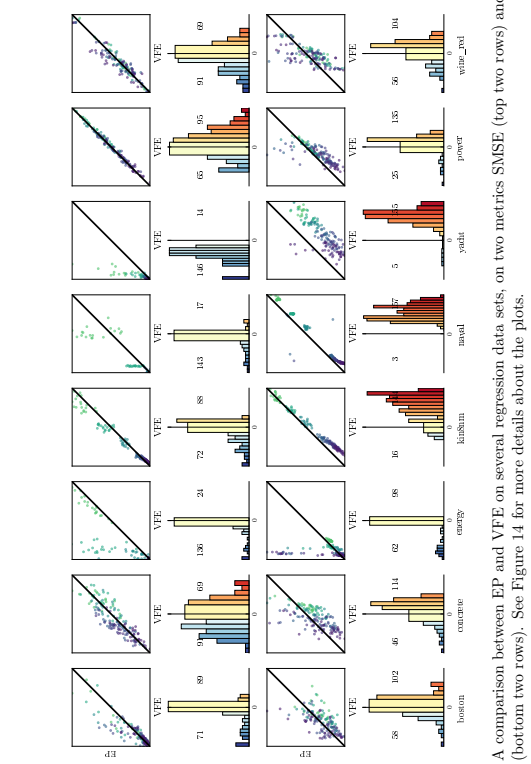

Figure 15: A comparison between EP and VFE on several regression data sets, on two metrics SMSE (top two rows) and SMLL (bottom two rows). See Figure 14 for more details about the plots.

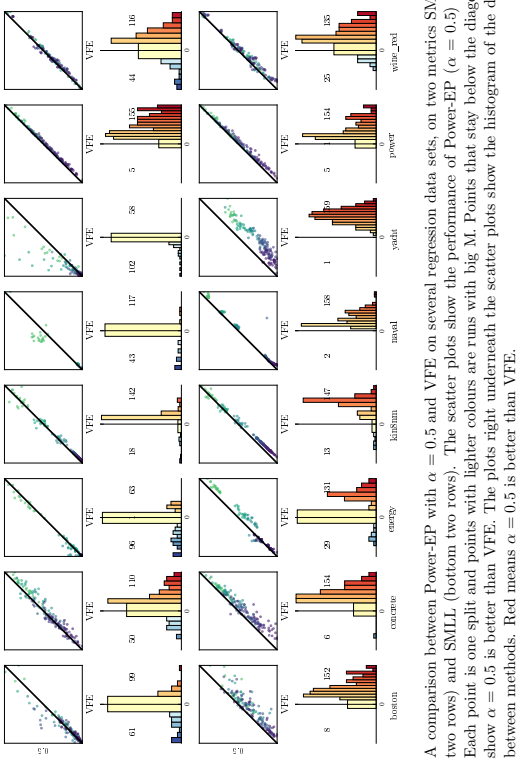

Figure 14: A comparison between Power-EP with $\alpha = 0.5$ and VFE on several regression data sets, on two metrics SMSE (top two rows) and SMLL (bottom two rows). The scatter plots show the performance of Power-EP ($\alpha = 0.5$) vs VFE. Each point is one split and points with lighter colours are runs with big M. Points that stay below the diagonal line show $\alpha = 0.5$ is better than VFE. The plots right underneath the scatter plots show the histogram of the difference between methods. Red means $\alpha = 0.5$ is better than VFE.

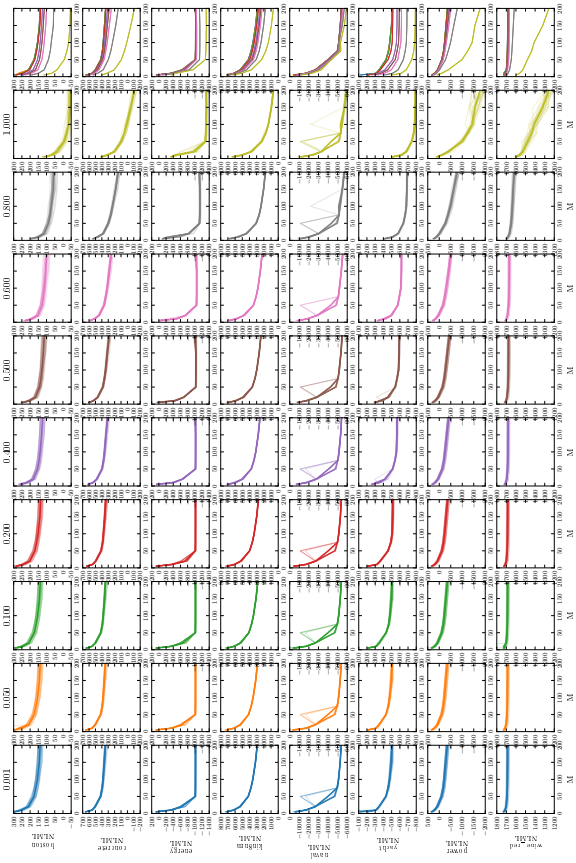

Figure 17: Results on real-world regression problems: Negative training log-marginal likelihood for different data sets, various values of α and various number of pseudo-points M. Each trace is for one split, bold line is the mean. The rightmost figures show the mean for various α for comparison. Lower is better [however, lower could mean overestimation].

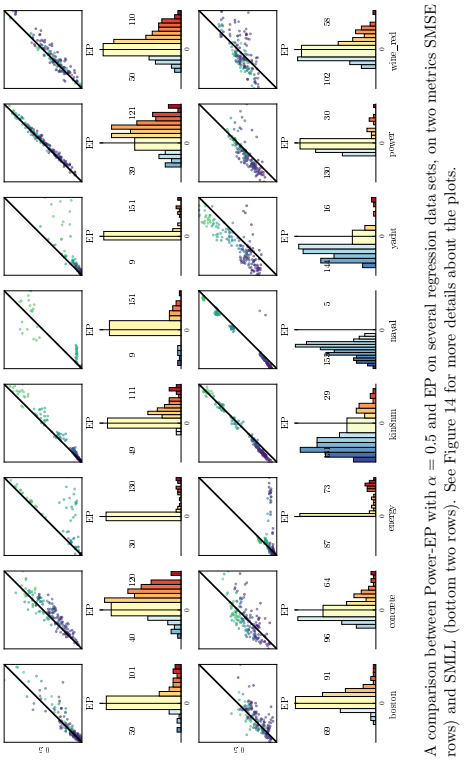

Figure 16: A comparison between Power-EP with $\alpha = 0.5$ and EP on several regression data sets, on two metrics SMSE (top two rows) and SMLL (bottom two rows). See Figure 14 for more details about the plots.

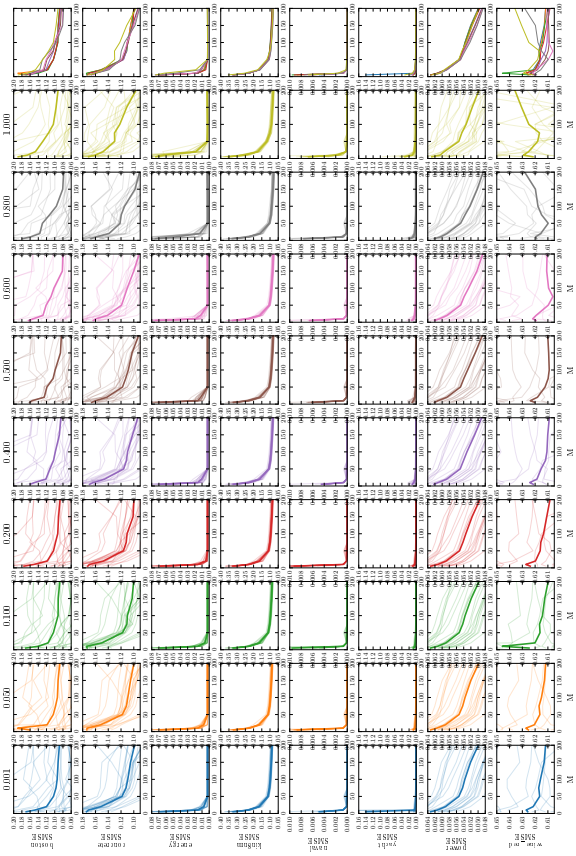

Figure 19: Results on real-world regression problems: Standardised mean squared error on the test set for different data sets, various values of α and various number of pseudo-points M. Each trace is for one split, bold line is the mean. The rightmost figures show the mean for various α for comparison. Lower is better.

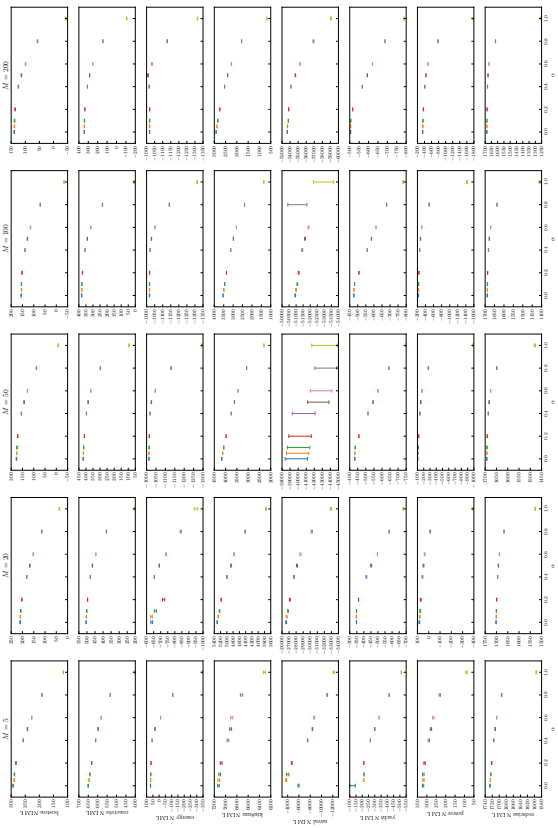

Figure 18: Results on real-world regression problems: Negative training log-marginal likelihood for different data sets, various values of α and various number of pseudo-points M, averaged over 20 splits. Lower is better [however, lower could mean overestimation].

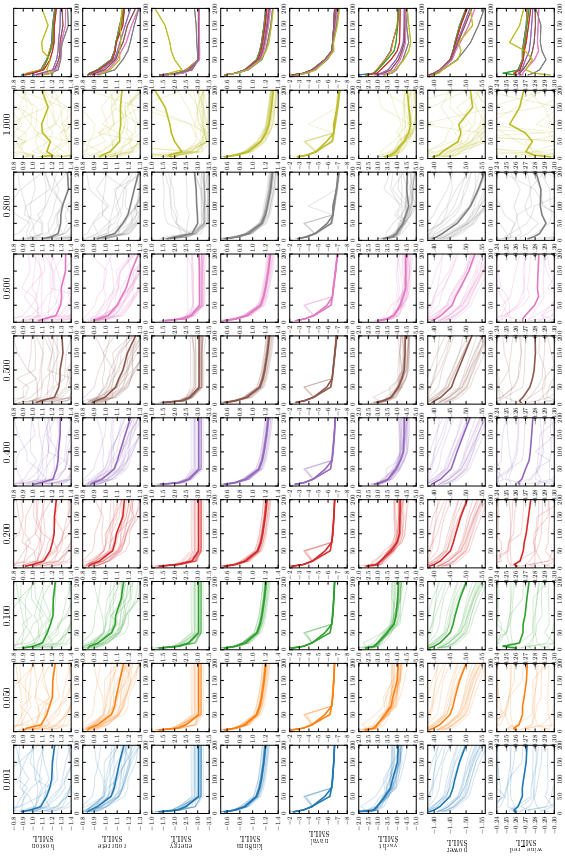

Figure 21: Results on real-world regression problems: Standardised mean log loss on the test set for different data sets, various values of α and various number of pseudo-points M. Each trace is for one split, bold line is the mean. The rightmost figures show the mean for various α for comparison. Lower is better.

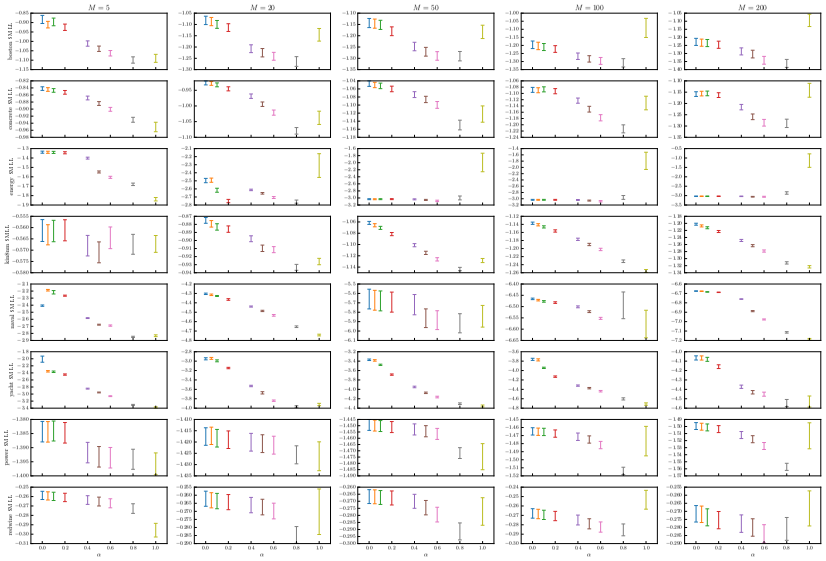

Figure 22: Results on real-world regression problems: Standardised mean log loss on the test set for different data sets, various values of α and various number of pseudo-points M, averaged over 20 splits. Lower is better.

I.3 Real-world Classification

It was demonstrated in (Hernández-Lobato and Hernández-Lobato, 2016; Hensman et al., 2015) that, once optimised, the pseudo points tend to concentrate around the decision boundary for VFE, and spread out to cover the data region in EP. Figure 23 illustrates the same effect as α goes from close to 0 (VFE) to 1 (EP).

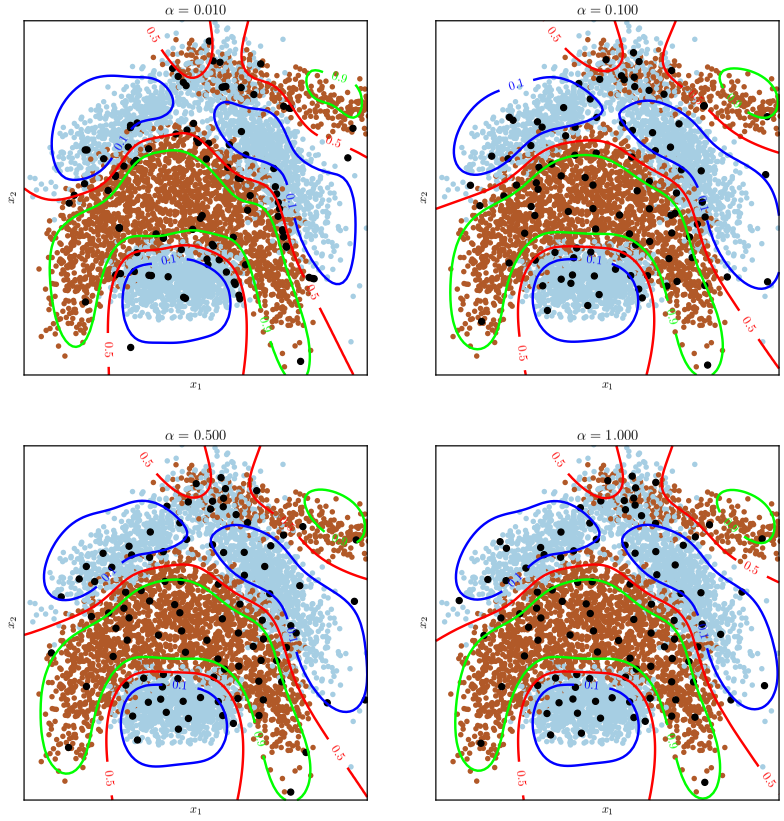

Figure 23: The locations of pseudo data points vary with α.. Best viewed in colour.

We include the details of the classification data sets in Table 2 and several comparisons of α values in Figures 27 to 30.

data set	N train/test	D	N positive/negative
australian	621/69	15	222/468
breast	614/68	11	239/443
crabs	180/20	7	100/100

I.5 When $M = N$ and $\alpha = 1$, Do We Recover EP for GPC (Rasmussen and Williams, 2005, sec. 3.6)?

The key difference between the EP method in this manuscript when $M = N$ and the pseudo-inputs and the training inputs are identical, and the standard EP method as described by (Rasmussen and Williams, 2005, sec. 3.6) is the factor representation. While Rasmussen and Williams (2005) used a one dimensional unnormalised Gaussian distribution that touches only *one* function value f_n to approximate each exact factor, the approximate factor used in the EP scheme described in the main text touches *all* M pseudo-points, hence *all* N function values when the pseudo-inputs are placed at the training inputs. However, in

practice both methods give virtually identical results. Figure 33 shows the approximate log marginal likelihood and the negative test log-likelihood, given by running the EP procedure described in the main text on the `ionosphere` data set. We note that these results are similar to that of the standard EP method (see Kuss and Rasmussen, 2005).

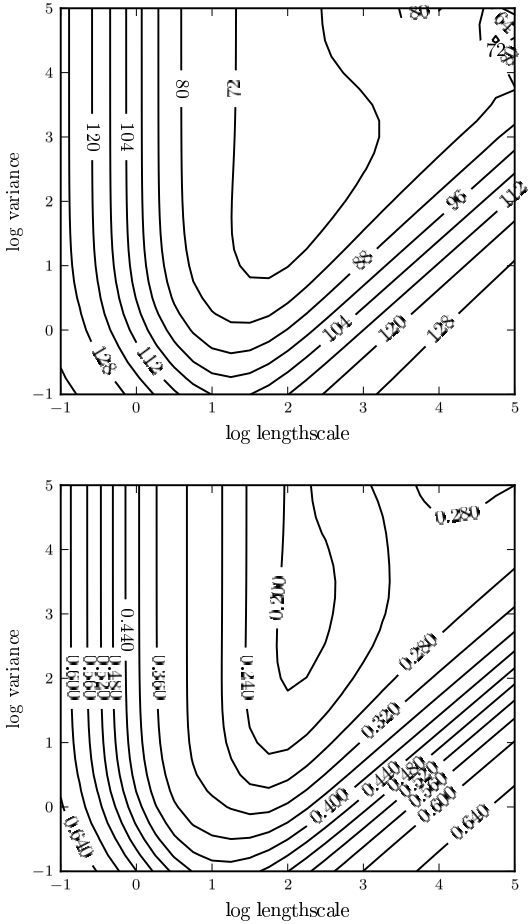

Figure 33: EP energy on the train set [TOP] and the average negative log-likelihood on the test set[BOTTOM] when $M = N$.

Abstract

We consider the stochastic nested composition optimization problem where the objective is a composition of two expected-value functions. We propose a new stochastic first-order method, namely the accelerated stochastic compositional proximal gradient (ASC-PG) method. This algorithm updates the solution based on noisy gradient queries using a two-timescale iteration. The ASC-PG is the first proximal gradient method for the stochastic composition problem that can deal with nonsmooth regularization penalty. We show that the ASC-PG exhibits faster convergence than the best known algorithms, and that it achieves the optimal sample-error complexity in several important special cases. We demonstrate the application of ASC-PG to reinforcement learning and conduct numerical experiments.

Keywords: Large-scale optimization, stochastic gradient, composition optimization, sample complexity.

1. Introduction

The popular stochastic gradient methods are well suited for minimizing expected-value objective functions or the sum of a large number of loss functions. Stochastic gradient methods find wide applications in estimation, online learning, and training of deep neural networks. Despite their popularity, they do not apply to the minimization of a nonlinear function involving expected values or a composition between two expected-value functions.

In this paper, we consider the *stochastic composition problem*, given by

$$\min_{\mathbf{x}\in X} \quad H(\mathbf{x}) := \underbrace{\mathbb{E}_v(f_v(\mathbb{E}_w(g_w(\mathbf{x}))))}_{=:F(\mathbf{x})} + R(\mathbf{x}) \tag{1}$$

where $f(g(\mathbf{x})) = (f \circ g)(\mathbf{x})$ denotes the function composition, $g_w(\cdot): \Re^n \mapsto \Re^m$ and $f_v(\cdot): \Re^m \mapsto \Re$ are continuously differentiable functions, v, w are random variables, and $R(\mathbf{x}): \Re^n \mapsto \Re \cup \{+\infty\}$ is an extended real-valued closed convex function, X is a convex and closed set. We assume throughout that there exists at least one optimal solution $\mathbf{x}^* \in X$ to problem (1). We focus on the case where f_v and g_w are smooth, but we allow R to be a nonsmooth penalty such as the ℓ_1-norm. We do no require either the outer function f_v or the inner function g_w to be convex or monotone. As a result, the composition problem cannot be reformulated into a saddle point problem in general.

Our algorithmic objective is to develop efficient algorithms for solving problem (1) based on random evaluations of f_v, g_w and their gradients. Our theoretical objective is to analyze the rate of convergence for the stochastic algorithm and to improve it when possible. In the online setting, the iteration complexity of our stochastic methods can be interpreted as a sample-error complexity upper bound for estimating the optimal solution of problem (1).

1.1 Motivating Examples

One motivating example is *reinforcement learning* (Sutton and Barto, 1998). Consider a controllable Markov chain with states $1, \ldots, S$. Estimating the value-per-state of a fixed control policy π is known as on-policy learning. It can be casted into an $S \times S$ system of Bellman equations:

$$\gamma P^\pi V^\pi + r^\pi = V^\pi,$$

where $\gamma \in (0,1)$ is a discount factor, $P^\pi_{s\tilde{s}}$ is the transition probability from state s to state $\tilde{s}$, and r^π_s is the expected state transition reward at state s. The solution V^π to the Bellman equation is the value vector, with $V^\pi(s)$ being the total expected reward starting at state s. In the blackbox simulation environment, P^π, r^π are unknown but can be sampled from a simulator. As a result, solving the Bellman equation becomes a special case of the stochastic composition optimization problem:

$$\min_{\mathbf{x}\in X} \quad \|\mathbb{E}[A]\mathbf{x} - \mathbb{E}[\mathbf{b}]\|^2, \tag{2}$$

where A, B, b are random matrices and random vectors such that $\mathbb{E}[A] = I - \gamma P^\pi$ and $\mathbb{E}[b] = r^\pi$. It can be viewed as the composition of the square norm function $f(\cdot) \equiv f_v(\cdot) = \|\cdot\|$ and the expected linear function $g(\mathbf{x}) = \mathbb{E}[A]\mathbf{x} - \mathbb{E}[\mathbf{b}]$. We will give more details on the reinforcement learning application in Section 4.

Another motivating example is *risk-averse learning*. For example, consider the mean-variance minimization problem

$$\min_{\mathbf{x}\in X} \quad \mathbb{E}_{a,b}[h(\mathbf{x}; a, b)] + \lambda \mathrm{Var}_{a,b}[h(\mathbf{x}; a, b)],$$

where $h(x; a, b)$ is some loss function parameterized by random variables a and b, and $\lambda > 0$ is a regularization parameter. In particular, the mean-variance minimization takes the composition form where $g(\mathbf{x}) = (\mathbb{E}[\mathbf{x}], \mathbb{E}[h(\mathbf{x}; a, b)])$, and $f(y_1, y_2) = \mathbb{E}[h(y_1; a, b)] + \lambda \mathbb{E}\Big(h(y_1; a, b) - y_2\Big)^2$. Its batch version takes the form

$$\min_{\mathbf{x}\in X} \quad \frac{1}{N}\sum_{i=1}^N h(\mathbf{x}; a_i, b_i) + \frac{\lambda}{N}\sum_{i=1}^N \left(h(\mathbf{x}; a_i, b_i) - \frac{1}{N}\sum_{i=1}^N h(\mathbf{x}; a_i, b_i)\right)^2.$$

Here the variance term is the composition of the mean square function and an expected loss function.

Although the stochastic composition problem (1) was barely studied, it actually finds a broad spectrum of emerging applications in estimation and machine learning (see Wang et al. (2017) for a list of applications). Fast optimization algorithms with theoretical guarantees will lead to new computation tools and online learning methods for a broader problem class, no longer limited to the expectation minimization problem.

1.2 Related Works and Contributions

Contrary to the expectation minimization problem, "unbiased" gradient samples are no longer available for the stochastic composition problem (1). The objective is *nonlinear* in the joint probability distribution of (w, v), which substantially complicates the problem. In a recent work by Dentcheva et al. (2016), a special case of the stochastic composition problem, i.e., risk-averse optimization, has been studied. A central limit theorem has been established, showing that the K-sample batch problem converges to the true problem at the rate of $O(1/\sqrt{K})$ in a proper sense. For the case where $R(x) = 0$, Wang et al. (2017) has proposed and analyzed a class of *stochastic compositional gradient/subgradient methods* (SCGD). The SCGD involves two iterations of different time scales, one for estimating x^* by a stochastic quasi-gradient iteration, the other for maintaining a running estimate of $g(x^*)$. Wang and Liu (2016) studies the SCGD in the setting where samples are corrupted with Markov noises (instead of i.i.d. zero-mean noises). Both works establish almost sure convergence of the algorithm and several convergence rate results, which are the best-known convergence rate prior to the current paper.

The idea of using two-timescale quasi-gradient traced back to the earlier work Ermoliev (1976). It proposed for the first time a stochastic iteration that updates the solution and an auxiliary variable using two different stepsizes. The incremental treatment of proximal gradient iteration has been studied extensively for the expectation minimization problem, see for examples Nedić and Bertsekas (2001); Nemirovski et al. (2009); Wang et al. (2015); Wang and Bertsekas (2016) and references therein. However, except for Wang et al. (2017) and Wang and Liu (2016), all of these works focus on variants of the expectation minimization problem and do not apply to the stochastic composition problem (1). Another work partially related to this paper is by Dai et al. (2017). They consider a special case of problem (1) arising in kernel estimation, where they assume that all functions f_v's are convex and their conjugate functions $f_v^\star$'s can be easily obtained/sampled. Under these additional assumptions, they essentially rewrite the problem into a saddle point optimization involving functional variables.

In this paper, we propose a new accelerated stochastic compositional proximal gradient (ASC-PG) method that applies to the penalized problem (1), which is a more general problem than the one considered in Wang et al. (2017). We use a *coupled martingale stochastic analysis* to show that ASC-PG achieves significantly better sample-error complexity in various cases. We also show that ASC-PG exhibits optimal sample-error complexity in two important special cases: the case where the outer function is linear and the case where the inner function is linear. Note that the current work has a preliminary conference version (Wang et al., 2016).

The current journal version provides more complete technical details as well as important theoretical extensions (Theorem 3).

Our major contributions are summarized as follows:

1. We propose the first stochastic *proximal-gradient* method for the stochastic composition problem. This is the first algorithm that is able to address the nonsmooth regularization penalty $R(\cdot)$ without deteriorating the convergence rate.

2. We obtain a convergence rate $O(K^{-4/9})$ for smooth optimization problems that are not necessarily convex, where K is the number of queries to the stochastic first-order oracle. This improves the best known convergence rate and provides a new benchmark for the stochastic composition problem.

3. We provide a comprehensive analysis and results that apply to various special cases. In particular, our results contain as special cases the known optimal rate results for the expectation minimization problem, i.e., $O(1/\sqrt{K})$ for general objectives and $O(1/K)$ for strongly convex objectives.

4. In the special case where the inner function $g(\cdot)$ is a linear mapping, we show that it is sufficient to use one timescale to guarantee convergence. Our result achieves the non-improvable rate of convergence $O(1/K)$ for optimal strongly convex optimization and $O(1/\sqrt{K})$ for convex optimization and nonconvex smooth optimization. It implies that the inner linearity does not bring fundamental difficulty to the stochastic composition problem.

5. We show that the proposed method leads to a new on-policy reinforcement learning algorithm. The new learning algorithm achieves the optimal convergence rate $O(1/\sqrt{K})$ for solving Bellman equations based on K observations of state-to-state transitions.

In comparison with Wang et al. (2017), our analysis is more succinct and leads to stronger results. To the best of our knowledge, Theorems 1,2,3 in this paper provide the best-known rates for the stochastic composition problem.

Paper Organization. Section 2 states the sampling oracle and the accelerated stochastic compositional proximal gradient algorithm (ASC-PG). Section 3 states the convergence rate results in the case of general nonconvex objective and in the case of strongly convex objective, respectively. Section 4 describes an application of ASC-PG to reinforcement learning and gives numerical experiments.

Notations and Definitions. For $\mathbf{x} \in \Re^n$, we denote by $\mathbf{x}'$ its transpose, and by $\|\mathbf{x}\|$ its Euclidean norm (i.e., $\|\mathbf{x}\| = \sqrt{\mathbf{x}'\mathbf{x}}$). For two sequences $\{\mathbf{y}_k\}$ and $\{\mathbf{z}_k\}$, we write $\mathbf{y}_k = O(\mathbf{z}_k)$ if there exists a constant $c > 0$ such that $\|\mathbf{y}_k\| \leq c\|\mathbf{z}_k\|$ for each k. We denote by $\mathbf{I}_{\text{condition}}^{\text{value}}$ the indicator function, which returns "value" if the "condition" is satisfied; otherwise 0. We denote by H^* the optimal objective function value of problem (1), denote by X^* the set of optimal solutions, and denote by $\mathcal{P}_S(\mathbf{x})$ the Euclidean projection of $\mathbf{x}$ onto S for any convex set S. We also denote by short that $f(\mathbf{y}) = \mathbb{E}_v[f_v(\mathbf{y})]$ and $g(\mathbf{x}) = \mathbb{E}_w[g_w(\mathbf{x})]$.

2. Algorithm

We focus on the black-box sampling environment. Suppose that we have access to a stochastic first-order oracle, which returns random realizations of first-order information upon queries. This is a typical simulation oracle that is available in both online and batch learning. More specifically, assume that we are given a **Sampling Oracle** (**SO**) such that

- Given some $\mathbf{x} \in \Re^n$, the **SO** returns a random vector $g_w(x)$ and a noisy subgradient $\nabla g_w(\mathbf{x})$.
- Given some $\mathbf{y} \in \Re^m$, the **SO** returns a noisy gradient $\nabla f_v(\mathbf{y})$.

Now we propose the Accelerated Stochastic Compositional Proximal Gradient (ASC-PG) algorithm, see Algorithm 1. ASC-PG is a generalization of the SCGD proposed by Wang et al. (2017), in which a proximal step is used to replace the projection step.

Algorithm 1 Accelerated Stochastic Compositional Proximal Gradient (ASC-PG)

Require: $\mathbf{x}_1 \in \Re^n$, **SO**, K, stepsize sequences $\{\alpha_k\}_{k=1}^K$, and $\{\beta_k\}_{k=1}^K$.
Ensure: $\{\mathbf{x}_k\}_{k=1}^K$

1: Initialize $\mathbf{z}_1 = \mathbf{x}_1$ and $\mathbf{y}_1 = 0$.
2: **for** $k = 1, \cdots, K$ **do**
3: Query the **SO** and obtain gradient samples $\nabla f_{v_k}(\mathbf{y}_k)$, $\nabla g_{w_k}(\mathbf{z}_k)$.
4: Update the main iterate by

$$\mathbf{x}_{k+1} = \text{prox}_{\alpha_k R(\cdot)}\left(\mathbf{x}_k - \alpha_k \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k)\right).$$

5: Update auxillary iterates by an *extrapolation-smoothing* scheme:

$$\begin{aligned}\mathbf{z}_{k+1} &= \left(1 - \frac{1}{\beta_k}\right)\mathbf{x}_k + \frac{1}{\beta_k}\mathbf{x}_{k+1},\\ \mathbf{y}_{k+1} &= (1-\beta_k)\mathbf{y}_k + \beta_k g_{w_{k+1}}(\mathbf{z}_{k+1}),\end{aligned}$$

where the sample $g_{w_{k+1}}(\mathbf{z}_{k+1})$ is obtained via querying the **SO**.
6: **end for**

In Algorithm 1, the *extrapolation-smoothing scheme* (i.e., the $(\mathbf{y}, \mathbf{z})$-step) is critical to the acceleration of convergence. The acceleration is due to the fast running estimation of the unknown quantity $g(\mathbf{x}_k) := \mathbb{E}_w[g_w(\mathbf{x}_k)]$. At iteration k, the running estimate $\mathbf{y}_k$ of $g(\mathbf{x}_k)$ is obtained using a weighted smoothing scheme, corresponding to the $\mathbf{y}$-step; while the new query point $\mathbf{z}_{k+1}$ is obtained through extrapolation, corresponding to the $\mathbf{z}$-step. The updates are constructed in a way such that $\mathbf{y}_k$ is a nearly unbiased estimate of $g(\mathbf{x}_k)$. To see how the extrapolation-smoothing scheme works, we let the weights be

$$\xi_t^{(k)} = \begin{cases}\beta_t \prod_{i=t+1}^k (1-\beta_i), & \text{if } k > t \geq 0\\ \beta_k, & \text{if } k = t \geq 0.\end{cases} \tag{3}$$

Then,we can verify the following important relations:

$$\mathbf{x}_{k+1} = \sum_{t=0}^k \xi_t^{(k)} \mathbf{z}_{t+1}, \qquad \mathbf{y}_{k+1} = \sum_{t=0}^k \xi_t^{(k)} g_{w_{t+1}}(\mathbf{z}_{t+1}),$$

which essentially say that $\mathbf{x}_{k+1}$ is a damped weighted average of $\{z_{t+1}\}_0^{k+1}$ and $\mathbf{y}_{k+1}$ is a damped weighted average of $\{g_{w_{t+1}}(z_{t+1})\}_0^{k+1}$.

An Analytical Example of the Extrapolation-Smooth Scheme Now consider the special case where $g_w(\cdot)$ is always a linear mapping $g_w(z) = A_w z + b_z$ and $\beta_k = 1/(k+1)$. We can verify that $\xi_t^{(k)} = 1/(k+1)$ for all t. Then we have

$$g(\mathbf{x}_{k+1}) = \frac{1}{k+1}\sum_{t=0}^k \mathbb{E}[A_w]\mathbf{z}_{t+1} + \mathbb{E}[\mathbf{b}_w], \qquad \mathbf{y}_{k+1} = \frac{1}{k+1}\sum_{t=0}^k A_{w_{t+1}}\mathbf{z}_{t+1} + \frac{1}{k+1}\sum_{t=0}^k \mathbf{b}_{w_{t+1}}.$$

In this way, we can see that the scaled error

$$k(\mathbf{y}_{k+1} - g(\mathbf{x}_{k+1})) = \sum_{t=0}^k (A_{w_{t+1}} - \mathbb{E}[A_w])\mathbf{z}_{t+1} + \sum_{t=0}^k (\mathbf{b}_{w_{t+1}} - \mathbb{E}[\mathbf{b}_w])$$

is a *zero-mean* and *zero-drift* martingale. Under additional technical assumptions, we have

$$\mathbb{E}[\|\mathbf{y}_{k+1} - g(\mathbf{x}_{k+1})\|^2] \leq O\left(\frac{1}{k}\right).$$

Note that the zero-drift property of the error martingale is the key to the fast convergence rate. The zero-drift property comes from the near-unbiasedness of $\mathbf{y}_k$, which is due to the special construction of the extrapolation-smoothing scheme. In the more general case where g_w is not necessarily linear, we can use a similar argument to show that $\mathbf{y}_k$ is a nearly unbiased estimate of $g(\mathbf{x}_k)$. As a result, the extrapolation-smoothing $(\mathbf{y}, \mathbf{z})$-step ensures that $\mathbf{y}_k$ tracks the unknown quantity $g(\mathbf{x}_k)$ efficiently.

3. Main Results

We present our main theoretical results in this section. Note that for ease of presentation, we defer all detailed proofs for the theorems, and technical lemmas to Appendix. Let us begin by stating our assumptions. Note that all assumptions involving random realizations of v, w hold with probability 1.

Assumption 1 *The samples generated by the* **SO** *are unbiased in the following sense:*

1. $\mathbb{E}_{\{w_k, v_k\}}(\nabla g_{w_k}^\top(\mathbf{x})\nabla f_{v_k}(\mathbf{y})) = \nabla g^\top(\mathbf{x})\nabla f(\mathbf{y}) \quad \forall k = 1, 2, \cdots, K, \quad \forall \mathbf{x}, \forall \mathbf{y}.$
2. $\mathbb{E}_{w_k}(g_{w_k}(\mathbf{x})) = g(\mathbf{x}) \quad \forall \mathbf{x}.$

Note that w_k and v_k are not necessarily independent.

Assumption 2 *The sample gradients and values generated by the* **SO** *satisfy*

$$\mathbb{E}_w(\|g_w(\mathbf{x}) - g(\mathbf{x})\|^2) \leq \sigma^2 \quad \forall \mathbf{x}.$$

Assumption 3 *The sample gradients generated by the* **SO** *are uniformly bounded, and the penalty function R has bounded gradients.*

$$\|\nabla f_v(\mathbf{x})\| \leq \Theta(1), \quad \|\nabla g_w(\mathbf{x})\| \leq \Theta(1), \quad \|\partial R(\mathbf{x})\| \leq \Theta(1) \quad \forall \mathbf{x}, \forall w, \forall v$$

Assumption 4 *There exists $L_F, L_f, L_g > 0$ such that*

1. $F(\mathbf{z}) - F(\mathbf{x}) \leq \langle \nabla F(\mathbf{x}), \mathbf{z} - \mathbf{x} \rangle + \frac{L_F}{2}\|\mathbf{z} - \mathbf{x}\|^2 \quad \forall \mathbf{x}\ \forall \mathbf{z}.$
2. $\|\nabla f_v(\mathbf{y}) - \nabla f_v(\mathbf{w})\| \leq L_f \|\mathbf{y} - \mathbf{w}\| \quad \forall \mathbf{y}\ \forall \mathbf{w}\ \forall v.$
3. $\|g(\mathbf{x}) - g(\mathbf{z}) - \nabla g(\mathbf{z})^\top (\mathbf{x} - \mathbf{z})\| \leq \frac{L_g}{2}\|\mathbf{x} - \mathbf{z}\|^2 \quad \forall \mathbf{x}\ \forall \mathbf{z}.$

Condition 1 of Assumption 4 requires that the function $F(\cdot)$ is L_f-smooth. Condition 2 requires that f_v has Lipschitz gradient for all v. Condition 3 requires that the function $g(\cdot)$ is L_g smooth. Note that the case where $L_f = 0$ or $L_g = 0$ coincides with the special case where either f_v or g is linear, respectively. The constants L_F, L_f, L_g jointly characterize the smoothness and complexity of stochastic composition optimization. They do not admit any straightforward dependence relation.

Our first main result concerns with general optimization problems which are not necessarily convex.

Theorem 1 (Smooth (Nonconvex) Optimization) *Let Assumptions 1, 2, 3, and 4 hold. Denote by $F(\mathbf{x}) := (\mathbb{E}_v(f_v) \circ \mathbb{E}_w(g_w))(\mathbf{x})$ for short and suppose that $R(\mathbf{x}) = 0$ in (1) and $\mathbb{E}(F(\mathbf{x}_k))$ is bounded from above. Choose $\alpha_k = k^{-a}$ and $\beta_k = 2k^{-b}$ where $a \in (0,1)$ and $b \in (0,1)$ in Algorithm 1. Then we have*

$$\frac{\sum_{k=1}^K \mathbb{E}(\|\nabla F(\mathbf{x}_k)\|^2)}{K} \leq O(K^{a-1} + L_f^2 L_g K^{4b-4a} \mathbf{I}_{4a-4b=1}^{\log K} + L_f^2 K^{-b} + K^{-a}). \tag{4}$$

If $L_g \neq 0$ and $L_f \neq 0$, choose $a = 5/9$ and $b = 4/9$, yielding

$$\frac{\sum_{k=1}^K \mathbb{E}(\|\nabla F(\mathbf{x}_k)\|^2)}{K} \leq O(K^{-4/9}). \tag{5}$$

If $L_g = 0$ or $L_f = 0$, choose $a = b = 1/2$, yielding

$$\frac{\sum_{k=1}^K \mathbb{E}(\|\nabla F(\mathbf{x}_k)\|^2)}{K} \leq O(K^{-1/2}). \tag{6}$$

The result of Theorem 1 strictly improves the best-known results given by Wang et al. (2017). First the result of (5) improves the finite-sample error bound from $O(k^{-2/7})$ to $O(k^{-4/9})$ for general convex and nonconvex optimization. This improves the best known convergence rate and provides a new benchmark for the stochastic composition problem. Note that it is possible to relax the condition "$\mathbb{E}(F(\mathbf{x}_k))$ is bounded from above" in Theorem 1. However, it would make the analysis more cumbersome and yield an additional term $\log K$ in the error bound.

Our second main result concerns strongly convex objective functions. We say that the objective function H is *optimally strongly convex* with parameter $\lambda > 0$ if

$$H(\mathbf{x}) - H(\mathcal{P}_{X^*}(\mathbf{x})) \geq \lambda \|\mathbf{x} - \mathcal{P}_{X^*}(\mathbf{x})\|^2 \quad \forall \mathbf{x}. \tag{7}$$

(see Liu and Wright (2015)). Note that any strongly convex function is optimally strongly convex, but the reverse does not hold. For example, the objective function (2) in on-policy reinforcement learning is always optimally strongly convex (even if $\mathbb{E}(A)$ is a rank deficient matrix), but not necessarily strongly convex.

We point out that there are other class of functions that are not strongly convex, for which first-order algorithms still achieve linear convergence. See Karimi et al. (2016) and Necoara et al. (2015) for examples. For ease of presentation, in this work, we only consider optimally strongly convex functions.

Theorem 2 *(Strongly Convex Optimization) Suppose that the objective function $H(\mathbf{x})$ in (1) is optimally strongly convex with parameter $\lambda > 0$ defined in (7). Set $\alpha_k = C_a k^{-a}$ and $\beta_k = C_b k^{-b}$ where $C_a > 4\lambda$, $C_b > 2$, $a \in (0,1]$, and $b \in (0,1]$ in Algorithm 1. Under Assumptions 1, 2, 3, and 4, we have*

$$\mathbb{E}(\|\mathbf{x}_K - \mathcal{P}_{X^*}(\mathbf{x}_K)\|^2) \leq O\left(K^{-a} + L_f^2 L_g K^{-4a+4b} + L_f^2 K^{-b}\right). \tag{8}$$

If $L_g \neq 0$ and $L_f \neq 0$, choose $a = 1$ and $b = 4/5$, yielding

$$\mathbb{E}(\|\mathbf{x}_K - \mathcal{P}_{X^*}(\mathbf{x}_K)\|^2) \leq O(K^{-4/5}). \tag{9}$$

If $L_g = 0$ or $L_f = 0$, choose $a = 1$ and $b = 1$, yielding

$$\mathbb{E}(\|\mathbf{x}_K - \mathcal{P}_{X^*}(\mathbf{x}_K)\|^2) \leq O(K^{-1}). \tag{10}$$

Let us discuss the results of Theorem 2. In the general case where $L_f \neq 0$ and $L_g \neq 0$, the convergence rate in (9) is consistent with the result of Wang et al. (2017). Now consider the special case where $L_g = 0$, i.e., the inner mapping is linear. This result finds an immediate application to Bellman error minimization problem (2) which arises from reinforcement learning problem in (and with ℓ_1 norm regularization). The proposed ASC-PG algorithm is able to achieve the optimal rate $O(1/K)$ without any extra assumption on the outer function f_v. To the best of our knowledge, this is the best (also optimal) sample-error complexity for on-policy reinforcement learning.

Theorem 3 *(General Convex Optimization) Suppose that both $F(\mathbf{x})$ and $H(\mathbf{x})$ are convex, and the feasible set X is bounded. Set $\alpha_k = \Theta(k^{-a})$ and $\beta_k = \Theta(k^{-b})$ with $a \in (0,1)$, and $b \in (0,1]$ in Algorithm 1. Under Assumptions 1, 2, 3, and 4, we have for any $c > 0$:*

$$\begin{aligned} H(\bar{x}_K) - H^* \leq O\Big(&K^{a-1} + K^{a-c}\mathbf{I}_{c=1}^{\log K} + K^{-a} \\ &+ L_f^2 L_g K^{-5a+4b+c} \mathbf{I}_{6a-4b-c=1}^{\log K} + L_f^2 K^{-a-b+c} \mathbf{I}_{2a+b-c=1}^{\log K}\Big). \end{aligned} \tag{11}$$

where $\bar{\mathbf{x}}_K := \frac{\sum_{k=2}^{K+1} \alpha_k \mathbf{x}_k}{\sum_{k=2}^{K+1} \alpha_k}$. *If* $L_g \neq 0$ *and* $L_f \neq 0$, *choose* $a = 5/7$, $b = 4/7$, $c = 1$, *yielding*

$$H(\bar{x}_K) - H^* \leq O(K^{-2/7}). \tag{12}$$

If $L_g = 0$ *or* $L_f = 0$, *choose* $a = 1/2$, $b = 1$, *and* $c = 1$, *yielding*

$$H(\bar{x}_K) - H^* \leq O(K^{-1/2} \log K). \tag{13}$$

Theorem 3 gives stronger results than the best-known results of Wang et al. (2017) and requires milder assumptions. In the general case where $L_f \neq 0$ and $L_g \neq 0$, the convergence rate in (12) matches the result of Wang et al. (2017). When either $L_g = 0$ (i.e., the inner mapping is linear or $L_f = 0$ (i.e., the outer mapping is linear), the proposed ASC-PG algorithm is able to achieve the optimal rate $O(1/\sqrt{K})$ up to a logarithmic factor.

Remarks Theorems 1, 2, and 3 give important implications about the special cases where $L_f = 0$ or $L_g = 0$. In these cases, we argue that our convergence rate (10) is "*optimal*" with respect to the sample size K. To see this, it is worth pointing out the $O(1/K)$ rate of convergence is optimal for strongly convex expectation minimization problem. Because the expectation minimization problem is a special case of the problem (1), the $O(1/K)$ convergence rate must be optimal for the stochastic composition problem too. Similarly, the $O(1/\sqrt{K})$ rate of convergence is also optimal for general convex optimization due to the same argument.

- Consider the case where $L_f = 0$, which means that the outer function $f_v(\cdot)$ is linear with probability 1. Then the stochastic composition problem (1) reduces to an expectation minimization problem since $(\mathbb{E}_v f_v \circ \mathbb{E}_w g_w)(\mathbf{x}) = \mathbb{E}_v(f_v(\mathbb{E}_w g_w(\mathbf{x}))) = \mathbb{E}_v \mathbb{E}_w (f_v \circ g_w)(\mathbf{x})$. Therefore, it makes a perfect sense to obtain the optimal convergence rate.
- Consider the case where $L_g = 0$, which means that the inner function $g(\cdot)$ is a linear mapping. The result is quite surprising. Note that even $g(\cdot)$ is a linear mapping, it does not reduce problem (1) to an expectation minimization problem. However, the ASC-PG still achieves the optimal convergence rate. This suggests that, when inner linearity holds, the stochastic composition problem (1) is not fundamentally more difficult than the expectation minimization problem.

The convergence rate results unveiled in Theorems 1 and 2 are the best known results for the composition problem. We believe that they provide important new result which provides insights into the complexity of the stochastic composition problem.

4. Application to Reinforcement Learning

In this section, we apply the proposed ASC-PG algorithm to conduct policy value evaluation in reinforcement learning through attacking Bellman equations. Suppose that there are in total S states. Let the policy of interest be π. Denote the value function of states by $V^\pi \in \Re^S$, where $V^\pi(s)$ denotes the value of being at state s under policy π. The Bellman equation of the problem is

$$V^\pi(s_1) = \mathbb{E}_\pi\{r_{s_1,s_2} + \gamma \cdot V^\pi(s_2)|s_1\} \text{ for all } s_1, s_2 \in \{1, ..., S\},$$

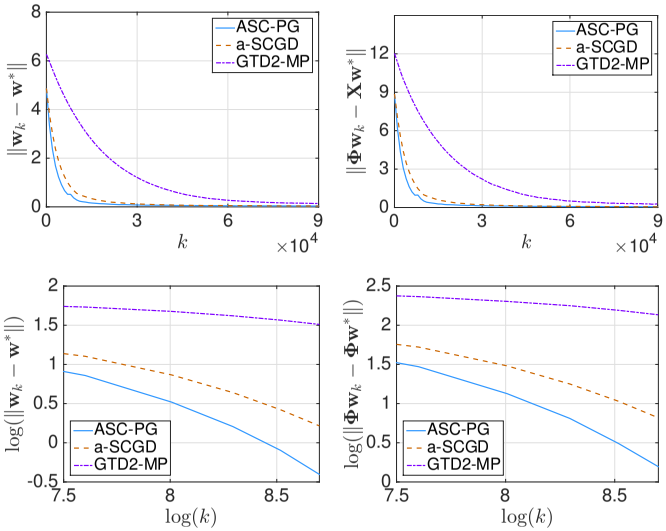

Figure 1: Empirical convergence rate of the ASC-PG algorithm and the GTD2-MP algorithm under Experiment 1 averaged over 100 runs, where $\mathbf{w}_k$ denotes the solution at the k-th iteration.

where r_{s_1,s_2} denotes the reward of moving from state s_1 to s_2, and the expectation is taken over all possible future state s_2 conditioned on current state s_1 and the policy π. We have that the solution $V^* \in \Re^S$ to the above equation satisfies that $V^* = V^\pi$. Here a moderately large S will make solving the Bellman equation directly impractical. To resolve the curse of dimensionality, in many practical applications, we approximate the value of each state by some linear map of its feature $\boldsymbol{\phi}_s \in \Re^d$, where $d < S$ to reduce the dimension. In particular, we assume that $V^\pi(s) \approx \boldsymbol{\phi}_s^T \mathbf{w}^*$ for some $\mathbf{w}^* \in \Re^m$.

To compute $\mathbf{w}^*$, we formulate the problem as a Bellman residual minimization problem that

$$\min_{\mathbf{w}} \sum_{s=1}^{S} (\boldsymbol{\phi}_s^T \mathbf{w} - q_{\pi,s}(\mathbf{w}))^2,$$

where $q_{\pi,s}(\mathbf{w}) = \mathbb{E}_\pi\{r_{s,s'} + \gamma \cdot \boldsymbol{\phi}_{s'}^T \mathbf{w}\} = \sum_{s'} P_{ss'}^\pi(\{r_{s,s'} + \gamma \cdot \boldsymbol{\phi}_{s'}^T \mathbf{w}\}$; $\gamma < 1$ is a discount factor, and $r_{s,s'}$ is the random reward of transition from state s to state s'. It is clearly seen that the proposed ASC-PG algorithm could be directly applied to solve this problem where we take

$$g(\mathbf{w}) = (\boldsymbol{\phi}_1^T \mathbf{w}, q_{\pi,1}(\mathbf{w}), ..., \boldsymbol{\phi}_S^T \mathbf{w}, q_{\pi,S}(\mathbf{w})) \in \Re^{2S},$$

$$f\Big((\boldsymbol{\phi}_1^T \mathbf{w}, q_{\pi,1}(\mathbf{w}), ..., \boldsymbol{\phi}_S^T \mathbf{w}, q_{\pi,S}(\mathbf{w}))\Big) = \sum_{s=1}^{S} (\boldsymbol{\phi}_s \mathbf{w} - q_{\pi,s}(\mathbf{w}))^2 \in \Re.$$

We point out that the $g(\cdot)$ function here is a linear map. By our theoretical analysis, we expect to achieve a faster $O(1/k)$ rate of convergence, which is justified empirically in our later simulation study.

We consider three experiments, where in the first two experiments, we compare our proposed accelerated ASC-PG algorithm with accelerated SCGD (a-SCGD) algorithm (Wang et al., 2017) and the recently proposed GTD2-MP algorithm (Liu et al., 2015). Also, in the first two experiments, we do not add any regularization term, i.e. $R(\cdot) = 0$. We point out here that in experiments 1 and 2, since there is no penalization term, i.e., $R(\cdot) = 0$, the ASC-PG algorithm essentially matches the a-SCGD algorithm in Wang et al. (2017). However, note that the choice of stepsizes $\{\alpha_k\}$ and $\{\beta_k\}$ of ASC-PG are different from the stepsizes of a-SCGD, where for ASC-PG $\alpha_k = k^{-1}$ and $\beta_k = k^{-1}$, and for a-SCGD $\alpha_k = k^{-1}$ and $\beta_k = k^{-4/5}$. In the third experiment, we add an ℓ_1-penalization term $\lambda\|\mathbf{w}\|_1$. In all cases, we choose the step sizes via comparison studies as in Dann et al. (2014):

- Experiment 1: We use the Baird's example (Baird, 1995), which is a well-known example to test the off-policy convergent algorithms. This example contains $S = 6$ states, and two actions at each state. We refer the readers to Baird (1995) for more detailed information of the example.

- Experiment 2: We generate a Markov decision problem (MDP) using similar setup as in White and White (2016). In each instance, we randomly generate an MDP which contains $S = 100$ states, and three actions at each state. The dimension of the Given one state and one action, the agent can move to one of four next possible states. In our simulation, we generate the transition probabilities for each MDP instance uniformly from $[0, 1]$ and normalize the sum of transitions to one, and we generate the reward for each transition also uniformly in $[0, 1]$.

- Experiment 3: We generate the data same as Experiment 2 except that we have a larger $d = 100$ dimensional feature space, where only the first 4 components of $\mathbf{w}^*$ are non-zeros. We add an ℓ_1-regularization term, $\lambda\|\mathbf{w}\|_1$, to the objective function.

Denote by $\mathbf{w}_k$ the solution at the k-th iteration. For the first two experiments, we report the empirical convergence performance $\|\mathbf{w}_k - \mathbf{w}^*\|$ and $\|\mathbf{\Phi}\mathbf{w}_k - \mathbf{\Phi}\mathbf{w}^*\|$, where $\mathbf{\Phi} = (\boldsymbol{\phi}_1, ..., \boldsymbol{\phi}_S)^T \in \Re^{S\times d}$ and $\mathbf{\Phi}\mathbf{w}^* = V$, and all $\mathbf{w}_k$'s are averaged over 100 runs, in the first two subfigures of Figures 1 and 2. It is seen that the ASC-PG algorithm achieves the fastest convergence rate empirically in both experiments. To further evaluate our theoretical results, we plot $\log(t)$ vs. $\log(\|\mathbf{w}_k - \mathbf{w}^*\|)$ (or $\log(\|\mathbf{\Phi}\mathbf{w}_k - \mathbf{\Phi}\mathbf{w}^*\|)$ averaged over 100 runs for the first two experiments in the second two subfigures of Figures 1 and 2. The empirical results further support our theoretical analysis that $\|\mathbf{w}_k - \mathbf{w}^*\|^2 = O(1/k)$ for the ASC-PG algorithm when $g(\cdot)$ is a linear mapping.

For Experiment 3, as the optimal solution is unknown, we run the ASC-PG algorithm for one million iterations and take the corresponding solution as the optimal solution $\hat{\mathbf{w}}^*$, and we report $\|\mathbf{w}_k - \hat{\mathbf{w}}^*\|$ and $\|\mathbf{\Phi}\mathbf{w}_k - \mathbf{\Phi}\hat{\mathbf{w}}^*\|$ averaged over 100 runs in Figure 3. It is seen the the ASC-PG algorithm achieves fast empirical convergence rate.

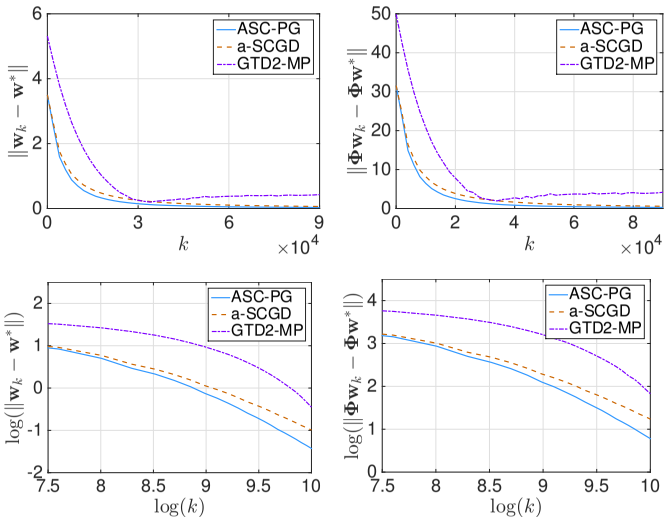

Figure 2: Empirical convergence rate of the ASC-PG algorithm and the GTD2-MP algorithm under Experiment 2 averaged over 100 runs, where $\mathbf{w}_k$ denotes the solution at the k-th iteration.

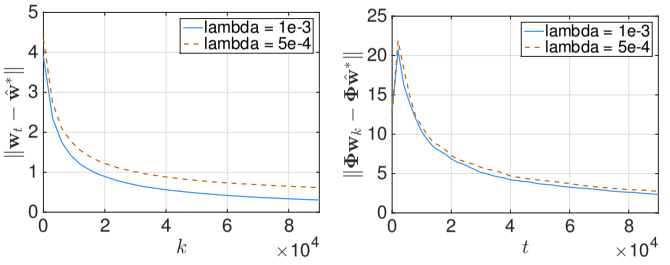

Figure 3: Empirical convergence rate of the ASC-PG algorithm with the ℓ_1-regularization term $\lambda\|\mathbf{w}\|_1$ under Experiment 3 averaged over 100 runs, where $\mathbf{w}_k$ denotes the solution at the t-th iteration.

5. Conclusion

We develop the first proximal gradient method for stochastic composition optimization with nonsmooth penalties. The algorithm updates by interacting with a stochastic first-order

oracle. Finite-sample convergence rates are established under a variety of assumptions, which provide new rate benchmarks that improve the best-known results prior to this paper. Application of the ASC-PG to reinforcement learning leads to a new on-policy learning algorithm, which achieves faster convergence than the best known algorithms. For future research, it remains open whether or under what circumstances the current $O(K^{-4/9})$ can be further improved. Another direction is to customize and adapt the algorithm and analysis to more specific problems arising from reinforcement learning and risk-averse optimization, in order to fully exploit the potential of the proposed method.

Acknowledgments

We thank the Editor, the Action Editor and two anonymous reviewers for the careful consideration and invaluable suggestions, which help us further improve the paper. Appendix

This appendix includes all detailed proofs for the theorems in the main text. The key idea of deriving the rate convergence of our algorithm is to find a sequence of random vectors associated with the output solutions at each iteration, which converge at fast rates. To better analyze the convergence process, we have constructed two auxiliary sequences of random variables $\{m_k\}$ and $\{n_k\}$, which are defined in the beginng of Lemma 7, that converge jointly to 0 at a fast rate. The convergence of $\{m_k\}$ and $\{n_k\}$ further imply that $\{\mathbf{x}_k\}$ and $\{\mathbf{y}_k\}$ converge rapidly to their limits respectively. Then we are able to improve the convergence rate of $\mathbf{y}_k$. Intuitively, we show that the improved iterate $\mathbf{y}_k$ tracks the unknown quantity $\mathbb{E}[g(x_k)]$ more closely than in the previous work. This explains why our new algorithm achieves an improved rate of convergence and sample complexity.

A. Proof to Theorem 1

In this section, we provide the detailed proof for Theorem 1. We start by some technical lemmas, The first one provides a convergence result of the generated solutions, where we bound the term $\|\mathbf{x}_k - \mathbf{x}_{k+1}\|^2$ as k increases.

Lemma 4 *Under Assumption 3, two subsequent iterates in Algorithm 1 satisfy*

$$\|\mathbf{x}_k - \mathbf{x}_{k+1}\|^2 \leq \Theta(\alpha_k^2).$$

Proof From the definition of the proximal operation, we have

$$\begin{aligned}\mathbf{x}_{k+1} &= \text{prox}_{\alpha_k R(\cdot)}(\mathbf{x}_k - \alpha_k \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k)) \\ &= \arg\min_x \frac{1}{2}\|\mathbf{x} - \mathbf{x}_k + \alpha_k \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k)\|^2 + \alpha_k R(\mathbf{x}).\end{aligned}$$

The optimality condition suggests the following equality:

$$\mathbf{x}_{k+1} - \mathbf{x}_k = -\alpha_k(\nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k) + \mathbf{s}_{k+1}) \tag{14}$$

where $\mathbf{s}_{k+1} \in \partial R(\mathbf{x}_{k+1})$ is some vector in the sub-differential set of $R(\cdot)$ at $\mathbf{x}_{k+1}$. Then apply the boundedness condition in Assumption 3 to yield

$$\begin{aligned}\|\mathbf{x}_{k+1} - \mathbf{x}_k\| &= \alpha_k\|(\nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k) + \mathbf{s}_{k+1})\| \\ &\leq \alpha_k(\|\nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k)\| + \|\mathbf{s}_{k+1}\|) \\ &\leq \alpha_k(\|\nabla g_{w_k}^\top(\mathbf{x}_k)\|\|\nabla f_{v_k}(\mathbf{y}_k)\| + \|\mathbf{s}_{k+1}\|) \\ &\overset{\text{(Assumption 3)}}{\leq} \Theta(1)\alpha_k,\end{aligned}$$

which implies the claim. ■

Next, we provide a simple bound which quantifies the difference between the random variable $\|\nabla g_w^\top(\mathbf{x})\nabla_v f(g(\mathbf{x})) - \nabla g_w^\top(\mathbf{x})\nabla_v f(\mathbf{y}))\|$ and its population version $\|\mathbf{y} - g(\mathbf{x})\|$.

Lemma 5 *Under Assumptions 3 and 4, we have*

$$\|\nabla g_w^\top(\mathbf{x})\nabla_v f(g(\mathbf{x})) - \nabla g_w^\top(\mathbf{x})\nabla_v f(\mathbf{y}))\| \leq \Theta(L_f\|\mathbf{y} - g(\mathbf{x})\|).$$

Proof We have

$$\begin{aligned}\|\nabla g_w^\top(\mathbf{x})\nabla f_v(g(\mathbf{x})) - \nabla g_w^\top(\mathbf{x})\nabla f_v(\mathbf{y}))\| &\leq \|\nabla g_w^\top(\mathbf{x})\|\|\nabla f_v(g(\mathbf{x})) - \nabla f_v(\mathbf{y})\| \\ &\overset{\text{(Assumption 3)}}{\leq} \Theta(1)\|\nabla f_v(g(\mathbf{x})) - \nabla f_v(\mathbf{y})\| \\ &\overset{\text{(Assumption 4)}}{\leq} \Theta(L_f)\|\mathbf{y} - g(\mathbf{x})\|.\end{aligned}$$

It completes the proof. ■

Then, we prove two lemmas which provides the convergence rate of $\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2)$.

Lemma 6 *Given two sequences of positive scalars $\{s_k\}_{k=1}^\infty$ and $\{\gamma_k\}_{k=1}^\infty$ satisfying*

$$s_{k+1} \leq (1 - \gamma_k + C_1\gamma_k^2)s_k + C_2 k^{-a} \tag{15}$$

where $C_1 \geq 0$, $C_2 \geq 0$, and $a \geq 0$. Letting $\gamma_k \in \Re$ as $\gamma_k = C_3 k^{-b}$ where $b \in (0, 1]$ and $C_3 > 2$, the sequence can be bounded by

$$v_k \leq Ck^{-c}$$

where C and c are defined as

$$C := \max_{k \leq (C_1 C_3^2)^{1/b}+1} s_k k^c + \frac{C_2}{C_3 - 2} \quad \text{and} \quad c := a - b.$$

In other words, we have

$$s_k \leq \Theta(k^{-a+b}).$$

Proof We prove it by induction. First it is easy to verify that the claim holds for $k \leq (C_1C_3^2)^{1/b}$ from the definition for C. Next we prove from "k" to "$k+1$", that is, given $s_k \leq Ck^{-c}$ for $k > (C_1C_3^2)^{1/b}$, we need to prove $s_{k+1} \leq C(k+1)^{-c}$.

$$\begin{aligned} s_{k+1} &\leq (1-\gamma_k+C_1\gamma_k^2)s_k + C_2k^{-a} \\ &\leq (1-C_3k^{-b}+C_1C_3^2k^{-2b})Ck^{-c} + C_2k^{-a} \\ &= Ck^{-c} - CC_3k^{-b-c} + CC_1C_3^2k^{-2b-c} + C_2k^{-a}. \end{aligned} \tag{16}$$

To prove that (16) is bounded by $C(k+1)^{-c}$, it suffices to show that

$$\Delta := (k+1)^{-c} - k^{-c} + C_3k^{-b-c} - C_1C_3^2k^{-2b-c} > 0 \quad \text{and} \quad C \geq \frac{C_2k^{-a}}{\Delta}.$$

From the convexity of function $h(t) = t^{-c}$, we have the inequality $(k+1)^{-c} - k^{-c} \geq (-c)k^{-c-1}$. Therefore we obtain

$$\begin{aligned} \Delta &\geq -ck^{-c-1} + C_3k^{-b-c} - C_1C_3^2k^{-2b-c} \\ &\overset{(b\leq 1,\ k>(C_1C_3^2)^{1/b})}{\geq} (C_3-2)(k^{-b-c}) \\ &\overset{(C_3>2)}{>} 0. \end{aligned}$$

To verify the second one, we have

$$\frac{C_2k^{-a}}{\Delta} \leq \frac{C_2}{C_3-2}k^{-a+b+c} \overset{(c=a+b)}{=} \frac{C_2}{C_3-2} \leq C$$

where the last inequality is due to the definition of C. It completes the proof. ■

Lemma 7 *Choose β_k to be $\beta_k = C_bk^{-b}$ where $C_b > 2$, $b \in (0,1]$, and $\alpha_k = C_ak^{-a}$. Under Assumptions 1 and 2, we have*

$$\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2) \leq L_g\Theta(k^{-4a+4b}) + \Theta(k^{-b}). \tag{17}$$

Proof Denote by m_{k+1}

$$m_{k+1} := \sum_{t=0}^{k} \xi_t^{(k)} \|\mathbf{x}_{k+1} - \mathbf{z}_{t+1}\|^2$$

and n_{k+1}

$$n_{k+1} := \left\| \sum_{t=0}^{k} \xi_t^{(k)} (g_{w_{t+1}}(\mathbf{z}_{t+1}) - g(\mathbf{z}_{t+1})) \right\|$$

for short.

From Lemma 10 in (Wang et al., 2017), we have

$$\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2 \leq \left(\frac{L_g}{2}m_k + n_k\right)^2 \leq L_gm_k^2 + 2n_k^2. \tag{18}$$

From Lemma 11 in (Wang et al., 2017), m_{k+1} can be bounded by

$$m_{k+1} \leq (1-\beta_k)m_k + \beta_kq_k + \frac{2}{\beta_k}\|\mathbf{x}_k - \mathbf{x}_{k+1}\|^2 \tag{19}$$

where q_k is bounded by

$$\begin{aligned} q_{k+1} &\leq (1-\beta_k)q_k + \frac{4}{\beta_k}\|\mathbf{x}_{k+1} - \mathbf{x}_k\|^2 \\ &\overset{\text{(Lemma 4)}}{\leq} (1-\beta_k)q_k + \frac{\Theta(1)\alpha_k^2}{\beta_k} \\ &\leq (1-\beta_k)q_k + \Theta(k^{-2a+b}). \end{aligned}$$

Taking $s_k = q_k$, and $\gamma_k = \beta_k$, applying Lemma 6 implies the following decay rate

$$q_k \leq \Theta(k^{-2a+b+b}) = \Theta(k^{-2a+2b}).$$

Together with (19), we have

$$\begin{aligned} m_{k+1} &\leq (1-\beta_k)m_k + \beta_kq_k + \frac{2}{\beta_k}\|\mathbf{x}_k - \mathbf{x}_{k+1}\|^2 \\ &\leq (1-\beta_k)m_k + \Theta(k^{-2a+b}) + \Theta(k^{-2a+b}) \\ &\leq (1-\beta_k)m_k + \Theta(k^{-2a+b}), \end{aligned}$$

which leads to

$$m_k \leq \Theta(k^{-2a+2b}) \quad \text{and} \quad m_k^2 \leq \Theta(k^{-4a+4b}). \tag{20}$$

by using Lemma 6 again. Then we estimate the upper bound for $\mathbb{E}(n_k^2)$. From Lemma 11 in (Wang et al., 2017), we know $\mathbb{E}(n_k^2)$ is bounded by

$$\mathbb{E}(n_{k+1}^2) \leq (1-\beta_k)^2\mathbb{E}(\|n_k\|^2) + \beta_k^2\sigma_g^2 = (1-2\beta_k+\beta_k^2)\mathbb{E}(\|n_k\|^2) + \beta_k^2\sigma_g^2.$$

By using Lemma 6 again, we have

$$\mathbb{E}(n_k^2) \leq \Theta(k^{-b}). \tag{21}$$

Now we are ready to estimate the upper bound of $\|\mathbf{y}_{k+1} - g(\mathbf{x}_{k+1})\|^2$ by following (18)

$$\begin{aligned} \mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2) &\leq L_g\mathbb{E}(m_k^2) + 2\mathbb{E}(n_k^2) \\ &\overset{(20)+(21)}{\leq} L_g\Theta(k^{-4a+4b}) + \Theta(k^{-b}). \end{aligned}$$

It completes the proof. ■

Now we are ready to prove Theorem 1.

Proof to Theorem 1. From the Lipschitzian condition in Assumption 4, we have

$$F(\mathbf{x}_{k+1}) - F(\mathbf{x}_k)$$

$$
\begin{aligned}
&\leq && \langle \nabla F(\mathbf{x}_k),\ \mathbf{x}_{k+1}-\mathbf{x}_k\rangle + \frac{L_F}{2}\|\mathbf{x}_{k+1}-\mathbf{x}_k\|^2 \\
&\text{(Lemma 6)} \\
&\leq && -\alpha_k \langle \nabla F(\mathbf{x}_k),\ \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k)\rangle + \Theta(\alpha_k^2) \\
&= && -\alpha_k\|\nabla F(\mathbf{x}_k)\|^2 + \alpha_k \underbrace{\langle \nabla F(\mathbf{x}_k),\ \nabla F(\mathbf{x}_k) - \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k)\rangle}_{=:T} \\
& && +\Theta(\alpha_k^2) \qquad (22)
\end{aligned}
$$

Next we estimate the upper bound for $\mathbb{E}(T)$:

$$
\begin{aligned}
\mathbb{E}(T) &= && \mathbb{E}(\langle \nabla F(\mathbf{x}_k),\ \nabla F(\mathbf{x}_k) - \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(g(\mathbf{x}_k))\rangle) \\
& && +\mathbb{E}(\langle \nabla F(\mathbf{x}_k),\ \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(g(\mathbf{x}_k)) - \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k)\rangle) \\
&\text{(Assumption 1)} \\
& = && \mathbb{E}(\langle \nabla F(\mathbf{x}_k),\ \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(g(\mathbf{x}_k)) - \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k)\rangle) \\
& \leq && \frac{1}{2}\mathbb{E}(\|\nabla F(\mathbf{x}_k)\|^2) + \frac{1}{2}\mathbb{E}(\|\nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(g(\mathbf{x}_k)) - \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k)\|^2) \\
&\text{(Lemma 5)} \\
& \leq && \frac{1}{2}\mathbb{E}(\|\nabla F(\mathbf{x}_k)\|^2) + \Theta(L_f^2)\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2).
\end{aligned}
$$

Take expectation on both sides of (22) and substitute $\mathbb{E}(T)$ by its upper bound:

$$
\begin{aligned}
& && \frac{\alpha_k}{2}\|\nabla F(\mathbf{x}_k)\|^2 \\
&\leq && \mathbb{E}(F(\mathbf{x}_k)) - \mathbb{E}(F(\mathbf{x}_{k+1})) + \Theta(L_f^2\alpha_k)\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2) + \Theta(\alpha_k^2) \\
&\text{(Lemma 7)} \\
&\leq && \mathbb{E}(F(\mathbf{x}_k)) - \mathbb{E}(F(\mathbf{x}_{k+1})) + L_g\Theta(L_f^2\alpha_k)\Theta(k^{-4a+4b}) + \Theta(L_f^2\alpha_k k^{-b}) + \Theta(\alpha_k^2) \\
&\leq && \mathbb{E}(F(\mathbf{x}_k)) - \mathbb{E}(F(\mathbf{x}_{k+1})) + L_f^2 L_g\Theta(k^{-5a+4b}) + L_f^2\Theta(k^{-a-b}) + \Theta(k^{-2a})
\end{aligned}
$$

which suggests that

$$
\begin{aligned}
& && \mathbb{E}(\|\nabla F(\mathbf{x}_k)\|^2) \\
&\leq && 2\alpha_k^{-1}\mathbb{E}(F(\mathbf{x}_k)) - 2\alpha_k^{-1}\mathbb{E}(F(\mathbf{x}_{k+1})) + L_f^2 L_g\Theta(k^{-4a+4b}) + L_f^2\Theta(k^{-b}) + \Theta(k^{-a}) \\
&\leq && 2k^a\mathbb{E}(F(\mathbf{x}_k)) - 2k^a\mathbb{E}(F(\mathbf{x}_{k+1})) + L_f^2 L_g\Theta(k^{-4a+4b}) + L_f^2\Theta(k^{-b}) + \Theta(k^{-a}). \qquad (23)
\end{aligned}
$$

Sum Eq. (23) from $k=1$ to K and obtain

$$
\begin{aligned}
\frac{\sum_{k=1}^K \mathbb{E}(\|\nabla F(\mathbf{x}_k)\|^2)}{K} &\leq 2K^{-1}\alpha_1^{-1}F(\mathbf{x}_1) + K^{-1}\sum_{k=2}^K((k+1)^a - k^a)\mathbb{E}(F(\mathbf{x}_k)) \\
&\quad + K^{-1}\sum_{k=1}^K L_f^2 L_g\Theta(k^{-4a+4b}) + K^{-1}L_f^2\sum_{k=1}^K\Theta(k^{-b}) + K^{-1}\sum_{k=1}^K\Theta(k^{-a}) \\
&\leq 2K^{-1}F(\mathbf{x}_0) + K^{-1}\sum_{k=2}^K ak^{a-1}\mathbb{E}(F(\mathbf{x}_k)) \\
&\quad + K^{-1}\sum_{k=1}^K L_f^2 L_g\Theta(k^{-4a+4b}) + K^{-1}L_f^2\sum_{k=1}^K\Theta(k^{-b}) + K^{-1}\sum_{k=1}^K\Theta(k^{-a})
\end{aligned}
$$

$$
\leq O(K^{a-1} + L_f^2 L_g K^{4b-4a}\mathbf{I}_{4a-4b=1}^{\log K} + L_f^2 K^{-b} + K^{-a}),
$$

where the second inequality uses the fact that $h(t) = t^a$ is a concave function suggesting $(k+1)^a \leq k^a + ak^{a-1}$, and the last inequality uses the condition $\mathbb{E}(F(\mathbf{x}_k)) \leq \Theta(1)$.

Letting $a^* = 5/9$ and $b^* = 4/9$, we obtain the desired convergence rate $O(K^{-4/9})$. ■

B. Proof to Theorem 2

In this section, we provide the detailed proof for Theorem 2. The proof is based on the following key lemma, which provides a "contraction" property of $(\mathbb{E}(H(\mathbf{x}_{k+1})) - H^*)$ and $\mathbb{E}(\|\mathbf{x}_{k+1} - \mathcal{P}_{X^*}(\mathbf{x}_{k+1})\|^2)$.

Lemma 8 *Assume that both $F(\mathbf{x})$ and $R(\mathbf{x})$ are convex. Under Assumptions 1, 2, 3, and 4, the iterates generated by Algorithm 1 satisfies for any sequence of positive scalars $\{\phi_k\}$:*

$$
\begin{aligned}
&2\alpha_k(\mathbb{E}(H(\mathbf{x}_{k+1})) - H^*) + \mathbb{E}(\|\mathbf{x}_{k+1} - \mathcal{P}_{X^*}(\mathbf{x}_{k+1})\|^2) \qquad (24) \\
&\quad \leq (1+\phi_k)\mathbb{E}(\|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2) + \Theta(\alpha_k^3) + \Theta(L_f^2\alpha_k^2/\phi_k)\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2) + \Theta(\alpha_k^2).
\end{aligned}
$$

Proof Following the line of the proof to Lemma 4, we have

$$
\mathbf{x}_{k+1} - \mathbf{x}_k = -\alpha_k(\nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k) + \mathbf{s}_{k+1}) \qquad (25)
$$

where $\mathbf{s}_{k+1} \in \partial R(\mathbf{x}_{k+1})$ is some vector in the sub-differential set of $R(\cdot)$ at $\mathbf{x}_{k+1}$. Then we consider $\|\mathbf{x}_{k+1} - \mathcal{P}_{X^*}(\mathbf{x}_{k+1})\|^2$:

$$
\begin{aligned}
& && \|\mathbf{x}_{k+1} - \mathcal{P}_{X^*}(\mathbf{x}_{k+1})\|^2 \\
&\leq && \|\mathbf{x}_{k+1} - \mathbf{x}_k + \mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2 \\
&= && \|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2 - \|\mathbf{x}_{k+1} - \mathbf{x}_k\|^2 + 2\langle \mathbf{x}_{k+1} - \mathbf{x}_k, \mathbf{x}_{k+1} - \mathcal{P}_{X^*}(\mathbf{x}_k)\rangle \\
&\overset{(25)}{=} && \|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2 - \|\mathbf{x}_{k+1} - \mathbf{x}_k\|^2 - 2\alpha_k\langle \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k) + \mathbf{s}_{k+1},\ \mathbf{x}_{k+1} - \mathcal{P}_{X^*}(\mathbf{x}_k)\rangle \\
&= && \|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2 - \|\mathbf{x}_{k+1} - \mathbf{x}_k\|^2 + 2\alpha_k\langle \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k), \mathcal{P}_{X^*}(\mathbf{x}_k) - \mathbf{x}_{k+1}\rangle \\
& && +2\alpha_k\langle \mathbf{s}_{k+1},\ \mathcal{P}_{X^*}(\mathbf{x}_k) - \mathbf{x}_{k+1}\rangle \\
&\leq && \|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2 - \|\mathbf{x}_{k+1} - \mathbf{x}_k\|^2 + 2\alpha_k\langle \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k), \mathcal{P}_{X^*}(\mathbf{x}_k) - \mathbf{x}_{k+1}\rangle \\
& && +2\alpha_k(R(\mathcal{P}_{X^*}(\mathbf{x}_k)) - R(\mathbf{x}_{k+1})) \qquad \text{(due to the convexity of } R(\cdot)) \\
&\leq && \|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2 - \|\mathbf{x}_{k+1} - \mathbf{x}_k\|^2 + 2\alpha_k \underbrace{\langle \nabla F(\mathbf{x}_k), \mathcal{P}_{X^*}(\mathbf{x}_k) - \mathbf{x}_{k+1}\rangle}_{T_1} \\
& && +2\alpha_k \underbrace{\langle \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k) - \nabla F(\mathbf{x}_k),\ \mathcal{P}_{X^*}(\mathbf{x}_k) - \mathbf{x}_{k+1}\rangle}_{T_2} \\
& && +2\alpha_k(R(\mathcal{P}_{X^*}(\mathbf{x}_k)) - R(\mathbf{x}_{k+1})) \qquad (26)
\end{aligned}
$$

where the second equality follows from $\|a+b\|^2 = \|b\|^2 - \|a\|^2 + 2\langle a,\ a+b\rangle$ with $a = \mathbf{x}_{k+1} - \mathbf{x}_k$ and $b = \mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)$. We next estimate the upper bound for T_1 and T_2 respectively:

$$
T_1 = \langle \nabla F(\mathbf{x}_k),\ \mathbf{x}_k - \mathbf{x}_{k+1}\rangle + \langle \nabla F(\mathbf{x}_k),\ -\mathbf{x}_k + \mathcal{P}_{X^*}(\mathbf{x}_k)\rangle
$$

$$\begin{aligned}
&\leq \underbrace{F(\mathbf{x}_k) - F(\mathbf{x}_{k+1}) + \frac{L_F}{2}\|\mathbf{x}_{k+1} - \mathbf{x}_k\|^2}_{\text{due to Assumption 4}} + \underbrace{F(\mathcal{P}_{X^*}(\mathbf{x}_k)) - F(\mathbf{x}_k)}_{\text{due to the convexity of } F(\cdot)} \\
&= F(\mathcal{P}_{X^*}(\mathbf{x}_k)) - F(\mathbf{x}_{k+1}) + \frac{L_F}{2}\|\mathbf{x}_{k+1} - \mathbf{x}_k\|^2 \\
&\leq F(\mathcal{P}_{X^*}(\mathbf{x}_k)) - F(\mathbf{x}_{k+1}) + \Theta(\alpha_k^2),
\end{aligned}$$

where the last inequality uses Lemma 4.

$$\begin{aligned}
T_2 &= \langle \nabla F(\mathbf{x}_k) - \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k),\ \mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\rangle \\
&\quad + \langle \nabla F(\mathbf{x}_k) - \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k),\ \mathbf{x}_{k+1} - \mathbf{x}_k\rangle \\
&\leq \underbrace{\langle \nabla F(\mathbf{x}_k) - \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(g(\mathbf{x}_k)),\ \mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\rangle}_{T_{2,1}} \\
&\quad + \underbrace{\langle \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(g(\mathbf{x}_k)) - \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k),\ \mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\rangle}_{T_{2,2}} \\
&\quad + \frac{\alpha_k}{2}\underbrace{\|\nabla F(\mathbf{x}_k) - \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k)\|^2}_{T_{2,3}} + \frac{1}{2\alpha_k}\|\mathbf{x}_k - \mathbf{x}_{k+1}\|^2
\end{aligned}$$

where the last line is due to the inequality $\langle a, b\rangle \leq \frac{1}{2\alpha_k}\|a\|^2 + \frac{\alpha_k}{2}\|b\|^2$. For $T_{2,1}$, we have $\mathbb{E}(T_{2,1}) = 0$ due to Assumption 1. For $T_{2,2}$, we have

$$\begin{aligned}
T_{2,2} &\leq \frac{\alpha_k}{2\phi_k}\|\nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(g(\mathbf{x}_k)) - \nabla g_{w_k}^\top(\mathbf{x}_k)\nabla f_{v_k}(\mathbf{y}_k)\|^2 + \frac{\phi_k}{2\alpha_k}\|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2 \\
&\overset{\text{(Lemma 5)}}{\leq} \Theta\left(L_f^2\frac{\alpha_k}{\phi_k}\right)\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2 + \frac{\phi_k}{2\alpha_k}\|\mathbf{x}_k - \mathbf{x}_{k+1}\|^2.
\end{aligned}$$

$T_{2,3}$ can be bounded by a constant

$$T_{2,3} \leq 2\|\nabla F(\mathbf{x}_k)\|^2 + 2\|\nabla g_{w_k}^\top \nabla f_{v_k}(\mathbf{y}_k)\|^2 \overset{\text{(Assumption 3)}}{\leq} \Theta(1).$$

Take expectation on T_2 and put all pieces into it:

$$\mathbb{E}(T_2) \leq \Theta\left(L_f^2\frac{\alpha_k}{\phi_k}\right)\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2 + \frac{1}{2\alpha_k}(\phi_k\|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2 + \|\mathbf{x}_k - \mathbf{x}_{k+1}\|^2) + \Theta(\alpha_k).$$

Taking expectation on both sides of (26) and plugging the upper bounds of T_1 and T_2 into it, we obtain

$$\begin{aligned}
&2\alpha_k(\mathbb{E}(H(\mathbf{x}_{k+1})) - H^*) + \mathbb{E}(\|\mathbf{x}_{k+1} - \mathcal{P}_{X^*}(\mathbf{x}_{k+1})\|^2) \\
&\quad \leq (1+\phi_k)\mathbb{E}(\|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2) + \Theta(\alpha_k^3) + \Theta(L_f^2\alpha_k^2/\phi_k)\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2) + \Theta(\alpha_k^2),
\end{aligned}$$

which completes the proof. ■

Then, we prove the Theorem 2 based on the previous lemma.

Proof to Theorem 2 Apply the optimally strong convexity in (7) to Lemma 8, yielding

$$\begin{aligned}
&(1+2\lambda\alpha_k)\mathbb{E}(\|\mathbf{x}_{k+1} - \mathcal{P}_{X^*}(\mathbf{x}_{k+1})\|^2) \\
&\quad \leq (1+\phi_k)\mathbb{E}(\|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2) + \Theta(\alpha_k^3) + \Theta(L_f^2\alpha_k^2/\phi_k)\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2) + \Theta(\alpha_k^2).
\end{aligned}$$

It follows by dividing $1 + 2\lambda\alpha_k$ on both sides

$$\begin{aligned}
&\mathbb{E}(\|\mathbf{x}_{k+1} - \mathcal{P}_{X^*}(\mathbf{x}_{k+1})\|^2) \\
&\quad \leq \frac{1+\phi_k}{1+2\lambda\alpha_k}\mathbb{E}(\|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2) + \Theta(\alpha_k^3) + \Theta(L_f^2\alpha_k^2/\phi_k)\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2) + \Theta(\alpha_k^2).
\end{aligned}$$

Choosing $\phi_k = \lambda\alpha_k - 2\lambda^2\alpha_k^2 \geq 0.5\lambda\alpha_k$ yields

$$\begin{aligned}
&\mathbb{E}(\|\mathbf{x}_{k+1} - \mathcal{P}_{X^*}(\mathbf{x}_{k+1})\|^2) \\
&\leq (1-\lambda\alpha_k)\mathbb{E}(\|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2) + \Theta(\alpha_k^2) + \frac{\Theta(L_f^2\alpha_k)}{\lambda}\mathbb{E}(\|g(\mathbf{x}_k) - \mathbf{y}_k\|^2) \\
&\leq (1-\lambda\alpha_k)\mathbb{E}(\|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2) + \Theta(k^{-2a}) + \Theta(L_g L_f^2 k^{-5a+4b} + L_f^2 k^{-a-b}).
\end{aligned}$$

Apply Lemma 6 and substitute the subscript k by K to obtain the first claim in (8)

$$\mathbb{E}(\|\mathbf{x}_K - \mathcal{P}_{X^*}(\mathbf{x}_K)\|^2) \leq O\left(K^{-a} + L_f^2 L_g K^{-4a+4b} + L_f^2 K^{-b}\right).$$

The followed specification of a and b can easily verified. ■

C. Proof to Theorem 3

In what follows, we provide the detailed proof to Theorem 3.

Proof to Theorem 3 Let $P_k = 2\alpha_k(\mathbb{E}(H(\mathbf{x}_{k+1})) - H^*) + \mathbb{E}(\|\mathbf{x}_{k+1} - \mathcal{P}_{X^*}(\mathbf{x}_{k+1})\|^2)$, which is the left hand side of inequality (24). Summing P_k up from $k = 1$ to $k = K$ and taking $\phi_k = \Theta(k^{-c})$ yields

$$\begin{aligned}
&2\sum_{k=1}^K \alpha_k(\mathbb{E}(H(\mathbf{x}_{k+1})) - H^*) + \mathbb{E}(\|\mathbf{x}_{K+1} - \mathcal{P}_{X^*}(\mathbf{x}_{K+1})\|^2) \\
&\leq (1+\phi_1)\mathbb{E}(\|\mathbf{x}_1 - \mathcal{P}_{X^*}(\mathbf{x}_1)\|^2) + \sum_{k=2}^K \phi_k\mathbb{E}(\|\mathbf{x}_k - \mathcal{P}_{X^*}(\mathbf{x}_k)\|^2) \\
&\quad + \sum_{k=2}^K \Theta(L_f^2\alpha_k^2/\phi_k)\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2) + \Theta(\alpha_k^2) \\
&\leq \Theta(1) + \Theta\left(\sum_{k=2}^K \phi_k\right) + \Theta(K^{1-2a}) + \sum_{k=2}^K \Theta(L_f^2\alpha_k^2/\phi_k)\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2)
\end{aligned}$$

$$\leq \quad \Theta(1) + \Theta\left(K^{1-c}\mathbf{I}_{c=1}^{\log K}\right) + O(K^{1-2a}) + \sum_{k=2}^{K} \Theta(L_f^2 \alpha_k^2/\phi_k)\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2). \quad (27)$$

Note that the second inequality holds by the condition that the feasible set X is bounded, and thus $\|x_k - \mathcal{P}_{X^*}(x_k)\|^2$ is bounded.

We continue to bound the last term on the right hand side of (27):

$$\begin{aligned} & \sum_{k=2}^{K} \Theta(L_f^2 \alpha_k^2/\phi_k)\mathbb{E}(\|\mathbf{y}_k - g(\mathbf{x}_k)\|^2) \\ \text{(Lemma 7)} \quad \leq \quad & \sum_{k=2}^{K} L_f^2 L_g \Theta(k^{-6a+4b-c}) + L_f^2 \Theta(k^{-2a-b-c}) \\ \leq \quad & L_f^2 L_g \Theta(K^{1-6a+4b-c}\mathbf{I}_{6a-4b-c=1}^{\log K}) + L_f^2 \Theta(K^{1-2a-b-c}\mathbf{I}_{2a+b-c=1}^{\log K}). \quad (28) \end{aligned}$$

Plugging (28) into (27) and dividing $2\sum_{k=1}^{K}\alpha_k$ on both sides:

$$\begin{aligned} & \frac{2\sum_{k=1}^{K}\alpha_k H(\mathbf{x}_{k+1}) - H^*}{2\sum_{k=1}^{K}\alpha_k} \\ \leq \quad & \frac{\Theta(1) + \Theta\left(K^{1-c}\mathbf{I}_{c=1}^{\log K}\right) + \Theta(K^{1-2a})}{2\sum_{k=1}^{K}\alpha_k} \\ & + \frac{L_f^2 L_g \Theta(K^{1-6a+4b+c}\mathbf{I}_{6a-4b-c=1}^{\log K}) + L_f^2\Theta(K^{1-2a-b+c}\mathbf{I}_{2a-b+c=1}^{\log K})}{2\sum_{k=1}^{K}\alpha_k} \\ \leq \quad & O(K^{a-1}) + O(K^{a-c}\mathbf{I}_{c=1}^{\log K}) + O(K^{-a}) \\ & + O(L_f^2 L_g K^{-5a+4b+c}\mathbf{I}_{6a-4b-c=1}^{\log K}) + O(L_f^2 K^{-a-b+c}\mathbf{I}_{2a+b-c=1}^{\log K}) \\ = \quad & O\left(K^{a-1} + K^{a-c}\mathbf{I}_{c=1}^{\log K} + K^{-a} + L_f^2 L_g K^{-5a+4b+c}\mathbf{I}_{6a-4b-c=1}^{\log K} + L_f^2 K^{-a-b+c}\mathbf{I}_{2a+b-c=1}^{\log K}\right). \end{aligned}$$

where the last inequality uses the fact $\sum_{k=1}^{K}\alpha_k \geq \Theta(K^{1-a})$. To finish the proof of (11), we use Jensen's inequality

$$\frac{2\sum_{k=1}^{K}\alpha_k H(\mathbf{x}_{k+1})}{2\sum_{k=1}^{K}\alpha_k} \geq H(\bar{\mathbf{x}}_K).$$

Abstract

This paper makes two contributions to Bayesian machine learning algorithms. Firstly, we propose stochastic natural gradient expectation propagation (SNEP), a novel alternative to expectation propagation (EP), a popular variational inference algorithm. SNEP is a black box variational algorithm, in that it does not require any simplifying assumptions on the distribution of interest, beyond the existence of some Monte Carlo sampler for estimating the moments of the EP tilted distributions. Further, as opposed to EP which has no guarantee of convergence, SNEP can be shown to be convergent, even when using Monte Carlo moment estimates. Secondly, we propose a novel architecture for distributed Bayesian learning which we call the posterior server. The posterior server allows scalable and robust Bayesian learning in cases where a data set is stored in a distributed manner across a cluster, with each compute node containing a disjoint subset of data. An independent Monte Carlo sampler is run on each compute node, with direct access only to the local data subset, but which targets an approximation to the global posterior distribution given all data across the whole cluster. This is achieved by using a distributed asynchronous implementation of SNEP to pass messages across the cluster. We demonstrate SNEP and the posterior server on distributed Bayesian learning of logistic regression and neural networks.

Keywords: Distributed Learning, Large Scale Learning, Deep Learning, Bayesian Learning, Variational Inference, Expectation Propagation, Stochastic Approximation, Natural Gradient, Markov chain Monte Carlo, Parameter Server, Posterior Server.

1. Introduction

Algorithms and systems for enabling machine learning from large scale data sets are becoming increasingly important in the era of Big Data. This has driven many developments, including various forms of stochastic gradient descent, parallel and distributed learning systems, use of GPUs, sketching, random Fourier features, divide-and-conquer methods, as well as various approximation schemes. These large scale machine learning systems have in turn driven significant advances across many data-oriented sciences and technologies, ranging from the biological sciences, neuroscience, social sciences, signal processing, speech processing, natural language processing, computer vision etc.

In this paper we will consider methods for large scale *Bayesian* machine learning. As opposed to the more common empirical risk minimisation or maximum likelihood approaches, where learning is phrased as finding a set of parameters optimal with respect to a data set and to a loss or likelihood function, Bayesian machine learning rests upon probabilistic models which capture the dependencies among all observed and unobserved variables, and where learning is phrased as computing the posterior distribution over unobserved variables (including both latent variables and model parameters) given the observed data.

The Bayesian framework can more fully capture the uncertainty in learnt parameters and prevent overfitting. In principle this allows the use of more complex and larger scale models. However, Bayesian approaches are generally more computationally intensive than optimisation-based ones, and have to date not led to methods which are as scalable.

For complex models, exact computation of the posterior distribution is intractable and approximate schemes such as variational inference (VI) (Wainwright and Jordan, 2008), Markov chain Monte Carlo (MCMC) (Gilks et al., 1996) and sequential Monte Carlo (Doucet et al., 2001) are needed. Scalable methods in both traditions include: stochastic variational inference (Hoffman et al., 2013, Mnih and Gregor, 2014, Rezende et al., 2014) which apply minibatch stochastic gradient descent (Robbins and Monro, 1951) to optimise the variational objective function, stochastic gradient MCMC (Welling and Teh, 2011, Patterson and Teh, 2013, Ding et al., 2014, Teh et al., 2015, Leimkuhler, B. and Shang, X., 2016, Ma et al., 2015, Li et al., 2016) which uses minibatch stochastic gradients within MCMC, austerity MCMC (Korattikara et al., 2014, Bardenet et al., 2014) which uses data subsampling to reduce computational cost of Metropolis-Hastings acceptance steps, and embarrassingly parallel MCMC (Huang and Gelman, 2005, Scott et al., 2013, Wang and Dunson, 2013, Neiswanger et al., 2014) which distribute data across a cluster, runs independent MCMC samplers on each worker and combines samples across the cluster only at the end to reduce network communication costs. In addition, standard learning schemes have also been successfully deployed in large scale settings. A successful example that is particularly relevant to our work is expectation propagation (EP), introduced by (Minka, 2001) and (Opper and Winther, 2000) which iteratively constructs approximations to a factorized distribution. EP is at the heart of the TrueSkill XBox player rating and matching system (Herbrich et al., 2007).

Our work builds upon prior work on using EP for performing distributed Bayesian learning (Xu et al., 2014, Gelman et al., 2014). In this framework, a data set is partitioned into disjoint subsets with each subset stored on a worker node in a cluster. Learning is performed at each worker based on the data subset there using MCMC sampling. As

opposed to embarrassingly parallel MCMC methods which only communicate the samples to the master at the end of learning, EP is used to communicate messages (infrequently) across the cluster. These messages coordinate the samplers such that the target distributions (which coincidentally are the tilted distributions in EP) of all samplers on all workers share certain moments, e.g. means and variances, hence the name sampling via moment sharing (SMS) coined by (Xu et al., 2014). At convergence, it can be shown that the target distributions of the samplers also share moments with the EP approximation to the global posterior distribution given all data, hence the target distributions on the workers can themselves be treated as approximations to the global posterior.

While SMS works well on simpler models like Bayesian logistic regression, we have found that it did not work for more complex, high-dimensional, and non-convex models like Bayesian deep neural networks. This is due to the non-convergence of EP, particularly as the moments of the tilted distributions needed by EP are estimated using MCMC sampling, with estimation noise that further compounds the well-known lack of convergence guarantees for EP, and the fact that extremely long MCMC runs are needed for the samplers to equilibrate due to the complex posterior distribution in these models.

Our first contribution is thus the development of stochastic natural-gradient EP (SNEP), an alternative algorithm to power EP (a generalisation of EP) (Minka, 2004) which optimises the same variational objective function. SNEP is a double-loop algorithm with convergence guarantees. The inner loop is a stochastic natural-gradient descent algorithm which tolerates estimation noise, so that SNEP is convergent even with moments estimated using MCMC samplers. Our derivation of SNEP improves upon the derivation of the convergent EP algorithm of (Heskes and Zoeter, 2002) in that ours works for a more general class of models, we make explicit the underlying variational objective function that is being optimised, and ours uses a natural-gradient descent algorithm (Amari and Nagaoka, 2001) more tolerant of Monte Carlo noise.

Building upon the development of SNEP, our second contribution is a distributed Bayesian learning architecture which we call the posterior server. In analogy to the parameter server (Ahmed et al., 2012) which maintains and serves the parameter vector to a cluster of workers, the posterior server maintains and serves (an approximation to) the posterior distribution. Figure 1 gives a schematic for the steps involved. Each worker has a subset of data, from which we get a likelihood function. It also maintains a tractable approximation of the likelihood and a cavity distribution which is effectively a conditional distribution over the parameters given all data on other workers. An MCMC sampler targets the normalised product of the cavity distribution and the (true) likelihood, and forms a stochastic estimate of the required moments, which is in turn used to update the likelihood approximation using stochastic natural-gradient descent. Each worker communicates with the posterior server asynchronously and in a non-blocking manner, sending the current likelihood approximation and receiving the new cavity distribution. This communication protocol makes more efficient use of computational resources on workers than SMS, which requires either synchronous or blocking asynchronous protocols.

Note that our set-up of the distributed learning problem is that each worker has access to a subset of data, and no worker has access to all data. This situation might occur in situations other than large scale learning. For example, when working with sensitive patient data which cannot be shared directly, we might still want to be able to make use

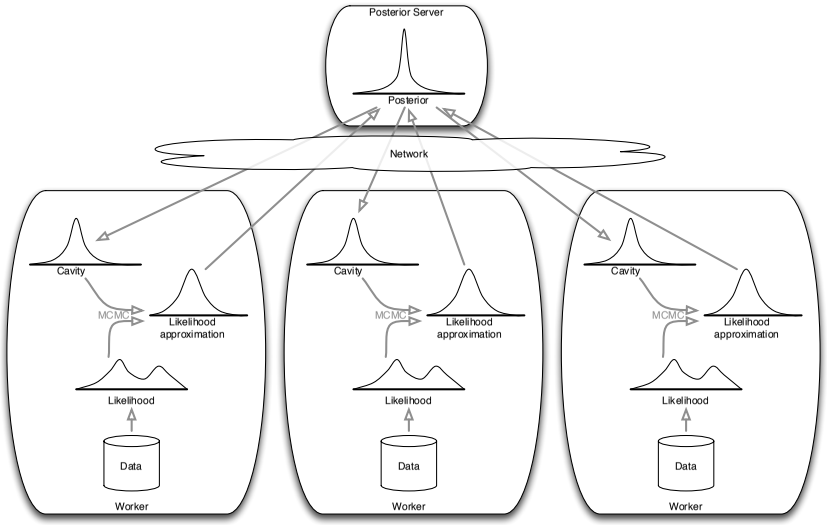

Figure 1: The posterior server.

of all available data across multiple sites to improve inference. Typically known as divide-and-conquer or consensus inference (Zhang et al., 2015b, Zhao et al., 2016, Kleiner et al., 2014, Battey et al., 2015), it is also well-known that this situation is harder than typical distributed learning settings where it is assumed that all data is accessible on all workers, which are settings assumed in DistBelief networks (Dean et al., 2012) and elastic-averaging SGD (Zhang et al., 2015a), two state-of-the-art distributed learning algorithms for neural networks.

In the following, Section 2 describes our set up of distributed Bayesian learning and reviews the necessary background on exponential families and convex duality. Section 3 formulates EP and power EP within the framework of variational inference. Our contributions are contained in Section 4 deriving SNEP and Section 5 describing the posterior server architecture. Section B describes additional techniques we used to make the method work on more complex problems like neural networks. We demonstrate the approach Bayesian logistic regression and Bayesian neural networks in Section 6. Section 7 concludes with a summary and discussion of future work.

2. Problem Set-up and Background

In this section we set-up the problem of distributed Bayesian learning, using the framework of variational inference in exponential families. For an excellent introduction to exponential families and variational inference we refer the interested reader to (Wainwright and Jordan, 2008). Section 2.1 reviews exponential families and convex duality while introducing nota-

tion used throughout the paper. Readers familiar with these concepts can skim ahead to section 2.2.

2.1 Exponential Families and Convex Duality

.

Consider an exponential family described by a d-dimensional sufficient statistics function $s(x)$. A member p_θ of this exponential family is parameterized by a natural parameter $\theta \in \mathbb{R}^d$, and has density (with respect to some base measure, say Lebesgue),

$$p_\theta(x) = \exp\left(\theta^\top s(x) - A(\theta)\right),$$
$$A(\theta) = \log \int \exp\left(\theta^\top s(x)\right) dx.$$

The log partition function $A(\theta)$ is convex and finite on the natural domain of the exponential family,

$$\Theta := \{\theta : A(\theta) < \infty\} \subset \mathbb{R}^d,$$

which is a convex subset of $\mathbb{R}^d$.

Associated with any distribution p and the d-dimensional sufficient statistics function $s(x)$ is a mean parameter,

$$\mu := \mathbb{E}_p[s(x)],$$

where $\mathbb{E}_p$ denotes the expectation operator with respect to p. The set of valid mean parameters $\mathcal{M}$ is a closed convex set, which we refer to as the mean domain,

$$\mathcal{M} = \{\mu : \exists \text{ distribution } p \text{ with } \mu = \mathbb{E}_p[s(x)]\} \subset \mathbb{R}^d$$

Given a natural parameter $\theta \in \Theta$, the exponential family member p_θ is also associated with a mean parameter $\mu = \mathbb{E}_\theta[s(x)]$ (where $\mathbb{E}_\theta$ denotes the expectation with respect to p_θ), which we can write as a function of the natural parameters, $\mu(\theta)$. If the exponential family is minimal[1], then the mapping $\theta \mapsto \nabla A(\theta)$ is one-to-one and onto the interior of $\mathcal{M}$, and maps θ to the mean parameter, $\mu(\theta) = \nabla A(\theta)$.

We will assume that our exponential family of interest is minimal.

The convex conjugate of $A(\theta)$ is,

$$A^*(\mu) := \sup_{\theta \in \Theta} \theta^\top \mu - A(\theta).$$

Evaluated at the mean parameter $\mu(\theta)$, the conjugate is the negative entropy of p_θ,

$$A^*(\mu(\theta)) = \mathbb{E}_\theta[\log p_\theta(x)].$$

1. The exponential family is minimal if the d 1-dimensional functions making up the sufficient statistics function $s(x)$ are linearly independent, i.e. $\theta^\top s(x) = 0$ for all x implies $\theta = 0$.

Conversely, we have

$$A(\theta) = \sup_{\mu \in \mathcal{M}} \theta^\top \mu - A^*(\mu)$$

and that the natural parameter associated with μ is $\theta = \theta(\mu) = \nabla A^*(\mu)$. In the following we will make extensive use of the duality between A and A^* and between θ and μ described above.

It is useful to write down formulae for the KL divergence between two exponential family distributions, parameterized by natural and mean parameter pairs θ, μ and θ', μ' respectively:

$$\begin{aligned}
\mathrm{KL}(p_\theta \| p_{\theta'}) &= \mathbb{E}_\theta[\log p_\theta(x) - \log p_{\theta'}(x)] \\
&= \mathbb{E}_\theta[\theta^\top s(x) - A(\theta) - (\theta')^\top s(x) + A(\theta')] \\
&= \mu^\top(\theta - \theta') - A(\theta) + A(\theta') \\
&= A^*(\mu) + A(\theta') - \mu^\top \theta' \\
&= A^*(\mu) - A^*(\mu') + (\mu' - \mu)^\top \theta'. \qquad (1)
\end{aligned}$$

We will write $\mathrm{KL}(\theta \| \theta'), \mathrm{KL}(\mu \| \theta')$ etc. to refer to the same KL divergence between the same two distributions.

As an example, for a diagonal covariance Gaussian of dimension $d/2$, we have

$$\begin{aligned}
p(x) &= \prod_{j=1}^{d/2} \frac{1}{\sqrt{2\pi\sigma_j^2}} \exp\left(-\frac{1}{2\sigma_j^2}(x_j - u_j)^2\right) \\
&= \exp\left(\sum_{j=1}^{d/2} (u_j \sigma_j^{-2})(x_j) + (-\sigma_j^{-2})(\tfrac{1}{2}x_j^2) - \tfrac{1}{2}(u_j^2 \sigma_j^{-2} + \log(2\pi\sigma_j^2))\right)
\end{aligned}$$

So the sufficient statistics are x_j and $\frac{1}{2}x_j^2$, mean parameters are $\mu_{j1} = u_j$ and $\mu_{j2} = \frac{1}{2}(u_j^2 + \sigma_j^2)$, natural parameters are $\theta_{j1} = u_j \sigma_j^{-2}$ and $\theta_{j2} = -\sigma_j^{-2}$, and

$$A(\theta) = \sum_{j=1}^{d/2} \frac{1}{2}(u_j^2 \sigma_j^{-2} + \log(2\pi\sigma_j^2))$$
$$A^*(\mu) = \sum_{j=1}^{d/2} \frac{-1}{2}(1 + \log(2\pi\sigma_j^2))$$

The conversions between natural and mean parameters are:

$$\begin{aligned}
&u_j = \mu_{j1} = -\theta_{j1}\theta_{j2}^{-1} && \theta_{j1} = \mu_{j1}(2\mu_{j2} - \mu_{j1}^2)^{-1} && \mu_{j1} = -\theta_{j1}\theta_{j2}^{-1} \\
&\sigma_j^2 = 2(\mu_{j2} - \mu_{j1}^2) = -\theta_{j2}^{-1} && \theta_{j2} = -(2\mu_{j2} - \mu_{j1}^2)^{-1} && \mu_{j2} = \frac{1}{2}(\theta_{j1}^2\theta_{j2}^{-2} - \theta_{j2}^{-1})
\end{aligned}$$

We will use a diagonal covariance Gaussian as our exponential family in most of our experiments, due to the high-dimensionality of the models used.

2.2 Distributed Bayesian Learning

We assume that our model is parameterized by a high-dimensional parameter vector x. Let the prior distribution $p_0(x)$ be a member of a tractable and minimal exponential family distribution, with natural parameter $\theta_0 \in \Theta \subset \mathbb{R}^d$, sufficient statistics function $s(x)$ and log partition function $A(\theta_0)$. Specifically, we will take $p_0(x)$ to be a diagonal covariance Gaussian. We refer to this exponential family as the *base exponential family*.

We assume that our training data set is spread across a cluster of n compute nodes or workers, with log likelihood $\ell_i(x)$ on compute node $i = 1, \ldots, n$. For example, if we let $\{S_i\}$ be a partition of the data indices, each compute node i could store the corresponding subset of the data $D_i = \{y_c\}_{c \in S_i}$, so that the log likelihood $\ell_i(x)$ is a sum over terms, each corresponding to the log density of one data point stored on node i,

$$\ell_i(x) = \sum_{c \in S_i} \log p(y_c \mid x).$$

Covariates and input vectors can be easily incorporated in the above. The target posterior distribution is then,

$$\tilde{p}(x) := p(x \mid \{D_i\}_{i=1}^n) \propto p_0(x) \exp\left(\sum_{i=1}^n \ell_i(x)\right). \tag{2}$$

Using neural networks as an example, x corresponds to all learnable weights and biases in a network, $\log p(y_c \mid x)$ gives the probability of the class of data item c given the corresponding input vector, and the Gaussian prior corresponds to weight decay.

The learning task is then to compute the posterior distribution. For example, we may want to estimate the posterior mean or variance of the model parameters x, or we may want to draw samples distributed according to $\tilde{p}(x)$, using these to predict on test data by averaging the predictive densities over the samples as a Monte Carlo estimate of the marginal predictive density. In the rest of the paper we will aim to obtain these efficiently but approximately.

3. Variational Inference in an Extended Exponential Family

In general, the likelihood functions are intractable and approximations are necessary. In this paper we will formulate the learning task as variational inference in an extended exponential family. In particular, we will consider a class of variational methods known as *power expectation propagation* (power EP) (Minka, 2004).

3.1 Extended Exponential Family

To start with, we may trivially formulate the target posterior distribution as an *extended exponential family distribution* with sufficient statistics $\tilde{s}(x) := [s(x), \ell_1(x), \ldots, \ell_n(x)]$ and natural parameters $\tilde{\theta} := [\theta_0, \mathbf{1}_n]$ where $\mathbf{1}_n$ is a vector of 1's of length n:

$$\tilde{p}(x) = \exp\left(\tilde{\theta}^\top \tilde{s}(x) - \tilde{A}(\tilde{\theta})\right).$$

The extended log partition function $\tilde{A}(\tilde{\theta})$ is (up to a constant) the log marginal probability of the data,

$$\begin{aligned}\tilde{A}(\tilde{\theta}) = \log \int \exp\left(\tilde{\theta}^\top \tilde{s}(x)\right) dx &= \log \int \exp\left(\theta_0^\top s(x) + \sum_{i=1}^n \ell_i(x)\right) dx \\ &= \log \mathbb{E}_{\theta_0}\left[\exp\left(\sum_{i=1}^n \ell_i(x)\right)\right] + A(\theta_0) \\ &= \log p(\{D_i\}_{i=1}^n) + A(\theta_0).\end{aligned}$$

Denoting the convex conjugate by $\tilde{A}^*(\tilde{\mu})$ and the extended mean domain by $\tilde{\mathcal{M}} \subset \mathbb{R}^{d+n}$, the problem of posterior computation can be expressed as the following concave variational maximization problem:

$$\max_{\tilde{\mu} \in \tilde{\mathcal{M}}} \tilde{\theta}^\top \tilde{\mu} - \tilde{A}^*(\tilde{\mu}). \tag{3}$$

For example, if the prior exponential family is a diagonal covariance Gaussian, then the optimal mean parameter is $\tilde{\mu}^* := [\mu^*, \nu_1^*, \ldots \nu_n^*]$, where $\mu^* := \mathbb{E}_{\tilde{\theta}}[s(x)] \in \mathbb{R}^d$ corresponds to the posterior means and variances of the model parameters x, while $\nu_i^* := \mathbb{E}_{\tilde{\theta}}[\ell_i(x)]$ is the posterior expectation of the ith log likelihood $\ell_i(x)$. Hence the extended mean parameters capture the important aspects of the posterior distribution.

3.2 Power Expectation Propagation

In this section we derive another class of variational approximations corresponding to a generalization of expectation propagation (EP) (Minka, 2001) called power EP (Minka, 2004). The derivation is a straightforward generalisation of the variational formulation of Wainwright and Jordan (2008) from EP to power EP.

For each worker node i let $\beta_i > 0$ be a given positive real number. Typically, we take $\beta_i = 1$ which corresponds to standard EP, while $\beta_i \to \infty$ corresponds to variational Bayes (Wiegerinck and Heskes, 2003, Minka, 2004). In the formulation of Wainwright and Jordan (2008), EP involves two approximations; both associated with simpler exponential families, which we refer to as *locally extended exponential families* (or sometimes *local exponential families*). For each i, let the ith locally extended exponential family be associated with the sufficient statistics function $s_i(x) := [s(x), \ell_i(x)]$. Let Θ_i, $\mathcal{M}_i$, A_i, A_i^* be the associated (local) natural domain, mean domain, log partition function and negative entropy respectively. A distribution in this locally extended exponential family with natural parameter $[\theta_i, \eta_i] \in \Theta_i$ has the form

$$p_{\theta_i, \eta_i}(x) = \exp\left(\theta_i^\top s(x) + \eta_i \ell_i(x) - A_i(\theta, \eta_i)\right), \tag{4}$$

which is a distribution obtained by tilting a tractable distribution with density proportional to $\exp(\theta_i^\top s(x))$ by a single intractable likelihood $\exp(\ell_i(x))$ raised to the power of η_i. This family can be thought of as treating the ith likelihood term exactly, while approximating all other likelihood terms by projecting them onto the tractable base exponential family,

the hope being that this family is still tractable while being closer to the true posterior distribution $\tilde{p}(x)$.

For the first approximation, the extended negative entropy $\tilde{A}^*$ is approximated using a tree-like approximation constructed using only the locally extended negative entropies,

$$\tilde{A}^*([\mu, \nu_1, \ldots, \nu_n]) \approx A^*(\mu) + \sum_{i=1}^n \beta_i (A_i^*(\mu, \nu_i) - A^*(\mu)).$$

This approximation is related to the Bethe entropy of loopy belief propagation (Yedidia et al., 2001) and fractional belief propagation (Wiegerinck and Heskes, 2003). Secondly, the extended mean domain $\tilde{\mathcal{M}}$ is approximated by a local mean domain,

$$\mathcal{L} := \{[\mu, \nu_1, \ldots, \nu_n] : [\mu, \nu_i] \in \mathcal{M}_i \text{ for all } i = 1, \ldots, n\}. \tag{5}$$

The local mean domain is an outer bound, $\mathcal{L} \supset \tilde{\mathcal{M}}$. Intuitively, the constraints described by $\tilde{\mathcal{M}}$ are replaced by the weaker constraints described by the local mean domains. We assume that working with the local exponential families in these ways will be more tractable than working with the full extended exponential family.

Let $\mu_0 \in \mathcal{M}$ be a mean parameter in the base exponential family. For the ith local exponential family, we denote a mean parameter by $[\mu_i, \nu_i] \in \mathcal{M}_i$, and require the marginalization constraint $\mu_i = \mu_0$. The power EP variational problem, which is not in general concave, is,

$$\begin{aligned} \max_{\mu_0, [\mu_i, \nu_i]_{i=1}^n} \quad & \theta_0^\top \mu_0 + \sum_{i=1}^n 1 \cdot \nu_i - A^*(\mu_0) - \sum_{i=1}^n \beta_i (A_i^*(\mu_i, \nu_i) - A^*(\mu_i)) \\ \text{subject to} \quad & \mu_0 \in \mathcal{M} \\ & [\mu_i, \nu_i] \in \mathcal{M}_i \quad \text{for } i = 1, \ldots, n \\ & \mu_0 = \mu_i \quad \text{for } i = 1, \ldots, n \end{aligned} \tag{6}$$

Note in particular that the entropy and mean domain in the original variational problem (3) have been replaced by their respective approximations.

3.3 Deriving EP and Power EP Updates

In this section, for completeness' sake, we derive the updates for EP and power EP as fixed-point equations that solve the variational problem. Readers familiar with this derivation can skip ahead to section 3.4.

First we introduce Lagrange multipliers λ_i for the equality constraints $\mu_0 = \mu_i$, so that the above is equivalent to,

$$\begin{aligned} \max_{\mu_0, [\mu_i, \nu_i]_{i=1}^n} \min_{[\lambda_i]_{i=1}^n} \quad & \underbrace{\theta_0^\top \mu_0 - A^*(\mu_0) + \sum_{i=1}^n \Big(\nu_i - \lambda_i^\top (\mu_i - \mu_0) - \beta_i (A_i^*(\mu_i, \nu_i) - A^*(\mu_i))\Big)}_{=: L(\mu_0, [\mu_i, \nu_i, \lambda_i]_{i=1}^n)} \\ \text{subject to} \quad & \mu_0 \in \mathcal{M} \\ & [\mu_i, \nu_i] \in \mathcal{M}_i \quad \text{for } i = 1, \ldots, n \end{aligned} \tag{7}$$

where the domain of λ_i is $\mathbb{R}^d$. Let the Lagrangian above be denoted by $L(\mu_0, [\mu_i, \nu_i, \lambda_i]_{i=1}^n)$. The Karush-Kuhn-Tucker (KKT) conditions of the above variational problem have to be satisfied at an optimum, and simply involve setting the derivatives with respect to $\mu_0, \mu_i, \nu_i, \lambda_i$ to zero:

$$\frac{dL}{d\lambda_i} = 0 : \qquad \mu_i = \mu_0 \tag{8a}$$

$$\frac{dL}{d\mu_0} = 0 : \qquad \theta_0 - \nabla A^*(\mu_0) + \sum_{j=1}^n \lambda_j = 0$$

$$\theta_0 + \sum_{j=1}^n \lambda_j = \nabla A^*(\mu_0) \tag{8b}$$

$$\frac{dL}{d\mu_i} = 0 : \qquad -\lambda_i - \beta_i \nabla_{\mu_i} A_i^*(\mu_i, \nu_i) + \beta_i \nabla A^*(\mu_i) = 0$$

$$\theta_0 + \sum_{j=1}^n \lambda_j - \beta_i^{-1} \lambda_i = \nabla_{\mu_i} A_i^*(\mu_i, \nu_i) \tag{8c}$$

$$\frac{dL}{d\nu_i} = 0 : \qquad \beta_i^{-1} = \nabla_{\nu_i} A_i^*(\mu_i, \nu_i) \tag{8d}$$

Equation (8b) shows that an optimal μ_0 has to be the mean parameter corresponding to a (base) exponential family distribution with natural parameter $\theta_0 + \sum_{j=1}^n \lambda_j$. Specifically, the posterior distribution can be approximated as,

$$\tilde{p}(x) \propto p_0(x) \exp\left(\sum_{j=1}^n \ell_j(x)\right) \approx \exp\left(\left(\theta_0 + \sum_{j=1}^n \lambda_j\right)^\top s(x)\right). \tag{9}$$

In other words, we can interpret λ_j as the natural parameter of an exponential family approximation to the likelihood factor $\exp(\ell_j(x))$.

Further, from (8c) and (8d) above, we see that the optimal $[\mu_i, \nu_i]$ is the mean parameter associated with the local posterior distribution,

$$p_i(x) \propto \exp\left(\left(\theta_0 + \sum_{j=1}^n \lambda_j - \beta_i^{-1} \lambda_i\right)^\top s(x) + \beta_i^{-1} \ell_i(x)\right). \tag{10}$$

For standard EP, where $\beta_i = 1$, we get,

$$p_i(x) \propto \exp\left(\left(\theta_0 + \sum_{j \neq i} \lambda_j\right)^\top s(x) + \ell_i(x)\right).$$

The above local posterior distribution is known as the tilted distribution in EP, with the term $(\theta_0 + \sum_{j=1}^n \lambda_j - \beta_i^{-1} \lambda_i)^\top s(x)$ corresponding to the cavity distribution with (the β_i^{-1}th power of) the exponential family approximation to the ith likelihood removed, and replaced

by (the β_i^{-1}th power of) the likelihood factor itself. Each step of EP involves first computing $[\mu_i, \nu_i]$ as the mean parameter of the tilted distribution, then updating λ_i, using (8a) and (8b):

$$\lambda_i^{\text{new}} = \nabla A^*(\mu_i) - \theta_0 - \sum_{j \neq i} \lambda_j, \tag{11}$$

where we recall that $\nabla A^*(\mu_i)$ computes the natural parameter corresponding to the mean parameter μ_i in the base exponential family. The EP update ensures that the expectation of the sufficient statistics function under the tilted distribution $p_i(x)$ and under its exponential family approximation (with natural parameters $\theta_0 + \sum_{j=1}^n \lambda_j - \beta_i^{-1}\lambda_i + \beta_i^{-1}\lambda_i^{\text{new}}$) match. At convergence, this ensures that the expectations under all the tilted distributions and under the approximated posterior distribution (9) match.

Note that the (power) EP updates are derived as fixed point equations and have no guarantees of convergence. In practice, damped updates can be used to avoid oscillations without affecting the fixed points:

$$\lambda_i^{\text{new}} = \alpha\lambda_i + (1-\alpha)\left(\nabla A^*(\mu_i) - \theta_0 - \sum_{j \neq i} \lambda_j\right). \tag{12}$$

where $\alpha \in [0, 1)$ is a damping factor. Another potential issue is that λ_i^{new} as computed may not lie in the natural domain Θ, in which case higher damping factors ensuring that it does can be used, or the update can be discarded.

3.4 Computing Mean Parameters

Assuming that the base exponential family is tractable, the above steps of EP involve additions, subtractions, and conversions between mean and natural parameters so are easy to compute. The only difficulty is in the computation of the mean parameters (expectations of the sufficient statistics function) of the tilted distributions, which involve the log likelihoods $\ell_i(x)$. In typical applications of EP to graphical models, these are either obtained analytically or using numerical quadrature.

In more complex and general scenarios, both analytic or quadrature-based methods are ruled out. A successful and common class of methods for calculating expectations under otherwise intractable distributions is Monte Carlo. A number of papers have proposed such an approach, including Barthelmé and Chopin (2011), Heess et al. (2013), Gelman et al. (2014) using importance sampling and Xu et al. (2014), Gelman et al. (2014) using Markov chain Monte Carlo (MCMC). In addition, Heess et al. (2013), Eslami et al. (2014), Jitkrittum et al. (2015) use learning techniques to speed-up the process by directly predicting the natural parameters given properties of the tilted distribution.

We have explored the sampling via moment sharing (SMS) algorithm (Xu et al., 2014) in the context of distributed Bayesian learning of deep neural networks. Unfortunately, the SMS algorithm did not work even for relatively small neural networks and data sets, partly because of the high dimensionality and partly because the Monte Carlo estimation is inherently stochastic, both of which we found affected the convergence of the EP fixed point equations.

4. Stochastic Natural-gradient Expectation Propagation

In this section we will derive a novel convergent stochastic approximation based alternative to EP and power EP, which optimises the same variational objective but is significantly more tolerant of Monte Carlo noise. Our algorithm is derived using a modified variational objective with additional auxiliary variables but with the same optima as the original problem, and solving the dual problem using a stochastic approximation algorithm (Robbins and Monro, 1951). In the following we will use "EP" to refer to both EP and power EP for simplicity.

4.1 Auxiliary Variational Problem

For each i, we introduce an auxiliary natural parameter vector $\theta_i' \in \Theta$, and introduce a term $-\sum_{i=1}^n \mathrm{KL}(p_{\mu_i} \| p_{\theta_i'})$ into the variational objective (7), where p_{μ_i} and $p_{\theta_i'}$ are the base exponential family distribution given by mean parameter μ_i and natural parameter θ_i', respectively. This results in a lower bound on the original objective and is reminiscent of the EM algorithm (Dempster et al., 1977, Neal and Hinton, 1999) and of typical variational Bayes approximations (Beal, 2003, Wainwright and Jordan, 2008). Plugging the relevant formula for the KL divergence (1) into (7), we have the resulting variational problem

$$\begin{aligned} \max_{\mu_0, [\mu_i, \nu_i, \theta_i']_{i=1}^n} \quad & \theta_0^\top \mu_0 - A^*(\mu_0) + \sum_{i=1}^n \left(\nu_i - \beta_i \left(A_i^*(\mu_i, \nu_i) - \mu_i^\top \theta_i' + A(\theta_i')\right)\right) \\ \text{subject to} \quad & \mu_0 \in \mathcal{M} \\ & [\mu_i, \nu_i] \in \mathcal{M}_i \quad \text{for } i = 1, \ldots, n \\ & \theta_i' \in \Theta \quad \text{for } i = 1, \ldots, n \\ & \mu_0 = \mu_i \quad \text{for } i = 1, \ldots, n \end{aligned} \tag{13}$$

Maximizing over θ_i' while keeping the other variables fixed will simply set $\theta_i' = \nabla A^*(\mu_i)$, so that the KL terms vanish and resulting in the original problem (6). On the other hand, the constrained maximization over the original parameters $\mu_0, [\mu_i, \nu_i]_{i=1}^n$ requires introducing Lagrange multipliers,

$$\begin{aligned} \max_{[\theta_i']_{i=1}^n} \max_{\mu_0, [\mu_i, \nu_i]_{i=1}^n} \min_{[\lambda_i]_{i=1}^n} \quad & \theta_0^\top \mu_0 - A^*(\mu_0) + \sum_{i=1}^n \Big(\nu_i - \lambda_i^\top(\mu_i - \mu_0) - \beta_i \Big(A_i^*(\mu_i, \nu_i) - \mu_i^\top \theta_i' + A(\theta_i')\Big)\Big) \\ \text{subject to} \quad & \mu_0 \in \mathcal{M} \\ & [\mu_i, \nu_i] \in \mathcal{M}_i \quad \text{for } i = 1, \ldots, n \\ & \theta_i' \in \Theta \quad \text{for } i = 1, \ldots, n \end{aligned} \tag{14}$$

We can solve this inner constrained optimization by transforming to the convex dual. Noticing that the Lagrangian is concave in $\mu_0, [\mu_i, \nu_i]_{i=1}^n$ and that Slater's condition holds, the

duality gap is zero and we have,

$$\max_{[\theta_i']_{i=1}^n} \min_{[\lambda_i]_{i=1}^n} \max_{\mu_0,[\mu_i,\nu_i]_{i=1}^n} \theta_0^\top \mu_0 - A^*(\mu_0) + \sum_{i=1}^n \Big(\nu_i - \lambda_i^\top(\mu_i - \mu_0) - \beta_i\Big(A_i^*(\mu_i,\nu_i) - \mu_i^\top\theta_i' + A(\theta_i')\Big)\Big)$$
$$\text{subject to} \quad \mu_0 \in \mathcal{M} \qquad (15)$$
$$[\mu_i,\nu_i] \in \mathcal{M}_i \quad \text{for } i = 1,\ldots,n$$
$$\theta_i' \in \Theta \quad \text{for } i = 1,\ldots,n$$

Now maximizing over $\mu_0, [\mu_i,\nu_i]_{i=1}^n$, we have the equivalent dual problem, whose objective function we will denote with $L([\theta_j',\lambda_j]_{j=1}^n)$,

$$\max_{[\theta_i']_{i=1}^n} \min_{[\lambda_i]_{i=1}^n} \underbrace{A\left(\theta_0 + \sum_{i=1}^n \lambda_i\right) + \sum_{i=1}^n \beta_i \left(A_i\left(\theta_i' - \beta_i^{-1}\lambda_i, \beta_i^{-1}\right) - A(\theta_i')\right)}_{=:L([\theta_j',\lambda_j]_{j=1}^n)}$$
$$\text{subject to} \quad \theta_i' \in \Theta \quad \text{for } i = 1,\ldots,n \qquad (16)$$

In summary, our algorithm is coordinate maximization of (13), where we alternate between maximizing $[\theta_i']_{i=1}^n$ given $\mu_0, [\mu_i,\nu_i]_{i=1}^n$, and maximizing $\mu_0, [\mu_i,\nu_i]_{i=1}^n$ given $[\theta_i']_{i=1}^n$. To solve the second maximization, we transform to the dual and minimize (16) with respect to the Lagrange multipliers $[\lambda_i]_{i=1}^n$. This requires an inner iteration loop involving stochastic natural gradient descent, which is described next. The structure of our derived algorithm is the same as the convergent double loop EP algorithm of (Heskes and Zoeter, 2002). Our derivation is interesting and useful in that a single global variational problem is described, rather than a sequence of variational problems each obtained by minorizing around the current parameters and then maximizing, as in the minorization-maximization (MM) algorithm) (Hunter and Lange, 2004) and the CCCP algorithm (Yuille, 2002). Our algorithm is also different in the choice of stochastic natural gradient descent inner loop.

4.2 Stochastic Natural Gradient Descent

The gradient of the dual objective $L([\theta_j',\lambda_j]_{j=1}^n)$ is,

$$\frac{dL}{d\lambda_i} = \nabla A\left(\theta_0 + \sum_{j=1}^n \lambda_j\right) - \nabla_{\theta_i} A_i\left(\theta_i' - \beta_i^{-1}\lambda_i, \beta_i^{-1}\right) \qquad (17)$$

where we used the notation $\nabla_{\theta_i} A_i$ for the partial derivative of $A_i(\cdot,\cdot)$ with respect to its first (d-dimensional) argument. While this gradient is the direction of steepest descent in a Euclidean geometry it does not take into account the geometry of the base exponential family. In other words, the gradient is not covariant[2] (MacKay, 1999) and the corresponding gradient descent algorithm is not expected to perform well.

2. A covariant gradient descent algorithm roughly means that the size of the gradient in a direction positively covaries with the length scale in that direction hence with the desired step size. An example of a non-covariant gradient descent algorithm is steepest descent with standard Euclidean geometry, say for a 2D quadratic loss function that is long in the x-axis and short in the y-axis. The gradient will be close to pointing vertically up or down, but the best descent direction points horizontally instead.

A better approach is to use natural gradient descent (Amari et al., 1996, Amari and Nagaoka, 2001) or, equivalently, mirror descent (Beck and Teboulle, 2003, Raskutti and Mukherjee, 2015) instead. These methods treat the parameter space as a Riemannian manifold where the metric tensor is given by the Fisher information. The direction of steepest descent in this geometry is given by the gradient preconditioned by the inverse metric. Natural gradient descent has appealing theoretical properties as it incorporates second order information to be more covariant. As we will see below we can take advantage of natural gradient descent at no additional computational cost by reparametrising. As noted in the previous section, the Lagrange multiplier λ_i can be interpreted as the natural parameters of the base exponential family approximation to the likelihood $\exp(\ell_i(x))$. Reparameterising using the corresponding mean parameter γ_i instead, with $\lambda_i = \nabla A^*(\gamma_i)$, the gradient is,

$$\begin{aligned}\frac{dL}{d\gamma_i} &= \frac{d\lambda_i}{d\gamma_i}\left(\nabla A\left(\theta_0 + \sum_{j=1}^n \lambda_j\right) - \nabla_{\theta_i} A_i\left(\theta_i' - \beta_i^{-1}\lambda_i, \beta_i^{-1}\right)\right) \\ &= \nabla^2 A^*(\gamma_i)\left(\nabla A\left(\theta_0 + \sum_{j=1}^n \lambda_j\right) - \nabla_{\theta_i} A_i\left(\theta_i' - \beta_i^{-1}\lambda_i, \beta_i^{-1}\right)\right) \qquad (18)\end{aligned}$$

The appropriate metric in the mean parameter space is simply $\nabla^2 A^*(\gamma_i)$, so that its inverse cancels the $\nabla^2 A^*(\gamma_i)$ term (Raskutti and Mukherjee, 2015), and the natural gradient update is simply,

$$\gamma_i^{(t+1)} = \gamma_i^{(t)} + \epsilon_t\left(\nabla_{\theta_i} A_i\left(\theta_i' - \beta_i^{-1}\lambda_i^{(t)}, \beta_i^{-1}\right) - \nabla A\left(\theta_0 + \sum_{j=1}^n \lambda_j^{(t)}\right)\right) \qquad (19)$$

where the corresponding natural parameter is given as a function of the mean parameter, $\lambda_i^{(t)} := \nabla A^*(\gamma_i^{(t)})$, and ϵ_t is the step size at iteration t. These updates can be performed in series or parallel fashion. In our distributed Bayesian learning setting they are performed in an asynchronous distributed fashion (Section 5).

Recall that derivatives of the log partition function compute the mean parameters from the natural parameters. Hence the first term of the natural gradient step is the mean parameter of the current local tilted distribution,

$$p_i^{(t)}(x) = \exp\left((\theta_i' - \beta_i^{-1}\lambda_i^{(t)})^\top s(x) + \beta_i^{-1}\ell_i(x) - A_i(\theta_i' - \beta_i^{-1}\lambda_i^{(t)}, \beta_i^{-1})\right), \qquad (20)$$

while the second term is the mean parameter of the current exponential family approximation to the global posterior. Their difference gives the update for the mean parameter of the likelihood approximation. The gradient is zero when both terms are equal, precisely the condition from which the EP fixed point equation is derived.

In general, the first term cannot be obtained in closed form, and we instead use a Markov chain Monte Carlo (MCMC) estimate, leading to a stochastic natural-gradient descent algorithm. Specifically, let $\mathcal{K}_i(\cdot \,|\, x; \theta_i' - \beta_i^{-1}\lambda_i^{(t)}, \beta_i)$ be a Markov chain kernel with previous state x whose invariant distribution is the local tilted distribution (20). Let $x_i^{(t)}$ be

the state of the Markov chain at iteration t. The next state $x_i^{(t+1)}$ is obtained by simulating from the Markov chain, using the current values of the parameters,

$$x_i^{(t+1)} \sim \mathcal{K}_i\left(\cdot \mid x_i^{(t)}; \theta_i' - \beta_i^{-1}\lambda_i^{(t)}, \beta_i\right). \tag{21}$$

In summary, the stochastic natural gradient update is,

$$\gamma_i^{(t+1)} = \gamma_i^{(t)} + \epsilon_t \left(s\left(x_i^{(t+1)}\right) - \nabla A\left(\theta_0 + \sum_{j=1}^{n} \lambda_j^{(t)}\right)\right) \tag{22}$$

We refer to the resulting algorithm as "Stochastic Natural-gradient EP", or SNEP for short.

Technically, the stochastic natural-gradient descent requires unbiased estimates of gradients, and the mean parameter estimates obtained using MCMC updates are only unbiased if the Markov chain equilibrates in between gradient updates. In practice, we find that using MCMC samples works well regardless, an observation consistent with past experiences with stochastic approximation algorithms in machine learning (Neal and Hinton, 1999, Tieleman, 2008).

The stochastic natural gradient descent algorithm above serves as the inner loop of our double loop algorithm, and solves for the constrained maximization of the mean parameters $\mu_0, [\mu_i, \nu_i]_{i=1}^n$ given auxiliary parameters $[\theta_i']_{i=1}^n$. Returning now to the outer loop update, maximizing θ_i' involves simply setting it to be $\nabla A^*(\mu_i)$, the natural parameter corresponding to the mean parameter μ_i of the local tilted distribution (see the discussion after Equation 13). Assuming that the inner loop has converged, this and the mean parameters of all other tilted distributions would be equal to μ_0, so that the t'th outer loop update is,

$$(\theta_i')^{(t'+1)} = \nabla A^*(\mu_i) = \nabla A^*(\mu_0) = \theta_0 + \sum_{j=1}^{n} \lambda_j^{(\infty)} \tag{23}$$

where $\lambda_j^{(\infty)}$ is the converged value of the dual parameters in the inner loop. In practice, we simply perform the outer loop update infrequently (and before the inner loop has fully converged). In our experiments we do not see instabilities resulting from this, an observation also consistent with past experiences with double loop algorithms (Teh and Welling, 2002, Yuille, 2002, Heskes and Zoeter, 2002).

In the extreme case where the outer loop update is performed after every inner loop update, we can roll both updates into the following update,

$$\gamma_i^{(t+1)} = \gamma_i^{(t)} + \epsilon_t \left(\nabla_{\theta_i} A_i \left(\theta_0 + \sum_{j=1}^{n} \lambda_j^{(t)} - \beta_i^{-1}\lambda_i^{(t)}, \beta_i^{-1}\right) - \nabla A\left(\theta_0 + \sum_{j=1}^{n} \lambda_j^{(t)}\right)\right) \tag{24}$$

It is interesting to contrast the above with a damped EP update, which in our notation is given by,

$$\lambda_i^{(t+1)} = \lambda_i^{(t)} + \epsilon_t \left(\nabla A^* \left(\nabla_{\theta_i} A_i \left(\theta_0 + \sum_{j=1}^{n} \lambda_j^{(t)} - \beta_i^{-1}\lambda_i^{(t)}, \beta_i^{-1}\right)\right) - \left(\theta_0 + \sum_{j=1}^{n} \lambda_j^{(t)}\right)\right) \tag{25}$$

Note that $\nabla A^*(\cdot)$ converts from mean parameters to natural parameters, so that the first term in parentheses can be read as first computing the moments (mean parameters) of the tilted distribution then converting into the corresponding natural parameter. Hence each term in the damped EP update is obtained by converting the corresponding term in (24) from mean to natural parameters, i.e. applying $\nabla A^*(\cdot)$. In other words the update (24) can be thought of as a mean parameter space version of a damped EP update. When mean parameters are estimated with Monte Carlo noise, updating using mean parameters rather than natural parameters leads to more stable behaviour; see Section 6.1 for empirical results supporting this claim.

4.3 Discussion and Related Works

While we developed SNEP in the context of distributed Bayesian learning, it is clear that it is generally applicable, since the distribution (2) targeted is simply a product of factors, each of which is approximated by a factor in the base exponential family, precisely the setting of EP. SNEP can therefore be used in place of EP in situations where Monte Carlo moment estimates are used, including graphical models (Heess et al., 2013, Eslami et al., 2014, Jitkrittum et al., 2015, Lienart et al., 2015), hierarchical Bayesian models (Gelman et al., 2014), and approximate Bayesian computation (Barthelmé and Chopin, 2011).

Since Minka (2001), there have been a substantial number of extensions and alternatives to EP proposed. Stochastic EP (Li et al., 2015) and averaged EP (Dehaene and Barthelmé, 2015) assume that all factors can be well approximated by the *same* exponential family factor via parameter tying. This saves memory storage and was shown to work well. This is an orthogonal idea to our work, and it is possible to apply it to SNEP as well in the future, although in the distributed learning setting considered in this paper each worker must keep a copy of the parameters anyway, which means it would not reduce memory requirements. Convergent EP (Heskes and Zoeter, 2002) is also a double loop coordinate descent algorithm with convergence guarantees but SNEP differs in that the inner loop is a stochastic natural-gradient descent which is more robust to the use of Monte Carlo estimated moments. We note here that stochastic natural-gradient descent has also been used in Stochastic Variational Inference (Hoffman et al., 2013).

SNEP can be considered a black-box variational inference algorithm, as the only requirement on the model is the existence of MCMC samplers targeting the tilted distributions. Black-box methods have recently been developed for variational Bayes (Ranganath et al., 2014, Black-box Variational Inference or BBVI) and for power EP (Hernandez-Lobato et al., 2016, Black-box Alpha or BB-α). BB-α and SNEP are both methods for Bayesian learning based on power EP and both operate in the mean parameter space. BB-α uses the parameter tying idea of stochastic and averaged EP to construct a further approximated objective function which is then optimised using a convergent single-loop algorithm. As a result the fixed points of the algorithm are different from power EP. Single loop algorithms are generally preferrable as it is well known that double loop algorithms can be slow if the inner loop is run until convergence. In our experiments, we do not run the inner loop of SNEP until convergence, and have found empirically that even a single iteration of the inner loop per outer loop update does not affect convergence or stability. In fact, on a two-layer feedforward neural network, SNEP converges in less than one tenth of the number of epochs

and a fraction of the running times of those quoted by Hernandez-Lobato et al. (2016). In both BBVI and BB-α, naive Monte Carlo estimators are used, with samples drawn from the approximating distribution. The resulting estimators can have high variance, requiring techniques for variance reduction. In contrast, SNEP uses MCMC samplers targeting the tilted distribution. It is generally accepted that, in high-dimensional settings, MCMC samplers often have lower variance than naive Monte Carlo and as a result work better, with the tradeoff being that MCMC samplers need to equilibrate and produce correlated samples.

Our application of SNEP to distributed Bayesian learning applies one exponential family approximation per subset of data on each worker node. This contrasts with typical applications of EP and variational inference in general, which applies one approximation per data item. This is made possible due to the black-box flexibility of our approach, since the likelihood associated with a data subset is more complex than for a single data item. In cases where the subset is itself quite large, and the Bernstein-von Mises theorem holds, the likelihood will be close to a Gaussian, so that if we use a (full-covariance) Gaussian as the base exponential family, the approximation will introduce negligible biases. For a recent study of EP in the large data limit, see (Dehaene and Barthelmé, 2015). We can think of our approach as a hybrid which interpolates between a pure variational approach (when $n = N$) and a pure MCMC approach (when $n = 1$), with smaller n corresponding to less bias introduced by approximations but higher variance/computational costs.

In our experiments, we apply SNEP to deep neural networks. Deep learning has been extremely successful in a large number of different domains. However, one drawback of neural networks trained by stochastic optimisation techniques is that they do not provide uncertainty estimates. Both black-box variational methods and stochastic gradient MCMC methods can be applied to neural networks yielding uncertainty estimates. Probabilistic backpropagation (Hernandez-Lobato and Adams, 2015, PBP) relies on assumed density filtering (ADF), a sequential form of EP. Other approaches are based on mean field variational inference, which optimises a lower bound of the marginal likelihood. Graves (2011) proposed an algorithm using a biased Monte Carlo estimate of this lower bound to optimise it. More recently, this approach has been extended by Blundell et al. (2015, Bayes by Backprop) who obtain unbiased Monte Carlo estimates of the same objective using the reparametrization trick (Kingma and Welling, 2014).

5. The Posterior Server

Our development of SNEP is motivated by the problem of distributed Bayesian learning outlined in Section 2.2, where each log likelihood term $\ell_i(x)$ corresponds to the log probability/density of the data subset on worker node i. Using SNEP, each worker node iteratively learns an exponential family approximation of $\ell_i(x)$, with a master node coordinating the learning across workers. We call the master node the *posterior server*, as it maintains and serves the exponential family approximation of the posterior distribution, obtained by combining the prior with the likelihood approximations at the workers.

In more detail, the posterior server maintains the natural parameter $\theta_{\text{posterior}} := \theta_0 + \sum_{j=1}^{n} \lambda_j$ of the global posterior approximation, while each worker node i maintains the mean and natural parameters γ_i, λ_i of the likelihood approximation and the state of the MCMC

sampler x_i. It also maintains the auxiliary parameter θ_i' used in the outer loop. Learning at the worker proceeds by alternating between the MCMC (21) and inner loop updates (22), with periodic outer loop updates (23). These updates require access to the data subset at the node, as well as the cavity distribution, with natural parameters $\theta_{-i} := \theta_0 + \sum_{j \neq i} \lambda_j$, which is obtained by getting $\theta_{\text{posterior}}$ from the posterior server and subtracting the local λ_i.

Communication between the worker node and the posterior server involves the worker first sending the posterior server the difference $\Delta_i := \lambda_i^{\text{new}} - \lambda_i^{\text{old}}$ between the current natural parameters λ_i^{new} and the one during the previous communication with the server, λ_i^{old}. The posterior server updates its global posterior approximation via $\theta_{\text{posterior}}^{\text{new}} = \theta_{\text{posterior}}^{\text{old}} + \Delta_i$, and sends the new value $\theta_{\text{posterior}}^{\text{new}}$ back to the worker. The worker in turn uses this to update the cavity, $\theta_{-i}^{\text{new}} = \theta_{\text{posterior}}^{\text{new}} - \lambda_i^{\text{new}}$.

The pseudocode for the overall algorithm is given in Algorithm 1. Note that all communications are performed asynchronously and in a non-blocking fashion. In particular, Steps 11-17 are performed in a separate coroutine from the main loop (Steps 7-18), and Step 15 can happen several iterations of the main loop after Step 14. This is so that compute nodes can spend most of their time learning (Steps 8-10) and do not have to wait for network communications to complete. However, this means that the previous copy of the natural parameter λ_i used when the last message was sent to the master (Step 13) needs to be stored, in addition to the most recent one. We also note that faster compute nodes need not wait for slower ones since they each learn their own separate likelihood approximation parameters. It would be interesting for future research to explore adaptive methods to allow faster compute nodes to increase the data subsets that they learn from, and slower ones to decrease, to balance the learning progress across compute nodes more evenly.

5.1 Discussion and Related Works

Our naming of the posterior server contrasts with that of the parameter server (Ahmed et al., 2012) which is typically used for maximum likelihood (or minimum empirical risk) estimation of model parameters. Note however that our algorithmic contribution is effectively orthogonal to (Ahmed et al., 2012), who proposed a generic and robust computational architecture for distributed machine learning. We believe it is possible to implement our algorithm using the parameter server software framework.

One of the difficulties of the parameter server architecture is that learning happens at the level of parameters, with a single set of parameters being maintained across the cluster. Since the data subsets on workers are disjoint, the learning on each worker tends to make the local copy of the parameters diverge from those on the parameter server and on other workers. As a result, frequent synchronisation with the parameter server is necessary to prevent stale parameters and gradients. As an example, in the DistBelief method (Dean et al., 2012), experiments were conducted where the communication with the master was performed after every iteration, which can significantly slow down the learning process. On the other hand, one of the interesting aspects of the posterior server is that it lifts learning from the level of parameters to the level of distributions over parameters. As a result each worker can maintain a distinct parameter set in the MCMC sampler and a distinct likelihood approximation (since the likelihoods on different workers are indeed different as they have different data subsets) without requiring frequent communication with the posterior server.

Algorithm 1 Posterior Server: Distributed Bayesian Learning via SNEP

for each compute node $i = 1, \ldots, n$ **asynchronously do**
  let $\gamma_i^{(1)}$ be the initial mean parameter of local likelihood approximation.
  let $\lambda_i^{\text{old}} := \lambda_i^{(1)} := \nabla A^*(\gamma_i^{(1)})$ be the initial natural parameter of local likelihood approximation.
  let $\theta_{-i} := \theta_0 + \sum_{j \neq i} \lambda_j^{(1)}$ be the initial natural parameter of cavity distribution
  let $\theta_i' := \theta_{-i} + \lambda_i^{(1)}$ be the initial auxiliary parameter.
  let $x_i^{(1)} \sim p_{\theta_{-i} + \lambda_i^{(1)}}$ be the initial state of MCMC sampler.
  for $t = 1, 2, \ldots$ until convergence **do**
    update local state via MCMC:

$$x_i^{(t+1)} \sim \mathcal{K}_i \left(\cdot \mid x_i^{(t)}; \theta_i' - \beta_i^{-1} \lambda_i^{(t)}, \beta_i^{-1} \right)$$

    update local likelihood approximation:

$$\gamma_i^{(t+1)} := \gamma_i^{(t)} + \epsilon_t \left(s(x_i^{(t+1)}) - \nabla A \left(\theta_{-i} + \lambda_i^{(t)} \right) \right)$$
$$\lambda_i^{(t+1)} := \nabla A^*(\gamma_i^{(t+1)})$$

    every N_{outer} iterations **do**: update auxiliary parameter:

$$\theta_i' := \theta_{-i} + \lambda_i^{(t)}$$

    every N_{sync} iterations **asynchronously do:** communicate with posterior server:
      let $\Delta_i := \lambda_i^{(t)} - \lambda_i^{\text{old}}$.
      update $\lambda_i^{\text{old}} := \lambda_i^{(t)}$.
      send Δ_i to posterior server.
      receive $\theta_{\text{posterior}}$ from posterior server.
      update $\theta_{-i} := \theta_{\text{posterior}} - \lambda_i^{\text{old}}$.
  end for
end for
for the posterior server **do**
  let $\theta_{\text{posterior}} := \theta_0 + \sum_{j=1}^n \lambda_i^{(1)}$ be the initial natural parameter of the posterior approximation.
  maintain a queue of messages from workers.
  for each message Δ_i received from some worker i **do**
    update $\theta_{\text{posterior}} := \theta_{\text{posterior}} + \Delta_i$.
    send $\theta_{\text{posterior}}$ to worker i.
  end for
end for

The only role of communication here is for the cavity distributions, which can be thought of as a way for the system to focus the learning happening on the workers on the relevant regions of the parameter space (Xu et al., 2014). Empirically, the precise parameterisation of the cavity distribution is not very important. For an extreme example, suppose both the prior and likelihood terms are close to being Gaussians and the tractable family is also Gaussian. Then the likelihood approximation will not in fact depend on the cavity distribution at all, and will converge to the true likelihood on each worker independently. See also Zhang et al. (2015a) for elastic-averaging SGD, a similar idea of allowing each worker a separate parameter vector, using an ADMM-like methodology.

6. Experiments

In this section we present our experiments on SNEP and the posterior server. Our implementation, which is available at `http://bigbayes.github.com/PosteriorServer`, is in the Julia[3] technical computing language. In our setup, the master and workers are run on separate system processes (that is, in separate memory spaces) on a many-core computing cluster, making use of the high-level parallel programming abstractions provided by Julia. Other architectures are possible; for example, multiple threads sharing an address space, multiple GPUs, or nodes communicating over a network using MPI. For the MCMC sampler on workers, we chose an adaptive version of stochastic gradient Langevin dynamics (SGLD) (Welling and Teh, 2011) related to Adam (Kingma and Ba, 2015), which is more computationally scalable to larger neural network models and data sets than standard MCMC (see Appendix B for details). Our neural network models are implemented in the Mocha[4] deep learning Julia package.

6.1 Comparison to SMS on Bayesian Logistic Regression

In this section we compare SNEP against *Sampling via Moment Sharing* (SMS) (Xu et al., 2014), a related algorithm for distributed Bayesian learning whereby each worker has a separate MCMC sampler and coordination across workers is achieved using plain EP. SMS was originally proposed to scale up MCMC methods and as such it assumes that MCMC chains can be run for many iterations to convergence in between communications with the master. SMS uses the MCMC iterates to estimate the moments required for EP updates and so, as discussed in the introduction, requires a large number of iterations to produce the low Monte Carlo noise for EP updates to work properly.

We illustrate below the differing dynamics of SMS and SNEP when applied to a Bayesian logistic regression model with simulated data. We took a similar setup as in the SMS paper (Xu et al., 2014), generating a dataset $\mathcal{D} = \{(z_c, y_c)\}_{c=1}^N$ where covariates $z_c \in \mathbb{R}^d$ and response $y_c \in \{0, 1\}$. The conditional distribution of y_c given z_c and weights x is

$$p(y_c = 1 \mid z_c, x) = \sigma(z_c^\top x) \tag{26}$$

where σ denotes the logistic function. We used a Gaussian prior $p_0(x) = \mathcal{N}(x; 0_d, 10 I_d)$ on x and the aim is to construct an approximation to the posterior $p(x \mid \mathcal{D})$. We generated

3. `http://julialang.org`.
4. `https://github.com/pluskid/Mocha.jl`.

$N = 50000$ data points with $d = 50$ using iid draws for the covariates, $z_c \sim \mathcal{N}(\mu, \Sigma)$ where $\mu \in [0, 1]^d$ and $\Sigma = PP^\top$ with $P \in [-1, 1]^{d\times d}$, with entries drawn uniformly at random for both P and μ. The generating weight vector x^* is drawn from the prior $\mathcal{N}(x; 0_d, 10I_d)$. The labels y_c are then sampled according to the model.

Both algorithms were run with three workers each with one third of the data. SNEP is run with 1 inner loop iteration per synchronisation with the master (for the purpose of comparing against SMS). Varying numbers of MCMC samples per inner loop iteration were used for both algorithms, to investigate the effect of Monte Carlo noise on the performances of the algorithms (low number of samples meaning high noise and both lower performance and lower computational cost). The damping for SMS and the learning rate for SNEP were tuned for best performances. As the base exponential family, we used a full-covariance Gaussian. We compared the predictive RMSE $\sqrt{\sum_c |\hat{p}_c - y_c|^2/N}$ obtained with both methods over time where $\hat{p}_c = \sigma(z_c^T \overline{x})$ where $\overline{x}$ is the currently estimated posterior mean. We also compared the relative difference between the estimated posterior mean and that estimated from a long run of the No-U-Turn sampler (Hoffman and Gelman, 2014) as implemented in Stan (Carpenter et al., 2017) with 4 chains and 50000 iterations.

Figure 2 illustrates the performances of both algorithms and how they are influenced by the number of MCMC samples used per iteration. It can be observed that SNEP is more robust and better performing than SMS in the presence of noise. In general, we found that the number of samples needed for SMS to perform well grows with the dimensionality of the problem. In models with very high dimensionality and multi-modality (e.g., neural networks), the number of samples needed per step is very large leading to iterations that are computationally impractical, whereas SNEP can afford to use many fewer samples.

6.2 Bayesian Neural Networks

In this section we report experimental results applying SNEP and the posterior server to distributed Bayesian learning of neural networks. We have found that the SMS algorithm exhibited significant instabilities and was not suitable for these larger scale problems. Instead our aim here is to explore the behaviour of SNEP when varying various key hyperparameters. We used diagonal covariance Gaussians as the approximating exponential family due to computational cost considerations. While a diagonal Gaussian approximation can be quite poor for the full Bayesian posterior, past works have shown that they can produce good predictive performances (Hernandez-Lobato and Adams, 2015, Blundell et al., 2015, Kirkpatrick et al., 2017). Hence our aim is to evaluate the predictive performance of SNEP, treated as a distributed learning algorithm for neural networks, and comparing it to Adam (Kingma and Ba, 2015), a state-of-the-art stochastic gradient descent (SGD) algorithm with access to the whole data set on a single computer, as well as several state-of-the-art distributed SGD algorithms: asynchronous SGD (A-SGD) (Dean et al., 2012) and elastic averaging SGD (EASGD) (Zhang et al., 2015a).

In our experiments we used stochastic gradient Langevin dynamics with an preconditioning scheme reminiscent of Adam as the MCMC sampler. The preconditioning scheme is the same as the one proposed by (Li et al., 2016) except for the addition of a debiasing reminiscent of Adam. We found that sometimes this adaptive scheme lead to large injected noise, especially at the start of training which was detrimental to learning. To mitigate

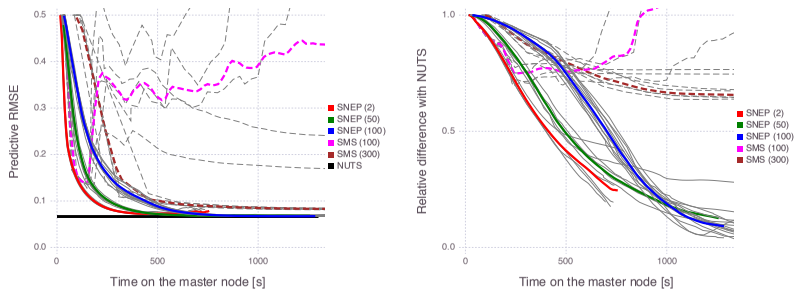

Figure 2: (left) Comparison of the predictive RMSE obtained with SMS (dashed-lines) and SNEP (full lines) versus the time on the master node when varying the number of MCMC samples per iteration (numbers reported in the legend). When too few samples are used for the moment estimates, SMS becomes unstable whilst SNEP does not suffer from this. SNEP is also consistently faster and more accurate than SMS. The accuracy obtained with the posterior mean estimated with a long run of Stan/NUTS is also displayed as comparison (horizontal line). (right) Relative difference between the posterior means estimated using Stan/NUTS and using SMS (dashed lines) or SNEP (full lines). Each coloured line corresponds to an average over several runs (represented in light grey).

this effect we limited the standard deviation of the injected noise to be at most ϵ in our experiments. For further details see Appendix B.

6.2.1 MNIST, Two Layer Fully Connected Network

In this section we look at training a fully connected neural network on the MNIST data set[5], which consists of 60000 training images of handwritten digits of size 28×28 and 10000 test images, the task being to classify each image into one of ten classes. The network has two hidden layers with 500 and 300 rectified linear units (ReLUs) respectively and softmax output units.

In the first set of experiments, we varied a number of hyperparameters of the learning regime while keeping the rest kept at default values, to investigate the sensitivity of the learning to these hyperparameters. The default values were chosen by hand in a rough initial round of experimentation as follows: the minibatch size is 100, the learning rate for SNEP was 0.02 and step size for the adaptive SGLD sampler was 0.001, the number of inner loop iterations per communication with master is $N_{sync} = 10$, the number of inner loop iterations per outer loop update is $N_{outer} = 10$, and the parameters were initialised with the popular Xavier initialisation (Glorot and Bengio, 2010). We set a minimum variance of 0.01 for the likelihood approximations, as we found that the estimated variances are otherwise too small due to the diagonal Gaussian approximation. Unless otherwise stated, we used four workers to explore the distributed behaviour. Test curves were produced by evaluating

5. `http://yann.lecun.com/exdb/mnist/`.

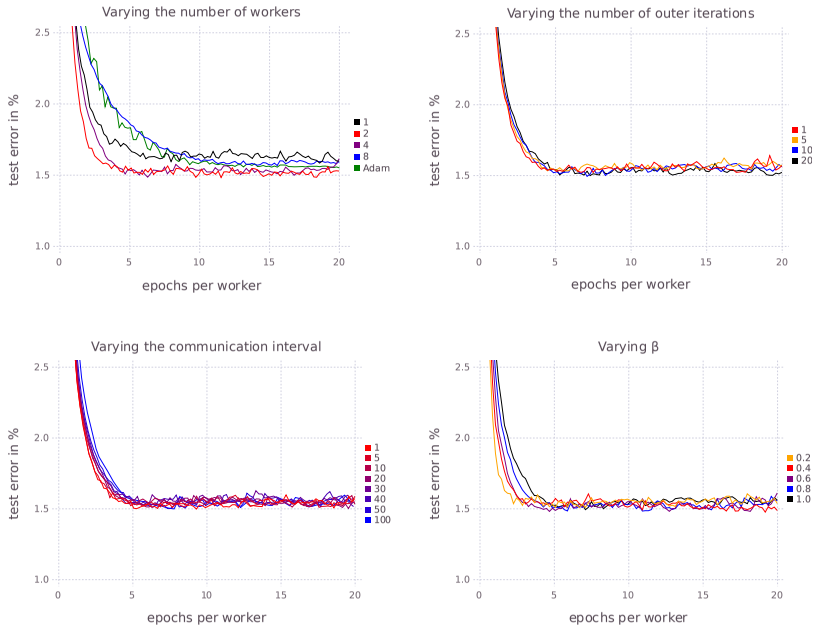

Figure 3: Results on a two-layer densely connected model on MNIST varying the parameters of SNEP and comparing against SGD, A-SGD, and EASGD. Four workers were used in the distributed methods in the experiments that held the number of workers fixed. This demonstrates that SNEP is insensitive to the full convergence of the outer loop, is robust to large communication intervals, that convergence is faster for a lower β (on this data set), and that SNEP produces competitive results quickly. Detailed analyses of sub-figures (left to right, top to bottom) are reported in the main text.

networks based on the approximate posterior means at the master. Each reported curve in the figures is an average over ten repetitions. In our experiments we used one CPU core per worker process. See Figure 3 for the results of this set of experiments.

First, we examined the behaviour of SNEP as N_{worker} is varied. We see that two workers perform significantly better than one worker or Adam. However, performance deteriorates as the number of workers is increased further. This is possibly due to smaller number of data items per worker which makes the variational approximation more severe. Another factor we found is that because we imposed a minimum variance in for the likelihood approximations, using more workers gives tighter cavity distributions which can affect the scale of the natural-gradients and slow convergence significantly.

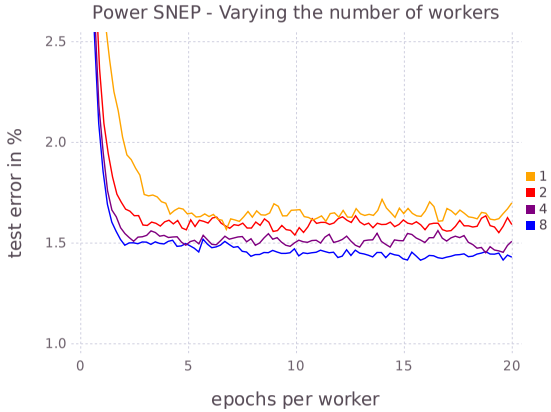

Figure 4: Results on a two-layer densely connected model on MNIST for power SNEP ($\beta = 1/N_{workers}$) varying the number of workers. There is a clear improvement in terms of convergence speed and final accuracy for more workers.

Second, we investigated the effect of varying N_{sync} and N_{outer}. Figure 3 demonstrates that SNEP is insensitive to these hyperparameters over reasonably large range of values. Note in particular that infrequent communications with the posterior server (up to once every 100 iterations in this experiment) did not significantly deteriorate the learning process at all. In fact, the related SMS algorithm (Xu et al., 2014) effectively involves communications with the master once every thousands of iterations.

Third, we investigated the effect of varying the β parameter. Interestingly, lower values of β sped up convergence significantly. The literature on power EP links the β parameter with locally minimising $\alpha-$divergences (where $\beta = 1/\alpha$). Lower values of β correspond to local approximations that are likely to capture more of the full posterior rather than matching one mode (Minka, 2005). Another factor is that given the minimum variance setting, lower values of β increase the variance of the cavity distribution allowing for more local exploration. Generally, In our experiments we found that a heuristic of setting $\beta = 1/N_{workers}$ worked particularly well for MNIST. We call the resulting algorithm power SNEP (p-SNEP). With this parameter setting we see a clear advantage for more workers (see figure 4). More workers give better results in terms of the test error and convergence is fastest for eight workers. Note that eight workers reach a test error of 1.5% after about two epochs, which is much faster than our experiments with $\beta = 1.0$.

Finally, we compared SNEP with two distributed SGD algorithms, asynchronous SGD (A-SGD, also known as Downpour) (Dean et al., 2012) and elastic averaging SGD (EASGD) (Zhang et al., 2015a). Our implementations differ slightly from those given in the papers. For A-SGD, both the workers and master performed Adam updates with independently

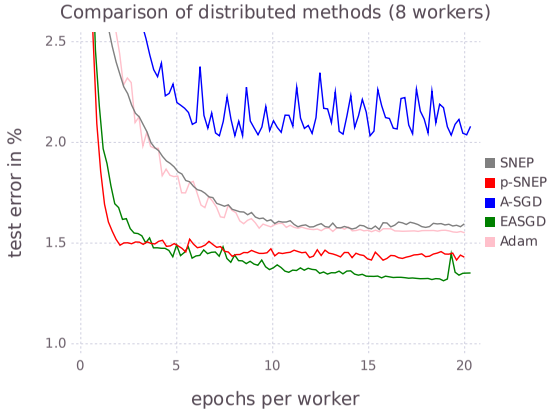

Figure 5: Results on a two-layer densely connected model on MNIST comparing SNEP and p-SNEP to asychronous SGD and elastic averaging SGD.

chosen step size constants. The authors of EASGD do not address the case of distributing the data among the workers. Nonetheless, we found this posed no problem to the algorithm. All hyperparameters were tuned to optimise performances. We used the same length of communication intervals $N_{sync} = 10$ and four workers for all algorithms. As shown in figure 5, SNEP (with $\beta = 1$) and p-SNEP (with $\beta = 1/N_{workers}$) achieve performances comparable to these state-of-the-art methods, both in terms of speed and final test accuracies. SNEP is comparable to Adam and better than A-SGD. p-SNEP outperforms A-SGD, Adam and SNEP, and is slightly faster initially than EASGD but achieves slightly higher test errors. It is important to note that we are tackling a harder problem with SNEP/p-SNEP, that of Bayesian learning rather than optimisation.

6.2.2 MNIST, Very Deep Fully Connected Network

Deeper models pose a much harder learning problem—as the depth increases, the number of saddle points increases exponentially (Dauphin et al., 2014). Moreover, learning often gets stuck not at critical points but in large plateaus of the error surface (Lipton, 2016). It is, therefore, interesting to evaluate (p-)SNEP against standard methods on a deeper fully-connected network, and we chose the architecture from Neelakantan et al. (2016), which has 20 hidden layers of 50 units each.

The experimental setup was similar to the previous section. The distributed methods used a communication intervals of $N_{sync} = 10$ and a varying number of workers. For p-SNEP, we optimized the prior variance, scaling of the injected noise, learning rate, step size, and beta hyperparameters by a course grid search over five orders of magnitude.

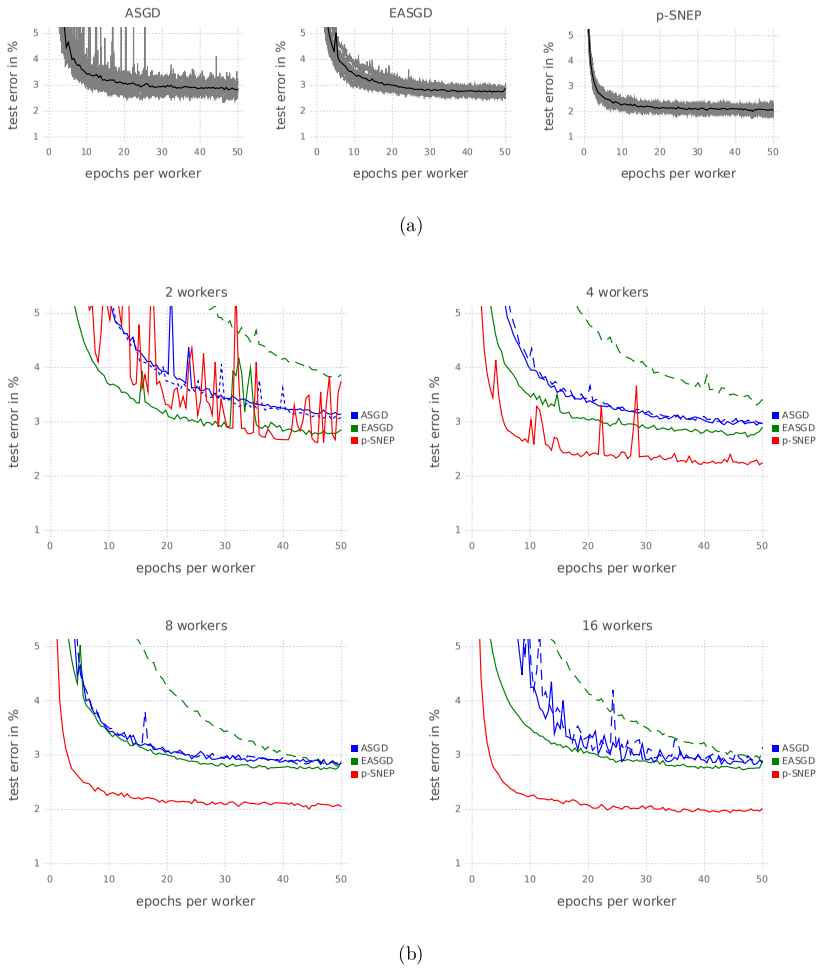

Figure 6: Results on deep narrow model for MNIST. (a) Comparing distributed methods for 8 workers. p-SNEP attains an extra percent of accuracy with less variability in the runs. The solid line is the average over 10 runs. (b) Varying the number of workers, averaged over 10 runs. The dashed line indicates result with no prelearning phase for A-SGD and EASGD, whereas for those methods the solid line indicates an Adam pre-learning phase of a third of an epoch.

Similarly, for A-SGD we optimized the Adam step size constants, separately on the workers and master, for EASGD the moving rate and Adam step size constants, and for SGD the Adam step size constants and scaling of injected noise, from no noise to three orders of magnitude. All methods were initialized by the Xavier method, and run with and without a non-distributed pre-learning phase of a third of an epoch. We found that pre-learning was essential for EASGD, while it was unnecessary for A-SGD and p-SNEP. In fact, for SNEP, too long a pre-learning phase is actually harmful to the final solution reached, which we suggest is due to the reduced exploration between workers. We only report results for p-SNEP without pre-learning (as per the previous section).

The same Adam step size constant was found to be optimal across all methods, 0.00065. For p-SNEP, the prior variance was set to 0.05, β to 1/8, and the learning rate to 0.04. For EASGD, the moving rate was set to 0.25. For A-SGD, the worker step sizes were set to 0.00065 and the master step size to a third of this; it must be slower to account for the staleness of the parameters. For SGD, we discovered that a small amount of noise, the same constant as is optimal for p-SNEP, reduces the variance of the runs around their mean by helping some runs avoid getting stuck in bad solutions. However, SGD did not converge to within the plot limits within the time set for experiments and so is omitted in the results shown in Figure 6a.

p-SNEP was found to significantly outperform A-SGD and EASGD, obtaining an extra percent of accuracy relative to other methods after fifty epochs for 8 and 16 workers. From the perspective of traditional neural network learning, our algorithm has two advantages for learning deep models: the addition of noise, and a principled method of regularizing the parameters. As in Neelakantan et al. (2016), we found it was important to add noise to the SGD methods. Although with a good initialization, added noise only improved the worst runs and not the best, smoothing out convergence. We conjecture that the added noise helps learning escape the difficult saddle points and plateaus. For this model, a strong prior variance was found to be important for p-SNEP to extract the full capacity of the model. We conjecture that this allows the gradients to flow back through the network more easily by forcing the parameters of the top layers to be small. Surprisingly, we found L2 regularization did not help with A-SGD and EASGD. p-SNEP also clearly benefits from additional workers in this setting, in contrast to A-SGD and EASGD (see Figure 6b).

It is interesting to note that this model has about one sixth the parameters of the previous two layer model. Yet, due to the deeper architecture and ability to successfully navigate the difficult learning landscape, p-SNEP is able to obtain similar test accuracies.

6.2.3 CIFAR-10, Convolutional Network

We also experimented with distributed Bayesian learning of convolutional neural networks, applying these to the CIFAR-10 data set (Krizhevsky, 2009) which consists of 50000 training instances and 10000 test instances from 10 classes, each instance being a 32x32 colour natural image. The network used is the one described in Alex Krizhesky's CIFAR tutorial[6] and consists of 8 layers: a first convolutional layer followed by max-pooling and local response normalization, a second convolutional layer also followed by max-pooling and local response normalization, and a third convolutional layer followed by a fully connected layer.

6. `https://code.google.com/p/cuda-convnet/wiki/Methodology`

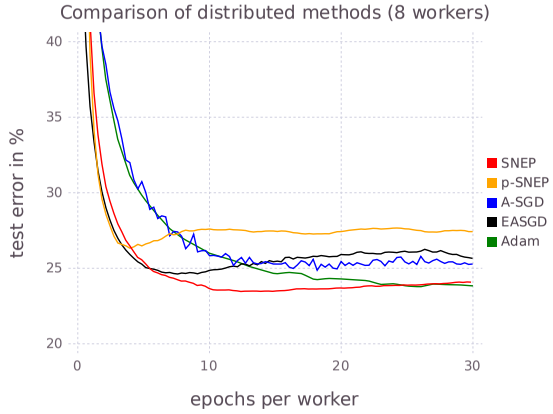

Figure 7: Learning curves varying the number of workers (averaged over three runs). The green line shows Adam with default parameters for comparison. Best viewed in colour.

For SNEP, we used the following settings: $N_{sync} = 10$, $N_{outer} = 10$, mini-batch size 100, weights initialised with the Xavier initialisation, and SNEP learning rate and adaptive SGLD step sizes of 0.02. We did not investigate improving performance by building in invariances using data perturbations or having multiple learning phases with different learning rates. Learning curves averaged over 3 runs are shown in Figure 7. All distributed algorithms are shown with hand-tuned optimal hyperparameter settings. On this data set SNEP outperforms other distributed algorithms. It converges as quickly as EASGD and p-SNEP but reaches a better final test accuracy. p-SNEP converges very fast but to a worse local optimum. It is not clear why p-SNEP performed better on previous experiments but not here; understanding the optimal choice of β is an interesting area for future research as we have observed that this parameter has a strong influence on the performance of the algorithm.

7. Discussion

In this paper, we have proposed a novel alternative to expectation propagation called stochastic natural-gradient expectation propagation (SNEP). SNEP is demonstrably convergent, even when using Monte Carlo estimates of the moments/mean parameters of tilted distributions. Experimentally, we find that SNEP converges more efficiently and more stably than other methods considered, particularly when Monte Carlo noise is high. Using SNEP, we have proposed the posterior server architecture for distributed Bayesian learning using an asynchronous non-blocking message-passing protocol. The architecture uses a

separate MCMC sampler on each worker, and SNEP to coordinate the samplers across the cluster so that the target distributions agree on the moments which characterise the base exponential family. In contrast with typical maximum likelihood parameter server architectures, the posterior server allows each worker to learn separate variational parameters, and as a result requires less frequent synchronisation across the cluster. We believe that this insight can allow for significant advances to distributed learning, although more work is still needed to make this reality. Finally, we applied SNEP and the posterior server to distributed Bayesian learning of both fully-connected and convolutional neural networks, where we showed performances on par with or better than state-of-the-art distributed and non-distributed optimisation algorithms. In conclusion, we have demonstrated that Bayesian learning of large complex models can be achieved efficiently and effectively in a distributing computing setting, and can achieve state-of-the-art performances on learning neural networks.

Our work leaves open a number of interesting avenues of future research, which we have discussed throughout the paper. It would be interesting to develop other novel convergent alternatives to EP with potentially faster convergence (e.g. using a single loop instead of double loop algorithm), and to apply such methods to other settings where Monte Carlo estimates are used within EP. It would also be interesting to further investigate combining SNEP with ideas from other projects such as the parameter tying idea of stochastic and averaged EP. We also believe that further explorations of learning regimes and hyperparameters, as well as of larger data sets, is called for, and will demonstrate further improvements to the method. These explorations can include using samples obtained at workers to form predictive probabilities, evaluating the algorithms using test log probabilities and on their abilities to quantify uncertainties, understanding the role of the β parameter, and combining SNEP with simulated annealing for optimisation. Another interesting area for application is on-device machine learning which falls naturally into our distributed data set-up. It would be interesting to compare SNEP to existing approaches such as federated learning (McMahan et al., 2016) We have also noted that our application of SNEP to neural network learning necessitates a diagonal covariance Gaussian approximation for computational reasons. Further work can consider richer posterior approximations, such as block-diagonal covariances or the use of matrix variate Gaussian distributions (Louizos and Welling, 2016). Ultimately, we believe these explorations will demonstrate the utility of a distributed Bayesian approach to learning.

Appendix A. Relationship of Ideal Variational Problem in the Extended Exponential Family to Variational Inference

As expected, the ideal variational problem in the extended exponential family in (3) is intractable and approximations are needed for tractability, with different approximations leading to different variational approaches. For readers unfamiliar with this framework, it might be illuminating to link the above framework to standard mean field variational inference, which corresponds to approximating the mean domain $\tilde{\mathcal{M}}$ by the set of moments achievable by some family of factorised distributions q over x. The standard evidence lower bound on the log marginal probability (also known as the variational free energy) is,

$$\begin{aligned} p(\{D_i\}_{i=1}^n) &\geq \mathbb{E}_q[\log p(x, \{D_i\}_{i=1}^n) - \log q(x)] \\ &= \mathbb{E}_q\left[\theta_0^\top s(x) - A(\theta_0) + \sum_{i=1}^n \ell_i(x)\right] - \mathbb{E}_q\left[\log q(x)\right] \\ &= \tilde{\theta}^\top \tilde{\mu} - A(\theta_0) - \mathbb{E}_q\left[\log q(x)\right] \end{aligned}$$

where we have introduced $\mu = \mathbb{E}_q[s(x)]$ and $\nu_i = \mathbb{E}_q[\ell_i(x)]$ as the moments of q, and we have used the definition of the extended natural and mean parameters $\tilde{\theta}$, $\tilde{\mu}$. The second term is a constant not dependent on q, while the third term above is the negative entropy, so that the above is equivalent to (3) except that the optimisation is only over a family of factorised distributions q.

Appendix B. Additional Techniques for Bayesian Neural Networks

In our experiments we investigated the use of SNEP and the posterior server for distributed Bayesian learning of neural networks. To get the method working well on the notoriously complicated posterior distributions for neural networks, a number of additional techniques are needed, which we describe here.

B.1 Adaptive Stochastic Gradient Langevin Dynamics

Most of the computational costs associated with the algorithm involve the MCMC updates to the state x_i. When the number of data points stored on each compute node is large, standard MCMC updates are infeasible as each update requires computations involving every data point. In our experiments we used the stochastic gradient Langevin dynamics (SGLD) algorithm proposed by Welling and Teh (2011) which scales well to large data sets.

SGLD uses mini-batches of data to provide unbiased estimates of gradients which are used in a time discretized Langevin dynamics simulation whose stationary distribution is the desired tilted distribution (20). SGLD injects noise in every step. As the discretization stepsize decreases the noise due to the stochastic gradients is eventually dominated by the injected noise and hence neglibible. Likewise the discretization introduces errors which tend to zero as the discretization step sizes decreases to zero; see (Teh et al., 2015, Vollmer

et al., 2016). Recall that the data points on compute node i is $D_i = \{y_c\}_{c \in S_i}$, and the log likelihood is

$$\ell_i(x_i) = \sum_{c \in S_i} \log p(y_c \mid x_i).$$

Let $B^{(t)} \subset S_i$ be a mini-batch of data, chosen uniformly at random with fixed size. Each SGLD update is,

$$x_i^{(t+1)} = x_i^{(t)} + \kappa_t (M^{(t)})^{-1} \left(\nabla s(x_i^{(t)})^\top (\theta_i' - \beta_i^{-1} \lambda_i^{(t)}) + \beta_i^{-1} \frac{|S_i|}{|B^{(t)}|} \sum_{c \in B^{(t)}} \nabla \log p(y_c | x_i^{(t)}) \right) + \eta_t,$$
$$\eta_t \sim \mathcal{N}(0, 2\kappa_t (M^{(t)})^{-1}). \tag{27}$$

The term inside the parentheses is an unbiased estimate of the gradient of the log density of the tilted distribution (20), κ_t is the discretization step size, $M^{(t)}$ is (an adaptive) diagonal mass matrix, while η_t is an injected normally-distributed noise, which prevents SGLD from converging to a mode of the distribution and distinguishes it from stochastic gradient descent. See Welling and Teh (2011) for details.

In (27), $M^{(t)}$ is a mass matrix which effectively controls the length scale of updates to each dimension of x_i. It is well known that in neural networks the length scales of gradients differ significantly across different parameters and adaptation of learning rates specific to each parameter is crucial for successful deployment of stochastic gradient descent learning. We have found that this is the case for SGLD as well, and used an adaptation scheme for the mass matrix reminiscent of Adam (Kingma and Ba, 2015). The adaptation scheme is the same as the one proposed by (Li et al., 2016) except for the addition of a debiasing reminiscent of Adam. At iteration t let g_t be the stochastic gradient estimate in (27). We use a diagonal mass matrix M_t that is updated according to the following update equations:

$$v_t = \beta v_{t-1} + (1 - \beta) g_t \odot g_t$$
$$\mathrm{diag}(M_t) = \frac{v_t}{1 - \beta^2},$$

where $\odot$ denotes the elementwise product. We used $\beta = 0.999$ in our experiments. The actual adaptive stepsize is then given by

$$\kappa_t = \frac{\epsilon}{\sqrt{M_t} + \delta},$$

where $\epsilon = 10^{-3}$ and $\delta = 10^{-8}$ is added for numerical stability. We found that sometimes this adaptive scheme lead to large injected noise, specially at the start of training which was detrimental to learning. To mitigate this effect we limited the standard deviation of injected noise to be at most ϵ in our experiments. An alternative solution to this problem could be the approach proposed by Lu et al. (2017).

B.2 Shifting MCMC States After Communication with Posterior Server

After each communication with the posterior server, the target distribution of the MCMC sampler on the worker, say i, is changed, because of θ_{-i} being updated in Step 16 of

Algorithm 1. Assuming that the MCMC sampler had previously converged, it will now not be so anymore because of this shift in the target distribution, and a number of burn-in iterations may be needed before the mean parameter estimates can be used for SNEP updates again.

For Gaussian base exponential families, we can shift the MCMC state along with the target distribution when θ_{-i} is updated in the following way. Suppose μ_i^{old}, Σ_i^{old}, μ_i^{new}, Σ_i^{new} are the means and covariances of the approximate Gaussian posterior before and after the update to θ_{-i} (with natural parameters $\lambda_i + \theta_{-i}^{\text{old}}$, $\lambda_i + \theta_{-i}^{\text{new}}$ respectively where λ_i is the current natural parameter of the Gaussian likelihood approximation). Suppose x_i^{old} is the MCMC state before the update. Then we shift the MCMC state as follows:

$$x_i^{\text{new}} = \mu_i^{\text{new}} + (\Sigma_i^{\text{new}})^{\frac{1}{2}} (\Sigma_i^{\text{old}})^{-\frac{1}{2}} (x_i^{\text{old}} - \mu_i^{\text{old}}). \tag{28}$$

The idea is that x_i^{new} should be at the same location relative to the new Gaussian approximation to the posterior as x_i^{old} is relative to the old Gaussian approximation. We have found that no burn-in is needed with this shift in the MCMC state after each communication.

Abstract

Dictionaries are collections of vectors used for the representation of a class of vectors in Euclidean spaces. Recent research on optimal dictionaries is focused on constructing dictionaries that offer sparse representations, i.e., ℓ_0-optimal representations. Here we consider the problem of finding optimal dictionaries with which representations of a given class of vectors is optimal in an ℓ_2-sense: optimality of representation is defined as attaining the minimal average ℓ_2-norm of the coefficients used to represent the vectors in the given class. With the help of recent results on rank-1 decompositions of symmetric positive semidefinite matrices, we provide an explicit description of ℓ_2-optimal dictionaries as well as their algorithmic constructions in polynomial time.

Keywords: ℓ_2-optimal dictionary, rank-1 decomposition, finite tight frames

1. Introduction

A *dictionary* is a collection of vectors in a finite-dimensional vector space over $\mathbb{R}$, with which other vectors of the vector space are represented. A dictionary is a generalization of a basis: While the number of vectors in a basis is exactly equal to the dimension of the vector space, a dictionary may contain more elements. In this article we consider a problem of finding an optimal dictionary, where optimality is interpreted as the minimum expected average size of the coefficients required to represent a certain collection of vectors drawn from a given probability distribution.

We begin with a toy example to motivate the problems treated in this article. Let V be a random vector that attains values 'close' to $\begin{pmatrix}0 & 2\end{pmatrix}^\top$ with high probability; the situation is demonstrated below:

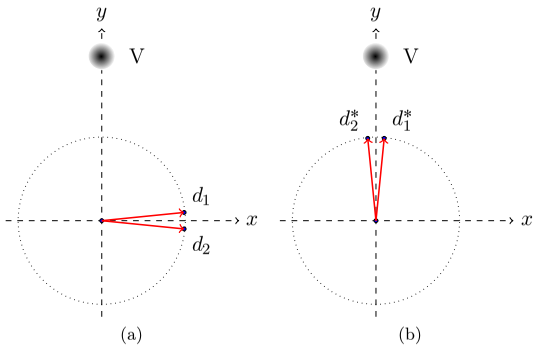

Figure 1: Comparison of two dictionaries.

Suppose that our dictionary consists of the vectors $d_1 = \begin{pmatrix}1 & -\epsilon\end{pmatrix}^\top$ and $d_2 = \begin{pmatrix}1 & \epsilon\end{pmatrix}^\top$ in $\mathbb{R}^2$, with a small positive value of ϵ. Since we must represent V using d_1 and d_2, the corresponding coefficients α_1 and α_2 must be such that $\alpha_1 \begin{pmatrix}1 & \epsilon\end{pmatrix}^\top + \alpha_2 \begin{pmatrix}1 & -\epsilon\end{pmatrix}^\top = V \approx \begin{pmatrix}0 & 2\end{pmatrix}^\top$. A quick calculation shows that the magnitudes of the coefficients α_1 and α_2 should then be approximately equal to $1/(\epsilon)$ with high probability. To wit, the magnitudes of these coefficients are large for small values of ϵ. It is therefore more appropriate in this situation to consider a dictionary consisting of vectors $d_1^* = \begin{pmatrix}\epsilon & 1\end{pmatrix}^\top$ and $d_2^* = \begin{pmatrix}-\epsilon & 1\end{pmatrix}^\top$ to represent the samples of V, in which case, the magnitudes of the coefficients of the representations are closer to 1 with high probability. The latter values are comparatively far smaller compared to the values close to $1/(\epsilon)$ obtained with the preceding dictionary. This simple example shows that given some statistical information about the random vectors to be represented, the question of designing a dictionary that minimizes the average cost of representation can be better addressed.

Let us now turn to a situation in which considering the average cost of representations is natural. Our motivation comes from a control theoretic ideas perspective. Consider a linear time-invariant control system modeled by the recursion

$$x(t+1) = Ax(t) + Bu(t), \quad t = 0, 1, \dots, \tag{1}$$

where the 'system matrix' $A \in \mathbb{R}^{n\times n}$ and the 'control matrix' $B \in \mathbb{R}^{n\times m}$ are given, with the initial boundary condition $x(0) = \bar{x} \in \mathbb{R}^n$ fixed. For an arbitrarily selected $\hat{x} \in \mathbb{R}^n$, consider the standard *reachability problem* for (1), that is:

$$\begin{aligned}&\text{If possible, find a sequence } (u(t))_t \subset \mathbb{R}^m \text{ of control vectors}\\ &\text{that steer the system states to } \hat{x}.\end{aligned} \tag{2}$$

A necessary and sufficient condition for such a sequence to exist for every pair $(\bar{x}, \hat{x})$ is that the rank of the matrix $\mathfrak{R}_K(A,B) := \begin{pmatrix}B & AB & \cdots & A^{n-1}B\end{pmatrix}$ is equal to n, which we impose for the moment. Letting $K := \min\left\{k \geqslant 0 \;\middle|\; \operatorname{rank}\left(\mathfrak{R}_K(A,B)\right) = n\right\}$ denote the 'reachability

index' of (1), we see at once that the control vectors $(u(t))_{t=0}^{K-1}$ needed to execute the transfer of the states of (1) from $\bar{x}$ to $\hat{x}$ must be a solution to the linear equation

$$\hat{x} - A^K \bar{x} = \sum_{t=0}^{K-1} A^t B u(t) = \mathfrak{R}_K(A,B) \begin{pmatrix} u(K-1) \\ \vdots \\ u(1) \\ u(0) \end{pmatrix}.$$

It is now natural to consider the 'control cost' of transferring $\bar{x}$ to $\hat{x}$, for which, a natural candidate is the associated ℓ_2 performance index $\sum_{i=0}^{K-1} \|u(t)\|^2$. Since in practice, the ℓ_2 performance index is analogous to the amount of energy spent to control the system, its practical importance can hardly be overstated in the context of control. Let us list three examples:

- In attitude control/orientation problems of space vehicles, one must execute most of the rapid manoeuvre using the energy from the limited amount of fuel on board, or with the energy available from on-board batteries; minimizing the energy expenditure, therefore, is crucial.
- In controlled automated mobile robots (e.g., automated cars) designed to reach a given location within a certain time, reduction of energy consumption leads directly to reduction in fuel consumed.
- In control of electronic systems such as power electronic drives, the associated ℓ_2 performance index involves information of the amount of power drawn from the electricity grid to control the system, leading directly to minimization of power consumption and thereby heating.

Minimization of control effort has been an integral part of control theory, and is generally studied under the class of Linear Quadratic problems; see, e.g., (Bertsekas, 1995), (Anderson and Moore, 2007), (Clarke, 2013), (Liberzon, 2012), or any standard book on optimal control. It is evident that the task of designing control systems that require minimum control energy for their typical manoeuvres is of great importance.

It is a standard practice to study the reachability problem (2), for $\bar{x} = 0$ and $\hat{x}$ on the unit sphere; due to linearity of (1), this special case provides sufficient insight into the general case. Let us consider the following optimal control problem:

$$\begin{aligned} \underset{(u(t))_t}{\text{minimize}} \quad & \mathsf{E}\left[\sum_{t=0}^{K-1} \|u(t)\|^2\right] \\ \text{subject to} \quad & \begin{cases} x(t+1) = Ax(t) + Bu(t) \quad \text{for all } t = 0, \dots, K-1, \\ x(0) = 0, \\ x(K) = \hat{x} \text{ distributed according to } \mu, \end{cases} \end{aligned} \tag{3}$$

where μ is a probability distribution on $\mathbb{R}^d$. It is known that if $\hat{x}$ is uniformly distributed over the unit sphere, then the optimal control problem (3) admits an unique optimal solution and the optimum value is proportional to $\mathrm{tr}\big(W_{A,B}^{-1}\big)$, where $W_{A,B} \coloneqq \mathfrak{R}_K(A,B)\mathfrak{R}_K(A,B)^\top$ is the *controllability grammian* of the system; for details see, e.g., (Müller and Weber, 1972) and (Pasqualetti et al., 2014). It can be readily shown that if $\Sigma \coloneqq \mathsf{E}[\hat{x}\hat{x}^\top]$ is well defined, then the optimum value of (3) is equal to $\mathrm{tr}\big(\Sigma W_{A,B}^{-1}\big)$. Evidently, for a given distribution of

$\hat{x}$, different linear systems (1) — described completely by the pair (A,B) — incur different optimum values $\mathrm{tr}\big(\Sigma W_{A,B}^{-1}\big)$ of (3).

Against the above backdrop, consider the question of *designing* the linear control system (1) such that the value of (3) is as low as possible. Since most control problems involve designing control sequences to execute a class of desired manoeuvres, for a given distribution of $\hat{x}$ it is then natural to design the linear systems in order to minimize the optimum value $\mathrm{tr}\big(\Sigma W_{A,B}^{-1}\big)$ of the optimal control problem (3). In this case, the system design problem is similar to the one of finding an ℓ_2-optimal dictionary as described above: here the matrices A and B are to be designed, within a feasible region, such that the column vectors constituting the matrix $\mathfrak{R}_K(A,B)$ lead to minimal expected average cost of reachability, i.e., minimal value of (3). Such problems routinely arise in networked control, where the pair (A,B) is a function of the constituent systems and the connectivity of the network. From an operational standpoint, it is good for a networked system to have its components connected in a way such that the resulting system incurs small expected average state transfer costs. Indeed, control systems are typically designed (Müller and Weber, 1972) by optimizing a *figure of merit / measure of quality / measure of controllability*; in particular, networked control systems are designed in (Pasqualetti et al., 2014) using a measure of quality defined there. Based on this work on ℓ_2-optimal dictionaries, we have proposed a novel measure of quality in (Sheriff and Chatterjee, 2017), and further developments for algorithmic synthesis of large-scale control systems will be reported elsewhere. Besides these applications in control theory and practice, one of the key objective of our work here is to investigate and understand the physical nature of the ℓ_2-optimal dictionaries independent of their connection with control theory. Such a study will shed light on other control theoretic properties of observability and estimation.

There has been significant recent research into finding optimal dictionaries, briefly outlined in (Tošić and Frossard, 2011); current research centers around the development of learning algorithms for finding optimal dictionaries. Much of the thrust is on arriving at dictionaries that offer sparse representations of sample vectors. One of the first learning algorithms to develop a dictionary that offers sparse representation of images was given in (Olshausen and Field, 1997). Since then many learning algorithms have been developed to obtain dictionaries that offer sparse representation along with other special properties such as online computation capability (Mairal et al., 2009a), better classification property (Mairal et al., 2009b; Yang et al., 2011), better adaptive properties (Skretting and Engan, 2010); several other algorithms are given in (K. Delgado et al., 2003; Yaghoobi et al., 2009; Mallat and Zhang, 1993).

The problem addressed in this article differs from the mainstream research of finding dictionaries offering sparse (ℓ_0-optimal) representations in the sense that our objective is to find dictionaries that give minimum average ℓ_2-norm of the coefficient vector used for representation. Intuitively, optimization of the ℓ_2-norm of the representation vector tends to 'distribute' the information of the data being represented among all components of the representation vector; this makes the representation robust to accidental changes in the coefficients.

- An advantage of considering the ℓ_2-cost is that it involves a norm arising from an inner product; consequently, it comes with a rich set of properties associated with it. These properties are crucially employed in this article to modify the intrinsically non-convex

problem of finding an ℓ_2-optimal dictionary into an *equivalent* convex optimization problem,[1] allowing us to compute an optimal dictionary in *polynomial time* and arrive at *analytical expressions of the optimal costs*. We provide these algorithms in Sections 4.1 and 4.3.

- One more advantage of considering optimization in the ℓ_2-sense is related to the fact that the ℓ_2-cost involves the natural notion of *energy* which is extremely important in practice, especially in control theoretic applications.
- The results presented here also add to the recent developments in the advantages of representing signals/vectors using tight frames for finite-dimensional Hilbert spaces.

This article unveils as follows: In Section 2 we formally introduce our problem of finding an optimal dictionary which offers least square representation. Section 2 is the heart of this article, where we solve the problem of finding an ℓ_2-optimal dictionary, and arrive at an explicit solution. Algorithms to construct ℓ_2-optimal dictionaries are given in Section 4, where we present the proofs of our main results. The case of representing random vectors distributed uniformly on the unit sphere is treated in Subsection 2.4; we demonstrate that the ℓ_2-optimal dictionaries in this case are *finite tight frames*. The intermediate Section 3 contains results related to rank-1 decomposition of positive semidefinite matrices; these constitute essential tools for the solutions of our main results. We conclude in Section 5 with a summary of this work and future directions.

Notations

We employ standard notations in this article. As usual, $\|\cdot\|$ is the standard Euclidean norm. The $n \times n$ identity and $m \times n$ zero matrices are denoted by I_n and $O_{m\times n}$, respectively. For a matrix M we let $\mathrm{tr}(M)$ and M^+ denote its trace and Moore-Penrose pseudo-inverse, respectively. The set of $n \times n$ symmetric and positive (semi-)definite matrices with real entries is denoted by $\mathbb{S}^{n\times n}_{++}$ ($\mathbb{S}^{n\times n}_{+}$), and the set of $n \times n$ symmetric matrices with real entries is denoted by $\mathbb{S}^{n\times n}$. For a Borel probability measure μ defined on $\mathbb{R}^n$, we let $\mathsf{E}_\mu[\cdot]$ denote the corresponding mathematical expectation. The image of a map f is written as $\mathrm{image}(f)$. The gradient of a continuously differentiable function f is denoted by ∇f. For finite ordered sets A and B, we let $A \uplus B$ denote the ordered set consisting of the elements (in their order) of A followed by the elements (in their order) of B; for instance, if $A = (1, 2)$ and $B = (-5, -7)$, then $A \uplus B = (1, 2, -5, -7)$. Suppose that A and B are two ordered sets such that $B \subset A$ as sets, then $A\backslash B$ is the ordered sub-collection in A after deleting the elements of the set B. Finally, given an ordered collection of vectors $(x_i)_{i=1}^n$ in $\mathbb{R}^\nu$ with $\nu \geqslant n$ and equipped with the standard inner product, $\mathrm{Ortho}\big((x_i)_{i=1}^n\big)$ gives the result of Gram-Schmidt orthonormalization of the collection $(x_i)_{i=1}^n$ considered in the order in which they appear i.e., $x_1, x_2, \ldots, x_n$.

2. The ℓ_2-optimal dictionary problem and its solution

Let V denote an $\mathbb{R}^n$-valued random vector defined on some probability space, and having distribution (i.e., Borel probability measure,) μ. We assume that V has finite variance. Let

1. By equivalence of two optimization problems we mean that an optimal solution to either of the problems can be obtained from an optimal solution to the other problem.

R_V denote the support of μ,[2] and let X_V be the smallest subspace of $\mathbb{R}^n$ containing R_V. Our goal is to represent the instances/samples of V with the help of a *dictionary* of vectors:

$$D_K := \big\{d_i \in \mathbb{R}^n \;\big|\; \|d_i\| = 1 \text{ for } i = 1, \ldots, K\big\} \quad \text{with a given } K \geqslant n,$$

in an optimal fashion. A *representation* of an instance v of the random vector V is given by the coefficient vector $\alpha = (\alpha_1 \;\ldots\; \alpha_K)^\top$, such that

$$v = \sum_{i=1}^K \alpha_i d_i. \tag{4}$$

A *reconstruction* of the sample v from the representation α is carried out by taking the linear combination $\sum_{i=1}^K \alpha_i d_i$. We define the *cost* associated with representing v in terms of the coefficient vector α as $\sum_{i=1}^K \alpha_i^2$. Since the dictionary vectors $\{d_i\}_{i=1}^K$ must be able to represent any sample of V, the property that $\mathrm{span}\{d_i\}_{i=1}^K \supset R_V$ is essential. A dictionary $D_K = \{d_i\}_{i=1}^K \subset \mathbb{R}^n$ is said to be *feasible* if $\mathrm{span}\{d_i\}_{i=1}^K \supset R_V$. We denote by $\mathcal{D}_K$ the set of all feasible dictionaries.

For a feasible dictionary $D_K = \{d_i\}_{i=1}^K$, with $m := \dim\big(\mathrm{span}\{d_i\}_{i=1}^K\big)$, and for any $v \in R_V$, the linear equation (4) is satisfied by infinitely many values of α whenever $K > m$. In fact, the solution set of (4) constitutes a $(K-m)$-dimensional affine subspace of $\mathbb{R}^K$. Therefore, in order to represent a given v uniquely, one must define a mechanism of selecting a particular point from this affine subspace, thus making the coefficient vector $\alpha = (\alpha_1 \;\ldots\; \alpha_K)^\top$ a function of v. Let f denote such a function; to wit, $f(v) := \alpha$ is the coefficient vector used to represent the sample v. We call such a map $R_V \ni v \longmapsto f(v) \in \mathbb{R}^K$ a *scheme of representation*. Representation of samples of the random vector V using a dictionary D_K and a scheme f is said to be *proper* if any vector $v \in R_V$ can be uniquely represented and then exactly reconstructed back. It is clear that for proper representation of V with a dictionary D_K consisting of vectors $\{d_i\}_{i=1}^K$, the mapping $R_V \ni v \longmapsto f(v) \in \mathbb{R}^K$ should be an injection that satisfies

$$V = \begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix} f(V) \quad \mu\text{-almost surely.} \tag{5}$$

A scheme f of representation is said to be *feasible* if for some feasible dictionary $D_K := \{d_i\}_{i=1}^K \in \mathcal{D}_K$ the equality $\begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix} f(V) = V$ is satisfied almost surely. We denote by $\mathcal{F}$ the set of all feasible schemes of representation.

Given a scheme f of representation, the (random) cost associated with representing V is given by $\|f(V)\|^2$. The problem of finding an ℓ_2-optimal dictionary can now be posed as:

> Find a pair consisting of a dictionary $D_K^* \in \mathcal{D}_\mathcal{K}$ and a feasible scheme f^* of representation such that the average cost $\mathsf{E}_\mu\big[\|f^*(V)\|^2\big]$ of representation is minimal.

Here the subscript μ indicates the distribution of random vector V with respect to which the expectation is evaluated. In other words, we have the following optimization problem:

$$\begin{aligned} &\underset{D_K, f}{\text{minimize}} && \mathsf{E}_\mu\big[\|f(V)\|^2\big] \\ &\text{subject to} && \begin{cases} D_K \in \mathcal{D}_K, \\ f \in \mathcal{F}. \end{cases} \end{aligned} \tag{6}$$

2. Recall (Parthasarathy, 2005, Theorem 2.1, Definition 2.1, pp. 27-28) that the support of μ is the set of points $z \in \mathbb{R}^n$ such that the μ-measure of every open neighbourhood of z is positive.

The problem given in (6) will be referred to as the ℓ_2-*optimal dictionary* problem. It should be noted that the ℓ_2-optimal dictionary problem is non-convex due to the constraint that the dictionary vectors $\{d_i\}_{i=1}^K$ of a feasible dictionary must be of unit length. Even if we change this constraint to $\{\|d_i\| \leqslant 1\}$ from $\{\|d_i\| = 1\}$, which makes the feasible region of dictionary vectors convex, the set of feasible schemes of representation is not known to be a convex set a priori.

In this article we solve the ℓ_2-optimal dictionary problem given in (6) in two steps:
(Step I) We let $X_V = \mathbb{R}^n$.
(Step II) We let X_V be any proper nontrivial subspace of $\mathbb{R}^n$.[3]
The remainder of this section is devoted to describing Steps I and II by exposing our main results, followed by discussions, a numerical example, and a treatment of the important case of the uniform distribution on the unit sphere of $\mathbb{R}^n$.

2.1 Step I: $X_V = \mathbb{R}^n$

If $X_V = \mathbb{R}^n$, a dictionary of vectors $D_K = \{d_i\}_{i=1}^K \subset \mathbb{R}^n$ is feasible if and only if $\|d_i\| = 1$ for all $i = 1, \ldots, K$, and $\operatorname{span}\{d_i\}_{i=1}^K = \mathbb{R}^n$. Thus, the ℓ_2-optimization problem (6) reduces to:

$$\begin{aligned} &\underset{\{d_i\}_{i=1}^K, f}{\text{minimize}} && \mathsf{E}_\mu\big[\|f(V)\|^2\big] \\ &\text{subject to} && \begin{cases} \|d_i\| = 1 \text{ for all } i = 1, \ldots, K, \\ \operatorname{span}\{d_i\}_{i=1}^K = \mathbb{R}^n, \\ \begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix} f(V) = V \quad \mu\text{-almost surely.} \end{cases} \end{aligned} \tag{7}$$

Let $\Sigma_V \coloneqq \mathsf{E}_\mu[VV^\top]$. We claim that Σ_V is positive definite. Indeed, if not, then there exists a nonzero vector $x \in \mathbb{R}^n$ such that $x^\top V = 0$ almost surely, which contradicts the assumption that $X_V = \mathbb{R}^n$.

Existence and characterization of the optimal solutions to (7) is done by the following:

Theorem 1. *Consider the optimization problem* (7)*, and let* $\Sigma_V \coloneqq \mathsf{E}_\mu\big[VV^\top\big]$.
- (7) *admits an optimal solution.*
- *The optimal value corresponding to* (7) *is* $\dfrac{\big(\operatorname{tr}(\Sigma_V^{1/2})\big)^2}{K}$.
- *Optimal solutions of* (7) *are characterized by:*
  - *a dictionary* $D_K^* = \{d_i^*\}_{i=1}^K$ *that is feasible for* (7) *and that satisfies*

$$\sum_{i=1}^K d_i^* d_i^{*\top} = M^* \coloneqq \frac{K}{\operatorname{tr}\big(\Sigma_V^{1/2}\big)}\, \Sigma_V^{1/2}, \tag{8}$$

  and
  - *a scheme* $f_{D_K^*}^*(v) \coloneqq \begin{pmatrix} d_1^* & d_2^* & \cdots & d_K^* \end{pmatrix}^+ v$.

Moreover, all optimal dictionary-scheme pairs can be obtained via the procedure described in Algorithm 2 on p. 22.

3. The trivial case of $X_V = \{0\}$ is discarded because then there is nothing to prove; we therefore limit ourselves to 'nontrivial' subspaces of $\mathbb{R}^n$.

2.2 Step II: X_V is a strict nontrivial subspace of $\mathbb{R}^n$

Let X_V be any proper nontrivial subspace of $\mathbb{R}^n$. In this situation it is reasonable to expect that no optimal dictionary that solves (6) contains elements that do not belong to X_V. That this indeed happens is the assertion of the following Lemma, whose proof is provided in Section 4:

Lemma 2. *Optimal solutions, if any exists, of problem* (6) *are such that the optimal dictionary vectors* $\{d_i^*\}_{i=1}^K$ *satisfy* $d_i^* \in X_V$ *for all* $i = 1, \ldots, K$.

Lemma 2 guarantees that if the problem (6) admits a solution, then the corresponding optimal dictionary vectors must be elements of X_V. This means that it is enough to optimize over dictionaries with their elements in X_V instead of the whole of $\mathbb{R}^n$. Therefore, the constraint $\operatorname{span}\{d_i\}_{i=1}^K \supset R_V$ can be equivalently stated as $\operatorname{span}\{d_i\}_{i=1}^K = X_V$.

Let the dimension of X_V be m with $m < n$, and let $\mathcal{B} = \{b_i\}_{i=1}^m$ be a basis for X_V. It should be noted that $X_V = \operatorname{image}(\Sigma_V)$, and therefore, a basis of X_V can be obtained by computing a basis of the subspace $\operatorname{image}(\Sigma_V)$. An example of such a basis of X_V is the collection of unit eigenvectors of Σ_V corresponding to its non-zero eigenvalues.

Fix a basis $\mathcal{B} = \{b_i\}_{i=1}^m$ of X_V. Let B be a matrix containing the vectors $\{b_i\}_{i=1}^m$ as its columns:

$$B \coloneqq \begin{pmatrix} b_1 & b_2 & \cdots & b_m \end{pmatrix}.$$

If δ_i is the representation of the dictionary vector d_i in the basis $\mathcal{B}$, i.e., $d_i = B\delta_i$, then the constraints on the family $\{d_i\}_{i=1}^K$ get transformed to the following ones on $\{\delta_i\}_{i=1}^K$:
- $\|d_i\|^2 = 1 \quad \Rightarrow \quad \delta_i^\top \big(B^\top B\big)\delta_i = 1$, and
- $\operatorname{span}\{d_i\}_{i=1}^K \supset R_V \quad \Rightarrow \quad \operatorname{span}\{d_i\}_{i=1}^K = X_V \quad \Rightarrow \quad \operatorname{span}\{\delta_i\}_{i=1}^K = \mathbb{R}^m$.

We define the random vector

$$V_X \coloneqq \big((B^\top B)^{-1} B^\top\big) V.$$

Then V_X is an $\mathbb{R}^m$ valued random vector which is the representation of random vector V in the basis $\mathcal{B}$. For every scheme f that is feasible for (6), let us define an associated scheme for representing samples of the random vector V_X by

$$\mathbb{R}^m \ni v \longmapsto f_X(v) \coloneqq f(Bv) \in \mathbb{R}^K.$$

The conditions on feasibility of f in (6) imply that the scheme f_X is feasible if for a feasible dictionary of vectors $\{\delta_i\}_{i=1}^K$,

$$\begin{pmatrix} \delta_1 & \delta_2 & \cdots & \delta_K \end{pmatrix} f_X(V_X) = V_X \quad \mu\text{-almost surely.}$$

In other words, in contrast to the problem (6), where the optimization is carried out over vectors in $\mathbb{R}^n$, we can equivalently consider the same problem in $\mathbb{R}^m$, but with the following modified constraints:

$$\begin{aligned} &\underset{\{\delta_i\}_{i=1}^K, f_X}{\text{minimize}} && \mathsf{E}_\mu\big[\|f_X(V_X)\|^2\big] \\ &\text{subject to} && \begin{cases} \delta_i^\top \big(B^\top B\big)\delta_i = 1 \text{ for all } i = 1, \ldots, K, \\ \operatorname{span}\{\delta_i\}_{i=1}^K = \mathbb{R}^m, \\ \begin{pmatrix} \delta_1 & \delta_2 & \cdots & \delta_K \end{pmatrix} f_X(V_X) = V_X \quad \mu\text{-almost surely.} \end{cases} \end{aligned} \tag{9}$$

In relation to the problem (9) let us define the following quantities

$$\begin{cases} \Sigma_V \coloneqq \mathsf{E}_\mu[VV^\top] \\ \Sigma \coloneqq (B^\top B)^{-1/2}\big(B^\top \Sigma_V B\big)(B^\top B)^{-1/2} \\ H^* \coloneqq \dfrac{K}{\operatorname{tr}\big(\Sigma^{1/2}\big)}\big((B^\top B)^{-1/2}\Sigma^{1/2}(B^\top B)^{-1/2}\big). \end{cases} \tag{10}$$

Since the support of V_X is m-dimensional, we conclude from previous discussion that $\Sigma_{V_X} \coloneqq \mathsf{E}_\mu\big[V_X V_X^\top\big]$ is positive definite. Since $\Sigma = (B^\top B)^{1/2}\Sigma_{V_X}(B^\top B)^{1/2}$, it follows that Σ is positive definite, which in turn implies that H^* is positive definite.

To summarize, an ℓ_2-optimal dictionary-scheme pair that solves the optimization problem (6) is equivalently obtained from an optimal solution of the problem (9), and is characterized by the following:

Theorem 3. *Consider the optimization problem* (9)*.*
- ∘ (9) *admits an optimal solution.*
- ∘ *The optimal value corresponding to* (9) *is* $\dfrac{\big(\operatorname{tr}(\Sigma^{1/2})\big)^2}{K}$.
- ∘ *Optimal solutions of* (9) *are characterized by:*
  - ▻ *a dictionary* $D_K^* = \{\delta_i^*\}_{i=1}^K$ *that is feasible for* (9) *and that satisfies*

$$\sum_{i=1}^K \delta_i^* \delta_i^{*\top} = H^*, \tag{11}$$

  and
  - ▻ *a scheme* $f_X^*(u) \coloneqq \begin{pmatrix}\delta_1^* & \delta_2^* & \cdots & \delta_K^*\end{pmatrix}^+ u$.

Consequently, an optimal solution of the ℓ_2-optimal dictionary problem (6) *consisting of an ℓ_2-optimal dictionary-scheme pair is given by*
- ∘ *A collection of vectors* $\{d_i^*\}_{i=1}^K$ *defined as* $d_i^* \coloneqq B\delta_i^*$ *for* $i = 1, 2, \ldots, K$*, and*
- ∘ *the scheme* $f^*(v) \coloneqq \begin{pmatrix}d_1^* & d_2^* & \cdots & d_K^*\end{pmatrix}^+ v$.

Moreover, all optimal dictionary-scheme pairs can be obtained via the procedure given in Algorithm 3 on p. 26.

2.3 Discussion and a numerical example

Remark 4. The problem (6) does not a priori hypothesize an affine/linear structure of candidate schemes. The fact that linear schemes are optimal in (6) is one of the crucial assertions of both Theorem 1 and Theorem 3.

Remark 5. Algorithmic computation of an ℓ_2-optimal dictionary relies on the second moment Σ_V of the random vector V. Complete knowledge of the distribution μ is, therefore, unnecessary. This is an advantage since in practical situations, learning/estimating Σ_V from data is comparatively less demanding than getting a description of the distribution μ itself.

Remark 6. Let $M \in \mathbb{S}_+^{n\times n}$ be such that $\operatorname{image}(M) = X_V$, let $\mathcal{B} = \{b_i\}_{i=1}^m$ be a basis for X_V evaluated as a basis for $\operatorname{image}(M)$. Let

$$B \coloneqq \begin{pmatrix}b_1 & b_2 & \cdots & b_m\end{pmatrix}$$

$$\Sigma(M) \coloneqq (B^\top B)^{-1/2}\big(B^\top M B\big)(B^\top B)^{-1/2}$$
$$H(M) \coloneqq \frac{K}{\operatorname{tr}\Big(\big(\Sigma(M)\big)^{1/2}\Big)}\big((B^\top B)^{-1/2}\big(\Sigma(M)\big)^{1/2}(B^\top B)^{-1/2}\big).$$

Suppose that $\{d_i\}_{i=1}^K$ and $f(\cdot)$ are the dictionary and the scheme obtained using the procedure given in Algorithm 3 using M and K as inputs. By simplifying the pseudo-inverse $\begin{pmatrix}d_1 & d_2 & \cdots & d_K\end{pmatrix}^+$ in $f(\cdot)$, the average cost $J(M)$ of representing V using the scheme $f(\cdot)$ turns out to be

$$\begin{aligned} J(M) &= \mathsf{E}_\mu\Big[V^\top B(B^\top B)^{-1}\big(H(M)\big)^{-1}(B^\top B)^{-1}B^\top V\Big] \\ &= \operatorname{tr}\Big(\big(H(M)\big)^{-1}(B^\top B)^{-1}B^\top \Sigma_V B(B^\top B)^{-1}\Big) \\ &= \operatorname{tr}\Big(\big(H(M)\big)^{-1}(B^\top B)^{-1/2}\,\Sigma\,(B^\top B)^{-1/2}\Big) \\ &= \operatorname{tr}\Big((B^\top B)^{-1/2}\big(H(M)\big)^{-1}(B^\top B)^{-1/2}\,\Sigma\Big) \\ &= \frac{1}{K}\,\operatorname{tr}\Big(\big(\Sigma(M)\big)^{1/2}\Big)\,\operatorname{tr}\Big(\big(\Sigma(M)\big)^{-1/2}\Sigma\Big). \end{aligned} \tag{12}$$

Let $S \coloneqq \big\{T \in \mathbb{S}_+^{n\times n} \;\big|\; \operatorname{image}(T) = X_V\big\}$. Since the sequence of maps

$$\begin{aligned} S \ni T &\longmapsto \Sigma(T) \in \mathbb{S}_{++}^{m\times m}, \\ \mathbb{S}_{++}^{m\times m} \ni T &\longmapsto T^{1/2} \in \mathbb{S}_{++}^{m\times m}, \\ \mathbb{S}_{++}^{m\times m} \ni T &\longmapsto T^{-1}\Sigma \in \mathbb{S}_{++}^{m\times m}, \\ \mathbb{S}_{+}^{m\times m} \ni T &\longmapsto \operatorname{tr}(T) \in \mathbb{R}, \end{aligned}$$

are, evidently, continuous, it follows at once that the map $S \ni M \longmapsto J(M) \in \mathbb{R}$ is also continuous. If $\widehat{\Sigma}_V$ denotes the estimated second moment of V, and the estimation is carried out with a large enough number of samples of V, with probability one we have $\operatorname{image}(\widehat{\Sigma}_V) = X_V$. Therefore, by continuity of $M \longmapsto J(M)$, we see at once that

$$J(\widehat{\Sigma}_V) \xrightarrow[\widehat{\Sigma}_V \longrightarrow \Sigma_V]{} J(\Sigma_V) = \frac{\big(\operatorname{tr}(\Sigma^{1/2})\big)^2}{K}.$$

Remark 7. The optimal average cost of representation of a random vector V is inversely proportional to the size K of the optimal dictionary, as is evident from the optimal costs in Theorems 1 and 3. To wit, the optimal average cost of representation decreases monotonically with K, which is expected.

Remark 8. ℓ_2-optimal dictionaries for representing a random vector V are also optimal for representing any scalar multiple αV of V for any $0 \neq \alpha \in \mathbb{R}$. Indeed, it is clear that H^* defined in (10) is invariant under nonzero scalar multiplications of V. Therefore, ℓ_2-optimal dictionaries are also invariant under nonzero scalar multiplications of the random vector V. This fact also follows from the observation made in Remark 4.

Remark 9. An ℓ_2-optimal dictionary as characterized by Theorem 3 appears there in the form of what is known as a *rank*-1 *decomposition* of the positive definite matrix H^*. Elements

of the theory of rank-1 decompositions of positive definite matrices is discussed below in Section 3. This particular decomposition plays a crucial rôle in transforming the search space of the ℓ_2-optimal dictionary problem (7) from the set of dictionaries to the set of symmetric positive definite matrices with real entries, and translating the non-convex ℓ_2-optimal dictionary problem into a tractable convex one.

Remark 10. All ℓ_2-optimal dictionaries are unique upto rank-1 decompositions of a unique positive definite matrix that is obtained from the second moment $\mathsf{E}[VV^\top]$ of the random vector V. That is, for a given random vector whose samples are to be optimally represented, every ℓ_2-optimal dictionary is obtained from a rank-1 decomposition of a unique positive definite matrix.

Remark 11. Looking ahead at Algorithm 3, it becomes evident that non-uniqueness of optimal dictionaries can be attributed to the non-uniqueness in the selection of C in Step 5 of Algorithm 3, and the element of choice associated to the selection of p_j and p_k in Step 2 of Algorithm 1. The number of optimal solutions may be infinite depending on the distribution of the random vector V. For instance, if V is uniformly distributed over the unit sphere of $\mathbb{R}^n$ and $K = n$, then the elements in an ℓ_2-optimal dictionary form an orthonormal basis of $\mathbb{R}^n$. (The special case of uniform distribution of V over spheres is discussed in Section 2.4.) Of course, there are infinitely many orthonormal bases of $\mathbb{R}^n$ for $n \geqslant 2$.

Remark 12. From Algorithm 3 on p. 26 we can infer that by calculating the matrix B there, consisting of the eigenvectors of Σ_V corresponding to its non-zero eigenvalues, the computations of $(B^\top B)^{-1/2}$, $\Sigma^{1/2}$, and C in the decomposition given in Step 5 become straightforward. Therefore, the chief computational load in Algorithm 3 consists of eigen-decomposition of Σ_V and that in Algorithm 1 (in Step 6), both of which can be performed in polynomial time.

Example 1. Let $V = \begin{pmatrix} V_1 \\ V_2 \end{pmatrix}$ be a random vector taking values in $\mathbb{R}^2$, with V_1 and V_2 being independent random variables. Let the density functions of V_1 and V_2 be

$$\rho_{V_1}(v) = 2(v-1)\mathbb{1}_{[1,2]}(v) \quad \text{and} \quad \rho_{V_2}(v) = 2(2-v)\mathbb{1}_{[1,2]}(v),$$

respectively. The support of V is, therefore, the square $[1,2] \times [1,2]$. Elementary calculations lead to $\Sigma_V := \mathsf{E}_\rho[VV^\top] = \begin{pmatrix} 17/6 & 20/9 \\ 20/9 & 11/6 \end{pmatrix}$. We employed the procedure described in Algorithm 2 for the given matrix Σ_V and $K = 3$ in MATLAB. An optimal dictionary $\{y_1^*, y_2^*, y_3^*\}$ was obtained, with

$$y_1^* = \begin{pmatrix} 0.9789 \\ 0.2045 \end{pmatrix}, \quad y_2^* = \begin{pmatrix} 0.6792 \\ 0.7339 \end{pmatrix}, \quad y_3^* = \begin{pmatrix} 0.5870 \\ 0.8096 \end{pmatrix};$$

the optimum value of the objective function was reported to be 1.8930. This collection $\{y_i^*\}_{i=1}^3$ of optimal vectors are marked with crosses on the circumference of the unit circle shown in Figure 2. A second optimal dictionary $\{z_1^*, z_2^*, z_3^*\}$ was obtained, also using Algorithm 2, with dictionary vectors

$$z_1^* = \begin{pmatrix} 0.4214 \\ 0.9069 \end{pmatrix}, \quad z_2^* = \begin{pmatrix} 0.9284 \\ 0.3717 \end{pmatrix}, \quad z_3^* = \begin{pmatrix} 0.8513 \\ 0.5247 \end{pmatrix},$$

with an identical optimal value as in the former case. The vectors $\{z_i^*\}_{i=1}^3$ are marked with dark circles on the circumference of the unit circle in Figure 2.

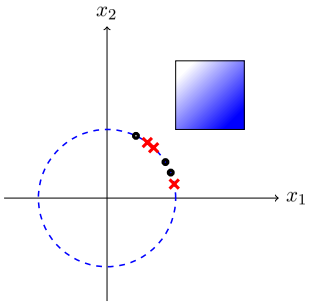

Figure 2: The two optimal dictionaries in Example 1.

It is expected that the optimal dictionary vectors are concentrated towards the bottom right corner of the support $[1,2] \times [1,2]$ (the region with strong shading in figure 2). In the optimal solution $\{z_i^*\}_{i=1}^3$, two vectors z_2^* and z_3^* point to the region where density of V is concentrated the most. Also, for the solution $\{y_i^*\}_{i=1}^3$, two vectors y_2^* and y_3^* are oriented towards the center of the square $[1,2] \times [1,2]$, with the remaining vector pointing towards the region of higher density. These results correlate positively with what may be expected out of ℓ_2-optimal dictionaries.

2.4 Uniform distribution over the unit sphere

We shall test our results on the important case of μ being the uniform distribution on the unit sphere. Note that due to (rigid) rotational symmetry of the distribution, it follows that rigid rotations of optimal dictionaries in this case are also optimal.

Let us consider a dictionary consisting of (unit) vectors that are 'close' to each other, i.e., the inner product between any two elements of the dictionary is close to 1. It is quite evident that such a dictionary is not optimal for representing uniformly distributed samples due to the fact that samples of V that are almost orthogonal to the dictionary vectors carry equal priority as any other vector but require large coefficients for their representation. It is, therefore, more natural to search for dictionaries in which the constituent vectors are 'maximally spaced out'.

Several examples of collections of vectors that are 'maximally spaced out' may be found in (Benedetto and Fickus, 2003, Section 4). Collections of vectors that are maximally far apart from each other are known to attain 'equilibria' under the actions of different kinds of forces defined and explained in (Benedetto and Fickus, 2003, Section 4) and (Saff and Kuijlaars, 1997, p. 6). Such collections of vectors are generalized by the ideas of *tight frames* as explained in (Benedetto and Fickus, 2003); see also (Christensen, 2016; Daubechies et al., 1986; Benedetto and Fickus, 2003; Zimmermann, 2001) for related information.

We recall here some standard definitions for completeness and to provide the necessary substratum for our next result. Let n, K be positive integers such that $K \geqslant n$. We say that a collection of vectors $\{x_i\}_{i=1}^K$ is a *frame* for $\mathbb{R}^n$ if there exist some constants $c, C > 0$ such that

$$c\,\|x\|^2 \leqslant \sum_{i=1}^{K} \langle x_i, x\rangle^2 \leqslant C\,\|x\|^2 \quad \text{for all } x \in \mathbb{R}^n.$$

We say that a frame $\{x_i\}_{i=1}^K \subset \mathbb{R}^n$ is *tight* if $c = C$. In addition, if $\{x_i\}_{i=1}^K \subset \mathbb{R}^n$ is a tight frame and $\|x_i\| = 1$ for all $i = 1, 2, \ldots, K$, we say that the collection $\{x_i\}_{i=1}^K$ is a *c-unit norm tight frame* (a c-UNTF).

We have the following connection between ℓ_2-optimal dictionaries and UNTFs:

Proposition 13. *A dictionary $D_K = \{d_i\}_{i=1}^K$ is optimal for representing samples of a random vector V that is uniformly distributed over the surface of the unit sphere of $\mathbb{R}^n$ if and only if the collection $\{d_i\}_{i=1}^K$ of vectors constitute a $\frac{K}{n}$-UNTF.*

Proof If V is uniformly distributed over the unit sphere, we have $\Sigma_V = \mathsf{E}[VV^\top] = \frac{1}{n} I_n$. According to Theorem 1 the collection $\{d_i\}_{i=1}^K$ is an optimal dictionary if and only if

$$\sum_{i=1}^{K} d_i d_i^\top = \frac{K}{\operatorname{tr}\left(\frac{1}{\sqrt{n}} I_n\right)} \left(\frac{1}{\sqrt{n}} I_n\right) = \frac{K}{n} I_n. \tag{13}$$

Since the family $\{d_i\}_{i=1}^K$ must span $\mathbb{R}^n$ by definition, it is a frame. The *frame operator* for the frame $\{d_i\}_{i=1}^K$ is given by (Benedetto and Fickus, 2003, Section 2)

$$\mathbb{R}^n \ni y \longmapsto S(y) \coloneqq \sum_{i=1}^{K} \langle d_i, y\rangle\, d_i = \left(\sum_{i=1}^{K} d_i d_i^\top\right) y \in \mathbb{R}^n,$$

where $\langle v, w\rangle = v^\top w$ is the standard inner product in $\mathbb{R}^n$. (Benedetto and Fickus, 2003, Theorem 3.1) asserts that a collection of unit norm vectors $\{d_i\}_{i=1}^K$ forms a tight frame in $\mathbb{R}^n$ if and only if the collection is a $\frac{K}{n}$-UNTF. From (Benedetto and Fickus, 2003, Theorem 2.1) it follows that a collection of vectors $\{d_i\}_{i=1}^K$ is a $\frac{K}{n}$-UNTF if and only if

$$S = \sum_{i=1}^{K} d_i d_i^\top = \frac{K}{n} I_n. \tag{14}$$

The assertion follows from (13) and (14). ∎

3. A particular class of rank-1 decompositions of matrices

We collect and establish here some results on the theory of rank-1 decompositions of matrices. While these facts will be needed for our main results, they are also of independent interest.

A standard result in matrix theory (Bhatia, 2009, p. 2) states that a symmetric positive semidefinite matrix with real entries $M \in \mathbb{S}_+^{n\times n}$, can be decomposed as $YY^\top$ for some

$Y \in \mathbb{R}^{n\times r}$, where $r \coloneqq \operatorname{rank}(M)$. Let y_i indicate the i th column of the matrix Y. Then the equality $M = YY^\top$ is equivalent to

$$M = \sum_{i=1}^{r} y_i y_i^\top.$$

More generally for $K \geqslant r$, let

$$\overline{M} \coloneqq \begin{pmatrix} M & O_{n\times(K-r)} \\ O_{(K-r)\times n} & I_{K-r} \end{pmatrix},$$

where O is a zero matrix of order $n \times (K - r)$. If we consider the decomposition of $\overline{M}$ as $\overline{M} = \overline{Y}\,\overline{Y}^\top$ with $\overline{Y} \in \mathbb{R}^{(n+K-r)\times K}$, and indicate by Y the upper $n \times K$ matrix block of $\overline{Y}$, we get $M = YY^\top$. In other words

$$M = \sum_{i=1}^{K} y_i y_i^\top. \tag{15}$$

There are numerous ways of decomposing positive semidefinite matrices; some of them are discussed in (Zhang, 2011, Theorem 7.3). The speciality of a particular decomposition lies in the characteristics exhibited by the vectors y_i's. A particular rank-1 decomposition which we will use to solve the ℓ_2-optimal dictionary problem is the one where for every $M \in \mathbb{S}_+^{n\times n}$ and $K \geqslant r \coloneqq \operatorname{rank}(M)$ there exists a collection of vectors $\{y_i\}_{i=1}^K \subset \mathbb{R}^n$ that satisfy

$$M = \sum_{i=1}^{K} y_i y_i^\top \quad \text{and} \quad y_i^\top y_i = \frac{\operatorname{tr}(M)}{K} \quad \text{for all } i = 1, \ldots, K. \tag{16}$$

We are now in a position to present Algorithm 1 and its associated Theorem 14, whose corollaries will give us the needed rank-1 decomposition of (16). We mention that Algorithm 1 is, in principle, similar to Procedure 1 of (Sturm and Zhang, 2003), and in particular, the assertions of Theorem 14 and its corollaries can be obtained by applying (Sturm and Zhang, 2003, Proposition 3 and Corollary 4) via some straightforward modifications. However, we provide the complete proofs here for the sake of completeness.

Theorem 14. *For any matrix $\Lambda \in \mathbb{R}^{n\times n}$ there exists an orthonormal collection $(x_i)_{i=1}^n \subset \mathbb{R}^n$ of vectors satisfying*

$$x_i^\top \Lambda x_i = \frac{\operatorname{tr}(\Lambda)}{n} \quad \textit{for all } i = 1, \ldots, n,$$

Moreover, such a collection can be obtained from Algorithm 1.

Proof First we establish that the collection of vectors $(x_i)_{i=1}^{n-1}$ contained in S_{n-1} (recall that S_{n-1} is generated in the **for** loop in the Algorithm 1,) are orthonormal, and satisfy $x_i^\top \Lambda x_i = \frac{\operatorname{tr}(\Lambda)}{n}$ for $i = 1, \ldots, n-1$. We shall prove this by induction on i.

The induction base: For $i = 1$, we have $P_1 = (e_1, e_2, \ldots, e_n)$. Since $\sum_{m=1}^n e_m^\top \Lambda e_m = \operatorname{tr}(\Lambda)$, vectors $p_j, p_k \in P_1$ exist such that $p_j^\top \Lambda p_j \leqslant \frac{\operatorname{tr}(\Lambda)}{n} \leqslant p_k^\top \Lambda p_k$. We solve for θ in the equation

$$g_{p_j;p_k}(\theta) \coloneqq \frac{\big((1-\theta)p_j + \theta p_k\big)^\top \Lambda \big((1-\theta)p_j + \theta p_k\big)}{\big((1-\theta)^2 + \theta^2\big)} = \frac{\operatorname{tr}(\Lambda)}{n}. \tag{17}$$

Algorithm 1: Calculation of orthonormal bases à la Theorem 14

Input: A matrix $\Lambda \in \mathbb{R}^{n\times n}$.

Output: An orthonormal collection of vectors $(x_i)_{i=1}^n \subset \mathbb{R}^n$ such that $x_i^\top \Lambda x_i = \frac{\operatorname{tr}(\Lambda)}{n}$ for all $i = 1, \ldots, n$.

Initialize quantities by $S_0 = \varnothing$, $i = 1$.

for i from 1 to $(n-1)$

do

$S_i' = S_{i-1} \uplus (e_1, e_2, \ldots, e_n)$.

$P_i = \operatorname{Ortho}(S_i')\backslash S_{i-1}$.

Find $p_j, p_k \in P_i$ such that $p_j^\top \Lambda p_j \leqslant \frac{\operatorname{tr}(\Lambda)}{n} \leqslant p_k^\top \Lambda p_k$.

Let $\Theta \in [0,1]$ be a solution of the equation (in θ)

$$\big((1-\theta)p_j + \theta p_k\big)^\top \Lambda \big((1-\theta)p_j + \theta p_k\big) = \frac{\operatorname{tr}(\Lambda)}{n}\big((1-\theta)^2 + \theta^2\big)$$

Define $x_i \coloneqq \frac{(1-\Theta)p_j + \Theta p_k}{((1-\Theta)^2+\Theta^2)^{1/2}}$.

Define $S_i \coloneqq S_{i-1} \uplus (x_i)$.

end for loop

$S_n' = S_{n-1} \uplus (e_1, e_2, \ldots, e_n)$.

Output $S_n \coloneqq \operatorname{Ortho}(S_n')$.

We know that a solution exists in $[0,1]$ because for $\theta = 0$ we have

$$g_{p_j;p_k}(0) = \left[\frac{((1-\theta)p_j + \theta p_k)^\top \Lambda((1-\theta)p_j + \theta p_k)}{((1-\theta)^2+\theta^2)}\right]_{\theta=0} = p_j^\top \Lambda p_j \leqslant \frac{\operatorname{tr}(\Lambda)}{n},$$

for $\theta = 1$ we have

$$g_{p_j;p_k}(1) = \left[\frac{((1-\theta)p_j + \theta p_k)^\top \Lambda((1-\theta)p_j + \theta p_k)}{((1-\theta)^2+\theta^2)}\right]_{\theta=1} = p_k^\top \Lambda p_k \geqslant \frac{\operatorname{tr}(\Lambda)}{n},$$

and $g_{p_j;p_k}(\cdot)$ is a continuous function of θ. Let Θ be such a solution. Then, following the notation in Algorithm 1, we have

$$x_1 \coloneqq \frac{(1-\Theta)p_j + \Theta p_k}{\sqrt{(1-\Theta)^2+\Theta^2}}.$$

Since p_j, p_k are elements of P_1, they are orthonormal; therefore,

$$\|x_1\| = \frac{\sqrt{(1-\Theta)^2\|p_j\|^2 + \Theta^2\|p_k\|^2}}{\sqrt{(1-\Theta)^2+\Theta^2}} = 1,$$

and since Θ is a solution of equation (17) we have

$$x_1^\top \Lambda x_1 = \frac{\operatorname{tr}(\Lambda)}{n}.$$

Induction hypothesis: Assume that for some i between 1 and $n-1$ the collection $S_i = (x_\ell)_{\ell=1}^i$ is orthonormal, and satisfies

$$x_\ell^\top \Lambda x_\ell = \frac{\operatorname{tr}(\Lambda)}{n} \quad \text{for all } \ell = 1, \ldots, i.$$

Induction step: In view of the induction hypothesis, we define

$$S_{i+1}' \coloneqq S_i \uplus (e_1, e_2, \ldots, e_n) = (x_1, x_2, \ldots x_i, e_1, e_2, \ldots, e_n),$$

and compute

$$\begin{aligned}\operatorname{Ortho}(S_{i+1}') &= (x_1, x_2, \ldots, x_i, p_1, p_2, \ldots, p_{n-i}),\\ P_{i+1} &= (p_1, p_2, \ldots, p_{n-i})\end{aligned}$$

as in Algorithm 1. Since the collection $(x_\ell)_{\ell=1}^i \uplus (p_\ell)_{\ell=1}^{n-i}$ is an orthonormal basis for $\mathbb{R}^n$, we have

$$\sum_{\ell=1}^{i} x_\ell^\top \Lambda x_\ell + \sum_{\ell=1}^{n-i} p_\ell^\top \Lambda p_\ell = \operatorname{tr}(\Lambda),$$

leading to

$$\sum_{\ell=1}^{n-i} p_\ell^\top \Lambda p_\ell = \frac{(n-i)}{n}\operatorname{tr}(\Lambda).$$

Thus, there exist vectors $p_j, p_k \in P_{i+1}$ such that $p_j^\top \Lambda p_j \leqslant \frac{\operatorname{tr}(\Lambda)}{n} \leqslant p_k^\top \Lambda p_k$. Let us consider the equation

$$g_{p_j,p_k}(\theta) \coloneqq \frac{((1-\theta)p_j + \theta p_k)^\top \Lambda((1-\theta)p_j + \theta p_k)}{((1-\theta)^2+\theta^2)} = \frac{\operatorname{tr}(\Lambda)}{n} \tag{18}$$

in θ. From arguments given in the case of $i = 1$, we know that a solution Θ of (18) exists on $[0,1]$. We define

$$x_{i+1} \coloneqq \frac{(1-\Theta)p_j + \Theta p_k}{\sqrt{(1-\Theta)^2+\Theta^2}}.$$

Since p_j, p_k are orthogonal to the vectors $(x_\ell)_{\ell=1}^i$, so is any linear combination of p_j, p_k. Therefore, x_{i+1} is orthogonal to the vectors $(x_\ell)_{\ell=1}^i$, which, along with the fact that

$$\|x_{i+1}\| = \frac{\sqrt{(1-\Theta)^2\|p_j\|^2 + \Theta^2\|p_k\|^2}}{\sqrt{(1-\Theta)^2+\Theta^2}} = 1,$$

makes the collection $(x_\ell)_{\ell=1}^{i+1}$ orthonormal. Also, since Θ is a solution of (18), we get

$$x_{i+1}^\top \Lambda x_{i+1} = \frac{\operatorname{tr}(\Lambda)}{n}.$$

Therefore, by mathematical induction, we conclude that the collection $(x_i)_{i=1}^{n-1}$ contained in S_{n-1} has the required properties.

Finally, in the 4th and 5th steps of Algorithm 1, we get

$$S'_n = (x_1, x_2, \ldots, x_{n-1}, e_1, e_2, \ldots, e_n),$$

and

$$\mathrm{Ortho}(S'_n) = (x_1, x_2, \ldots, x_{n-1}, x_n).$$

By construction, $(x_\ell)_{\ell=1}^n$ is an orthonormal collection, implying that $\sum_{i=1}^n x_i^\top \Lambda x_i = \mathrm{tr}(\Lambda)$. In turn, this leads to

$$\begin{aligned} x_n^\top \Lambda x_n &= \sum_{i=1}^{n} x_i^\top \Lambda x_i - \sum_{i=1}^{n-1} x_i^\top \Lambda x_i \\ &= \mathrm{tr}(\Lambda) - \left(\frac{n-1}{n}\right)\mathrm{tr}(\Lambda) \\ &= \frac{\mathrm{tr}(\Lambda)}{n}. \end{aligned}$$

Thus, Algorithm 1 yields a collection of orthonormal vectors $(x_i)_{i=1}^n$ such that

$$x_i^\top \Lambda x_i = \frac{\mathrm{tr}(\Lambda)}{n} \quad \text{for all } i = 1, 2, \ldots, n,$$

thereby completing the proof. ∎

Corollary 15 (Rank-1 decomposition)**.** *Let $X \in \mathbb{S}_+^{n\times n}$, define $r \coloneqq \mathrm{rank}(X)$, and let $T \in \mathbb{S}^{n\times n}$. There exists a collection of vectors $\{x_i\}_{i=1}^r \subset \mathbb{R}^n$ such that*

$$X = \sum_{j=1}^{r} x_j x_j^\top, \quad \textit{and} \quad x_i^\top T x_i = \frac{1}{r}\,\mathrm{tr}(XT) \ \textit{for all } i = 1, \ldots, r.$$

Proof We know (Bhatia, 2009, p. 2) that any symmetric positive semidefinite matrix X with real entries and of rank r can be decomposed as $CC^\top$ where $C \in \mathbb{R}^{n\times r}$. Let us define $\Lambda \in \mathbb{R}^{r\times r}$ as $\Lambda \coloneqq C^\top T C$. According to Theorem 14 a collection of orthonormal vectors $\{y_i\}_{i=1}^r \subset \mathbb{R}^r$ can be obtained such that

$$y_i^\top C^\top T\ C y_i = y_i^\top \Lambda y_i = \frac{\mathrm{tr}(\Lambda)}{r}.$$

We define a collection $\{x_i\}_{i=1}^r \subset \mathbb{R}^r$ by $x_i \coloneqq C y_i$ for $i = 1, \ldots, r$. Then

$$\sum_{i=1}^{r} x_i x_i^\top = C\left(\sum_{i=1}^{r} y_i y_i^\top\right)C^\top = C I_r C^\top = X.$$

Moreover, for every $i = 1, \ldots, r$,

$$x_i^\top T x_i = y_i^\top C^\top T C y_i = \frac{\mathrm{tr}(\Lambda)}{r} = \frac{1}{r}\,\mathrm{tr}(C^\top T C) = \frac{1}{r}\,\mathrm{tr}(XT).$$

The assertion follows. ∎

Corollary 15 is generalized slightly by the following one; we shall employ this particular form to solve the ℓ_2-optimal dictionary problem in Theorem 1.

Corollary 16. *Let $M \in \mathbb{S}_+^{n\times n}$ and define $r \coloneqq \mathrm{rank}(M)$. Let $A \in \mathbb{S}^{n\times n}$ and $K \geqslant r$ be given. There exists a collection of vectors $\{y_i\}_{i=1}^K \subset \mathbb{R}^n$ such that*

$$M = \sum_{j=1}^{K} y_j y_j^\top, \quad \textit{and} \quad y_i^\top A y_i = \frac{1}{K}\,\mathrm{tr}(MA) \ \textit{for all } i = 1, \ldots, K. \tag{19}$$

Proof Let us consider the square matrices X, T of order $K + n - r$ in Corollary 15 to be

$$X \coloneqq \begin{pmatrix} M & O_{n\times(K-r)} \\ O_{(K-r)\times n} & I_{K-r} \end{pmatrix} \quad \text{and} \quad T \coloneqq \begin{pmatrix} A & O_{n\times(K-r)} \\ O_{(K-r)\times n} & O_{(K-r)\times(K-r)} \end{pmatrix}.$$

Then $\mathrm{rank}(X) = K$ by construction. Therefore, vectors $\{x_i\}_{i=1}^K \subset \mathbb{R}^{n+K-r}$ exist satisfying the properties in Corollary 15. Let us denote $\mathbb{R}^n \ni y_i \coloneqq \begin{pmatrix} x_{i1} & \ldots & x_{in} \end{pmatrix}^\top$ for $i = 1, \ldots, K$; in other words, y_i is the vector formed by the first n components of x_i. Then

$$\sum_{i=1}^{K} y_i y_i^\top = M,$$

and for any $i = 1, \ldots, K$,

$$y_i^\top A y_i = x_i^\top T x_i = \frac{1}{K}\,\mathrm{tr}(XT) = \frac{1}{K}\,\mathrm{tr}(MA).$$

The assertion follows at once. ∎

4. Proofs of Theorem 1, Lemma 2, and Theorem 3

4.1 Proof of Theorem 1

Proof For a given dictionary $D_K \in \mathcal{D}_K$ of vectors $\{d_i\}_{i=1}^K$ that is feasible for (7), let us define a scheme of representation

$$\mathbb{R}^n \ni v \longmapsto f_{D_K}^*(v) \coloneqq \begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix}^+ v \in \mathbb{R}^K.$$

Quite clearly, $\begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix} f_{D_K}^*(v) = v$ for any $v \in \mathbb{R}^n$ by the definition of the pseudo-inverse because if $\mathrm{span}\{d_i\}_{i=1}^K = \mathbb{R}^n$, then $\begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix}^+ v$ solves the equation $\begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix} x = v$. Therefore,

$$\begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix} f_{D_K}^*(V) = V \ \ \mu\text{-almost surely.}$$

We know that $f_{D_K}^*(v) = \begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix}^+ v$ is the solution of the least squares problem

$$\begin{aligned} &\underset{x\in\mathbb{R}^K}{\text{minimize}} && \|x\|^2 \\ &\text{subject to} && \begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix} x = v. \end{aligned}$$

Therefore, for an arbitrary $f \in \mathcal{F}$ such that $\begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix} f(v) = v$ for all $v \in \mathbb{R}^n$, we must have

$$\left\| f^*_{D_K}(v) \right\|^2 \leqslant \|f(v)\|^2 \quad \text{for all } v \in \mathbb{R}^n.$$

Therefore,

$$\left\| f^*_{D_K}(V) \right\|^2 \leqslant \|f(V)\|^2 \quad \mu\text{-almost surely,}$$

and hence,

$$\mathsf{E}_\mu\left[\left\| f^*_{D_K}(V) \right\|^2\right] \leqslant \mathsf{E}_\mu\left[\|f(V)\|^2\right].$$

Minimizing over all feasible dictionaries and schemes, we get

$$\inf_{D_K \in \mathcal{D}_\mathcal{K}} \mathsf{E}_\mu\left[\left\| f^*_{D_K}(V) \right\|^2\right] \leqslant \inf_{\substack{D_K \in \mathcal{D}_K, \\ f \in \mathcal{F}}} \mathsf{E}_\mu\left[\|f(V)\|^2\right] \tag{20}$$

The problem on the left-hand side of the inequality (20) is

$$\begin{aligned} \underset{\{d_i\}_{i=1}^K}{\text{minimize}} \quad & \mathsf{E}_\mu\left[\left\| f^*_{D_K}(V) \right\|^2\right] \\ \text{subject to} \quad & \begin{cases} \|d_i\| = 1 \text{ for all } i = 1, \ldots, K, \\ \operatorname{span}\{d_i\}_{i=1}^K = \mathbb{R}^n. \end{cases} \end{aligned} \tag{21}$$

From (20) we can conclude that the optimal value, if it exists, of problem (7) is bounded below by the optimal value, if it exists, of the one given in (21). Our strategy is to demonstrate that optimization problem (21) admits a solution, and we shall furnish a feasible solution of (7) that achieves a value of the objective function that is equal to the optimal value of the problem (21). This will solve (7).

Let $D \coloneqq \begin{pmatrix} d_1 & d_2 & \cdots & d_K \end{pmatrix}$. The objective function in (21) can be computed as

$$\begin{aligned} \mathsf{E}_\mu\left[\left\| f^*_{D_K}(V) \right\|^2\right] &= \mathsf{E}_\mu\left[\left\| D^+ V \right\|^2\right] \\ &= \mathsf{E}_\mu\left[V^\top (D^+)^\top D^+ V\right] \\ &= \mathsf{E}_\mu\left[V^\top \left(D^\top (DD^\top)^{-1}\right)^\top \left(D^\top (DD^\top)^{-1}\right) V\right] \\ &= \mathsf{E}_\mu\left[V^\top (DD^\top)^{-1} DD^\top (DD^\top)^{-1} V\right] \\ &= \mathsf{E}_\mu\left[V^\top (DD^\top)^{-1} V\right] \\ &= \mathsf{E}_\mu\left[\operatorname{tr}(V^\top (DD^\top)^{-1} V)\right] \\ &= \mathsf{E}_\mu\left[\operatorname{tr}(VV^\top (DD^\top)^{-1})\right] \\ &= \operatorname{tr}\left(\mathsf{E}_\mu\left[VV^\top\right](DD^\top)^{-1}\right). \end{aligned}$$

Letting $\Sigma_V \coloneqq \mathsf{E}_\mu\left[VV^\top\right]$ and writing $DD^\top = \sum_{i=1}^K d_i d_i^\top$ the optimization problem (21) is rephrased as

$$\begin{aligned} \underset{\{d_i\}_{i=1}^K}{\text{minimize}} \quad & \operatorname{tr}\left(\Sigma_V \left(\sum_{i=1}^K d_i d_i^\top\right)^{-1}\right) \\ \text{subject to} \quad & \begin{cases} \|d_i\| = 1 \text{ for all } i = 1, \ldots, K, \\ \operatorname{span}\{d_i\}_{i=1}^K = \mathbb{R}^n. \end{cases} \end{aligned} \tag{22}$$

Let S be the feasible set for the problem in (22). At first (22) appears to be non-convex. Let us demonstrate that the objective function of (22) is convex in $DD^\top$. We know that whenever Σ_V is a positive definite matrix,

$$\operatorname{tr}(\Sigma_V M^{-1}) = \operatorname{tr}\left(\Sigma_V^{1/2} M^{-1} \Sigma_V^{1/2}\right) = \operatorname{tr}\left(\left(\Sigma_V^{-1/2} M \Sigma_V^{-1/2}\right)^{-1}\right).$$

From (Bhatia, 1997, p. 113 and Exercise V.1.15, p. 117) we know that inversion of a matrix is a *matrix convex* map on the set of positive definite matrices. Therefore, for any $\theta \in [0,1]$ and $M_1, M_2 \in \mathbb{S}^{n\times n}_{++}$ we have

$$\begin{aligned} &\left(\Sigma_V^{-1/2}\big((1-\theta)M_1 + \theta M_2\big)\Sigma_V^{-1/2}\right)^{-1} \\ &\qquad = \left((1-\theta)\left(\Sigma_V^{-1/2} M_1 \Sigma_V^{-1/2}\right) + \theta\left(\Sigma_V^{-1/2} M_2 \Sigma_V^{-1/2}\right)\right)^{-1} \\ &\qquad\qquad \preceq (1-\theta)\left(\Sigma_V^{-1/2} M_1 \Sigma_V^{-1/2}\right)^{-1} + \theta\left(\Sigma_V^{-1/2} M_2 \Sigma_V^{-1/2}\right)^{-1}, \end{aligned} \tag{23}$$

where $A \preceq B$ implies that $B - A$ is positive semidefinite. Since $\operatorname{tr}(\cdot)$ is a *linear functional* over the set of $n \times n$ matrices we have

$$\begin{aligned} \operatorname{tr}\left(\Sigma_V\big((1-\theta)M_1 + \theta M_2\big)^{-1}\right) &= \operatorname{tr}\left(\left(\Sigma_V^{-1/2}\big((1-\theta)M_1 + \theta M_2\big)\Sigma_V^{-1/2}\right)^{-1}\right) \\ &\leqslant (1-\theta)\operatorname{tr}\left(\left(\Sigma_V^{-1/2} M_1 \Sigma_V^{-1/2}\right)^{-1}\right) + \theta \operatorname{tr}\left(\left(\Sigma_V^{-1/2} M_2 \Sigma_V^{-1/2}\right)^{-1}\right) \\ &\leqslant (1-\theta)\operatorname{tr}(\Sigma_V M_1^{-1}) + \theta \operatorname{tr}(\Sigma_V M_2^{-1}). \end{aligned}$$

In other words, the function $M \longmapsto \operatorname{tr}(\Sigma_V M^{-1})$ is a convex function on the set of symmetric and positive definite matrices. Moreover, we know that for a collection $\{d_i\}_{i=1}^K$ that is feasible for (22),

$$\mathcal{D}_K \ni \{d_i\}_{i=1}^K \longmapsto h(d_1, \ldots, d_K) \coloneqq \sum_{i=1}^K d_i d_i^\top$$

maps into the set of positive definite matrices. Therefore, the objective function in (22) is a convex function on image(h). This allows us to translate the feasible set of the optimization problem (22) to the set of matrices M formed by all feasible collections $\{d_i\}_{i=1}^K$, i.e., on $h(\mathcal{D}_K)$.

Let $R \coloneqq \left\{M \in \mathbb{S}^{n\times n}_{++} \;\middle|\; \operatorname{tr}(M) = K\right\}$. On the one hand, from Corollary 16 with $A = I_n$, we know that any symmetric and positive definite matrix $M \in R$ can be decomposed as

$$M = \sum_{i=1}^K d_i d_i^\top \quad \text{with } \|d_i\| = \sqrt{\frac{\operatorname{tr}(M)}{K}} = 1 \text{ for all } i = 1, \ldots, K.$$

The fact that M is positive definite implies that $\operatorname{span}\{d_i\}_{i=1}^K = \mathbb{R}^n$. Therefore, $\{d_i\}_{i=1}^K \in \mathcal{D}_K$ and $M = h(d_1, \ldots, d_K)$, which implies that

$$R \subset h(S). \tag{24}$$

On the other hand, for any collection of vectors $\{d_i\}_{i=1}^K \in \mathcal{D}_K$, we have $h(d_1,\ldots,d_K) = \sum_{i=1}^K d_i d_i^\top \in \mathbb{S}_{++}^{n\times n}$ and $\operatorname{tr}\big(h(d_1,\ldots,d_K)\big) = \sum_{i=1}^K d_i^\top d_i = K$. Therefore, by definition of R,

$$h(S) \subset R. \tag{25}$$

From (24) and (25) we conclude that $h(\mathcal{D}_K) = R$. The optimization problem (22) is, therefore, equivalent to the one where the feasible set is the set of positive definite matrices with trace K, i.e., from (22),

$$\begin{aligned} &\underset{M\in\mathbb{S}_{++}^{n\times n}}{\text{minimize}} && \operatorname{tr}\big(\Sigma_V M^{-1}\big) \\ &\text{subject to} && \operatorname{tr}(M) - K = 0. \end{aligned} \tag{26}$$

The optimization problem in (26) is convex since its objective function is convex (as a function of M) and the feasible region is the intersection of a convex cone $\mathbb{S}_{++}^{n\times n}$ and the affine space $\big\{M \in \mathbb{R}^{n\times n} \;\big|\; \operatorname{tr}(M) - K = 0\big\}$. In the light of (Boyd and Vandenberghe, 2004, p. 244) it follows that (26) can be solved by considering just the first order optimality conditions. These first order optimality conditions are expressed in terms of a Lagrangian

$$L(M,\gamma) \coloneqq \operatorname{tr}(M^{-1}\Sigma_V) + \gamma\big(\operatorname{tr}(M) - K\big),$$

containing a KKT multiplier γ at an optimal point M^* as

$$\begin{aligned} 0 = \nabla_M L(M^*,\gamma) &= \nabla_M \Big(\operatorname{tr}(M^{-1}\Sigma_V) + \gamma\big(\operatorname{tr}(M) - K\big)\Big)\Big|_{M=M^*} \\ &= -\big((M^*)^{-1}\Sigma_V(M^*)^{-1}\big)^\top + \gamma I_n. \end{aligned} \tag{27}$$

But since $M^*, \Sigma_V \in \mathbb{S}_{++}^{n\times n}$, by symmetry it follows that $(M^*)^{-1}\Sigma_V(M^*)^{-1} = \gamma I_n$, leading to

$$\Sigma_V = \gamma (M^*)^2. \tag{28}$$

Since $\Sigma_V \neq O_{n\times n}$, we get $\gamma \neq 0$, and write M^* as

$$M^* = \frac{1}{\sqrt{\gamma}}\Sigma_V^{1/2}.$$

To evaluate γ we use the fact that by construction $K = \operatorname{tr}(M^*) = \frac{1}{\sqrt{\gamma}}\operatorname{tr}\big(\Sigma_V^{1/2}\big)$, which gives

$$\gamma = \left(\frac{\operatorname{tr}\big(\Sigma_V^{1/2}\big)}{K}\right)^2.$$

In other words, the final expression of the optimizer M^* in the problem (26) is

$$M^* = \frac{K}{\operatorname{tr}\big(\Sigma_V^{1/2}\big)}\Sigma_V^{1/2}. \tag{29}$$

It follows that the optimal value of the problem (26) (and therefore of (22)) is $\dfrac{\big(\operatorname{tr}(\Sigma_V^{1/2})\big)^2}{K}$. Therefore, this value must be a lower bound of the optimal value, if it exists, for the problem (7).

Employing Corollary 16 with $A = I_n$, we decompose M^* as

$$M^* = \sum_{i=1}^K d_i^* d_i^{*\top} \quad \text{with } \|d_i^*\| = 1 \text{ for each } i = 1,\ldots,K. \tag{30}$$

Let us consider the dictionary D_K^* consisting of the vectors $\{d_i^*\}_{i=1}^K$ obtained above. Since $X_V = \mathbb{R}^n$, the matrices $\Sigma_V, \Sigma_V^{1/2}$, and M^* are of rank n, and therefore, $\operatorname{span}\{d_i^*\}_{i=1}^K = \mathbb{R}^n$. Along with the fact that $\|d_i^*\| = 1$, we see that the dictionary D_K^* of vectors $\{d_i^*\}_{i=1}^K$ is feasible for the problem (7).

Let us define the scheme

$$\mathbb{R}^n \ni v \longmapsto f_{D_K^*}^*(v) \coloneqq \begin{pmatrix} d_1^* & d_2^* & \cdots & d_K^* \end{pmatrix}^+ v \in \mathbb{R}^K.$$

It is evident that this scheme $f_{D_K^*}^*$ is feasible for (7). But then the objective function in (7) evaluated at $D_K = D_K^*$ and $f = f_{D_K^*}^*$ must be equal to $\dfrac{\big(\operatorname{tr}(\Sigma_V^{1/2})\big)^2}{K}$. Since this particular value is also a lower bound for the optimal value of (7), the problem (7) is solvable. An optimal dictionary-scheme pair is given by

$$\begin{cases} D_K^* = \{d_i^*\}_{i=1}^K \text{ obtained from the decomposition (30), and} \\ \mathbb{R}^n \ni v \longmapsto f^*(v) \coloneqq \begin{pmatrix} d_1^* & d_2^* & \cdots & d_K^* \end{pmatrix}^+ v \in \mathbb{R}^K. \end{cases} \tag{31}$$

The proof is now complete. ∎

We provide the Algorithm 2 that computes optimal dictionary-scheme pairs for the case $X_V = \mathbb{R}^n$. The inputs to the algorithm are the matrix Σ_V and the size K of a dictionary:

Algorithm 2: ℓ_2-optimal dictionary for the case $X_V = \mathbb{R}^n$.

Input: A matrix $\Sigma_V \in \mathbb{S}_{++}^{n\times n}$ and a number $K \geqslant n$.
Output: An ℓ_2-optimal dictionary-scheme pair $\big(\{d_i^*\}_{i=1}^K, f^*\big)$.

1 Define $M_1 \coloneqq \frac{K}{\operatorname{tr}\left(\Sigma_V^{1/2}\right)}\,\Sigma_V^{1/2}$.
2 Define $M_2 \coloneqq \begin{pmatrix} M_1 & O_{n\times(K-n)} \\ O_{(K-n)\times n} & I_{K-n} \end{pmatrix}$, $A \coloneqq \begin{pmatrix} I_n & O_{n\times(K-n)} \\ O_{(K-n)\times n} & O_{(K-n)\times(K-n)} \end{pmatrix}$
3 Compute $C \in \mathbb{R}^{K\times K}$ such that $M_2 = CC^\top$.
4 Define $\Lambda \in \mathbb{R}^{K\times K}$ by $\Lambda \coloneqq C^\top A C$, and apply Algorithm 1 to get a collection of vectors $\{x_i\}_{i=1}^K \subset \mathbb{R}^K$.
5 Define the collection $\{v_i\}_{i=1}^K \subset \mathbb{R}^K$ by $v_i \coloneqq Cx_i$ for $i = 1,\ldots,K$.
6 Define the ℓ_2-optimal dictionary $\{d_i^*\}_{i=1}^K \subset \mathbb{R}^n$ such that the j^{th} component of d_i^* is given by $d_i^*(j) \coloneqq v_i(j)$ for $j = 1,\ldots,n$ and for every $i = 1,\ldots,K$.
7 Define the optimal scheme $\mathbb{R}^n \ni v \longmapsto f^*(v) \coloneqq \begin{pmatrix} d_1^* & d_2^* & \cdots & d_K^* \end{pmatrix}^+ v$.

4.2 Proof of Lemma 2

Proof We argue by contradiction. Suppose that the assertion of the Lemma is false. If we denote by x_i the orthogonal projection of d_i on X_V and by y_i the orthogonal projection of

d_i on the orthogonal complement of X_V, we must have $\|x_i\| < 1$ for at least one value of i. If f is an optimal scheme of representation, feasibility of f gives, for any $v \in R_V$,

$$\begin{aligned} v &= \sum_{i=1}^{K} d_i f_i(v) = \left(\sum_{i=1}^{K} x_i f_i(v)\right) + \left(\sum_{i=1}^{K} y_i f_i(v)\right) \\ &= \sum_{\substack{i=1,\\ \|x_i\|\neq 0}}^{K} x_i f_i(v) + 0. \end{aligned} \tag{32}$$

Fix a unit vector $x \in X_V$, and define a dictionary $\{d_i^*\}_{k=1}^K$ by

$$d_i^* := \begin{cases} \dfrac{x_i}{\|x_i\|} & \text{if } \|x_i\| \neq 0, \\ x & \text{otherwise.} \end{cases}$$

Then clearly

$$\operatorname{span}\{d_i^*\}_{i=1}^K \supset \operatorname{span}\{x_i\}_{i=1}^K \supset R_V \quad \text{and} \quad \|d_i^*\| = 1 \text{ for all } i = 1, \ldots, K.$$

In other words, the dictionary of vectors $\{d_i^*\}_{i=1}^K$ is feasible for the problem (6). Let us now define a scheme f^* by

$$\mathbb{R}^n \ni v \longmapsto f^*(v) := \operatorname{diag}\{\|x_1\|, \|x_2\|, \ldots, \|x_K\|\} f(v) \in \mathbb{R}^K.$$

For any $v \in R_V$, using the dictionary consisting of vectors $\{d_i^*\}_{i=1}^K$ we get

$$\sum_{i=1}^{K} d_i^* f_i^*(v) = \sum_{i=1}^{K} d_i^* \|x_i\| f_i(v) = \sum_{\substack{i=1,\\ \|x_i\|\neq 0}}^{K} \frac{x_i}{\|x_i\|} \|x_i\| f_i(v) = v, \tag{33}$$

where the last equality follows from (32). Thus, $f^*(\cdot)$ along with the dictionary of vectors $\{d_i^*\}_{i=1}^K$ is feasible for problem (6). But for any $v \in R_V$ we have

$$\|f^*(v)\|^2 = \sum_{i=1}^{K} \big(f_i^*(v)\big)^2 = \sum_{i=1}^{K} \|x_i\|^2 \big(f_i(v)\big)^2 < \sum_{i=1}^{K} \big(f_i(v)\big)^2 = \|f(v)\|^2,$$

where the inequality is due to the fact that $\|x_i\| < 1$ for at least one i. This contradicts the assumption that the pair $\{d_i\}_{i=1}^K$ along with the scheme f is optimal for (6). ■

4.3 Proof of Theorem 3

Proof The problem (9) is similar to problem (7) except for the first constraint. In (7) we optimize over vectors taking values on the surface of the unit sphere, whereas in (9) we optimize over vectors taking values on the surface of the ellipsoid $\{x \in \mathbb{R}^m \mid x^\top (B^\top B) x = 1\}$. Following the arguments in the proof of Theorem 1 till (22), one can conclude that the

optimal value, if it exists, of problem (9) is bounded below by the optimal value, if it exists, of the problem

$$\begin{aligned} \underset{\{\delta_i\}_{i=1}^K}{\text{minimize}} \quad & \operatorname{tr}\left(\Sigma_{V_X}\left(\sum_{i=1}^{K} \delta_i \delta_i^\top\right)^{-1}\right) \\ \text{subject to} \quad & \begin{cases} \delta_i^\top (B^\top B) \delta_i = 1 \text{ for all } i = 1, 2, \ldots, K, \\ \operatorname{span}\{\delta_i\}_{i=1}^K = \mathbb{R}^m, \end{cases} \end{aligned} \tag{34}$$

where $\Sigma_{V_X} := \mathsf{E}_\mu\big[V_X V_X^\top\big] = \big((B^\top B)^{-1} B^\top\big)\, \mathsf{E}_\mu\big[V V^\top\big] \big((B^\top B)^{-1} B^\top\big)^\top$.

Let us define:

- S to be the feasible region of the problem (34),
- $R := \big\{H \in \mathbb{S}_{++}^{m\times m} \;\big|\; \operatorname{tr}\big(H(B^\top B)\big) = K\big\}$, and
- the map $\big(\mathbb{R}^m\big)^K \ni (\delta_1, \delta_2, \ldots, \delta_K) \longmapsto h(\delta_1, \delta_2, \ldots, \delta_K) := \sum_{i=1}^K \delta_i \delta_i^\top \in \mathbb{S}_+^{m\times m}$.

From Corollary 16 we see that for every $H \in R$ there exists a collection of vectors $\{\delta_i\}_{i=1}^K$ such that

$$\sum_{i=1}^{K} \delta_i \delta_i^\top = H \quad \text{and} \quad \delta_i^\top (B^\top B) \delta_i = \frac{\operatorname{tr}\big(H(B^\top B)\big)}{K} = 1,$$

which, along with the fact that $\operatorname{rank}(H) = m \Rightarrow \operatorname{span}\{\delta_i\}_{i=1}^K = \mathbb{R}^m$, imply that

$$R \subset h(S). \tag{35}$$

Moreover, for any collection $\{\delta_i\}_{i=1}^K \in S$, we have

$$\operatorname{tr}\big(h(\delta_1, \delta_2, \ldots, \delta_K)(B^\top B)\big) = \sum_{i=1}^{K} \delta_i^\top (B^\top B) \delta_i = K \quad \text{and} \quad h(\delta_1, \delta_2, \ldots, \delta_K) \in \mathbb{S}_{++}^{m\times m},$$

which implies that

$$h(S) \subset R. \tag{36}$$

From (35) and (36) we conclude that $R = h(S)$. In other words, instead of optimizing over the feasible collection of vectors in S in (34), one can equivalently optimize over the set of symmetric positive definite matrices in R. This consideration leads us to the problem:

$$\begin{aligned} \underset{H \in \mathbb{S}_{++}^{m\times m}}{\text{minimize}} \quad & \operatorname{tr}\big(\Sigma_{V_X} H^{-1}\big) \\ \text{subject to} \quad & \operatorname{tr}\big(H(B^\top B)\big) - K = 0. \end{aligned} \tag{37}$$

Letting $M := (B^\top B)^{1/2} H (B^\top B)^{1/2}$, we write the optimization problem (37) with M as the variable instead of H. Due to this change of variables, the constraint and the objective function become

$$\operatorname{tr}\big(H(B^\top B)\big) = \operatorname{tr}\big((B^\top B)^{1/2} H (B^\top B)^{1/2}\big) = \operatorname{tr}(M),$$

and

$$\begin{aligned} \operatorname{tr}\big(\Sigma_{V_X} H^{-1}\big) &= \operatorname{tr}\big(\Sigma_{V_X} (B^\top B)^{1/2} M^{-1} (B^\top B)^{1/2}\big) \\ &= \operatorname{tr}\big((B^\top B)^{1/2} \Sigma_{V_X} (B^\top B)^{1/2} M^{-1}\big) \\ &= \operatorname{tr}\big(\Sigma M^{-1}\big), \end{aligned} \tag{38}$$

where

$$\begin{aligned}\Sigma &\coloneqq (B^\top B)^{1/2}\Sigma_{V_X}(B^\top B)^{1/2}\\ &= (B^\top B)^{1/2}\big((B^\top B)^{-1}B^\top\big)\,\mathsf{E}_\mu\big[VV^\top\big]\big((B^\top B)^{-1}B^\top\big)^\top(B^\top B)^{1/2}\\ &= (B^\top B)^{-1/2}\big(B^\top\Sigma_V B\big)(B^\top B)^{-1/2}.\end{aligned} \tag{39}$$

Using (38) we write the problem (37) equivalently as:

$$\begin{aligned}\underset{M\in\mathbb{S}^{n\times n}_{++}}{\text{minimize}}\quad & \operatorname{tr}\big(\Sigma M^{-1}\big)\\ \text{subject to}\quad & \operatorname{tr}(M)-K=0.\end{aligned} \tag{40}$$

The problem (40) is identical to (26), which implies that the problem (40) is solvable, and an optimizer is

$$M^* \coloneqq \frac{K}{\operatorname{tr}\big(\Sigma^{1/2}\big)}\Sigma^{1/2}.$$

Therefore, the problem (37) is solvable, and an optimizer is

$$\begin{aligned}H^* &\coloneqq (B^\top B)^{-1/2}M^*(B^\top B)^{-1/2}\\ &= \frac{K}{\operatorname{tr}\big(\Sigma^{1/2}\big)}\big((B^\top B)^{-1/2}\Sigma^{1/2}(B^\top B)^{-1/2}\big).\end{aligned} \tag{41}$$

From Corollary 16 it follows that there exists a collection $\{\delta_i^*\}_{i=1}^K$ of vectors such that

$$\sum_{i=1}^K \delta_i^*\delta_i^{*\top} = H^* \quad\text{and}\quad \delta_i^{*\top}\big(B^\top B\big)\delta_i^* = \frac{\operatorname{tr}\big(H^*(B^\top B)\big)}{K} = 1.$$

Employing arguments similar to those given in the proof of Theorem 1, we now conclude that the pair

- the collection of vectors $\{\delta_i^*\}_{i=1}^K$, and
- the scheme $f_X^*(u) = \begin{pmatrix}\delta_1^* & \delta_2^* & \cdots & \delta_K^*\end{pmatrix}^+ u$,

is optimal for the problem (9). Using the optimal solution of (9), we define a dictionary-scheme pair as:

$$\begin{cases} d_i^* \coloneqq B\delta_i^* \quad \text{for } i=1,\dots,K,\\ \mathbb{R}^n \ni v \longmapsto f^*(v) \coloneqq f_X^*\Big(\big((B^\top B)^{-1}B^\top\big)v\Big) = \begin{pmatrix}\delta_1^* & \delta_2^* & \cdots & \delta_K^*\end{pmatrix}^+\big((B^\top B)^{-1}B^\top\big)v.\end{cases} \tag{42}$$

It is clear that the pair in (42) is feasible for the problem (6), and that the corresponding objective function evaluates to the optimal value of the problem (34). Therefore, along with the assertion of Lemma 2 we can conclude that the problem (6) is solvable, and in fact an optimal solution is given by (42) with the optimal value of $\frac{\left(\operatorname{tr}(\Sigma^{1/2})\right)^2}{K}$. This completes the proof. ■

As in the case $X_V = \mathbb{R}^n$, we now provide the Algorithm 3 to obtain an optimal dictionary-scheme pair for the general ℓ_2-optimal dictionary problem (6). The algorithm takes the

matrix Σ_V and the size of the dictionary K as its inputs. From Σ_V we extract a matrix $B \in \mathbb{R}^{n\times m}$ containing a set of basis vectors for image(Σ_V) in its columns, these vectors form a basis for X_V.

Algorithm 3: A procedure to obtain ℓ_2-optimal dictionary.

Input: A matrix $\Sigma_V \in \mathbb{S}_+^{n\times n}$ and a number $K \geqslant m \coloneqq \dim(X_V) = \operatorname{rank}(\Sigma_V)$.
Output: An ℓ_2-optimal dictionary-scheme pair $\big(\{y_i^*\}_{i=1}^K, f^*\big)$.

1. Compute a basis $\{b_i\}_{i=1}^m$ for image(Σ_V) and define $B \coloneqq \begin{pmatrix}b_1 & b_2 & \cdots & b_m\end{pmatrix}$.
2. Define $\Sigma \coloneqq (B^\top B)^{-1/2}\big(B^\top\Sigma_V B\big)(B^\top B)^{-1/2}$.
3. Compute $H \coloneqq \frac{K}{\operatorname{tr}\left(\Sigma^{1/2}\right)}\big((B^\top B)^{-1/2}\Sigma^{1/2}(B^\top B)^{-1/2}\big)$.
4. Define $M \coloneqq \begin{pmatrix}H & O_{m\times(K-m)}\\ O_{(K-m)\times m} & I_{K-m}\end{pmatrix}$, $A \coloneqq \begin{pmatrix}B^\top B & O_{m\times(K-m)}\\ O_{(K-m)\times m} & O_{(K-m)\times(K-m)}\end{pmatrix}$
5. Compute $C \in \mathbb{R}^{K\times K}$ such that $M = CC^\top$.
6. Define $\Lambda \in \mathbb{R}^{K\times K}$ by $\Lambda \coloneqq C^\top AC$, and apply Algorithm 1 to get a collection of vectors $\{x_i\}_{i=1}^K \subset \mathbb{R}^K$.
7. Define the collection $\{v_i\}_{i=1}^K \subset \mathbb{R}^K$ as $v_i \coloneqq Cx_i$ for $i = 1,\dots,K$.
8. Define the collection $\{\delta_i^*\}_{i=1}^K \subset \mathbb{R}^m$ such that the j^{th} component of δ_i^* is given by $\delta_i^*(j) \coloneqq v_i(j)$ for $j = 1,\dots,m$ and for every $i = 1,\dots,K$.
9. Define the ℓ_2-optimal dictionary $\{d_i^*\}_{i=1}^K \subset \mathbb{R}^n$ as $d_i^* \coloneqq B\delta_i^*$ for $i = 1,\dots,K$.
10. Define the optimal scheme $\mathbb{R}^n \ni v \longmapsto f^*(v) \coloneqq \begin{pmatrix}d_1^* & d_2^* & \cdots & d_K^*\end{pmatrix}^+ v \in \mathbb{R}^K$.

5. Conclusion and future directions

In this article we have provided an explicit solution of the ℓ_2-optimal dictionary problem in the form of a *rank*-1 *decomposition* of a specific positive definite matrix derived from given data, together with algorithms to compute the corresponding ℓ_2-optimal dictionaries.

The analysis in this article assumes that the second moment of the random vector whose samples are to be represented is known. An online algorithm which estimates the second moment of the random vector and computes the dictionary vectors in parallel is being developed, and will be reported in subsequent articles.

Acknowledgments

We sincerely thank Prof. V. S. Borkar for his valuable pointers on convexity of the ℓ_2-optimal dictionary problem, Prof. K. S. Mallikarjuna Rao for pointing us to the literature on rank-1 decompositions of matrices, and Prof. N. Khaneja for helpful discussions.

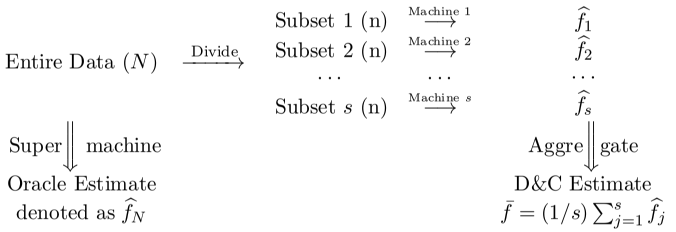
Abstract

In this paper, we explore statistical versus computational trade-off to address a basic question in the application of a distributed algorithm: what is the minimal computational cost in obtaining statistical optimality? In smoothing spline setup, we observe a phase transition phenomenon for the number of deployed machines that ends up being a simple proxy for computing cost. Specifically, a *sharp* upper bound for the number of machines is established: when the number is below this bound, statistical optimality (in terms of nonparametric estimation or testing) is achievable; otherwise, statistical optimality becomes impossible. These sharp bounds partly capture intrinsic computational limits of the distributed algorithm considered in this paper, and turn out to be fully determined by the smoothness of the regression function. We name the asymptotic analysis on such split-and-aggregation estimation/inference as "splitotic" theory. As a side remark, we argue that sample splitting may be viewed as an alternative form of regularization, playing a similar role as smoothing parameter.

Keywords: divide-and-conquer, computational limits, smoothing spline, splitotic theory

1. Introduction

In the parallel computing environment, divide-and-conquer (D&C) method distributes data to multiple machines, and then aggregates local estimates computed from each machine to produce a global one. Such a distributed algorithm often requires a *growing* number of machines in order to process an increasingly large dataset. A practically relevant question is "how many processors do we really need in this parallel computing?" or "shall we allocate all our computational resources in the data analysis?" Such questions are related to the minimal computational cost of this distributed method (which will be defined more precisely later).



The major goal of this paper is to provide some "theoretical" insights, namely, a splitotic theory, for the above questions from a statistical perspective. Specifically, we consider a classical nonparametric regression setup:

$$y_l = f(l/N) + \epsilon_l,\ l = 0, 1, \ldots, N-1, \tag{1}$$

where ϵ_l's are *iid* random errors with $E\{\epsilon_l\} = 0$ and $Var(\epsilon_l) = 1$, in the following distributed algorithm:

We assume that the total sample size is N, the number of machines is s and the size of each sub-sample is n. Hence, $N = s \times n$. Each machine produces an individual smoothing spline estimate $\widehat{f}_j$ to be defined in (3) (Wahba (1990)).

A known property of the above D&C strategy is that it can preserve statistical efficiency for a wide-ranging choice of s (as demonstrated in Figure 1), say $\log s/\log N \in [0, 0.4]$, while largely reducing computational burden as $\log s/\log N$ increases (as demonstrated in Figure 2). An important observation from Figure 1 is that there is an obvious blowup for mean squared errors of $\bar{f}$ when the above ratio is beyond some threshold, e.g, 0.8 for $N = 10000$. Hence, we are interested in knowing whether there exists a critical value of $\log s/\log N$ in theory, beyond which statistical optimality no longer exists. For example, mean squared errors will never achieve minimax optimal lower bound (at rate level) no matter how smoothing parameters are tuned. Such a sharpness result partly captures the computational limit of the particular D&C algorithm considered in this paper, also complementing the upper bound results in Shang and Cheng (2015); Zhang et al. (2015); Zhao et al. (2016).

Our first contribution is to establish a sharp upper bound of s under which $\bar{f}$ achieves the minimax optimal rate $N^{m/(2m+1)}$, where m represents the smoothness of f_0. By "sharp" upper bound, we mean the largest possible upper bound for s to gain statistical optimality. This result is established by directly computing (non-asymptotic) upper and lower bounds of mean squared error of $\bar{f}$. These two bounds hold *uniformly* as s diverges, and thus imply that the rate of mean squared error transits once s reaches the rate $N^{2m/(2m+1)}$, which we call as phase transition in divide-and-conquer estimation. In fact, the choice of smoothing parameter, denoted as λ, also plays a very subtle role in the above phase transition. For example, λ is not necessarily chosen at an optimal level when s attains the above bound as illustrated in Figure 3.

Our second contribution is a sharp upper bound of s under which a simple Wald-type testing method based on $\bar{f}$ is minimax optimal in the sense of Ingster (1993). It is not surprising that our testing method is consistent no matter s is fixed or diverges at any rate. Rather, this sharp bound is entirely determined by analyzing its (non-asymptotic) power. Specifically, we find that our testing method is minimax optimal if and only if s does not grow faster than $N^{(4m-1)/(4m+1)}$. Again, we observe a subtle interplay between s and λ as depicted in Figure 3.

One theoretical insight obtained in our setup is that a more smooth regression function can be optimally estimated or tested at a shorter time. In addition, the above Figure 3

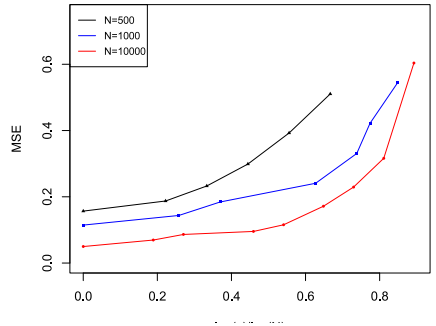

Figure 1: *Mean-square errors (MSE) of $\bar{f}$ based on 500 independent replications under different choices of N and s. The values of MSE stay at low levels for various choice of s with $\log s/\log N \in [0, 0.7]$. True regression function is $f_0(z) = 0.6b_{30,17}(z) + 0.4b_{3,11}(z)$ with b_{a_1,a_2} the density function for $Beta(a_1, a_2)$.*

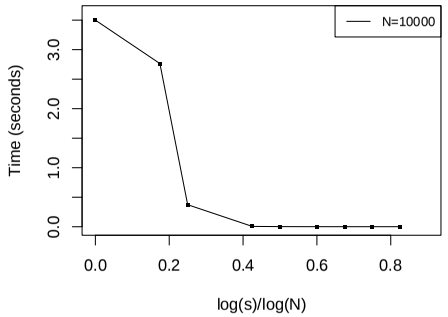

Figure 2: *Computing time of $\bar{f}$ based on a single replication under different choices of s when $N = 10,000$. The larger the s, the smaller the computing time.*

implies that s and λ play an interchangeable role in obtaining statistical optimality. Therefore, we argue that it might be attempting to view sample splitting as an alternative form of regularization, complementing the use of penalization in smoothing spline. In practice,

Figure 3: *Two lines indicate the choices of $s \asymp N^a$ and $\lambda \asymp N^{-b}$, leading to minimax optimal estimation rate (left) and minimax optimal testing rate (right). Whereas (a, b)'s outside these two lines lead to suboptimal rates. Results are based on smoothing spline regression with regularity $m \geq 1$.*

we propose to select λ via a distributed version of generalized cross validation (GCV); see Xu et al. (2017).

In the end, we want to mention that our theoretical results are developed in one-dimensional models under fixed design. This setting allows us to develop proofs based on exact analysis of various Fourier series, coupled with properties of circulant Bernoulli polynomial kernel matrix. The major goal of this work is to provide some theoretical insights in a relatively simple setup, which are useful in extending our results to more general setup such as random or multi-dimensional design. Efforts toward this direction have been made by Liu et al. (2017) who derived upper bounds of s for optimal estimation or testing in various nonparametric models when design is random and multi-dimensional.

2. Smoothing Spline Model

Suppose that we observe samples from model (1). The regression function f is smooth in the sense that it belongs to an m-order ($m \geq 1$) periodic Sobolev space:

$$S^m(\mathbb{I}) = \left\{ \sum_{\nu=1}^{\infty} f_\nu \varphi_\nu(\cdot) : \sum_{\nu=1}^{\infty} f_\nu^2 \gamma_\nu < \infty \right\},$$

where $\mathbb{I} := [0, 1]$ and for $k = 1, 2, \ldots,$

$$\varphi_{2k-1}(t) = \sqrt{2}\cos(2\pi kt), \quad \varphi_{2k}(t) = \sqrt{2}\sin(2\pi kt),$$

$$\gamma_{2k-1} = \gamma_{2k} = (2\pi k)^{2m}.$$

The entire dataset is distributed to each machine in a uniform manner as follows. For $j = 1, \ldots, s$, the jth machine is assigned with samples $(Y_{i,j}, t_{i,j})$, where

$$Y_{i,j} = y_{is-s+j-1} \text{ and } t_{i,j} = \frac{is - s + j - 1}{N}$$

for $i = 1, \ldots, n$. Obviously, $t_{1,j}, \ldots, t_{n,j}$ are evenly spaced points (with a gap $1/n$) across $\mathbb{I}$. At the jth machine, we have the following sub-model:

$$Y_{i,j} = f(t_{i,j}) + \epsilon_{i,j}, \ i = 1, \ldots, n, \tag{2}$$

where $\epsilon_{i,j} = \epsilon_{is-s+j-1}$, and obtain the jth sub-estimate as

$$\widehat{f_j} = \arg\min_{f \in S^m(\mathbb{I})} \ell_{j,n,\lambda}(f).$$

Here, $\ell_{j,n,\lambda}$ represents a penalized square criterion function based on the jth subsample:

$$\ell_{j,n,\lambda}(f) = \frac{1}{2n}\sum_{i=1}^{n}(Y_{i,j} - f(t_{i,j}))^2 + \frac{\lambda}{2}J(f,f), \tag{3}$$

with $\lambda > 0$ being a smoothing parameter and $J(f,g) = \int_{\mathbb{I}} f^{(m)}(t)g^{(m)}(t)dt$[1]

3. Minimax Optimal Estimation

In this section, we investigate the impact of the number of machines on the mean squared error of $\bar{f}$. Specifically, Theorem 3.1 provides an (non-asymptotic) upper bound for this mean squared error, while Theorem 3.2 provides a (non-asymptotic) lower bound. Notably, both bounds hold uniformly as s diverges. From these bounds, we observe an interesting phase transition phenomenon that $\bar{f}$ is minimax optimal if s does not grow faster than $N^{2m/(2m+1)}$ and an optimal $\lambda \asymp N^{-2m/(2m+1)}$ is chosen, but the minimax optimality breaks down if s grows even slightly faster (no matter how λ is chosen). Hence, the upper bound of s is sharp. Moreover, λ does not need to be optimal when this bound is attained. In some sense, a proper sample splitting can compensate a sub-optimal choice of λ.

In this section, we assume that ϵ_l's are *iid* zero-mean random variables with unit variance. Denote mean squared error as

$$\mathrm{MSE}_{f_0}(f) := E_{f_0}\{\|f - f_0\|_2^2\},$$

where $\|f\|_2 = \sqrt{\int_{\mathbb{I}} f(t)^2 dt}$. For simplicity, we write E_{f_0} as E later. Define $h = \lambda^{1/(2m)}$.

Theorem 3.1 *(Upper Bounds of Variance and Squared Bias) Suppose $h > 0$, and N is divisible by n. Then there exist absolute positive constants $b_m, c_m \geq 1$ (depending on m only) such that*

$$E\{\|\bar{f} - E\{\bar{f}\}\|_2^2\} \leq b_m\left(N^{-1} + (Nh)^{-1}\int_0^{\pi nh}\frac{1}{(1+x^{2m})^2}dx\right), \tag{4}$$

$$\|E\{\bar{f}\} - f_0\|_2 \leq c_m\sqrt{J(f_0)(\lambda + n^{-2m} + N^{-1})} \tag{5}$$

for any fixed $1 \leq s \leq N$.

1. For simplicity, we denote $J(f,f) = J(f)$ later.

From (17) and (18) in Appendix, we can tell that $\bar{f} - E\{\bar{f}\}$ is irrelevant to f_0. So is the upper bound for the (integrated) variance in (4). However, this is not the case for the (integrated) bias $\|E\{\bar{f}\} - f_0\|_2$, whose upper bound depends on f_0 through its norm $J(f_0)$. In particular, the (integrated) bias becomes zero if f_0 is in the null space, i.e., $J(f_0) = 0$, according to (5).

Since

$$\mathrm{MSE}_{f_0}(\bar{f}) = E\{\|\bar{f} - E\{\bar{f}\}\|_2^2\} + \|E\{\bar{f}\} - f_0\|_2^2, \tag{6}$$

Theorem 3.1 says that

$$\mathrm{MSE}_{f_0}(\bar{f}) \leq b_m\left(N^{-1} + (Nh)^{-1}\int_0^{\pi nh}\frac{1}{(1+x^{2m})^2}dx\right) + c_m^2 J(f_0)(\lambda + n^{-2m} + N^{-1}). \tag{7}$$

When we choose $h \asymp N^{-1/(2m+1)}$ and $n^{-2m} = O(\lambda)$, it can be seen from (7) that $\bar{f}$ is minimax optimal, i.e., $\|\bar{f} - f_0\|_2 = O_P(N^{-m/(2m+1)})$. Obviously, the above two conditions hold if

$$\lambda \asymp N^{-2m/(2m+1)} \text{ and } s = O(N^{2m/(2m+1)}). \tag{8}$$

From now on, we define the optimal choice of λ as $N^{-2m/(2m+1)}$, denoted as λ_*; according to Zhang et al. (2015). Alternatively, the minimax optimality can be achieved if $s \asymp N^{2m/(2m+1)}$ and $nh = o(1)$, i.e., $\lambda = o(\lambda_*)$. In other words, a sub-optimal choice of λ can be compensated by a proper sampling splitting strategy. See Figure 3 for the subtle relation between s and λ. It should be mentioned that λ_* depends on N (rather than n) for achieving optimal estimation rate. In practice, we propose to select λ via a distributed version of GCV; see Xu et al. (2017).

Remark 3.1 *Under random design and uniformly bounded eigenfunctions, Corollary 4 in Zhang et al. (2015) showed that the above rate optimality is achieved under the following upper bound on s (and $\lambda = \lambda_*$)*

$$s = O(N^{(2m-1)/(2m+1)}/\log N).$$

For example, when $m = 2$, their upper bound is $N^{0.6}/\log N$ (versus $N^{0.8}$ in our case). We improve their upper bound by applying a more direct proof strategy.

To understand whether our upper bound can be further improved, we prove a lower bound result in a "worst case" scenario. Specifically, Theorem 3.2 implies that once s is beyond the above upper bound, the rate optimality will break down for at least one true f_0.

Theorem 3.2 *(Lower Bound of Squared Bias) Suppose $h > 0$, and N is divisible by n. Then for any constant $C > 0$, it holds that*

$$\sup_{\substack{f_0 \in S^m(\mathbb{I}) \\ J(f_0) \leq C}} \|E\{\bar{f}\} - f_0\|_2^2 \geq C(a_m n^{-2m} - 8N^{-1}),$$

where $a_m \in (0,1)$ is an absolute constant depending on m only, for any fixed $1 < s < N$.

It follows by (6) that

$$\sup_{\substack{f_0\in S^m(\mathbb{I})\\ J(f_0)\le C}} \mathrm{MSE}_{f_0}(\bar f) \ge \sup_{\substack{f_0\in S^m(\mathbb{I})\\ J(f_0)\le C}} \|E\{\bar f\}-f_0\|_2^2 \ge C(a_m n^{-2m}-8N^{-1}). \tag{9}$$

It is easy to check that the above lower bound is strictly slower than the optimal rate $N^{-2m/(2m+1)}$ if s grows faster than $N^{2m/(2m+1)}$ no matter how λ is chosen. Therefore, we claim that $N^{2m/(2m+1)}$ is a sharp upper bound of s for obtaining an averaged smoothing spline estimate.

In the end, we provide a graphical interpretation for our sharp bound result. Let $s=N^a$ for $0\le a\le 1$ and $\lambda=N^{-b}$ for $0<b<2m$. Define $\rho_1(a),\rho_2(a)$ and $\rho_3(a)$ as

$$\begin{aligned}
\text{Upper bound of squared bias: } N^{-\rho_1(a)} &\asymp \lambda+n^{-2m}+N^{-1},\\
\text{Lower bound of squared bias: } N^{-\rho_2(a)} &\asymp \max\{n^{-2m}-N^{-1},0\},\\
\text{Upper bound of variance: } N^{-\rho_3(a)} &\asymp N^{-1}+(Nh)^{-1}\int_0^{\pi nh}\frac{1}{(1+x^{2m})^2}dx,
\end{aligned}$$

based on Theorems 3.1 and 3.2. A direct examination reveals that

$$\begin{aligned}
\rho_1(a) &= \min\{2m(1-a),1,b\}\\
\rho_2(a) &= \begin{cases} 2m(1-a), & a>(2m-1)/(2m)\\ \infty, & a\le(2m-1)/(2m)\end{cases}\\
\rho_3(a) &= \max\{a,(2m-b)/(2m)\}
\end{aligned}$$

Figure 4 displays ρ_1,ρ_2,ρ_3 for $\lambda=N^{-2m/(2m+1)}$. It can be seen that when $a\in[0,2m/(2m+1)]$, upper bounds of squared bias and variance maintain at the same optimal rate $N^{-2m/(2m+1)}$, while the exact bound of squared bias increases above $N^{-2m/(2m+1)}$ when $a\in(2m/(2m+1),1)$. This explains why transition occurs at the critical point $a=2m/(2m+1)$ (even when the upper bound of variance decreases below $N^{-2m/(2m+1)}$ when $a\in(2m/(2m+1),1)$).

It should be mentioned that when $\lambda\neq N^{-2m/(2m+1)}$, i.e., $b\neq 2m/(2m+1)$, suboptimal estimation almost always occurs. More explicitly, $b<2m/(2m+1)$ yields $\rho_1(a)<2m/(2m+1)$ for any $0\le a\le 1$. While $b>2m/(2m+1)$ yields $\rho_2(a)<2m/(2m+1)$ for any $2m/(2m+1)<a\le 1$; yields $\rho_3(a)<2m/(2m+1)$ for any $0\le a<2m/(2m+1)$. The only exception is $a=2m/(2m+1)$ which yields $\rho_1=\rho_2=\rho_3=2m/(2m+1)$ for any $b>2m/(2m+1)$.

Remark 3.2 *As a side remark, we notice that each machine is assigned with $n\asymp N^{1/(2m+1)}$ samples when s attains its upper bound in the estimation regime. This is very similar as the local polynomial estimation where approximately $N^{1/(2m+1)}$ local points are used for obtaining optimal estimation (although we realize that our data is distributed in a global manner).*

Remark 3.3 *Under repeated curves with a common design, Cai and Yuan (2011) observed a similar phase transition phenomenon for the minimax rate of a two-stage estimate, where the rate transits when the number of sample curves is nearly $N^{2m/(2m+1)}$. This coincides with our observation for s. However, the common design assumption, upon which their results crucially rely, clearly does not apply to our divide-and-conquer setup, and our proof techniques are significantly different. Rather, Theorems 3.1 and 3.2 imply that the results in Cai and Yuan (2011) may still hold for a non-common design.*

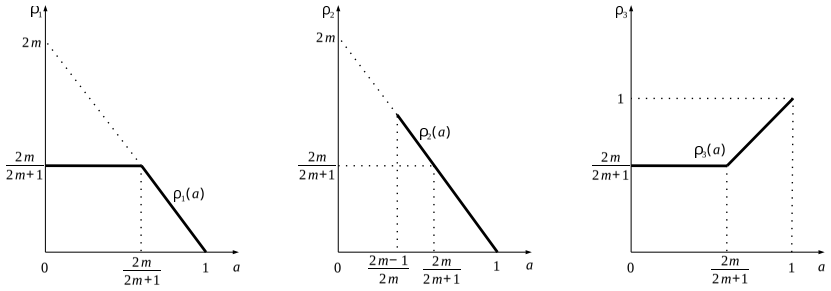

Figure 4: *Plots of $\rho_1(a),\rho_2(a),\rho_3(a)$ versus a, indicated by thick solid lines, under $\lambda=N^{-2m/(2m+1)}$. $\rho_1(a)$, $\rho_2(a)$ and $\rho_3(a)$ indicate upper bound of squared bias, lower bound of squared bias and upper bound of variance, respectively. $\rho_2(a)$ is plotted only for $(2m-1)/(2m)<a\le 1$; when $0\le a\le(2m-1)/(2m)$, $\rho_2(a)=\infty$, which is omitted.*

4. Minimax Optimal Testing

In this section, we consider nonparametric testing:

$$H_0: f=0 \ \text{ v.s. } \ H_1: f\in S^m(\mathbb{I})\backslash\{0\}. \tag{10}$$

In general, testing $f=f_0$ (for a known f_0) is equivalent to testing $f_*\equiv f-f_0=0$. So (10) has no loss of generality. Inspired by the classical Wald test (Shao (2003)), we propose a simple test statistic based on the $\bar f$ as

$$T_{N,\lambda}:=\|\bar f\|_2^2.$$

We find that testing consistency essentially requires no condition on the number of machines no matter it is fixed or diverges at any rate. However, our power analysis, which is non-asymptotically valid, depends on the number of machines in a nontrivial way. Specifically, we discover that our test method is minimax optimal in the sense of Ingster (Ingster (1993)) when s does not grow faster than $N^{(4m-1)/(4m+1)}$ and λ is chosen optimally (different from λ_*, though), but it is no longer optimal once s is beyond the above threshold (no matter how λ is chosen). This is a similar phase transition phenomenon as we observe in the estimation regime. Again, we notice an optimal choice of λ may not be necessary if the above upper bound of s is achieved.

In this section, we assume that the model errors $\epsilon_{i,j}$'s are *iid* standard normal for technical convenience. In fact, our results can be generalized to likelihood ratio test without

assuming Gaussian errors. This extension is possible (technically tedious, though) since likelihood ratio statistic can be approximated by $T_{N,\lambda}$ through quadratic expansion; see Shang and Cheng (2013).

Theorem 4.1 implies the consistency of our proposed test method with the following testing rule:

$$\phi_{N,\lambda} = I(|T_{N,\lambda} - \mu_{N,\lambda}| \geq z_{1-\alpha/2}\sigma_{N,\lambda}),$$

where $\mu_{N,\lambda} := \mathrm{E}_{H_0}\{T_{N,\lambda}\}$, $\sigma^2_{N,\lambda} := \mathrm{Var}_{H_0}\{T_{N,\lambda}\}$ and $z_{1-\alpha/2}$ is the $(1-\alpha/2)\times 100$ percentile of $N(0,1)$. The conditions required in Theorem 4.1 are so mild that our proposed testing is consistent no matter the number of machines is fixed or diverges at any rate.

Theorem 4.1 *(Testing Consistency) Suppose that $h \to 0$, $n \to \infty$ when $N \to \infty$, and $\lim_{N\to\infty} nh$ exists (which could be infinity). Then, we have under H_0,*

$$\frac{T_{N,\lambda} - \mu_{N,\lambda}}{\sigma_{N,\lambda}} \xrightarrow{d} N(0,1), \quad \text{as } N \to \infty.$$

Our next theorem analyzes the non-asymptotic power of $T_{N,\lambda}$, in which we pay particular attention to the impact of s on the separation rate of testing, defined as

$$d_{N,\lambda} = \sqrt{\lambda + n^{-2m} + \sigma_{N,\lambda}}.$$

Let $\mathcal{B} = \{f \in S^m(\mathbb{I}) : J(f) \leq C\}$ for a positive constant C.

Theorem 4.2 *(Upper Bound) Suppose that $h \to 0$, $n \to \infty$ when $N \to \infty$, and $\lim_{N\to\infty} nh$ exists (which could be infinity). Then for any $\varepsilon > 0$, there exist $C_\varepsilon, N_\varepsilon > 0$ s.t. for any $N \geq N_\varepsilon$,*

$$\inf_{\substack{f\in\mathcal{B} \\ \|f\|_2 \geq C_\varepsilon d_{N,\lambda}}} P_f\left(\phi_{N,\lambda} = 1\right) \geq 1 - \varepsilon. \tag{11}$$

Under assumptions of Theorem 4.1, it can be shown that (see (55) in Appendix)

$$\sigma^2_{N,\lambda} \asymp \begin{cases} \frac{n}{N^2}, & \text{if } \lim_{N\to 0} nh = 0, \\ \frac{1}{N^2 h}, & \text{if } \lim_{N\to\infty} nh > 0. \end{cases} \tag{12}$$

Given a range of λ leading to $\lim_{N\to\infty} nh > 0$, we have by (12) that $d_{N,\lambda} = \sqrt{\lambda + (Nh^{1/2})^{-1}}$. An optimal choice of λ (satisfying the above requirement) is $\lambda_{**} := N^{-4m/(4m+1)}$ since it leads to the optimal separating rate $d^*_{N,\lambda} := N^{-2m/(4m+1)}$; see Ingster (1993). Meanwhile, the constraint $\lim_{N\to\infty} nh > 0$ (together with the choice of λ_{**}) implies that

$$s = O(N^{(4m-1)/(4m+1)}). \tag{13}$$

The above discussions illustrate that we can always choose λ_{**} to obtain a minimax optimal testing (just as in the single dataset Shang and Cheng (2013)) as long as s does not grow faster than $N^{(4m-1)/(4m+1)}$. In the case that $\lim_{N\to\infty} nh = 0$, the minimax optimality can be maintained if $s \asymp N^{(4m-1)/(4m+1)}$, $h = o(1)$ and $nh = o(1)$. Such a selection of s gives us a lot of freedom in choosing λ that needs to satisfy $\lambda = o(\lambda_{**})$. A complete picture in depicting the relation between s and λ is given in Figure 3.

We further discover in Theorem 4.3 that the upper bound (13) turns out to be sharp.

Theorem 4.3 *(Lower Bound) Suppose that $s \gg N^{(4m-1)/(4m+1)}$, $h \to 0$, $n \to \infty$ when $N \to \infty$, and $\lim_{N\to\infty} nh$ exists (which could be infinity). Then there exists a positive sequence $\beta_{N,\lambda}$ with $\lim_{N\to\infty} \beta_{N,\lambda} = \infty$ s.t.*

$$\limsup_{N\to\infty} \inf_{\substack{f\in\mathcal{B} \\ \|f\|_2 \geq \beta_{N,\lambda} d^*_{N,\lambda}}} P_f\left(\phi_{N,\lambda} = 1\right) \leq \alpha. \tag{14}$$

Recall that $1-\alpha$ is the pre-specified significance level.

Theorem 4.3 says that when $s \gg N^{(4m-1)/(4m+1)}$, the test $\phi_{N,\lambda}$ is no longer powerful even when $\|f\|_2 \gg d^*_{N,\lambda}$. In other words, our test method fails to be optimal. Therefore, we claim that $N^{(4m-1)/(4m+1)}$ is a sharp upper bound of s to ensure our testing to be minimax optimal.

Remark 4.1 *As a side remark, the existence of $\lim_{N\to\infty} nh$ can be replaced by the following weaker condition under which the results in Theorems 4.1, 4.2 and 4.3 still hold:*

$$\textit{Condition } (\boldsymbol{R}) : \textit{either } \lim_{N\to\infty} nh = 0 \textit{ or } \inf_{N\geq 1} nh > 0.$$

Condition ($\boldsymbol{R}$) aims to exclude irregularly behaved s such as in the following case where s vibrates too much along with N:

$$s = \begin{cases} N^{b_1}, & N \textit{ is odd}, \\ N^{b_2}, & N \textit{ is even}, \end{cases} \tag{15}$$

where $h \asymp N^{-c}$ for some $c > 0$, $b_1, b_2 \in [0,1]$ satisfy $b_1 + c \geq 1$ and $b_2 + c < 1$. Clearly, Condition ($\boldsymbol{R}$) fails under (15).

5. Discussions

This paper offers "theoretical" suggestions on the allocation of data. In a relatively simple distributed algorithm, i.e., in m-order periodic splines with evenly spaced design, our recommendation proceeds as follows:

- Distribute to
$$s \asymp N^{2m/(2m+1)}$$
machines for obtaining an optimal estimate;
- Distribute to
$$s \asymp N^{(4m-1)/(4m+1)}$$
machines for performing an optimal test.

However, data-dependent formulae are still needed in picking a right number of machines in practice. This might be possible in light of Figure 3 indicating that sample splitting could be an alternative form of tuning. As for the choice of λ, we prove that it should be chosen in the order of N even when each subsample has size n. Hence, a distributed version of the generalized cross validation method is applied to each sub-sample; see Xu et al. (2017).

Another theoretically interesting direction is how much adaptive estimation (where m is unknown) can affect the computational limits.

6. Appendix

Proofs of our results are included in this section.

6.1 Proofs in Section 3

Proof [Proof of Theorem 3.1] We do a bit preliminary analysis before proving (4) and (5). It follows from Wahba (1990) that $(S^m(\mathbb{I}), J)$ is a reproducing kernel Hilbert space with reproducing kernel function

$$K(x,y)=\sum_{\nu=1}^{\infty}\frac{\varphi_\nu(x)\varphi_\nu(y)}{\gamma_\nu}=2\sum_{k=1}^{\infty}\frac{\cos(2\pi k(x-y))}{(2\pi k)^{2m}},\ x,y\in\mathbb{I}.$$

For convenience, define $K_x(\cdot)=K(x,\cdot)$ for any $x\in\mathbb{I}$. It follows from the representer theorem (Wahba (1990)) that the optimization to problem (3) has a solution

$$\widehat{f}_j=\sum_{i=1}^{n}\widehat{c}_{i,j}K_{t_{i,j}},\ j=1,2,\ldots,s, \tag{16}$$

where $\widehat{c}_j=(\widehat{c}_{1,j},\ldots,\widehat{c}_{n,j})^T=n^{-1}(\Sigma_j+\lambda I_n)^{-1}Y_j$, $Y_j=(Y_{1,j},\ldots,Y_{n,j})^T$, I_n is $n\times n$ identity matrix, and $\Sigma_j=[K(t_{i,j},t_{i',j})/n]_{1\le i,i'\le n}$. It is easy to see that $\Sigma_1=\Sigma_2=\cdots=\Sigma_s$. For convenience, denote $\Sigma=\Sigma_1$. Similarly, define

$$K'(x,y)=\sum_{\nu=1}^{\infty}\frac{\varphi_\nu(x)\varphi_\nu(y)}{\gamma_\nu^2}=2\sum_{k=1}^{\infty}\frac{\cos(2\pi k(x-y))}{(2\pi k)^{4m}},\ x,y\in\mathbb{I}.$$

For $1\le j\le s$, let $\Omega_j=[K'(t_{i,j},t_{i',j})/n]_{1\le i,i'\le n}$. It is easy to see that $\Omega_1=\Omega_2=\cdots=\Omega_s$. For convenience, denote $\Omega=\Omega_1$, and let $\Phi_{\nu,j}=(\varphi_\nu(t_{1,j}),\ldots,\varphi_\nu(t_{n,j}))$.

It is easy to examine that

$$\begin{aligned}\bar{f}&=\sum_{\nu=1}^{\infty}\frac{\sum_{j=1}^{s}\Phi_{\nu,j}(\Sigma+\lambda I_n)^{-1}Y_j}{N\gamma_\nu}\varphi_\nu\\&=\sum_{\nu=1}^{\infty}\frac{\sum_{j=1}^{s}\Phi_{\nu,j}(\Sigma+\lambda I_n)^{-1}(\mathbf{f}_{0,j}+\boldsymbol{\epsilon}_j)}{N\gamma_\nu}\varphi_\nu,\end{aligned} \tag{17}$$

and

$$E\{\bar{f}\}=\sum_{\nu=1}^{\infty}\frac{\sum_{j=1}^{s}\Phi_{\nu,j}(\Sigma+\lambda I_n)^{-1}\mathbf{f}_{0,j}}{N\gamma_\nu}\varphi_\nu, \tag{18}$$

where $\mathbf{f}_{0,j}=(f_0(t_{1,j}),\ldots,f_0(t_{n,j}))^T$ and $\boldsymbol{\epsilon}_j=(\epsilon_{1,j},\ldots,\epsilon_{n,j})^T$.

We now look at Σ and Ω. For $0\le l\le n-1$, let

$$\begin{aligned}c_l&=\frac{2}{n}\sum_{k=1}^{\infty}\frac{\cos(2\pi kl/n)}{(2\pi k)^{2m}},\\d_l&=\frac{2}{n}\sum_{k=1}^{\infty}\frac{\cos(2\pi kl/n)}{(2\pi k)^{4m}}.\end{aligned}$$

Since $c_l=c_{n-l}$ and $d_l=d_{n-l}$ for $l=1,2,\ldots,n-1$, Σ and Ω are both symmetric circulant of order n. Let $\varepsilon=\exp(2\pi\sqrt{-1}/n)$. Ω and Σ share the same normalized eigenvectors as

$$x_r=\frac{1}{\sqrt{n}}(1,\varepsilon^r,\varepsilon^{2r},\ldots,\varepsilon^{(n-1)r})^T,\ r=0,1,\ldots,n-1.$$

Let $M=(x_0,x_1,\ldots,x_{n-1})$. Denote M^* as the conjugate transpose of M. Clearly, $MM^*=I_n$ and Σ,Ω admits the following decomposition

$$\Sigma=M\Lambda_cM^*,\ \Omega=M\Lambda_dM^*, \tag{19}$$

where $\Lambda_c=\mathrm{diag}(\lambda_{c,0},\lambda_{c,1},\ldots,\lambda_{c,n-1})$ and $\Lambda_d=\mathrm{diag}(\lambda_{d,0},\lambda_{d,1},\ldots,\lambda_{d,n-1})$ with $\lambda_{c,l}=c_0+c_1\varepsilon^l+\ldots+c_{n-1}\varepsilon^{(n-1)l}$ and $\lambda_{d,l}=d_0+d_1\varepsilon^l+\ldots+d_{n-1}\varepsilon^{(n-1)l}$.

Direct calculations show that

$$\lambda_{c,l}=\begin{cases}2\sum_{k=1}^{\infty}\frac{1}{(2\pi kn)^{2m}}, & l=0,\\ \sum_{k=1}^{\infty}\frac{1}{[2\pi(kn-l)]^{2m}}+\sum_{k=0}^{\infty}\frac{1}{[2\pi(kn+l)]^{2m}}, & 1\le l\le n-1.\end{cases} \tag{20}$$

$$\lambda_{d,l}=\begin{cases}2\sum_{k=1}^{\infty}\frac{1}{(2\pi kn)^{4m}}, & l=0,\\ \sum_{k=1}^{\infty}\frac{1}{[2\pi(kn-l)]^{4m}}+\sum_{k=0}^{\infty}\frac{1}{[2\pi(kn+l)]^{4m}}, & 1\le l\le n-1.\end{cases} \tag{21}$$

It is easy to examine that

$$\lambda_{c,0}=2\bar{c}_m(2\pi n)^{-2m},\ \ \lambda_{d,0}=2\bar{d}_m(2\pi n)^{-4m}, \tag{22}$$

and for $1\le l\le n-1$,

$$\begin{aligned}\lambda_{c,l}&=\frac{1}{[2\pi(n-l)]^{2m}}+\frac{1}{(2\pi l)^{2m}}\\&\quad+\sum_{k=2}^{\infty}\frac{1}{[2\pi(kn-l)]^{2m}}+\sum_{k=1}^{\infty}\frac{1}{[2\pi(kn+l)]^{2m}},\\\lambda_{d,l}&=\frac{1}{[2\pi(n-l)]^{4m}}+\frac{1}{(2\pi l)^{4m}}\\&\quad+\sum_{k=2}^{\infty}\frac{1}{[2\pi(kn-l)]^{4m}}+\sum_{k=1}^{\infty}\frac{1}{[2\pi(kn+l)]^{4m}},\end{aligned} \tag{23}$$

and for $\bar{c}_m := \sum_{k=1}^{\infty} k^{-2m}$, $\underline{c}_m := \sum_{k=2}^{\infty} k^{-2m}$, $\bar{d}_m := \sum_{k=1}^{\infty} k^{-4m}$, $\underline{d}_m := \sum_{k=2}^{\infty} k^{-4m}$,

$$\underline{c}_m(2\pi n)^{-2m} \le \sum_{k=2}^{\infty} \frac{1}{[2\pi(kn-l)]^{2m}} \le \bar{c}_m(2\pi n)^{-2m},$$
$$\underline{c}_m(2\pi n)^{-2m} \le \sum_{k=1}^{\infty} \frac{1}{[2\pi(kn+l)]^{2m}} \le \bar{c}_m(2\pi n)^{-2m},$$

$$\underline{d}_m(2\pi n)^{-4m} \le \sum_{k=2}^{\infty} \frac{1}{[2\pi(kn-l)]^{4m}} \le \bar{d}_m(2\pi n)^{-4m},$$
$$\underline{d}_m(2\pi n)^{-4m} \le \sum_{k=1}^{\infty} \frac{1}{[2\pi(kn+l)]^{4m}} \le \bar{d}_m(2\pi n)^{-4m}.$$

For simplicity, we denote $I = E\{\|\bar{f} - E\{\bar{f}\}\|_2^2\}$ and $II = \|E\{\bar{f}\} - f_0\|_2^2$. Hence, $\mathrm{MSE}_{f_0}(\bar{f}) = I + II$.

Proof of (4)

Using (19) – (23), we get that

$$\begin{aligned}
I &= \sum_{\nu=1}^{\infty} \frac{\sum_{j=1}^{s} E\{|\Phi_{\nu,j}(\Sigma+\lambda I_n)^{-1}\boldsymbol{\epsilon}_j|^2\}}{N^2\gamma_\nu^2} \\
&= \sum_{\nu=1}^{\infty} \frac{\sum_{j=1}^{s} \mathrm{trace}((\Sigma+\lambda I_n)^{-1}\Phi_{\nu,j}^T\Phi_{\nu,j}(\Sigma+\lambda I_n)^{-1})}{N^2\gamma_\nu^2} \\
&= \frac{n}{N^2}\sum_{j=1}^{s} \mathrm{trace}\left((\Sigma+\lambda I_n)^{-1}\sum_{\nu=1}^{\infty}\frac{\Phi_{\nu,j}^T\Phi_{\nu,j}/n}{\gamma_\nu^2}(\Sigma+\lambda I_n)^{-1}\right) \\
&= \frac{n}{N^2}\sum_{j=1}^{s} \mathrm{trace}\left((\Sigma+\lambda I_n)^{-1}\Omega(\Sigma+\lambda I_n)^{-1}\right) \\
&= \frac{1}{N}\mathrm{trace}\left(M(\Lambda_c+\lambda I_n)^{-1}\Lambda_d(\Lambda_c+\lambda I_n)^{-1}M^*\right) \\
&= \frac{1}{N}\sum_{l=0}^{n-1}\frac{\lambda_{d,l}}{(\lambda+\lambda_{c,l})^2} \\
&\le \frac{2\bar{d}_m}{N(2\bar{c}_m+(2\pi n)^{2m}\lambda)^2} \\
&\quad +(1+\bar{d}_m)N^{-1}\sum_{l=1}^{n-1}\frac{(2\pi(n-l))^{-4m}+(2\pi l)^{-4m}}{(\lambda+(2\pi(n-l))^{-2m}+(2\pi l)^{-2m})^2} \\
&\le \frac{2\bar{d}_m}{N(2\bar{c}_m+(2\pi n)^{2m}\lambda)^2} \\
&\quad +2(1+\bar{d}_m)N^{-1}\sum_{1\le l\le n/2}\frac{(2\pi l)^{-4m}+(2\pi(n-l))^{-4m}}{(\lambda+(2\pi l)^{-2m}+(2\pi(n-l))^{-2m})^2} \\
&\le \frac{2\bar{d}_m}{N(2\bar{c}_m+(2\pi n)^{2m}\lambda)^2}+4(1+\bar{d}_m)N^{-1}\sum_{1\le l\le n/2}\frac{(2\pi l)^{-4m}}{(\lambda+(2\pi l)^{-2m})^2} \\
&\le \frac{2\bar{d}_m}{N(2\bar{c}_m+(2\pi n)^{2m}\lambda)^2}+\frac{2(1+\bar{d}_m)}{\pi Nh}\int_0^{\pi nh}\frac{1}{(1+x^{2m})^2}dx \\
&\le b_m\left(\frac{1}{N}+\frac{1}{Nh}\int_0^{\pi nh}\frac{1}{(1+x^{2m})^2}dx\right),
\end{aligned}$$

where $b_m \ge 1$ is an absolute constant depending on m only. This proves (4).

Proof of (5)

Throughout, let $\eta = \exp(2\pi\sqrt{-1}/N)$. For $1 \le j, l \le s$, define

$$\begin{aligned}
\Sigma_{j,l} &= \frac{1}{n}\sum_{\nu=1}^{\infty}\frac{\Phi_{\nu,j}^T\Phi_{\nu,l}}{\gamma_\nu}, \\
\sigma_{j,l,r} &= \frac{2}{n}\sum_{k=1}^{\infty}\frac{\cos\left(2\pi k\left(\frac{r}{n}-\frac{j-l}{N}\right)\right)}{(2\pi k)^{2m}},\ r=0,1,\ldots,n-1.
\end{aligned}$$

It can be shown that $\Sigma_{j,l}$ is a circulant matrix with elements $\sigma_{j,l,0}, \sigma_{j,l,1}, \ldots, \sigma_{j,l,n-1}$, therefore, by Brockwell and Davis (1987) we get that

$$\Sigma_{j,l} = M \Lambda_{j,l} M^*, \tag{24}$$

where M is the same as in (19), and $\Lambda_{j,l} = \mathrm{diag}(\lambda_{j,l,0}, \lambda_{j,l,1}, \ldots, \lambda_{j,l,n-1})$, with $\lambda_{j,l,r}$, for $r = 1, \ldots, n-1$, given by the following

$$\begin{aligned}
\lambda_{j,l,r} &= \sum_{t=0}^{n-1} \sigma_{j,l,t} \varepsilon^{rt} \\
&= \frac{2}{n} \sum_{t=0}^{n-1} \sum_{k=1}^{\infty} \frac{\cos\left(2\pi k \left(\frac{t}{n} - \frac{j-l}{N}\right)\right)}{(2\pi k)^{2m}} \varepsilon^{rt} \\
&= \frac{1}{n} \sum_{k=1}^{\infty} \frac{\eta^{-k(j-l)} \sum_{t=0}^{n-1} \varepsilon^{(k+r)t} + \eta^{k(j-l)} \sum_{t=0}^{n-1} \varepsilon^{(r-k)t}}{(2\pi k)^{2m}} \\
&= \sum_{q=1}^{\infty} \frac{\eta^{-(qn-r)(j-l)}}{[2\pi(qn-r)]^{2m}} + \sum_{q=0}^{\infty} \frac{\eta^{(qn+r)(j-l)}}{[2\pi(qn+r)]^{2m}},
\end{aligned} \tag{25}$$

and for $r = 0$, given by

$$\begin{aligned}
\lambda_{j,l,0} &= \sum_{t=0}^{n-1} \sigma_{j,l,t} \\
&= \frac{1}{n} \sum_{k=1}^{\infty} \frac{\sum_{t=0}^{n-1} \varepsilon^{kt} \eta^{k(j-l)} + \sum_{t=0}^{n-1} \varepsilon^{-kt} \eta^{-k(j-l)}}{(2\pi k)^{2m}} \\
&= \sum_{q=1}^{\infty} \frac{\eta^{qn(j-l)} + \eta^{-qn(j-l)}}{(2\pi qn)^{2m}}.
\end{aligned} \tag{26}$$

For $p \geq 0$, $1 \leq v \leq n$, $0 \leq r \leq n-1$ and $1 \leq j \leq s$, define

$$A_{p,v,r,j} = \frac{1}{s} \sum_{l=1}^{s} \lambda_{j,l,r} x_r^* \Phi_{2(pn+v)-1,l}^T, \quad B_{p,v,r,j} = \frac{1}{s} \sum_{l=1}^{s} \lambda_{j,l,r} x_r^* \Phi_{2(pn+v),l}^T.$$

By direct calculation, we have for $1 \leq v \leq n-1$,

$$\begin{aligned}
\Phi_{2(pn+v)-1,l} x_r &= \sqrt{n/2} \left(\eta^{(pn+v)(l-1)} I(r+v=n) + \eta^{-(pn+v)(l-1)} I(v=r)\right), \\
\Phi_{2(pn+v),l} x_r &= \sqrt{-n/2} \left(\eta^{(pn+v)(l-1)} I(r+v=n) - \eta^{-(pn+v)(l-1)} I(v=r)\right),
\end{aligned} \tag{27}$$

and

$$\begin{aligned}
\Phi_{2(pn+n)-1,l} x_r &= \sqrt{n/2} I(r=0) \left(\eta^{(p+1)n(l-1)} + \eta^{-(p+1)n(l-1)}\right), \\
\Phi_{2(pn+n),l} x_r &= \sqrt{-n/2} I(r=0) \left(\eta^{(p+1)n(l-1)} - \eta^{-(p+1)n(l-1)}\right).
\end{aligned} \tag{28}$$

Let $I(\cdot)$ be an indicator function. Then we have for $p \geq 0$, $1 \leq j \leq s$ and $1 \leq v, r \leq n-1$,

$$\begin{aligned}
B_{p,v,r,j} &= \frac{1}{s} \sum_{l=1}^{s} \lambda_{j,l,r} x_r^* \Phi_{2(pn+v),l}^T \\
&= -\frac{1}{s} \sqrt{-n/2} \sum_{l=1}^{s} \left(\sum_{q=1}^{\infty} \frac{\eta^{-(qn-r)(j-l)}}{[2\pi(qn-r)]^{2m}} + \sum_{q=0}^{\infty} \frac{\eta^{(qn+r)(j-l)}}{[2\pi(qn+r)]^{2m}} \right) \\
&\quad \times \left(\eta^{-(pn+v)(l-1)} I(r+v=n) - \eta^{(pn+v)(l-1)} I(r=v) \right) \\
&= -\sqrt{-n/2} \left(\sum_{u \geq -p/s} \frac{\eta^{-(pn+v)(j-1)}}{[2\pi(uN+pn+v)]^{2m}} I(r+v=n) \right. \\
&\quad - \sum_{u \geq (p+1)/s} \frac{\eta^{(pn+v)(j-1)}}{[2\pi(uN-pn-v)]^{2m}} I(r=v) \\
&\quad + \sum_{u \geq (p+1)/s} \frac{\eta^{-(pn+v)(j-1)}}{[2\pi(uN-pn-v)]^{2m}} I(r+v=n) \\
&\quad \left. - \sum_{u \geq -p/s} \frac{\eta^{(pn+v)(j-1)}}{[2\pi(uN+pn+v)]^{2m}} I(r=v) \right) = a_{p,v} x_r^* \Phi_{2(pn+v),j}^T,
\end{aligned} \tag{29}$$

where $a_{p,v} = \sum_{u \geq -p/s} \frac{1}{[2\pi(uN+pn+v)]^{2m}} + \sum_{u \geq (p+1)/s} \frac{1}{[2\pi(uN-pn-v)]^{2m}}$, for $p \geq 0$, $1 \leq v \leq n-1$.

For $v = n$, similar calculations give that

$$\begin{aligned}
B_{p,n,r,j} &= -\sqrt{-n/2} I(r=0) \left(\sum_{u \geq -p/s} \frac{\eta^{-(pn+n)(j-1)}}{[2\pi(uN+pn+n)]^{2m}} \right. \\
&\quad - \sum_{u \geq (p+2)/s} \frac{\eta^{(pn+n)(j-1)}}{[2\pi(uN-pn-n)]^{2m}} \\
&\quad \left. + \sum_{u \geq (p+2)/s} \frac{\eta^{-(pn+n)(j-1)}}{[2\pi(uN-pn-n)]^{2m}} - \sum_{u \geq -p/s} \frac{\eta^{(pn+n)(j-1)}}{[2\pi(uN+pn+n)]^{2m}} \right) \\
&= a_{p,n} x_r^* \Phi_{2(pn+n),j}^T,
\end{aligned} \tag{30}$$

where $a_{p,n} = \sum_{u \geq -p/s} \frac{1}{[2\pi(uN+pn+n)]^{2m}} + \sum_{u \geq (p+2)/s} \frac{1}{[2\pi(uN-pn-n)]^{2m}}$, for $p \geq 0$.

Similarly, we have $p \geq 0$, $1 \leq j \leq s$ and $1 \leq v, r \leq n-1$,

$$\begin{aligned} A_{p,v,r,j} &= \sqrt{n/2}\left(\sum_{u\geq -p/s}\frac{\eta^{-(pn+v)(j-1)}}{[2\pi(uN+pn+v)]^{2m}}I(r+v=n)\right. \\ &+\sum_{u\geq (p+1)/s}\frac{\eta^{(pn+v)(j-1)}}{[2\pi(uN-pn-v)]^{2m}}I(r=v) \\ &+\sum_{u\geq (p+1)/s}\frac{\eta^{-(pn+v)(j-1)}}{[2\pi(uN-pn-v)]^{2m}}I(r+v=n) \\ &\left.+\sum_{u\geq -p/s}\frac{\eta^{(pn+v)(j-1)}}{[2\pi(uN+pn+v)]^{2m}}I(r=v)\right) = a_{p,v}x_r^*\Phi^T_{2(pn+v)-1,j}, \end{aligned} \tag{31}$$

and for $v = n$,

$$\begin{aligned} A_{p,n,r,j} &= \sqrt{n/2}I(r=0)\left(\sum_{u\geq -p/s}\frac{\eta^{-(pn+n)(j-1)}}{[2\pi(uN+pn+n)]^{2m}}\right. \\ &+\sum_{u\geq (p+2)/s}\frac{\eta^{(pn+n)(j-1)}}{[2\pi(uN-pn-n)]^{2m}}+\sum_{u\geq (p+2)/s}\frac{\eta^{-(pn+n)(j-1)}}{[2\pi(uN-pn-n)]^{2m}} \\ &\left.+\sum_{u\geq -p/s}\frac{\eta^{(pn+n)(j-1)}}{[2\pi(uN+pn+n)]^{2m}}\right) = a_{p,n}x_r^*\Phi^T_{2(pn+n)-1,j}. \end{aligned} \tag{32}$$

It is easy to check that both (29) and (31) hold for $r = 0$. Summarizing (29)–(32), we have that for $p \geq 0$, $1 \leq j \leq s$, $1 \leq v \leq n$ and $0 \leq r \leq n-1$,

$$\begin{aligned} A_{p,v,r,j} &= a_{p,v}x_r^*\Phi^T_{2(pn+v)-1,j}, \\ B_{p,v,r,j} &= a_{p,v}x_r^*\Phi^T_{2(pn+v),j}. \end{aligned} \tag{33}$$

To show (5), let $\bar{\boldsymbol{f}}_j = (E\{\bar{f}(t_{1,j})\},\ldots,E\{\bar{f}(t_{n,j})\})^T$, for $1 \leq j \leq s$. It follows by (18) that

$$\begin{aligned} \bar{\boldsymbol{f}}_j &= \sum_{\nu=1}^{\infty}\frac{\sum_{l=1}^s \Phi_{\nu,l}(\Sigma+\lambda I_n)^{-1}\mathbf{f}_{0,l}}{N\gamma_\nu}\Phi^T_{\nu,j} \\ &= \frac{1}{s}\sum_{l=1}^{s}\left(\frac{1}{n}\sum_{\nu=1}^{\infty}\frac{\Phi^T_{\nu,j}\Phi_{\nu,l}}{\gamma_\nu}\right)(\Sigma+\lambda I_n)^{-1}\mathbf{f}_{0,l} \\ &= \frac{1}{s}\sum_{l=1}^{s}\Sigma_{j,l}(\Sigma+\lambda I_n)^{-1}\mathbf{f}_{0,l} \\ &= \frac{1}{s}\sum_{l=1}^{s}M\Lambda_{j,l}(\Lambda_c+\lambda I_n)^{-1}M^*\mathbf{f}_{0,l}, \end{aligned}$$

together with (33), leading to that

$$\begin{aligned} M^*\bar{\boldsymbol{f}}_j &= \frac{1}{s}\sum_{l=1}^{s}\Lambda_{j,l}(\Lambda_c+\lambda I_n)^{-1}M^*\mathbf{f}_{0,l} \\ &= \sum_{\mu=1}^{\infty}f_\mu^0\begin{pmatrix}\frac{\frac{1}{s}\sum_{l=1}^s\lambda_{j,l,0}x_0^*\Phi^T_{\mu,l}}{\lambda+\lambda_{c,0}}\\ \vdots \\ \frac{\frac{1}{s}\sum_{l=1}^s\lambda_{j,l,n-1}x_{n-1}^*\Phi^T_{\mu,l}}{\lambda+\lambda_{c,n-1}}\end{pmatrix} \\ &= \sum_{p=0}^{\infty}\sum_{v=1}^{n}f^0_{2(pn+v)-1}\begin{pmatrix}\frac{\frac{1}{s}\sum_{l=1}^s\lambda_{j,l,0}x_0^*\Phi^T_{2(pn+v)-1,l}}{\lambda+\lambda_{c,0}}\\ \vdots \\ \frac{\frac{1}{s}\sum_{l=1}^s\lambda_{j,l,n-1}x_{n-1}^*\Phi^T_{2(pn+v)-1,l}}{\lambda+\lambda_{c,n-1}}\end{pmatrix} \\ &+\sum_{p=0}^{\infty}\sum_{v=1}^{n}f^0_{2(pn+v)}\begin{pmatrix}\frac{\frac{1}{s}\sum_{l=1}^s\lambda_{j,l,0}x_0^*\Phi^T_{2(pn+v),l}}{\lambda+\lambda_{c,0}}\\ \vdots \\ \frac{\frac{1}{s}\sum_{l=1}^s\lambda_{j,l,n-1}x_{n-1}^*\Phi^T_{2(pn+v),l}}{\lambda+\lambda_{c,n-1}}\end{pmatrix} \\ &= \sum_{p=0}^{\infty}\sum_{v=1}^{n}f^0_{2(pn+v)-1}\begin{pmatrix}\frac{A_{p,v,0,j}}{\lambda+\lambda_{c,0}}\\ \vdots \\ \frac{A_{p,v,n-1,j}}{\lambda+\lambda_{c,n-1}}\end{pmatrix}+\sum_{p=0}^{\infty}\sum_{v=1}^{n}f^0_{2(pn+v)}\begin{pmatrix}\frac{B_{p,v,0,j}}{\lambda+\lambda_{c,0}}\\ \vdots \\ \frac{B_{p,v,n-1,j}}{\lambda+\lambda_{c,n-1}}\end{pmatrix} \\ &= \sum_{p=0}^{\infty}\sum_{v=1}^{n}f^0_{2(pn+v)-1}\begin{pmatrix}\frac{a_{p,v}}{\lambda+\lambda_{c,0}}x_0^*\Phi^T_{2(pn+v)-1,j}\\ \vdots \\ \frac{a_{p,v}}{\lambda+\lambda_{c,n-1}}x_{n-1}^*\Phi^T_{2(pn+v)-1,j}\end{pmatrix} \\ &+\sum_{p=0}^{\infty}\sum_{v=1}^{n}f^0_{2(pn+v)}\begin{pmatrix}\frac{a_{p,v}}{\lambda+\lambda_{c,0}}x_0^*\Phi^T_{2(pn+v),j}\\ \vdots \\ \frac{a_{p,v}}{\lambda+\lambda_{c,n-1}}x_{n-1}^*\Phi^T_{2(pn+v),j}\end{pmatrix}. \end{aligned}$$

On the other hand,

$$\begin{aligned} M^*\mathbf{f}_{0,j} &= \sum_{\mu=1}^{\infty}f_\mu^0M^*\Phi^T_{\mu,j} \\ &= \sum_{p=0}^{\infty}\sum_{v=1}^{n}f^0_{2(pn+v)-1}M^*\Phi^T_{2(pn+v)-1,j}+\sum_{p=0}^{\infty}\sum_{v=1}^{n}f^0_{2(pn+v)}M^*\Phi^T_{2(pn+v),j} \\ &= \sum_{p=0}^{\infty}\sum_{v=1}^{n}f^0_{2(pn+v)-1}\begin{pmatrix}x_0^*\Phi^T_{2(pn+v)-1,j}\\ \vdots \\ x_{n-1}^*\Phi^T_{2(pn+v)-1,j}\end{pmatrix}+\sum_{p=0}^{\infty}\sum_{v=1}^{n}f^0_{2(pn+v)}\begin{pmatrix}x_0^*\Phi^T_{2(pn+v),j}\\ \vdots \\ x_{n-1}^*\Phi^T_{2(pn+v),j}\end{pmatrix}. \end{aligned}$$

Therefore,

$$M^*(\bar{\boldsymbol{f}}_j - \mathbf{f}_{0,j}) = \sum_{p=0}^{\infty}\sum_{v=1}^{n} f^0_{2(pn+v)-1} \begin{pmatrix} b_{p,v,0}x_0^*\Phi^T_{2(pn+v)-1,j} \\ \vdots \\ b_{p,v,n-1}x_{n-1}^*\Phi^T_{2(pn+v)-1,j} \end{pmatrix} + \sum_{p=0}^{\infty}\sum_{v=1}^{n} f^0_{2(pn+v)} \begin{pmatrix} b_{p,v,0}x_0^*\Phi^T_{2(pn+v),j} \\ \vdots \\ b_{p,v,n-1}x_{n-1}^*\Phi^T_{2(pn+v),j} \end{pmatrix}, \quad (34)$$

where $b_{p,v,r} = \frac{a_{p,v}}{\lambda+\lambda_{c,r}} - 1$, for $p \geq 0$, $1 \leq v \leq n$ and $0 \leq r \leq n-1$.

It holds the trivial observation $b_{ks+g,v,r} = b_{g,v,r}$ for $k \geq 0$, $0 \leq g \leq s-1$, $1 \leq v \leq n$ and $0 \leq r \leq n-1$. Define $C_{g,r} = \sum_{k=0}^{\infty}(f^0_{2(kN+gn+n-r)-1} - \sqrt{-1}f^0_{2(kN+gn+n-r)})$ and $D_{g,r} = \sum_{k=0}^{\infty}(f^0_{2(kN+gn+r)-1} + \sqrt{-1}f^0_{2(kN+gn+r)})$, for $0 \leq g \leq s-1$ and $0 \leq r \leq n-1$. Also denote $\overline{C_{g,r}}$ and $\overline{D_{g,r}}$ as their conjugate. By (27) and (28), and direct calculations we get that, for $1 \leq j \leq s$ and $1 \leq r \leq n-1$,

$$\begin{aligned}\delta_{j,r} &\equiv \sum_{p=0}^{\infty}\left(\sum_{v=1}^{n} f^0_{2(pn+v)-1}b_{p,v,r}x_r^*\Phi^T_{2(pn+v)-1,j} + \sum_{v=1}^{n} f^0_{2(pn+v)}b_{p,v,r}x_r^*\Phi^T_{2(pn+v),j}\right) \\ &= \sqrt{\frac{n}{2}}\sum_{p=0}^{\infty}\Big[(f^0_{2(pn+n-r)-1} - \sqrt{-1}f^0_{2(pn+n-r)})b_{p,n-r,r}\eta^{-(pn+n-r)(j-1)} \\ &\quad +(f^0_{2(pn+r)-1} + \sqrt{-1}f^0_{2(pn+r)})b_{p,r,r}\eta^{(pn+r)(j-1)}\Big], \quad (35)\end{aligned}$$

leading to that

$$\begin{aligned}\sum_{j=1}^{s}|\delta_{j,r}|^2 &= \frac{n}{2}\sum_{j=1}^{s}\left|\sum_{p=0}^{\infty}\Big[(f^0_{2(pn+n-r)-1} - \sqrt{-1}f^0_{2(pn+n-r)})b_{p,n-r,r}\eta^{-(pn+n-r)(j-1)} \right.\\ &\quad \left. +(f^0_{2(pn+r)-1} + \sqrt{-1}f^0_{2(pn+r)})b_{p,r,r}\eta^{(pn+r)(j-1)}\Big]\right|^2 \\ &= \frac{n}{2}\sum_{j=1}^{s}\left|\sum_{g=0}^{s-1}\left(C_{g,r}b_{g,n-r,r}\eta^{-(gn+n-r)(j-1)} + D_{g,r}b_{g,r,r}\eta^{(gn+r)(j-1)}\right)\right|^2 \\ &= \frac{n}{2}\sum_{g,g'=0}^{s-1}\sum_{j=1}^{s}(C_{g,r}b_{g,n-r,r}\eta^{-(gn+n-r)(j-1)} + D_{g,r}b_{g,r,r}\eta^{(gn+r)(j-1)}) \\ &\quad \times(\overline{C_{g',r}}b_{g',n-r,r}\eta^{(g'n+n-r)(j-1)} + \overline{D_{g',r}}b_{g',r,r}\eta^{-(g'n+r)(j-1)}) \\ &= \frac{N}{2}\sum_{g=0}^{s-1}(|C_{g,r}|^2b^2_{g,n-r,r} + C_{g,r}\overline{D_{s-1-g,r}}b_{g,n-r,r}b_{s-1-g,r,r} \\ &\quad +D_{g,r}\overline{C_{s-1-g,r}}b_{g,r,r}b_{s-1-g,n-r,r} + |D_{g,r}|^2b^2_{g,r,r}) \\ &= \frac{N}{2}\sum_{g=0}^{s-1}|C_{g,r}b_{g,n-r,r} + D_{s-1-g,r}b_{s-1-g,r,r}|^2 \quad (36) \\ &\leq N\sum_{g=0}^{s-1}(|C_{g,r}|^2b^2_{g,n-r,r} + |D_{s-1-g,r}|^2b^2_{s-1-g,r,r}) \\ &= N\sum_{g=0}^{s-1}(|C_{g,r}|^2b^2_{g,n-r,r} + |D_{g,r}|^2b^2_{g,r,r}).\end{aligned}$$

It is easy to see that for $0 \leq g \leq s-1$ and $1 \leq r \leq n-1$,

$$\begin{aligned}|C_{g,r}|^2 &= (\sum_{k=0}^{\infty} f^0_{2(kN+gn+n-r)-1})^2 + (\sum_{k=0}^{\infty} f^0_{2(kN+gn+n-r)})^2 \\ &\leq \sum_{k=0}^{\infty}(|f^0_{2(kN+gn+n-r)-1}|^2 + |f^0_{2(kN+gn+n-r)}|^2)(kN+gn+n-r)^{2m} \\ &\quad \times\sum_{k=0}^{\infty}(kN+gn+n-r)^{-2m} \\ &\leq \sum_{k=0}^{\infty}(|f^0_{2(kN+gn+n-r)-1}|^2 + |f^0_{2(kN+gn+n-r)}|^2)(kN+gn+n-r)^{2m} \\ &\quad \times\frac{2m}{2m-1}(gn+n-r)^{-2m}, \quad (37)\end{aligned}$$

and

$$\begin{aligned}|D_{g,r}|^2 &\leq \sum_{k=0}^{\infty}(|f^0_{2(kN+gn+r)}|^2 + |f^0_{2(kN+gn+r)-1}|^2)(kN+gn+r)^{2m} \\ &\quad \times\frac{2m}{2m-1}(gn+r)^{-2m}. \quad (38)\end{aligned}$$

For $1 \leq g \leq s-1$, we have $a_{g,n-r} \leq \lambda_{c,r}$, which further leads to $|b_{g,n-r,r}| \leq 2$. Meanwhile, by (20), we have

$$0 \leq \lambda_{c,r} - a_{0,r} \leq (2\pi(n-r))^{-2m} + 2\bar{c}_m(2\pi n)^{-2m} \leq (1+2\bar{c}_m)(2\pi(n-r))^{-2m}.$$

Then we have

$$\begin{aligned}|b_{0,r,r}| &= \frac{\lambda+\lambda_{c,r}-a_{0,r}}{\lambda+\lambda_{c,r}} \\ &\leq \frac{\lambda+(1+2\bar{c}_m)(2\pi(n-r))^{-2m}}{\lambda+(2\pi r)^{-2m}+(2\pi(n-r))^{-2m}} \\ &\leq (1+2\bar{c}_m)\frac{\lambda+(2\pi(n-r))^{-2m}}{\lambda+(2\pi r)^{-2m}+(2\pi(n-r))^{-2m}},\end{aligned}$$

leading to

$$\begin{aligned}r^{-2m}b^2_{0,r,r} &\leq r^{-2m}(1+2\bar{c}_m)^2\left(\frac{\lambda+(2\pi(n-r))^{-2m}}{\lambda+(2\pi(n-r))^{-2m}+(2\pi r)^{-2m}}\right)^2 \\ &\leq r^{-2m}(1+2\bar{c}_m)^2\left(\frac{\lambda+(2\pi(n-r))^{-2m}}{\lambda+(2\pi(n-r))^{-2m}+(2\pi r)^{-2m}}\right) \\ &\leq (2\pi)^{2m}(1+2\bar{c}_m)^2(\lambda+(\pi n)^{-2m}). \quad (39)\end{aligned}$$

The last inequality can be proved in two different cases: $2r \leq n$ and $2r > n$. Similarly, it can be shown that $(n-r)^{-2m}b^2_{0,n-r,r} \leq (2\pi)^{2m}(1+2\bar{c}_m)^2(\lambda+(\pi n)^{-2m})$.

Then we have by (37)–(39) that

$$\begin{aligned}\sum_{r=1}^{n-1}\sum_{g=0}^{s-1}|D_{g,r}|^2b_{g,r,r}^2 &\le \sum_{r=1}^{n-1}\sum_{g=1}^{s-1}\sum_{k=0}^{\infty}(|f^0_{2(kN+gn+r)}|^2+|f^0_{2(kN+gn+r)-1}|^2)(kN+gn+r)^{2m}\\ &\quad\times\frac{2m}{2m-1}(gn+r)^{-2m}2^2+\sum_{r=1}^{n-1}\sum_{k=0}^{\infty}(|f^0_{2(kN+r)}|^2+|f^0_{2(kN+r)-1}|^2)(kN+r)^{2m}\\ &\quad\times\frac{2m}{2m-1}r^{-2m}b_{0,r,r}^2\\ &\le c'_m(\lambda+n^{-2m})\sum_{r=1}^{n-1}\sum_{g=0}^{s-1}\sum_{k=0}^{\infty}(|f^0_{2(kN+gn+r)}|^2+|f^0_{2(kN+gn+r)-1}|^2)\\ &\quad\times(2\pi(kN+gn+r))^{2m}, \qquad (40)\end{aligned}$$

where $c'_m=\max\{(2\pi)^{-2m}\frac{8m}{2m-1},(1+2\bar{c}_m)^2\frac{2m}{2m-1}\}$. Similarly, one can show that

$$\begin{aligned}\sum_{r=1}^{n-1}\sum_{g=0}^{s-1}|C_{g,r}|^2b_{g,n-r,r}^2 &\le c'_m(\lambda+n^{-2m})\sum_{r=1}^{n-1}\sum_{g=0}^{s-1}\sum_{k=0}^{\infty}(|f^0_{2(kN+gn+r)}|^2+|f^0_{2(kN+gn+r)-1}|^2)\\ &\quad\times(2\pi(kN+gn+r))^{2m}. \qquad (41)\end{aligned}$$

Combining (40) and (41) we get that

$$\begin{aligned}\sum_{r=1}^{n-1}\sum_{j=1}^{s}|\delta_{j,r}|^2 &\le 2c'_m(\lambda+n^{-2m})N\sum_{r=1}^{n-1}\sum_{g=0}^{s-1}\sum_{k=0}^{\infty}(|f^0_{2(kN+gn+r)}|^2+|f^0_{2(kN+gn+r)-1}|^2)\\ &\quad\times(2\pi(kN+gn+r))^{2m}. \qquad (42)\end{aligned}$$

To the end of proof of (5), by (34) we have for $1\le j\le s$,

$$\begin{aligned}\delta_{j,0} &\equiv \sum_{p=0}^{\infty}\left(\sum_{v=1}^{n}f^0_{2(pn+v)-1}b_{p,v,0}x_0^*\Phi^T_{2(pn+v)-1,j}+\sum_{v=1}^{n}f^0_{2(pn+v)}b_{p,v,0}x_0^*\Phi^T_{2(pn+v),j}\right)\\ &= \sum_{p=0}^{\infty}\left(f^0_{2(pn+n)-1}b_{p,n,0}x_0^*\Phi^T_{2(pn+n)-1,j}+f^0_{2(pn+n)}b_{p,n,0}x_0^*\Phi^T_{2(pn+n),j}\right)\\ &= \sqrt{\frac{n}{2}}\sum_{p=0}^{\infty}\Big[(f^0_{2(pn+n)-1}-\sqrt{-1}f^0_{2(pn+n)})b_{p,n,0}\eta^{-(p+1)n(j-1)}\\ &\quad+(f^0_{2(pn+n)-1}+\sqrt{-1}f^0_{2(pn+n)})b_{p,n,0}\eta^{(p+1)n(j-1)}\Big]\\ &= \sqrt{\frac{n}{2}}\sum_{g=0}^{s-1}\Big[\sum_{k=0}^{\infty}(f^0_{2(kN+gn+n)-1}-\sqrt{-1}f^0_{2(kN+gn+n)})b_{g,n,0}\eta^{-(gn+n)(j-1)}\\ &\quad+\sum_{k=0}^{\infty}(f^0_{2(kN+gn+n)-1}+\sqrt{-1}f^0_{2(kN+gn+n)})b_{g,n,0}\eta^{(gn+n)(j-1)}\Big]\\ &= \sqrt{\frac{n}{2}}\sum_{g=0}^{s-1}\Big[C_{g,0}b_{g,n,0}\eta^{-(gn+n)(j-1)}+D_{g,n}b_{g,n,0}\eta^{(gn+n)(j-1)}\Big], \qquad (43)\end{aligned}$$

which, together with Cauchy-Schwartz inequality, (37)–(38), and the trivial fact $|b_{g,n,0}|\le 2$ for $0\le g\le s-1$, leads to

$$\begin{aligned}\sum_{j=1}^{s}|\delta_{j,0}|^2 &\le n\sum_{j=1}^{s}\Big|\sum_{g=0}^{s-1}C_{g,0}b_{g,n,0}\eta^{-(gn+n)(j-1)}\Big|^2+n\sum_{j=1}^{s}\Big|\sum_{g=0}^{s-1}D_{g,n}b_{g,n,0}\eta^{(gn+n)(j-1)}\Big|^2\\ &= N\left(\sum_{g=0}^{s-1}|C_{g,0}|^2b_{g,n,0}^2+\sum_{g=0}^{s-1}|D_{g,n}|^2b_{g,n,0}^2\right)\\ &\le 2c'_mn^{-2m}N\sum_{g=0}^{s-1}\sum_{k=0}^{\infty}(|f^0_{2(kN+gn+n)-1}|^2+|f^0_{2(kN+gn+n)}|^2)\times(2\pi(kN+gn+n))^{2m}. \qquad (44)\end{aligned}$$

Combining (42) and (44) we get that

$$\begin{aligned}\sum_{j=1}^{s}\sum_{i=1}^{n}(E\{\bar{f}\}(t_{i,j})-f_0(t_{i,j}))^2 &= \sum_{r=0}^{n-1}\sum_{g=0}^{s-1}|\delta_{j,r}|^2\\ &\le 2c'_m(\lambda+n^{-2m})N\sum_{i=1}^{n}\sum_{g=0}^{s-1}\sum_{k=0}^{\infty}(|f^0_{2(kN+gn+i)}|^2+|f^0_{2(kN+gn+i)-1}|^2)\\ &\quad\times(2\pi(kN+gn+i))^{2m}=2c'_m(\lambda+n^{-2m})NJ(f_0). \qquad (45)\end{aligned}$$

Next we will apply (45) to show (5). Since $\widehat{f}_j$ is the minimizer of $\ell_{j,n,\lambda}(f)$, it satisfies for $1\le j\le s$,

$$-\frac{1}{n}\sum_{i=1}^{n}(Y_{i,j}-\widehat{f}_j(t_{i,j}))K_{t_{i,j}}+\lambda\widehat{f}_j=0.$$

Taking expectations, we get that

$$\frac{1}{n}\sum_{i=1}^{n}(E\{\widehat{f}_j\}(t_{i,j})-f_0(t_{i,j}))K_{t_{i,j}}+\lambda E\{\widehat{f}_j\},$$

therefore, $E\{\widehat{f}_j\}$ is the minimizer to the following functional

$$\ell_{0j}(f)=\frac{1}{2n}\sum_{i=1}^{n}(f(t_{i,j})-f_0(t_{i,j}))^2+\frac{\lambda}{2}J(f).$$

Define $g_j=E\{\widehat{f}_j\}$. Since $\ell_{0j}(g_j)\le\ell_{0j}(f_0)$, we get

$$\frac{1}{2n}\sum_{i=1}^{n}(g_j(t_{i,j})-f_0(t_{i,j}))^2+\frac{\lambda}{2}J(g_j)\le\frac{\lambda}{2}J(f_0).$$

This means that $J(g_j)\le J(f_0)$, leading to

$$\|\frac{1}{s}\sum_{j=1}^{s}g_j^{(m)}\|_2\le\frac{1}{s}\sum_{j=1}^{s}\|g_j^{(m)}\|_2\le\sqrt{J(f_0)}. \qquad (46)$$

Note that $E\{\bar{f}\} = \frac{1}{s}\sum_{j=1}^{s} g_j$. Define $g(t) = (E\{\bar{f}\}(t) - f_0(t))^2$. By (Eggermont and LaRiccia, 2009, Lemma (2.24), pp. 58), (46) and $m \geq 1$ we get that

$$\begin{aligned}\Big|\frac{1}{N}\sum_{l=0}^{N-1} g(l/N) - \int_0^1 g(t)dt\Big| &\leq \frac{2}{N}\int_0^1 \big|\frac{1}{s}\sum_{j=1}^{s} g_j(t) - f_0(t)\big| \times \big|\frac{1}{s}\sum_{j=1}^{s} g_j'(t) - f_0'(t)\big|dt \\ &\leq \frac{2}{N}\|\frac{1}{s}\sum_{j=1}^{s} g_j - f_0\|_2 \times \|\frac{1}{s}\sum_{j=1}^{s} g_j' - f_0'\|_2 \\ &\leq \frac{2}{N}\|\frac{1}{s}\sum_{j=1}^{s} g_j^{(m)} - f_0^{(m)}\|_2^2 \leq \frac{8J(f_0)}{N}. \end{aligned} \tag{47}$$

Combining (45) and (47) we get that

$$\|E\{\bar{f}\} - f_0\|_2^2 \leq c_m^2 J(f_0)(\lambda + n^{-2m} + N^{-1}),$$

where $c_m^2 = \max\{8, 2c_m'\}$. This completes the proof of (5). ■

Proof [Proof of Theorem 3.2] Suppose $f_0 = \sum_{\nu=1}^{\infty} f_\nu^0 \varphi_\nu$ with f_ν^0 satisfying

$$|f_\nu^0|^2 = \begin{cases} Cn^{-1}(2\pi(n+r))^{-2m}, & \nu = 2(n+r)-1, 1 \leq r \leq n/2, \\ 0, & \text{otherwise.} \end{cases} \tag{48}$$

It is easy to see that $J(f_0) = \sum_{1\leq r\leq n/2} |f_{2(n+r)-1}^0|^2 (2\pi(n+r))^{2m} \leq C$.

Consider the decomposition (34) and let $\delta_{j,r}$ be defined as in (35) and (43). It can be easily checked that $C_{g,r} = 0$ for $1 \leq r \leq n/2$ and $0 \leq g \leq s-1$. Furthermore, for $1 \leq r \leq n/2$,

$$\begin{aligned}\lambda_{c,r} - a_{1,r} &= \sum_{u=0}^{\infty}(2\pi(un+r))^{-2m} + \sum_{u=1}^{\infty}(2\pi(un-r))^{-2m} - \sum_{u=0}^{\infty}(2\pi(uN+n+r))^{-2m} \\ &\quad - \sum_{u=1}^{\infty}(2\pi(uN-n-r))^{-2m} \geq (2\pi r)^{-2m}.\end{aligned}$$

Therefore,

$$\begin{aligned} b_{1,r,r}^2 &= \left(\frac{\lambda + \lambda_{c,r} - a_{1,r}}{\lambda + \lambda_{c,r}}\right)^2 \\ &\geq \left(\frac{\lambda + (2\pi r)^{-2m}}{\lambda + 2(1+\bar{c}_m)(2\pi r)^{-2m}}\right)^2 \geq \frac{1}{4(1+\bar{c}_m)^2}. \end{aligned} \tag{49}$$

Using (36) and (49), we have

$$\begin{aligned}\sum_{j=1}^{s}(\bar{\boldsymbol{f}}_j - \mathbf{f}_{0,j})^T(\bar{\boldsymbol{f}}_j - \mathbf{f}_{0,j}) &= \sum_{j=1}^{s}\sum_{r=0}^{n-1}|\delta_{j,r}|^2 \\ &\geq \sum_{1\leq r\leq n/2}\sum_{j=1}^{s}|\delta_{j,r}|^2 \\ &= \sum_{1\leq r\leq n/2}\frac{N}{2}\sum_{g=0}^{s-1}|C_{g,r}b_{g,n-r,r} + D_{s-1-g,r}b_{s-1-g,r,r}|^2 \\ &= \sum_{1\leq r\leq n/2}\frac{N}{2}\sum_{g=0}^{s-1}|D_{s-1-g,r}|^2 b_{s-1-g,r,r}^2 \\ &= \sum_{1\leq r\leq n/2}\frac{N}{2}\sum_{g=0}^{s-1}|D_{g,r}|^2 b_{g,r,r}^2 \\ &\geq \sum_{1\leq r\leq n/2}\frac{N}{2}|D_{1,r}|^2 b_{1,r,r}^2 \\ &\geq \frac{N}{8(1+\bar{c}_m)^2}\sum_{1\leq r\leq n/2}|f_{2(n+r)-1}^0|^2 \\ &\geq \frac{NC}{16(3\pi)^{2m}(1+\bar{c}_m)^2}n^{-2m} \equiv a_m NC n^{-2m}, \end{aligned}$$

where $a_m = \frac{1}{16(3\pi)^{2m}(1+\bar{c}_m)^2} < 1$ is an absolute constant depending on m only. Then the conclusion follows by (47). Proof is completed. ■

6.2 Proofs in Section 4

Proof [Proof of Theorem 4.1] For $1 \leq j, l \leq s$, define

$$\begin{aligned}\Omega_{j,l} &= \frac{1}{n}\sum_{\nu=1}^{\infty}\frac{\Phi_{\nu,j}^T\Phi_{\nu,l}}{\gamma_\nu^2}, \\ \widetilde{\sigma}_{j,l,r} &= \frac{2}{n}\sum_{k=1}^{\infty}\frac{\cos\left(2\pi k\left(\frac{r}{n} - \frac{j-l}{N}\right)\right)}{(2\pi k)^{4m}},\ r = 0, 1, \ldots, n-1. \end{aligned}$$

Clearly $\Omega_{j,l}$ is a circulant matrix with elements $\widetilde{\sigma}_{j,l,0}, \widetilde{\sigma}_{j,l,1}, \ldots, \widetilde{\sigma}_{j,l,n-1}$. Furthermore, by arguments (24)–(26) we get that

$$\Omega_{j,l} = M\Gamma_{j,l}M^*, \tag{50}$$

where M is the same as in (19), and $\Gamma_{j,l} = \mathrm{diag}(\delta_{j,l,0}, \delta_{j,l,1}, \ldots, \delta_{j,l,n-1})$, with $\delta_{j,l,r}$, for $r = 1, \ldots, n-1$, given by the following

$$\delta_{j,l,r} = \sum_{q=1}^{\infty}\frac{\eta^{-(qn-r)(j-l)}}{[2\pi(qn-r)]^{4m}} + \sum_{q=0}^{\infty}\frac{\eta^{(qn+r)(j-l)}}{[2\pi(qn+r)]^{4m}}, \tag{51}$$

and for $r=0$, given by

$$\delta_{j,l,0}=\sum_{q=1}^{\infty}\frac{\eta^{qn(j-l)}+\eta^{-qn(j-l)}}{(2\pi qn)^{4m}}. \tag{52}$$

Define $A=\mathrm{diag}(\underbrace{(\Sigma+\lambda I_n)^{-1},\ldots,(\Sigma+\lambda I_n)^{-1}}_{s})$ and

$$B=\begin{pmatrix}\Omega_{1,1} & \Omega_{1,2} & \cdots & \Omega_{1,s}\\ \Omega_{2,1} & \Omega_{2,2} & \cdots & \Omega_{2,s}\\ \cdots & \cdots & \cdots & \cdots\\ \Omega_{s,1} & \Omega_{s,2} & \cdots & \Omega_{s,s}\end{pmatrix}.$$

Note that B is $N\times N$ symmetric. Under H_0, it can be shown that

$$\begin{aligned}\|\bar f\|_2^2 &= \sum_{\nu=1}^{\infty}\left(\frac{\sum_{l=1}^{s}\Phi_{\nu,l}(\Sigma+\lambda I_n)^{-1}\boldsymbol{\epsilon}_l}{N\gamma_\nu^2}\right)^2\\ &= \frac{1}{Ns}\sum_{j,l=1}^{s}\boldsymbol{\epsilon}_j^T(\Sigma+\lambda I_n)^{-1}\left(\frac{1}{n}\sum_{\nu=1}^{\infty}\frac{\Phi_{\nu,j}^T\Phi_{\nu,l}}{\gamma_\nu^2}\right)(\Sigma+\lambda I_n)^{-1}\boldsymbol{\epsilon}_l\\ &= \frac{1}{Ns}\sum_{j,l=1}^{s}\boldsymbol{\epsilon}_j^T(\Sigma+\lambda I_n)^{-1}\Omega_{j,l}(\Sigma+\lambda I_n)^{-1}\boldsymbol{\epsilon}_l\\ &= \frac{1}{Ns}\boldsymbol{\epsilon}^T ABA\boldsymbol{\epsilon}=\frac{1}{Ns}\boldsymbol{\epsilon}^T\Delta\boldsymbol{\epsilon},\end{aligned}$$

where $\boldsymbol{\epsilon}=(\boldsymbol{\epsilon}_1^T,\ldots,\boldsymbol{\epsilon}_s^T)^T$ and $\Delta\equiv ABA$.

This implies that $T_{N,\lambda}=\boldsymbol{\epsilon}^T\Delta\boldsymbol{\epsilon}/(Ns)$ with $\mu_{N,\lambda}=\mathrm{trace}(\Delta)/(Ns)$ and $\sigma_{N,\lambda}^2=2\mathrm{trace}(\Delta^2)/(Ns)^2$. Define $U=(T_{N,\lambda}-\mu_{N,\lambda})/\sigma_{N,\lambda}$. Then for any $t\in(-1/2,1/2)$,

$$\begin{aligned}\log E\{\exp(tU)\} &= \log E\{\exp(t\boldsymbol{\epsilon}^T\Delta\boldsymbol{\epsilon}/(Ns\sigma_{N,\lambda}))\}-t\mu_{N,\lambda}/\sigma_{N,\lambda}\\ &= -\frac{1}{2}\log\det(I_N-2t\Delta/(Ns\sigma_{N,\lambda}))-t\mu_{N,\lambda}/\sigma_{N,\lambda}\\ &= t\mathrm{trace}(\Delta)/(Ns\sigma_{N,\lambda})+t^2\mathrm{trace}(\Delta^2)/((Ns)^2\sigma_{N,\lambda}^2)\\ &\quad +O(t^3\mathrm{trace}(\Delta^3)/((Ns)^3\sigma_{N,\lambda}^3))-t\mu_{N,\lambda}/\sigma_{N,\lambda}\\ &= t^2/2+O(t^3\mathrm{trace}(\Delta^3)/((Ns)^3\sigma_{N,\lambda}^3)).\end{aligned}$$

It remains to show that $\mathrm{trace}(\Delta^3)/((Ns)^3\sigma_{N,\lambda}^3)=o(1)$ in order to conclude the proof.

In other words, we need to study $\mathrm{trace}(\Delta^2)$ (used in $\sigma_{N,\lambda}^2$) and $\mathrm{trace}(\Delta^3)$. We start from the former. By direct calculations, we get

$$\begin{aligned}\mathrm{trace}(\Delta^2) &= \mathrm{trace}(A^2BA^2B)\\ &= \sum_{l=1}^{s}\mathrm{trace}\left(\sum_{j=1}^{s}M(\Lambda_c+\lambda I_n)^{-2}\Gamma_{l,j}(\Lambda_c+\lambda I_n)^{-2}\Gamma_{j,l}M^*\right)\\ &= \sum_{j,l=1}^{s}\mathrm{trace}\left((\Lambda_c+\lambda I_n)^{-2}\Gamma_{l,j}(\Lambda_c+\lambda I_n)^{-2}\Gamma_{j,l}\right)=\sum_{j,l=1}^{s}\sum_{r=0}^{n-1}\frac{|\delta_{j,l,r}|^2}{(\lambda+\lambda_{c,r})^4}.\end{aligned}$$

For $1\le g\le s$ and $0\le r\le n-1$, define

$$A_{g,r}=\sum_{p=0}^{\infty}\frac{1}{[2\pi(pN+gn-r)]^{4m}}.$$

Using (51) and (52), it can be shown that for $r=1,2,\ldots,n-1$,

$$\begin{aligned}\sum_{j,l=1}^{s}|\delta_{j,l,r}|^2 &= \sum_{j,l=1}^{s}\left|\sum_{g=1}^{s}A_{g,r}\eta^{-gn(j-l)}+\sum_{g=1}^{s}A_{g,n-r}\eta^{(g-1)n(j-l)}\right|^2\\ &= \sum_{j,l=1}^{s}\left(\sum_{g,g'=1}^{s}A_{g,r}A_{g',r}\eta^{-(g-g')n(j-l)}+\sum_{g,g'=1}^{s}A_{g,n-r}A_{g',n-r}\eta^{(g-g')n(j-l)}\right.\\ &\quad \left.+\sum_{g,g'=1}^{s}A_{g,r}A_{g',n-r}\eta^{-(g+g'-1)n(j-l)}+\sum_{g,g'=1}^{s}A_{g,n-r}A_{g',r}\eta^{(g+g'-1)n(j-l)}\right)\\ &= s^2\sum_{g=1}^{s}A_{g,r}^2+s^2\sum_{g=1}^{s}A_{g,n-r}^2+2s^2\sum_{g=1}^{s}A_{g,r}A_{s+1-g,n-r}\\ &\ge s^2\sum_{g=1}^{s}A_{g,r}^2+s^2\sum_{g=1}^{s}A_{g,n-r}^2.\end{aligned}\tag{53}$$

Since

$$\sum_{g=1}^{s}A_{g,r}^2=\sum_{g=1}^{s}\left(\sum_{p=0}^{\infty}\frac{1}{[2\pi(pN+gn-r)]^{4m}}\right)^2\ge\frac{1}{[2\pi(n-r)]^{8m}}, \tag{54}$$

we get that

$$\begin{aligned}\mathrm{trace}(\Delta^2) &\ge \sum_{r=1}^{n-1}\frac{s^2(\sum_{g=1}^{s}A_{g,r}^2+\sum_{g=1}^{s}A_{g,n-r}^2)}{(\lambda+\lambda_{c,r})^4}\\ &\ge s^2\sum_{r=1}^{n-1}\frac{\frac{1}{[2\pi(n-r)]^{8m}}+\frac{1}{(2\pi r)^{8m}}}{(\lambda+\lambda_{c,r})^4}\\ &\ge \frac{2s^2}{(2+2\bar c_m)^4}\sum_{1\le r\le n/2}\frac{\frac{1}{(2\pi r)^{8m}}}{(\lambda+\frac{1}{(2\pi r)^{2m}})^4}\\ &= \frac{s^2}{8(1+\bar c_m)^4}\sum_{1\le r\le n/2}\frac{1}{(1+(2\pi rh)^{2m})^4}\\ &\ge \frac{s^2}{8(1+\bar c_m)^4}h^{-1}\int_h^{nh/2}\frac{1}{(1+(2\pi x)^{2m})^4}dx.\end{aligned}$$

Meanwhile, (53) indicates that for $1\le r\le n-1$,

$$\sum_{j,l=1}^{s}|\delta_{j,l,r}|^2\le 2s^2\sum_{g=1}^{s}A_{g,r}^2+2s^2\sum_{g=1}^{s}A_{g,n-r}^2.$$

From (54) we get that for $1 \le r \le n-1$,

$$\sum_{g=1}^{s} A_{g,r}^2 \le \frac{c_m}{(2\pi(n-r))^{8m}},$$

where $c_m > 0$ is a constant depending on m only.

Similar analysis to (53) shows that

$$\begin{aligned}\sum_{j,l=1}^{s} |\delta_{j,l,0}|^2 &= \sum_{j,l=1}^{s} \left| \sum_{g=1}^{s} A_{g,0}(\eta^{gn(j-l)} + \eta^{-gn(j-l)}) \right|^2 \\ &= 2s^2 \sum_{g=1}^{s} A_{g,0}^2 + 2s^2 \sum_{g=1}^{s-1} A_{g,0} A_{s-g,0} + 2s^2 A_{s,0}^2 \\ &\le 4s^2 \sum_{g=1}^{s} A_{g,0}^2 \le c_m s^2 (2\pi n)^{-8m}.\end{aligned}$$

Therefore,

$$\begin{aligned}\mathrm{trace}(\Delta^2) &\le \frac{4s^2 \sum_{g=1}^{s} A_{g,0}^2}{(\lambda+\lambda_{c,0})^4} + 2s^2 \sum_{r=1}^{n-1} \frac{\sum_{g=1}^{s} A_{g,r}^2 + \sum_{g=1}^{s} A_{g,n-r}^2}{(\lambda+\lambda_{c,r})^4} \\ &\le 4c_m s^2 \sum_{r=1}^{n} \frac{1}{(1+(2\pi r h)^{2m})^4} \\ &\le 4c_m s^2 h^{-1} \int_0^{nh} \frac{1}{(1+(2\pi x)^{2m})^4} dx.\end{aligned}$$

By the above statements, we get that

$$\sigma_{N,\lambda}^2 = 2\mathrm{trace}(\Delta^2)/(Ns)^2 \asymp \begin{cases} \frac{n}{N^2}, & \text{if } nh \to 0, \\ \frac{1}{N^2 h}, & \text{if } \lim_N nh > 0. \end{cases} \tag{55}$$

To the end, we look at the trace of Δ^3. By direct examinations, we have

$$\begin{aligned}\mathrm{trace}(\Delta^3) &= \mathrm{trace}(ABA^2BA^2BA) \\ &= \sum_{j,k=1}^{s} \mathrm{trace}\Big([\sum_{l=1}^{s} M(\Lambda_c+\lambda I_n)^{-2}\Gamma_{j,l}(\Lambda_c+\lambda I_n)^{-2}\Gamma_{l,k}M^*] \\ &\quad \times M(\Lambda_c+\lambda I_n)^{-2}\Gamma_{k,j}M^* \Big) \\ &= \sum_{j,k,l=1}^{s} \mathrm{trace}\left((\Lambda_c+\lambda I_n)^{-2}\Gamma_{j,l}(\Lambda_c+\lambda I_n)^{-2}\Gamma_{l,k}(\Lambda_c+\lambda I_n)^{-2}\Gamma_{k,j} \right) \\ &= \sum_{j,k,l=1}^{s} \sum_{r=0}^{n-1} \frac{\delta_{j,l,r}\delta_{l,k,r}\delta_{k,j,r}}{(\lambda+\lambda_{c,r})^6}.\end{aligned}$$

For $r = 1, 2, \ldots, n-1$, it can be shown that

$$\begin{aligned}\delta_{j,l,r}\delta_{l,k,r}\delta_{k,j,r} &= \left(\sum_{q=1}^{\infty} \frac{\eta^{-qn(j-l)}}{(2\pi(qn-r))^{4m}} + \sum_{q=0}^{\infty} \frac{\eta^{qn(j-l)}}{(2\pi(qn+r))^{4m}} \right) \\ &\quad \times \left(\sum_{q=1}^{\infty} \frac{\eta^{-qn(l-k)}}{(2\pi(qn-r))^{4m}} + \sum_{q=0}^{\infty} \frac{\eta^{qn(l-k)}}{(2\pi(qn+r))^{4m}} \right) \\ &\quad \times \left(\sum_{q=1}^{\infty} \frac{\eta^{-qn(k-j)}}{(2\pi(qn-r))^{4m}} + \sum_{q=0}^{\infty} \frac{\eta^{qn(k-j)}}{(2\pi(qn+r))^{4m}} \right).\end{aligned} \tag{56}$$

We next proceed to show that for $1 \le r \le n-1$,

$$\sum_{l,j,k=1}^{s} \delta_{j,l,r}\delta_{l,k,r}\delta_{k,j,r} \le \frac{96m}{12m-1} \left(\frac{4m}{4m-1} \right)^3 s^3 \left(\frac{1}{(2\pi(n-r))^{12m}} + \frac{1}{(2\pi r)^{12m}} \right). \tag{57}$$

Using the trivial fact that $A_{g,r} \le \frac{4m}{4m-1} \times \frac{1}{(2\pi(gn-r))^{4m}}$, the first term in (56) satisfies

$$\begin{aligned}&\sum_{j,l,k=1}^{s} \sum_{q_1=1}^{\infty} \frac{\eta^{-q_1 n(j-l)}}{(2\pi(q_1 n-r))^{4m}} \sum_{q_2=1}^{\infty} \frac{\eta^{-q_2 n(j-l)}}{(2\pi(q_2 n-r))^{4m}} \sum_{q_3=1}^{\infty} \frac{\eta^{-q_3 n(j-l)}}{(2\pi(q_3 n-r))^{4m}} \\ &= \sum_{j,l,k=1}^{s} \sum_{g_1=1}^{s} A_{g_1,r}\eta^{-g_1 n(j-l)} \sum_{g_2=1}^{s} A_{g_2,r}\eta^{-g_2 n(l-k)} \sum_{g_3=1}^{s} A_{g_3,r}\eta^{-g_3 n(k-j)} \\ &= \sum_{g_1,g_2,g_3=1}^{s} A_{g_1,r}A_{g_2,r}A_{g_3,r} \sum_{j,l,k=1}^{s} \eta^{-g_1 n(j-l)}\eta^{-g_2 n(l-k)}\eta^{-g_3 n(k-j)} \\ &= \sum_{g_1,g_2,g_3=1}^{s} A_{g_1,r}A_{g_2,r}A_{g_3,r} \sum_{j=1}^{s} \eta^{(g_3-g_1)n(j-1)} \sum_{l=1}^{s} \eta^{(g_1-g_2)n(l-1)} \sum_{k=1}^{s} \eta^{(g_2-g_3)n(k-1)} \\ &= s^3 \sum_{g=1}^{s} A_{g,r}^3 \\ &\le \left(\frac{4m}{4m-1} \right)^3 s^3 \sum_{g=1}^{s} \frac{1}{(2\pi(gn-r))^{12m}} \\ &\le \frac{12m}{12m-1} \left(\frac{4m}{4m-1} \right)^3 s^3 \frac{1}{(2\pi(n-r))^{12m}}.\end{aligned}$$

Similarly, one can show that all other terms in (56) are upper bounded by

$$\frac{12m}{12m-1} \left(\frac{4m}{4m-1} \right)^3 s^3 \left(\frac{1}{(2\pi(n-r))^{12m}} + \frac{1}{(2\pi r)^{12m}} \right).$$

Therefore, (57) holds. It can also be shown by (52) and similar analysis that

$$\sum_{j,l,k=1}^{s} \delta_{j,l,0}\delta_{l,k,0}\delta_{k,j,0} \le s^3 (2\pi n)^{-12m}. \tag{58}$$

Using (57) and (58), one can get that

$$\begin{aligned}\mathrm{trace}(\Delta^3) &= \sum_{l,j,k=1}^{s}\sum_{r=0}^{n-1}\frac{\delta_{j,l,r}\delta_{l,k,r}\delta_{k,j,r}}{(\lambda+\lambda_{c,r})^6}\\ &\lesssim s^3\sum_{r=1}^{n-1}\frac{\frac{1}{(2\pi(n-r))^{12m}}+\frac{1}{(2\pi r)^{12m}}}{(\lambda+\lambda_{c,r})}+s^3\frac{\frac{1}{(2\pi n)^{12m}}}{(\lambda+\lambda_{c,0})^{12m}}\\ &\lesssim s^3\sum_{r=1}^{n}\frac{1}{(1+(2\pi rh)^{2m})^6}\\ &\lesssim s^3h^{-1}\int_0^{nh}\frac{1}{(1+(2\pi x)^{2m})^6}dx \asymp \begin{cases} s^3n, & \text{if } nh\to 0,\\ s^3h^{-1}, & \text{if } \lim_N nh>0.\end{cases}\end{aligned} \tag{59}$$

Combining (55) and (59), and using the assumptions $n\to\infty$, $h\to 0$, we get that

$$\mathrm{trace}(\Delta^3)/((Ns)^3\sigma_{N,\lambda}^3) \lesssim \begin{cases} n^{-1/2}, & \text{if } nh\to 0,\\ h^{1/2}, & \text{if } \lim_N nh>0.\end{cases} = o(1).$$

Proof is completed. ■

Proof [Proof of Theorem 4.2] Throughout the proof, we assume that data $Y_1,\ldots,Y_N$ are generated from the sequence of alternative hypotheses: $f\in\mathcal{B}$ and $\|f\|_2\geq C_\varepsilon d_{N,\lambda}$. Define $\mathbf{f}_j=(f(t_{1,j}),\ldots,f(t_{n,j}))^T$ for $1\leq j\leq s$. Then it can be shown that

$$\begin{aligned}NsT_{N,\lambda} &= Ns\sum_{\nu=1}^{\infty}\bar{f}_\nu^2\\ &= \sum_{j,l=1}^{s}Y_j^T(\Sigma+\lambda I_n)^{-1}\Omega_{j,l}(\Sigma+\lambda I_n)^{-1}Y_l\\ &= \sum_{j,l=1}^{s}Y_j^TM(\Lambda_c+\lambda I_n)^{-1}\Gamma_{j,l}(\Lambda_c+\lambda I_n)^{-1}M^*Y_l\\ &= \sum_{j,l=1}^{s}\mathbf{f}_j^TM(\Lambda_c+\lambda I_n)^{-1}\Gamma_{j,l}(\Lambda_c+\lambda I_n)^{-1}M^*\mathbf{f}_l\\ &\quad+\sum_{j,l=1}^{s}\mathbf{f}_j^TM(\Lambda_c+\lambda I_n)^{-1}\Gamma_{j,l}(\Lambda_c+\lambda I_n)^{-1}M^*\boldsymbol{\epsilon}_l\\ &\quad+\sum_{j,l=1}^{s}\boldsymbol{\epsilon}_j^TM(\Lambda_c+\lambda I_n)^{-1}\Gamma_{j,l}(\Lambda_c+\lambda I_n)^{-1}M^*\mathbf{f}_l\\ &\quad+\sum_{j,l=1}^{s}\boldsymbol{\epsilon}_j^TM(\Lambda_c+\lambda I_n)^{-1}\Gamma_{j,l}(\Lambda_c+\lambda I_n)^{-1}M^*\boldsymbol{\epsilon}_l\\ &\equiv T_1+T_2+T_3+T_4.\end{aligned} \tag{60}$$

Next we will analyze all the four terms in the above. Let $f=\sum_{\nu=1}^{\infty}f_\nu\varphi_\nu$. For $0\leq r\leq n-1$ and $1\leq l\leq s$, define $d_{l,r}=x_r^*\mathbf{f}_l$. Then it holds that

$$d_{l,r}=\sum_{p=0}^{\infty}\sum_{v=1}^{n}f_{2(pn+v)-1}x_r^*\Phi_{2(pn+v)-1,l}^T+\sum_{p=0}^{\infty}\sum_{v=1}^{n}f_{2(pn+v)}x_r^*\Phi_{2(pn+v),l}^T.$$

Using (27) and (28), we get that for $1\leq r\leq n-1$,

$$\begin{aligned}d_{l,r} &= \sum_{p=0}^{\infty}\sum_{v=1}^{n-1}f_{2(pn+v)-1}\left(\sqrt{\frac{n}{2}}\right)\left(\eta^{-(pn+v)(l-1)}I(r+v=n)+\eta^{(pn+v)(l-1)}I(r=v)\right)\\ &\quad+\sum_{p=0}^{\infty}\sum_{v=1}^{n-1}f_{2(pn+v)}\left(-\sqrt{-\frac{n}{2}}\right)\left(\eta^{-(pn+v)(l-1)}I(r+v=n)-\eta^{(pn+v)(l-1)}I(r=v)\right)\\ &= \sqrt{\frac{n}{2}}\sum_{p=0}^{\infty}\Big[(f_{2(pn+n-r)-1}-\sqrt{-1}f_{2(pn+n-r)})\eta^{-(pn+n-r)(l-1)}\\ &\quad+(f_{2(pn+r)-1}+\sqrt{-1}f_{2(pn+r)})\eta^{(pn+r)(l-1)}\Big],\end{aligned} \tag{61}$$

and for $r=0$,

$$\begin{aligned}d_{l,0} &= \sum_{p=0}^{\infty}f_{2(pn+n)-1}x_0^*\Phi_{2(pn+n)-1,l}^T+\sum_{p=0}^{\infty}f_{2(pn+n)}x_0^*\Phi_{2(pn+n),l}^T\\ &= \sqrt{\frac{n}{2}}\sum_{p=0}^{\infty}\Big[(f_{2(pn+n)-1}-\sqrt{-1}f_{2(pn+n)})\eta^{-(pn+n)(l-1)}\\ &\quad+(f_{2(pn+n)-1}+\sqrt{-1}f_{2(pn+n)})\eta^{(pn+n)(l-1)}\Big].\end{aligned} \tag{62}$$

We first look at T_1. It can be examined directly that

$$\begin{aligned}T_1 &= \sum_{j,l=1}^{s}(\overline{d_{j,0}},\ldots,\overline{d_{j,n-1}})\mathrm{diag}\left(\frac{\delta_{j,l,0}}{(\lambda+\lambda_{c,0})^2},\ldots,\frac{\delta_{j,l,n-1}}{(\lambda+\lambda_{c,n-1})^2}\right)\times(d_{l,0},\ldots,d_{l,n-1})^T\\ &= \sum_{r=0}^{n-1}\frac{\sum_{j,l=1}^{s}\delta_{j,l,r}\overline{d_{j,r}}d_{l,r}}{(\lambda+\lambda_{c,r})^2}.\end{aligned} \tag{63}$$

Using similar arguments as (29)–(33), one can show that for $p\geq 0$, $1\leq v\leq n$, $0\leq r\leq n-1$ and $1\leq j\leq s$,

$$\begin{aligned}\frac{1}{s}\sum_{l=1}^{s}\delta_{j,l,r}x_r^*\Phi_{2(pn+v)-1,l}^T &= b_{p,v}x_r^*\Phi_{2(pn+v)-1,j}^T,\\ \frac{1}{s}\sum_{l=1}^{s}\delta_{j,l,r}x_r^*\Phi_{2(pn+v),l}^T &= b_{p,v}x_r^*\Phi_{2(pn+v),j}^T,\end{aligned} \tag{64}$$

where

$$b_{p,v}=\begin{cases}\sum_{u\geq -p/s}\frac{1}{(2\pi(uN+pn+v))^{4m}}+\sum_{u\geq (p+1)/s}\frac{1}{(2\pi(uN-pn-v))^{4m}}, & \text{for } 1\leq v\leq n-1,\\ \sum_{u\geq -p/s}\frac{1}{(2\pi(uN+pn+n))^{4m}}+\sum_{u\geq (p+2)/s}\frac{1}{(2\pi(uN-pn-n))^{4m}}, & \text{for } v=n.\end{cases}$$

By (64), we have

$$\begin{aligned}
\sum_{j,l=1}^{s}\delta_{j,l,r}\overline{d_{j,r}}d_{l,r} &= \sum_{j=1}^{s}\overline{d_{j,r}}\sum_{l=1}^{s}\delta_{j,l,r}d_{l,r}\\
&= \sum_{j=1}^{s}\overline{d_{j,r}}\sum_{l=1}^{s}\delta_{j,l,r}\left(\sum_{p=0}^{\infty}\sum_{v=1}^{n}f_{2(pn+v)-1}x_r^*\Phi_{2(pn+v)-1,l}\right.\\
&\quad\left.+\sum_{p=0}^{\infty}\sum_{v=1}^{n}f_{2(pn+v)}x_r^*\Phi^T_{2(pn+v),l}\right)\\
&= \sum_{j=1}^{s}\overline{d_{j,r}}\left(\sum_{p=0}^{\infty}\sum_{v=1}^{n}f_{2(pn+v)-1}\sum_{l=1}^{s}\delta_{j,l,r}x_r^*\Phi^T_{2(pn+v)-1,l}\right.\\
&\quad\left.+\sum_{p=0}^{\infty}\sum_{v=1}^{n}f_{2(pn+v)}\sum_{l=1}^{s}\delta_{j,l,r}x_r^*\Phi^T_{2(pn+v),l}\right)\\
&= s\sum_{j=1}^{s}\overline{d_{j,r}}\left(\sum_{p=0}^{\infty}\sum_{v=1}^{n}f_{2(pn+v)-1}b_{p,v}x_r^*\Phi^T_{2(pn+v)-1,j}+\sum_{p=0}^{\infty}\sum_{v=1}^{n}f_{2(pn+v)}b_{p,v}x_r^*\Phi^T_{2(pn+v),j}\right).
\end{aligned}$$

It then follows from (61) and (62), trivial facts $b_{s-1-g,r}=b_{g,n-r}$ and $C_{g,n-r}=\overline{D_{g,r}}$ (both $C_{g,r}$ and $D_{g,r}$ are defined similarly as those in the proof of Theorem 3.1, but with f_0 therein replaced by f), and direct calculations that for $1\le r\le n-1$

$$\begin{aligned}
\sum_{j,l=1}^{s}\delta_{j,l,r}\overline{d_{j,r}}d_{l,r} &= \frac{sn}{2}\sum_{j=1}^{s}\sum_{p=0}^{\infty}\Big[(f_{2(pn+n-r)-1}+\sqrt{-1}f_{2(pn+n-r)})\eta^{(pn+n-r)(j-1)}\\
&\quad+(f_{2(pn+r)-1}-\sqrt{-1}f_{2(pn+r)})\eta^{-(pn+r)(j-1)}\Big]\\
&\quad\times\sum_{p=0}^{\infty}\Big[(f_{2(pn+n-r)-1}-\sqrt{-1}f_{2(pn+n-r)})b_{p,n-r}\eta^{-(pn+n-r)(j-1)}\\
&\quad+(f_{2(pn+r)-1}+\sqrt{-1}f_{2(pn+r)})b_{p,r}\eta^{(pn+r)(j-1)}\Big]\\
&= \frac{N}{2}\sum_{j=1}^{s}\sum_{g=0}^{s-1}\sum_{k=0}^{\infty}\Big[(f_{2(kN+gn+n-r)-1}+\sqrt{-1}f_{2(kN+gn+n-r)})\eta^{(gn+n-r)(j-1)}\\
&\quad+(f_{2(kN+gn+r)-1}-\sqrt{-1}f_{2(kN+gn+r)})\eta^{-(gn+r)(j-1)}\Big]\\
&\quad\times\sum_{g=0}^{s-1}\sum_{k=0}^{\infty}\Big[(f_{2(kN+gn+n-r)-1}-\sqrt{-1}f_{2(kN+gn+n-r)})b_{ks+g,n-r}\eta^{-(gn+n-r)(j-1)}\\
&\quad+(f_{2(kN+gn+r)-1}+\sqrt{-1}f_{2(kN+gn+r)})b_{ks+g,r}\eta^{(gn+r)(j-1)}\Big]\\
&= \frac{N}{2}\sum_{j=1}^{s}\left[\sum_{g=0}^{s-1}\overline{C_{g,r}}\eta^{(gn+n)(j-1)}+\sum_{g=0}^{s-1}\overline{D_{g,r}}\eta^{-gn(j-1)}\right]\\
&\quad\times\left[\sum_{g=0}^{s-1}b_{g,n-r}C_{g,r}\eta^{-(gn+n)(j-1)}+\sum_{g=0}^{s-1}b_{g,r}D_{g,r}\eta^{gn(j-1)}\right]\\
&= \frac{Ns}{2}\left(\sum_{g=0}^{s-1}b_{g,n-r}|C_{g,r}|^2+\sum_{g=0}^{s-1}b_{s-1-g,r}\overline{C_{g,r}}D_{s-1-g,r}\right.\\
&\quad\left.+\sum_{g=0}^{s-1}b_{s-1-g,n-r}\overline{D_{g,r}}C_{s-1-g,r}+\sum_{g=0}^{s-1}b_{g,r}|D_{g,r}|^2\right),
\end{aligned}$$

which leads to

$$\sum_{r=1}^{n-1}\frac{\sum_{j,l=1}^{s}\delta_{j,l,r}\overline{d_{j,r}}d_{l,r}}{(\lambda+\lambda_{c,r})^2}=\frac{Ns}{2}\sum_{r=1}^{n-1}\frac{\sum_{g=0}^{s-1}b_{g,r}|C_{s-1-g,r}+D_{g,r}|^2}{(\lambda+\lambda_{c,r})^2}. \tag{65}$$

Since $J(f)\le C$, equivalently, $\sum_{\nu=1}^{\infty}(f_{2\nu-1}^2+f_{2\nu}^2)(2\pi\nu)^{2m}\le C$, we get that

$$\sum_{1\le r\le n/2}(f_{2r-1}^2+f_{2r}^2)\ge\|f\|_2^2-C(2\pi n)^{-2m}. \tag{66}$$

Meanwhile, for $1\le r\le n/2$, using similar arguments as (40) and (41) one can show that there exists a constant c'_m relying on C and m s.t.

$$\begin{aligned}
|C_{s-1,r}+D_{0,r}|^2 &= \left(f_{2r-1}+\sum_{k=0}^{\infty}f_{2(kN+N-r)-1}+\sum_{k=1}^{\infty}f_{2(kN+r)-1}\right)^2\\
&\quad+\left(f_{2r}+\sum_{k=1}^{\infty}f_{2(kN+r)}-\sum_{k=0}^{\infty}f_{2(kN+N-r)}\right)^2\\
&\ge \frac{1}{2}(f_{2r-1}^2+f_{2r-1}^2)-c'_mN^{-2m},
\end{aligned}\tag{67}$$

and

$$\begin{aligned}
&|C_{s-1,r}+D_{0,r}|^2(2\pi r)^{2m}\\
\le\ & 4\left[(\sum_{k=0}^{\infty}f_{2(kN+N-r)-1})^2+(\sum_{k=0}^{\infty}f_{2(kN+N-r)})^2\right.\\
&\left.+(\sum_{k=0}^{\infty}f_{2(kN+r)-1})^2+(\sum_{k=0}^{\infty}f_{2(kN+r)})^2\right](2\pi r)^{2m}\\
\le\ & \left(4\sum_{k=0}^{\infty}f_{2(kN+N-r)-1}^2(2\pi(kN+N-r))^{2m}\sum_{k=0}^{\infty}(2\pi(kN+N-r))^{-2m}\right.\\
&+4\sum_{k=0}^{\infty}f_{2(kN+N-r)}^2(2\pi(kN+N-r))^{2m}\sum_{k=0}^{\infty}(2\pi(kN+N-r))^{-2m}\\
&+4\sum_{k=0}^{\infty}f_{2(kN+r)-1}^2(2\pi(kN+r))^{2m}\sum_{k=0}^{\infty}(2\pi(kN+r))^{-2m}\\
&\left.+4\sum_{k=0}^{\infty}f_{2(kN+r)}^2(2\pi(kN+r))^{2m}\sum_{k=0}^{\infty}(2\pi(kN+r))^{-2m}\right)\times(2\pi r)^{2m}\\
\le\ & \left(\frac{8m}{2m-1}\sum_{k=0}^{\infty}(f_{2(kN+N-r)-1}^2+f_{2(kN+N-r)}^2)\gamma_{kN+N-r}(2\pi(N-r))^{-2m}\right.\\
&\left.+\frac{8m}{2m-1}\sum_{k=0}^{\infty}(f_{2(kN+r)-1}^2+f_{2(kN+r)}^2)\gamma_{kN+r}(2\pi r)^{-2m}\right)\times(2\pi r)^{2m},
\end{aligned}$$

which, together with the fact $N \geq 2r$ for $1 \leq r \leq n/2$, leads to that

$$\sum_{1\leq r\leq n/2} |C_{s-1,r} + D_{0,r}|^2 (2\pi r)^{2m} \leq c'_m. \tag{68}$$

Furthermore, it can be verified that for $1 \leq r \leq n/2$,

$$\begin{aligned}\frac{\lambda_{c,r}^2 - b_{0,r}}{(\lambda+\lambda_{c,r})}(2\pi r)^{-2m} &\leq \frac{((2\pi r)^{-2m} + (2\pi(n-r))^{-2m} + \bar{c}_m(2\pi n)^{-2m})^2 - (2\pi r)^{-4m}}{((2\pi r)^{-2m} + (2\pi(n-r))^{-2m})^2}(2\pi r)^{-2m} \\ &\leq c'_m n^{-2m}, \end{aligned} \tag{69}$$

which leads to that

$$\begin{aligned}\frac{(\lambda+\lambda_{c,r})^2 - b_{0,r}}{(\lambda+\lambda_{c,r})^2}(2\pi r)^{-2m} &= \frac{\lambda^2 + 2\lambda\lambda_{c,r}}{(\lambda+\lambda_{c,r})^2}(2\pi r)^{-2m} + \frac{\lambda_{c,r}^2 - b_{0,r}}{(\lambda+\lambda_{c,r})^2}(2\pi r)^{-2m} \\ &\leq 2\lambda + c'_m n^{-2m}. \end{aligned} \tag{70}$$

Then, using (63)–(65) and (66)–(70) one gets that

$$\begin{aligned} T_1 &\geq \frac{Ns}{2}\sum_{1\leq r\leq n/2} \frac{b_{0,r}|C_{s-1,r} + D_{0,r}|^2}{(\lambda+\lambda_{c,r})^2} \\ &= \frac{Ns}{2}\left[\sum_{1\leq r\leq n/2} |C_{s-1,r} + D_{0,r}|^2 - \sum_{1\leq r\leq n/2} \frac{(\lambda+\lambda_{c,r})^2 - b_{0,r}}{(\lambda+\lambda_{c,r})^2}|C_{s-1,r} + D_{0,r}|^2\right] \\ &\geq \frac{Ns}{2}\left(\frac{1}{2}\|f\|_2^2 - c'_m n^{-2m} - c'_m N^{-2m} - c'_m(2\lambda + c'_m n^{-2m})\right) \geq C' Ns\sigma_{N,\lambda}, \end{aligned} \tag{71}$$

where the last inequality follows by $\|f\|_2^2 \geq 4C'(\lambda + n^{-2m} + \sigma_{N,\lambda})$ for a large constant C' satisfying $2C' > 2c'_m + (c'_m)^2$. To achieve the desired power, we need to enlarge C' further. This will be described later. Combining (71) with (55) and (71) we get that

$$T_1 \gg s \ \text{ uniformly for } f \in \mathcal{B} \text{ with } \|f\|_2^2 \geq 4C' d_{N,\lambda}^2. \tag{72}$$

Terms T_2 and T_3 can be handled similarly. To handle T_2, note that $T_2 = \mathbf{f}^T\Delta\boldsymbol{\epsilon}$, where $\mathbf{f} = (\mathbf{f}_1^T, \ldots, \mathbf{f}_s^T)^T$, $\boldsymbol{\epsilon} = (\boldsymbol{\epsilon}_1^T, \ldots, \boldsymbol{\epsilon}_s^T)^T$, and Δ is defined in the proof of Theorem 4.1. We need to establish $\Delta \leq sI_N$. Define an arbitrary $\mathbf{a} = (a_1^T, \ldots, a_s^T)^T \in \mathbb{R}^N$, where each a_j is an (real) n-vector. Let $\xi_j = M^* a_j$ and $\xi = (\xi_1^T, \ldots, \xi_s^T)^T$. For simplicity, put $\xi_j = (\xi_{j,0}, \ldots, \xi_{j,n-1})^T$ for $1 \leq j \leq s$. Then based on (52) and (51), we have

$$\begin{aligned}\mathbf{a}^T\Delta\mathbf{a} &= \xi^*[(\Lambda_c + \lambda I_n)^{-1}\Gamma_{j,l}(\Lambda_c + \lambda I_n)^{-1}]_{1\leq j,l\leq s}\xi \\ &= \sum_{r=0}^{n-1}\sum_{j,l=1}^{s} \overline{\xi_{j,r}}\xi_{l,r}\frac{\delta_{j,l,r}}{(\lambda+\lambda_{c,r})^2} \\ &\leq \sum_{r=1}^{n-1}\frac{s\left(\frac{1}{(2\pi(n-r))^{4m}} + \frac{1}{(2\pi r)^{4m}}\right)\sum_{j=1}^{s}|\xi_{j,r}|^2}{(\lambda+\lambda_{c,r})^2} \\ &\quad + \frac{2s\sum_{q=1}^{\infty}\frac{1}{(2\pi q n)^{4m}}\sum_{j=1}^{s}|\xi_{j,0}|^2}{(\lambda+\lambda_{c,0})^2} \\ &\leq s\sum_{r=0}^{n-1}\sum_{j=1}^{s}|\xi_{j,r}|^2 = s\xi^*\xi = s\mathbf{a}^T\mathbf{a}, \end{aligned}$$

therefore, $\Delta \leq sI_N$. This leads to that, uniformly for $f \in \mathcal{B}$ with $\|f\|_2^2 \geq 4C' d_{N,\lambda}^2$, $E_f\{T_2^2\} = \mathbf{f}^T\Delta^2\mathbf{f} \leq sT_1$. Together with (72), we get that

$$\sup_{\substack{f\in\mathcal{B}\\ \|f\|_2\geq 2\sqrt{C'}d_{N,\lambda}}} P_f\left(|T_2| \geq \varepsilon^{-1/2}T_1^{1/2}s^{1/2}\right) \leq \varepsilon. \tag{73}$$

Note that (73) also applies to T_3. By Theorem 4.1, $(T_4/(Ns) - \mu_{N,\lambda})/\sigma_{N,\lambda}$ is $O_P(1)$ uniformly for f. Therefore, we can choose $C'_\varepsilon > 0$ s.t. $P_f(|T_4/(Ns) - \mu_{N,\lambda}|/\sigma_{N,\lambda} \geq C'_\varepsilon) \leq \varepsilon$ as $N \to \infty$.

It then follows by (71), (72) and (73) that for suitable large C' (e.g., $C' \geq 2(C'_\varepsilon + z_{1-\alpha/2})$), uniformly for $f \in \mathcal{B}$ with $\|f\|_2 \geq 2\sqrt{C'}d_{N,\lambda}$,

$$P_f\left(|T_{N,\lambda} - \mu_{N,\lambda}|/\sigma_{N,\lambda} \geq z_{1-\alpha/2}\right) \leq 3\varepsilon, \ \text{as } N \to \infty.$$

Proof is completed. ■

Proof [Proof of Theorem 4.3]

Define $B_N = \lfloor N^{2/(4m+1)} \rfloor$, the integer part of $N^{2/(4m+1)}$. We prove the theorem in two cases: $\lim_N nh > 0$ and $nh = o(1)$.

Case I: $\lim_N nh > 0$**.**

In this case, it can be shown by $s \gg N^{(4m-1)/(4m+1)}$ (equivalently $n \ll B_N$, leading to $B_N h \gg nh$ hence $B_N h \to \infty$) that $n^{-6m}h^{-4m+1/2}N \ll (B_N/n)^{6m}$. Choose g to be an integer satisfying

$$n^{-6m}h^{-4m+1/2}N \ll g^{6m} \ll (B_N/n)^{6m}. \tag{74}$$

Construct an $f = \sum_{\nu=1}^{\infty} f_\nu\varphi_\nu$ with

$$f_\nu^2 = \begin{cases} \frac{C}{n-1}(2\pi(gn+r))^{-2m}, & \nu = 2(gn+r)-1,\ r = 1,2,\ldots,n-1, \\ 0, & \text{otherwise.}\end{cases} \tag{75}$$

It can be seen that

$$J(f) = \sum_{r=1}^{s-1} f_{2(gn+r)-1}^2(2\pi(gn+r))^{2m} = C, \tag{76}$$

and

$$\begin{aligned}\|f\|_2^2 &= \sum_{r=1}^{n-1} f_{2(gn+r)-1}^2 \\ &= \frac{C}{n-1}\sum_{r=1}^{n-1}(2\pi(gn+r))^{-2m} \\ &\geq C(2\pi(gn+n))^{-2m} = \beta_{N,\lambda}^2 N^{-4m/(4m+1)}, \end{aligned} \tag{77}$$

where $\beta_{N,\lambda}^2 = C[B_N/(2\pi(gn+n))]^{2m}$. Due to (74) and $n \ll B_N$, we have $gn+n \ll 2B_N$, which further implies $\beta_{N,\lambda} \to \infty$ as $N \to \infty$.

Using the trivial fact $b_{s-2-g,n} = b_{g,n}$ for $0 \leq g \leq s-2$, one can show that

$$\begin{aligned}\sum_{j,l=1}^{s} \delta_{j,l,0}\overline{d_{j,0}}d_{l,0} &= \frac{Ns}{2}\left(2\sum_{g'=0}^{s-1}|C_{g',0}|^2 b_{g',n} + \sum_{g'=0}^{s-2} C_{s-2-g',0}C_{g',0}b_{g',n} + C_{s-1,0}^2 b_{s-1,n}\right. \\ &\quad \left. + \sum_{g'=0}^{s-2} D_{s-2-g',n}D_{g',n}b_{g',n} + D_{s-1,n}^2 b_{s-1,n}\right) \\ &\leq 2Ns\sum_{g'=0}^{s-1}|C_{g',0}|^2 b_{g',n} = 0, \end{aligned} \tag{78}$$

where the last equality follows by a trivial observation $C_{g',0} = 0$. It follows by (78), (63) and (65) that

$$\begin{aligned} T_1 &= \frac{Ns}{2}\sum_{r=1}^{n-1}\frac{\sum_{g'=0}^{s-1} b_{g',r}|C_{s-1-g',r} + D_{g',r}|^2}{(\lambda+\lambda_{c,r})^2} \\ &\leq Ns\sum_{r=1}^{n-1}\frac{\sum_{g'=0}^{s-1} b_{g',r}|C_{s-1-g',r}|^2}{(\lambda+\lambda_{c,r})^2} + Ns\sum_{r=1}^{n-1}\frac{\sum_{g'=0}^{s-1} b_{g',r}|D_{g',r}|^2}{(\lambda+\lambda_{c,r})^2} \\ &= Ns\sum_{r=1}^{n-1}\frac{\sum_{g'=0}^{s-1} b_{s-1-g',n-r}|C_{g',n-r}|^2}{(\lambda+\lambda_{c,r})^2} + Ns\sum_{r=1}^{n-1}\frac{\sum_{g'=0}^{s-1} b_{g',r}|D_{g',r}|^2}{(\lambda+\lambda_{c,r})^2} \\ &= 2Ns\sum_{r=1}^{n-1}\frac{\sum_{g'=0}^{s-1} b_{g',r}|D_{g',r}|^2}{(\lambda+\lambda_{c,r})^2} = 2Ns\sum_{r=1}^{n-1}\frac{b_{g,r}f_{2(gn+r)-1}^2}{(\lambda+\lambda_{c,r})^2}, \end{aligned} \tag{79}$$

where the last equality follows from the design of f, i.e., (75). Now it follows from (79) and the fact $b_{g,r} \leq c'_m(2\pi(gn+r))^{-4m}$, for some constant c'_m depending on m only, that

$$\begin{aligned} T_1 &\leq 2Ns\sum_{r=0}^{n-1}\frac{c'_m(2\pi(gn+r))^{-4m}\frac{C}{n-1}(2\pi(gn+r))^{-2m}}{(\lambda+\lambda_{c,r})^2} \\ &= \frac{2Nsc'_mC}{n-1}\sum_{r=1}^{n-1}\frac{(2\pi(gn+r))^{-6m}}{(\lambda+\lambda_{c,r})^2} \\ &\leq 2c'_mC(2\pi)^{-6m}Ns(gn)^{-6m}h^{-4m} \ll sh^{-1/2} \asymp Ns\sigma_{N,\lambda}, \end{aligned} \tag{80}$$

where the last "$\asymp$" follows from (12).

By (73) we have that

$$|T_2+T_3| = T_1^{1/2}s^{1/2}O_{P_f}(1) = o_{P_f}(sh^{-1/4}) = o_{P_f}(Ns\sigma_{N,\lambda}).$$

Hence, by (60) and Theorem 4.1 we have

$$\begin{aligned}\frac{T_{N,\lambda}-\mu_{N,\lambda}}{\sigma_{N,\lambda}} &= \frac{T_1+T_2+T_3}{Ns\sigma_{N,\lambda}} + \frac{T_4/(Ns)-\mu_{N,\lambda}}{\sigma_{N,\lambda}} \\ &= \frac{T_4/(Ns)-\mu_{N,\lambda}}{\sigma_{N,\lambda}} + o_{P_f}(1) \xrightarrow{d} N(0,1). \end{aligned}$$

Consequently, as $N \to \infty$

$$\inf_{\substack{f^\star \in \mathcal{B} \\ \|f^\star\|_2 \geq \beta_{N,\lambda}N^{-2m/(4m+1)}}} P_{f^\star}(\phi_{N,\lambda}=1) \leq P_f(\phi_{N,\lambda}=1) \to \alpha.$$

This shows the desired result in Case I.

Case II: $nh = o(1)$**.**

The proof is similar to Case I although a bit technical difference needs to be emphasized. Since $n \ll B_N$, it can be shown that $Nn^{-2m-1/2} \ll (B_N/n)^{6m}$. Choose g to be an integer satisfying

$$Nn^{-2m-1/2} \ll g^{6m} \ll (B_N/n)^{6m}. \tag{81}$$

Let $f = \sum_{\nu=1}^{\infty} f_\nu\varphi_\nu$ with f_ν satisfying (75). Similar to (76) and (77) one can show that $J(f) = C$ and $\|f\|_2^2 \geq \beta_{N,\lambda}^2 N^{-4m/(4m+1)}$, where $\beta_{N,\lambda}^2 = C[B_N/(2\pi(gn+n))]^{2m}$. It is clear that $\beta_{N,\lambda} \to \infty$ as $N \to \infty$. Then similar to (78), (63), (65) and (80) one can show that

$$\begin{aligned} T_1 &\leq 2Ns\sum_{r=1}^{n-1}\frac{b_{g,r}f_{2(gn+r)-1}^2}{(\lambda+\lambda_{c,r})^2} \\ &\leq \frac{2Nsc'_mC}{n-1}\sum_{r=1}^{n-1}\frac{(2\pi(gn+r))^{-6m}}{(\lambda+\lambda_{c,r})^2} \\ &\leq 2c'_mC(2\pi)^{-2m}Nsg^{-6m}n^{-2m} \\ &\ll sn^{1/2} \asymp Ns\sigma_{N,\lambda}, \end{aligned}$$

where the last line follows by (81) and (12). Then the desired result follows by arguments in the rest of Case I. Proof is completed. ■

Abstract

A fundamental challenge in developing high-impact machine learning technologies is balancing the need to model rich, structured domains with the ability to scale to big data. Many important problem areas are both richly structured and large scale, from social and biological networks, to knowledge graphs and the Web, to images, video, and natural language. In this paper, we introduce two new formalisms for modeling structured data, and show that they can both capture rich structure and scale to big data. The first, hinge-loss Markov random fields (HL-MRFs), is a new kind of probabilistic graphical model that generalizes different approaches to convex inference. We unite three approaches from the randomized algorithms, probabilistic graphical models, and fuzzy logic communities, showing that all three lead to the same inference objective. We then define HL-MRFs by generalizing this unified objective. The second new formalism, probabilistic soft logic (PSL), is a probabilistic programming language that makes HL-MRFs easy to define using a syntax based on first-order logic. We introduce an algorithm for inferring most-probable variable assignments (MAP inference) that is much more scalable than general-purpose convex optimization methods, because it uses message passing to take advantage of sparse dependency structures. We then show how to learn the parameters of HL-MRFs. The learned HL-MRFs are as accurate as analogous discrete models, but much more scalable. Together, these algorithms enable HL-MRFs and PSL to model rich, structured data at scales not previously possible.

Keywords: Probabilistic graphical models, statistical relational learning, structured prediction

1. Introduction

In many problems in machine learning, the domains are rich and structured, with many interdependent elements that are best modeled jointly. Examples include social networks, biological networks, the Web, natural language, computer vision, sensor networks, and so on. Machine learning subfields such as statistical relational learning (Getoor and Taskar, 2007), inductive logic programming (Muggleton and De Raedt, 1994), and structured prediction (Bakir et al., 2007) all seek to represent dependencies in data induced by relational structure. With the ever-increasing size of available data, there is a growing need for models that are highly scalable while still able to capture rich structure.

In this paper, we introduce *hinge-loss Markov random fields* (HL-MRFs), a new class of probabilistic graphical models designed to enable scalable modeling of rich, structured data. HL-MRFs are analogous to discrete MRFs, which are undirected probabilistic graphical models in which probability mass is log-proportional to a weighted sum of feature functions. Unlike discrete MRFs, however, HL-MRFs are defined over continuous variables in the $[0, 1]$ unit interval. To model dependencies among these continuous variables, we use linear and quadratic hinge functions, so that probability density is lost according to a weighted sum of hinge losses. As we will show, hinge-loss features capture many common modeling patterns for structured data.

When designing classes of models, there is generally a trade off between scalability and expressivity: the more complex the types and connectivity structure of the dependencies, the more computationally challenging inference and learning become. HL-MRFs address a crucial gap between the two extremes. By using hinge-loss functions to model the dependencies among the variables, which admit highly scalable inference without restrictions on their connectivity structure, HL-MRFs can capture a wide range of useful relationships. One reason they are so expressive is that hinge-loss dependencies are at the core of a number of scalable techniques for modeling both discrete and continuous structured data.

To motivate HL-MRFs, we unify three different approaches for scalable inference in structured models: (1) randomized algorithms for MAX SAT (Goemans and Williamson, 1994), (2) local consistency relaxation (Wainwright and Jordan, 2008) for discrete Markov random fields defined using Boolean logic, and (3) reasoning about continuous information with fuzzy logic. We show that all three approaches lead to the same convex programming objective. We then define HL-MRFs by generalizing this unified inference objective as a weighted sum of hinge-loss features and using them as the weighted features of graphical models. Since HL-MRFs generalize approaches that reason about relational data with weighted logical knowledge bases, they retain the same high level of expressivity. As we show in Section 6.4, they are effective for modeling both discrete and continuous data.

We also introduce *probabilistic soft logic* (PSL), a new probabilistic programming language that makes HL-MRFs easy to define and use for large, relational data sets.[1] This idea has been explored for other classes of models, such as Markov logic networks (Richardson and Domingos, 2006) for discrete MRFs, relational dependency networks (Neville and Jensen, 2007) for dependency networks, and probabilistic relational models (Getoor et al., 2002) for Bayesian networks. We build on these previous approaches, as well as the connection between hinge-loss potentials and logical clauses, to define PSL. In addition to

1. An open source implementation, tutorials, and data sets are available at http://psl.linqs.org.

probabilistic rules, PSL provides syntax that enables users to easily apply many common modeling techniques, such as domain and range constraints, blocking and canopy functions, and aggregate variables defined over other random variables.

Our next contribution is to introduce a number of inference and learning algorithms. First, we examine MAP inference, i.e., the problem of finding a most probable assignment to the unobserved random variables. MAP inference in HL-MRFs is always a convex optimization. Although any off-the-shelf optimization toolkit could be used, such methods typically do not leverage the sparse dependency structures common in graphical models. We introduce a consensus-optimization approach to MAP inference for HL-MRFs, showing how the problem can be decomposed using the alternating direction method of multipliers (ADMM) and how the resulting subproblems can be solved analytically for hinge-loss potentials. Our approach enables HL-MRFs to easily scale beyond the capabilities of off-the-shelf optimization software or sampling-based inference in discrete MRFs. We then show how to learn HL-MRFs from training data using a variety of methods: structured perceptron, maximum pseudolikelihood, and large margin estimation. Since structured perceptron and large margin estimation rely on inference as subroutines, and maximum pseudolikelihood estimation is efficient by design, all of these methods are highly scalable for HL-MRFs. We evaluate them on core relational learning and structured prediction tasks, such as collective classification and link prediction. We show that HL-MRFs offer predictive accuracy comparable to analogous discrete models while scaling much better to large data sets.

This paper brings together and expands work on scalable models for structured data that can be either discrete, continuous, or a mixture of both (Broecheler et al., 2010a; Bach et al., 2012, 2013, 2015b). The effectiveness of HL-MRFs and PSL has been demonstrated on many problems, including information extraction (Liu et al., 2016) and automatic knowledge base construction (Pujara et al., 2013), extracting and evaluating natural-language arguments on the Web (Samadi et al., 2016), high-level computer vision (London et al., 2013), drug discovery (Fakhraei et al., 2014) and predicting drug-drug interactions (Sridhar et al., 2016), natural language semantics (Beltagy et al., 2014; Sridhar et al., 2015; Deng and Wiebe, 2015; Ebrahimi et al., 2016), automobile-traffic modeling (Chen et al., 2014), recommender systems (Kouki et al., 2015), information retrieval (Alshukaili et al., 2016), and predicting attributes (Li et al., 2014) and trust (Huang et al., 2013; West et al., 2014) in social networks. The ability to easily incorporate latent variables into HL-MRFs and PSL (Bach et al., 2015a) has enabled further applications, including modeling latent topics in text (Foulds et al., 2015), and predicting student outcomes in massive open online courses (MOOCs) (Ramesh et al., 2014, 2015). Researchers have also studied how to make HL-MRFs and PSL even more scalable by developing distributed implementations (Miao et al., 2013; Magliacane et al., 2015). That they are already being widely applied indicates HL-MRFs and PSL address an open need in the machine learning community.

The paper is organized as follows. In Section 2, we first consider models for structured prediction that are defined using logical clauses. We unify three different approaches to scalable inference in such models, showing that they all optimize the same convex objective. We then generalize this objective in Section 3 to define HL-MRFs. In Section 4, we introduce PSL, specifying the language and giving many examples of common usage. Next we introduce a scalable message-passing algorithm for MAP inference in Section 5 and a

number of learning algorithms in Section 6, evaluating them on a range of tasks. Finally, in Section 7, we discuss related work.

2. Unifying Convex Inference for Logic-Based Graphical Models

In many structured domains, propositional and first-order logics are useful tools for describing the intricate dependencies that connect the unknown variables. However, these domains are usually noisy; dependencies among the variables do not always hold. To address this, logical semantics can be incorporated into probability distributions to create models that capture both the structure and the uncertainty in machine learning tasks. One common way to do this is to use logic to define feature functions in a probabilistic model. We focus on Markov random fields (MRFs), a popular class of probabilistic graphical models. Informally, an MRF is a distribution that assigns probability mass using a scoring function that is a weighted combination of feature functions called potentials. We will use logical clauses to define these potentials. We first define MRFs more formally to introduce necessary notation:

Definition 1 *Let $\boldsymbol{x} = (x_1, \ldots, x_n)$ be a vector of random variables and let $\boldsymbol{\phi} = (\phi_1, \ldots, \phi_m)$ be a vector of potentials where each potential $\phi_j(\boldsymbol{x})$ assigns configurations of the variables a real-valued score. Also, let $\boldsymbol{w} = (w_1, \ldots, w_m)$ be a vector of real-valued weights. Then, a* **Markov random field** *is a probability distribution of the form*

$$P(\boldsymbol{x}) \propto \exp\left(\boldsymbol{w}^\top \boldsymbol{\phi}(\boldsymbol{x})\right) . \tag{1}$$

In an MRF, the potentials should capture how the domain behaves, assigning higher scores to more probable configurations of the variables. If a modeler does not know how the domain behaves, the potentials should capture how it might behave, so that a learning algorithm can find weights that lead to accurate predictions. Logic provides an excellent formalism for defining such potentials in structured and relational domains.

We now introduce some notation to make this logic-based approach more formal. Consider a set of logical clauses $\boldsymbol{C} = \{C_1, \ldots, C_m\}$, i.e., a knowledge base, where each clause $C_j \in \boldsymbol{C}$ is a disjunction of literals and each literal is a variable x or its negation $\neg x$ drawn from the variables $\boldsymbol{x}$ such that each variable $x_i \in \boldsymbol{x}$ appears at most once in C_j. Let I_j^+ (resp. I_j^-) $\subset \{1, \ldots, n\}$ be the set of indices of the variables that are not negated (resp. negated) in C_j. Then C_j can be written as

$$\left(\bigvee_{i \in I_j^+} x_i\right) \bigvee \left(\bigvee_{i \in I_j^-} \neg x_i\right) . \tag{2}$$

Logical clauses of this form are expressive because they can be viewed equivalently as implications from conditions to consequences:

$$\bigwedge_{i \in I_j^-} x_i \implies \bigvee_{i \in I_j^+} x_i . \tag{3}$$

This "if-then" reasoning is intuitive and can describe many dependencies in structured data.

Assuming we have a logical knowledge base $\boldsymbol{C}$ describing a structured domain, we can embed it in an MRF by defining each potential ϕ_j using a corresponding clause C_j. If an assignment to the variables $\boldsymbol{x}$ satisfies C_j, then we let $\phi_j(\boldsymbol{x})$ equal 1, and we let it equal 0 otherwise. For our subsequent analysis we assume $w_j \geq 0$ $(\forall j = 1, \ldots, m)$. The resulting MRF preserves the structured dependencies described in $\boldsymbol{C}$ but enables much more flexible modeling. Clauses no longer must always hold, and the model can express uncertainty over different possible worlds. The weights express how strongly the model expects each corresponding clause to hold; the higher the weight, the more probable that it is true according to the model.

This notion of embedding weighted, logical knowledge bases in MRFs is an appealing one. For example, Markov logic (Richardson and Domingos, 2006) is a popular formalism that induces MRFs from weighted first-order knowledge bases. Given a data set, the first-order clauses are grounded using the constants in the data to create the set of propositional clauses $\boldsymbol{C}$. Each propositional clause has the weight of the first-order clause from which it was grounded. In this way, a weighted, first-order knowledge base can compactly specify an entire family of MRFs for a structured machine-learning task.

Although we now have a method for easily defining rich, structured models for a wide range of problems, there is a new challenge: finding a most probable assignment to the variables, i.e., MAP inference, is NP-hard (Shimony, 1994; Garey et al., 1976). This means that (unless P=NP) our only hope for performing tractable inference is to perform it approximately. Observe that MAP inference for an MRF defined by $\boldsymbol{C}$ is the integer linear program

$$\begin{aligned} \operatorname*{arg\,max}_{\boldsymbol{x} \in \{0,1\}^n} P(\boldsymbol{x}) &\equiv \operatorname*{arg\,max}_{\boldsymbol{x} \in \{0,1\}^n} \boldsymbol{w}^\top \boldsymbol{\phi}(\boldsymbol{x}) \\ &\equiv \operatorname*{arg\,max}_{\boldsymbol{x} \in \{0,1\}^n} \sum_{C_j \in \boldsymbol{C}} w_j \min \left\{ \sum_{i \in I_j^+} x_i + \sum_{i \in I_j^-} (1 - x_i), 1 \right\} . \end{aligned} \tag{4}$$

While this program is intractable, it does admit convex programming relaxations.

In this section, we show how convex programming can be used to perform tractable inference in MRFs defined by weighted knowledge bases. We first discuss in Section 2.1 an approach developed by Goemans and Williamson (1994) that views MAP inference as an instance of the classic MAX SAT problem and relaxes it to a convex program from that perspective. This approach has the advantage of providing strong guarantees on the quality of the discrete solutions it obtains. However, it has the disadvantage that general-purpose convex programming toolkits do not scale well to relaxed MAP inference for large graphical models (Yanover et al., 2006). In Section 2.2 we then discuss a seemingly distinct approach, local consistency relaxation, with complementary advantages and disadvantages: it offers highly scalable message-passing algorithms but comes with no quality guarantees. We then unite these approaches by proving that they solve equivalent optimization problems with identical solutions. Then, in Section 2.3, we show that the unified inference objective is also equivalent to exact MAP inference if the knowledge base $\boldsymbol{C}$ is interpreted using Łukasiewicz logic, an infinite-valued logic for reasoning about naturally continuous quantities such as similarity, vague or fuzzy concepts, and real-valued data.

That these three interpretations all lead to the same inference objective—whether reasoning about discrete or continuous information—is useful. To the best of our knowledge, we are the first to show their equivalence. This equivalence indicates that the same modeling formalism, inference algorithms, and learning algorithms can be used to reason scalably and accurately about both discrete and continuous information in structured domains. We generalize the unified inference objective in Section 3.1 to define hinge-loss MRFs, and in the rest of the paper we develop a probabilistic programming language and algorithms that realize the goal of a scalable and accurate framework for structured data, both discrete and continuous.

2.1 MAX SAT Relaxation

One approach to approximating objective (4) is to use relaxation techniques developed in the randomized algorithms community for the MAX SAT problem. Formally, the MAX SAT problem is to find a Boolean assignment to a set of variables that maximizes the total weight of satisfied clauses in a knowledge base composed of disjunctive clauses annotated with nonnegative weights. In other words, objective (4) is an instance of MAX SAT. Randomized approximation algorithms can be constructed for MAX SAT by independently rounding each Boolean variable x_i to true with probability p_i. Then, the expected weighted satisfaction $\hat{w}_j$ of a clause C_j is

$$\hat{w}_j = w_j \left(1 - \prod_{i \in I_j^+} (1 - p_i) \prod_{i \in I_j^-} p_i \right) , \tag{5}$$

also known as a (weighted) noisy-or function, and the expected total score $\hat{W}$ is

$$\hat{W} = \sum_{C_j \in \boldsymbol{C}} w_j \left(1 - \prod_{i \in I_j^+} (1 - p_i) \prod_{i \in I_j^-} p_i \right) . \tag{6}$$

Optimizing $\hat{W}$ with respect to the rounding probabilities would give the exact MAX SAT solution, so this randomized approach has not made the problem any easier yet, but Goemans and Williamson (1994) showed how to bound $\hat{W}$ below with a tractable linear program.

To approximately optimize $\hat{W}$, associate with each Boolean variable x_i a corresponding continuous variable $\hat{y}_i$ with domain $[0, 1]$. Then let $\hat{\boldsymbol{y}}^\star$ be the optimum of the linear program

$$\operatorname*{arg\,max}_{\hat{\boldsymbol{y}} \in [0,1]^n} \sum_{C_j \in \boldsymbol{C}} w_j \min \left\{ \sum_{i \in I_j^+} \hat{y}_i + \sum_{i \in I_j^-} (1 - \hat{y}_i), 1 \right\} . \tag{7}$$

Observe that objectives (4) and (7) are of the same form, except that the variables are relaxed to the unit hypercube in objective (7). Goemans and Williamson (1994) proved that if p_i is set to $\hat{y}_i^\star$ for all i, then $\hat{W} \geq .632\ Z^\star$, where $Z^\star$ is the optimal total weight for the MAX SAT problem. If each p_i is set using any function in a special class, then this

lower bound improves to a .75 approximation. One simple example of such a function is

$$p_i = \frac{1}{2}\hat{y}_i^\star + \frac{1}{4} \ . \tag{8}$$

In this way, objective (7) leads to an expected .75 approximation of the MAX SAT solution.

The following method of conditional probabilities (Alon and Spencer, 2008) can find a single Boolean assignment that achieves at least the expected score from a set of rounding probabilities, and therefore at least .75 of the MAX SAT solution when objective (7) and function (8) are used to obtain them. Each variable x_i is greedily set to the value that maximizes the expected weight over the unassigned variables, conditioned on either possible value of x_i and the previously assigned variables. This greedy maximization can be applied quickly because, in many models, variables only participate in a small fraction of the clauses, making the change in expectation quick to compute for each variable. Specifically, referring to the definition of $\hat{W}$ (6), the assignment to x_i only needs to maximize over the clauses C_j in which x_i participates, i.e., $i \in I_j^+ \cup I_j^-$, which is usually a small set.

This approximation is powerful because it is a tractable linear program that comes with strong guarantees on solution quality. However, even though it is tractable, general-purpose convex optimization toolkits do not scale well to large MAP problems. In the following subsection, we unify this approximation with a complementary one developed in the probabilistic graphical models community.

2.2 Local Consistency Relaxation

Another approach to approximating objective (4) is to apply a relaxation developed for Markov random fields called local consistency relaxation (Wainwright and Jordan, 2008). This approach starts by viewing MAP inference as an equivalent optimization over marginal probabilities.[2] For each $\phi_j \in \boldsymbol{\phi}$, let $\boldsymbol{\theta}_j$ be a marginal distribution over joint assignments $\boldsymbol{x}_j$. For example, $\theta_j(\boldsymbol{x}_j)$ is the probability that the subset of variables associated with potential ϕ_j is in a particular joint state $\boldsymbol{x}_j$. Also, let $x_j(i)$ denote the setting of the variable with index i in the state $\boldsymbol{x}_j$.

With this variational formulation, inference can be relaxed to an optimization over the *first-order local polytope* $\mathbb{L}$. Let $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_n)$ be a vector of probability distributions, where $\mu_i(k)$ is the marginal probability that x_i is in state k. The first-order local polytope is

$$\mathbb{L} \triangleq \left\{ (\boldsymbol{\theta}, \boldsymbol{\mu}) \geq \mathbf{0} \;\middle|\; \begin{array}{ll} \sum_{\boldsymbol{x}_j | x_j(i)=k} \theta_j(\boldsymbol{x}_j) = \mu_i(k) & \forall i, j, k \\ \sum_{\boldsymbol{x}_j} \theta_j(\boldsymbol{x}_j) = 1 & \forall j \\ \sum_{k=0}^{K_i - 1} \mu_i(k) = 1 & \forall i \end{array} \right\}, \tag{9}$$

which constrains each marginal distribution $\boldsymbol{\theta}_j$ over joint states $\boldsymbol{x}_j$ to be consistent only with the marginal distributions $\boldsymbol{\mu}$ over individual variables that participate in the potential ϕ_j.

MAP inference can then be approximated with the *first-order local consistency relaxation*:

$$\underset{(\boldsymbol{\theta}, \boldsymbol{\mu}) \in \mathbb{L}}{\arg\max} \ \sum_{j=1}^{m} w_j \sum_{\boldsymbol{x}_j} \theta_j(\boldsymbol{x}_j) \ \phi_j(\boldsymbol{x}_j), \tag{10}$$

2. This treatment is for discrete MRFs. We have omitted a discussion of continuous MRFs for conciseness.

which is an upper bound on the true MAP objective. Much work has focused on solving the first-order local consistency relaxation for large-scale MRFs, which we discuss further in Section 7. These algorithms are appealing because they are well-suited to the sparse dependency structures common in MRFs, so they can scale to large problems. However, in general, the solutions can be fractional, and there are no guarantees on the approximation quality of a tractable discretization of these fractional solutions.

We show that for MRFs with potentials defined by $\boldsymbol{C}$ and nonnegative weights, local consistency relaxation is equivalent to MAX SAT relaxation.

Theorem 2 *For an MRF with potentials corresponding to disjunctive logical clauses and associated nonnegative weights, the first-order local consistency relaxation of MAP inference is equivalent to the MAX SAT relaxation of Goemans and Williamson (1994). Specifically, any partial optimum $\boldsymbol{\mu}^\star$ of objective (10) is an optimum $\hat{\boldsymbol{y}}^\star$ of objective (7), and vice versa.*

We prove Theorem 2 in Appendix A. Our proof analyzes the local consistency relaxation to derive an equivalent, more compact optimization over only the variable pseudomarginals $\boldsymbol{\mu}$ that is identical to the MAX SAT relaxation. Theorem 2 is significant because it shows that the rounding guarantees of MAX SAT relaxation also apply to local consistency relaxation, and the scalable message-passing algorithms developed for local consistency relaxation also apply to MAX SAT relaxation.

2.3 Łukasiewicz Logic

The previous two subsections showed that the same convex program can approximate MAP inference in discrete, logic-based models, whether viewed from the perspective of randomized algorithms or variational methods. In this subsection, we show that this convex program can also be used to reason about naturally continuous information, such as similarity, vague or fuzzy concepts, and real-valued data. Instead of interpreting the clauses $\boldsymbol{C}$ using Boolean logic, we can interpret them using Łukasiewicz logic (Klir and Yuan, 1995), which extends Boolean logic to infinite-valued logic in which the propositions $\boldsymbol{x}$ can take truth values in the continuous interval $[0, 1]$. Extending truth values to a continuous domain enables them to represent concepts that are vague, in the sense that they are often neither completely true nor completely false. For example, the propositions that a sensor value is high, two entities are similar, or a protein is highly expressed can all be captured in a more nuanced manner in Łukasiewicz logic. We can also use the now continuous valued $\boldsymbol{x}$ to represent quantities that are naturally continuous (scaled to [0,1]), such as actual sensor values, similarity scores, and protein expression levels. The ability to reason about continuous values is valuable, as many important applications are not entirely discrete.

The extension to continuous values requires a corresponding extended interpretation of the logical operators $\wedge$ (conjunction), $\vee$ (disjunction), and $\neg$ (negation). The Łukasiewicz t-norm and t-co-norm are $\wedge$ and $\vee$ operators that correspond to the Boolean logic operators for integer inputs (along with the negation operator $\neg$):

$$x_1 \wedge x_2 = \max\{x_1 + x_2 - 1, 0\} \tag{11}$$

$$x_1 \vee x_2 = \min\{x_1 + x_2, 1\} \tag{12}$$

$$\neg x = 1 - x \ . \tag{13}$$

The analogous MAX SAT problem for Łukasiewicz logic is therefore

$$\arg\max_{\boldsymbol{x}\in[0,1]^n} \sum_{C_j\in\boldsymbol{C}} w_j \min\left\{\sum_{i\in I_j^+} x_i + \sum_{i\in I_j^-}(1-x_i), 1\right\} , \tag{14}$$

which is identical in form to the relaxed MAX SAT objective (7). Therefore, if an MRF is defined over continuous variables with domain $[0,1]^n$ and the logical knowledge base $\boldsymbol{C}$ defining the potentials is interpreted using Łukasiewicz logic, then *exact* MAP inference is identical to finding the optimum using the unified, relaxed inference objective derived for Boolean logic in the previous two subsections. This result shows the equivalence of all three approaches: MAX SAT relaxation, local consistency relaxation, and MAX SAT using Łukasiewicz logic.

3. Hinge-Loss Markov Random Fields

We have shown that a specific family of convex programs can be used to reason scalably and accurately about both discrete and continuous information. In this section, we generalize this family to define *hinge-loss Markov random fields* (HL-MRFs), a new kind of probabilistic graphical model. HL-MRFs retain the convexity and expressivity of convex programs discussed in Section 2, and additionally support an even richer space of dependencies.

To begin, we define HL-MRFs as density functions over continuous variables $\boldsymbol{y} = (y_1, \ldots, y_n)$ with joint domain $[0,1]^n$. These variables have different possible interpretations depending on the application. Since we are generalizing the interpretations explored in Section 2, HL-MRF MAP states can be viewed as rounding probabilities or pseudo-marginals, or they can represent naturally continuous information. More generally, they can be viewed simply as degrees of belief, confidences, or rankings of possible states; and they can describe discrete, continuous, or mixed domains. The application domain typically determines which interpretation is most appropriate. The formalisms and algorithms described in the rest of this paper are general with respect to such interpretations.

3.1 Generalized Inference Objective

To define HL-MRFs, we will first generalize the unified inference objective of Section 2 in several ways, which we first restate in terms of the HL-MRF variables $\boldsymbol{y}$:

$$\arg\max_{\boldsymbol{y}\in[0,1]^n} \sum_{C_j\in\boldsymbol{C}} w_j \min\left\{\sum_{i\in I_j^+} y_i + \sum_{i\in I_j^-}(1-y_i), 1\right\} . \tag{15}$$

For now, we are still assuming that the objective terms are defined using a weighted knowledge base $\boldsymbol{C}$, but we will quickly drop this requirement. To do so, we examine one term in isolation. Observe that the maximum value of any unweighted term is 1, which is achieved when a linear function of the variables is at least 1. We say that the term is *satisfied* whenever this occurs. When a term is unsatisfied, we can refer to its *distance to satisfaction*, which is how far it is from achieving its maximum value. Also observe that we can rewrite

the optimization explicitly in terms of distances to satisfaction:

$$\arg\min_{\boldsymbol{y}\in[0,1]^n} \sum_{C_j\in\boldsymbol{C}} w_j \max\left\{1 - \sum_{i\in I_j^+} y_i - \sum_{i\in I_j^-}(1-y_i), 0\right\} , \tag{16}$$

so that the objective is equivalently to minimize the total weighted distance to satisfaction. Each unweighted objective term now measures how far the linear constraint

$$1 - \sum_{i\in I_j^+} y_i - \sum_{i\in I_j^-}(1-y_i) \leq 0 \tag{17}$$

is from being satisfied.

3.1.1 Relaxed Linear Constraints

With this view of each term as a relaxed linear constraint, we can easily generalize them to arbitrary linear constraints. We no longer require that the inference objective be defined using only logical clauses, and instead each term can be defined using any function $\ell_j(\boldsymbol{y})$ that is linear in $\boldsymbol{y}$. These functions can capture more general dependencies, such as beliefs about the range of values a variable can take and arithmetic relationships among variables.

The new inference objective is

$$\arg\min_{\boldsymbol{y}\in[0,1]^n} \sum_{j=1}^{m} w_j \max\left\{\ell_j(\boldsymbol{y}), 0\right\} . \tag{18}$$

In this form, each term represents the distance to satisfaction of a linear constraint $\ell_j(\boldsymbol{y}) \leq 0$. That constraint could be defined using logical clauses as discussed above, or it could be defined using other knowledge about the domain. The weight w_j indicates how important it is to satisfy a constraint relative to others by scaling the distance to satisfaction. The higher the weight, the more distance to satisfaction is penalized. Additionally, two relaxed inequality constraints, $\ell_j(\boldsymbol{y}) \leq 0$ and $-\ell_j(\boldsymbol{y}) \leq 0$, can be combined to represent a relaxed equality constraint $\ell_j(\boldsymbol{y}) = 0$.

3.1.2 Hard Linear Constraints

Now that our inference objective admits arbitrary relaxed linear constraints, it is natural to also allow hard constraints that must be satisfied at all times. Hard constraints are important modeling tools. They enable groups of variables to represent mutually exclusive possibilities, such as a multinomial or categorical variable, and functional or partial functional relationships. Hard constraints can also represent background knowledge about the domain, restricting the domain to regions that are feasible in the real world. Additionally, they can encode more complex model components such as defining a random variable as an aggregate over other unobserved variables, which we discuss further in Section 4.3.5.

We can think of including hard constraints as allowing a weight w_j to take an infinite value. Again, two inequality constraints can be combined to represent an equality constraint. However, when we introduce an inference algorithm for HL-MRFs in Section 5, it

will be useful to treat hard constraints separately from relaxed ones, and further, treat hard inequality constraints separately from hard equality constraints. Therefore, in the definition of HL-MRFs, we will define these three components separately.

3.1.3 Generalized Hinge-Loss Functions

The objective terms measuring each constraint's distance to satisfaction are hinge losses. There is a flat region, on which the distance to satisfaction is 0, and an angled region, on which the distance to satisfaction grows linearly away from the hyperplane $\ell_j(\boldsymbol{y}) = 0$. This loss function is useful—as we discuss in the previous section, it is a bound on the expected loss in the discrete setting, among other things—but it is not appropriate for all modeling situations.

A piecewise-linear loss function makes MAP inference "winner take all," in the sense that it is preferable to fully satisfy the most highly weighted objective terms completely before reducing the distance to satisfaction of terms with lower weights. For example, consider the following optimization problem:

$$\underset{y_1 \in [0,1]}{\arg\min} \; w_1 \max\{y_1, 0\} + w_2 \max\{1 - y_1, 0\} \ . \tag{19}$$

If $w_1 > w_2 \geq 0$, then the optimizer is $y_1 = 0$ because the term that prefers $y_1 = 0$ overrules the term that prefers $y_1 = 1$. The result does not indicate any ambiguity or uncertainty, but if the two objective terms are potentials in a probabilistic model, it is sometimes preferable that the result reflect the conflicting preferences. We can change the inference problem so that it smoothly trades off satisfying conflicting objective terms by squaring the hinge losses. Observe that in the modified problem

$$\underset{y_1 \in [0,1]}{\arg\min} \; w_1 \left(\max\{y_1, 0\}\right)^2 + w_2 \left(\max\{1 - y_1, 0\}\right)^2 \tag{20}$$

the optimizer is now $y_1 = \frac{w_2}{w_1 + w_2}$, reflecting the relative influence of the two loss functions.

Another advantage of squared hinge-loss functions is that they can behave more intuitively in the presence of hard constraints. Consider the problem

$$\begin{aligned} \underset{(y_1, y_2) \in [0,1]^2}{\arg\min} \quad & \max\{0.9 - y_1, 0\} + \max\{0.6 - y_2, 0\} \\ \text{such that} \quad & y_1 + y_2 \leq 1 \ . \end{aligned} \tag{21}$$

The first term prefers $y_1 \geq 0.9$, the second term prefers $y_2 \geq 0.6$, and the constraint requires that y_1 and y_2 are mutually exclusive. Such problems are very common and arise when conflicting evidence of different strengths support two mutually exclusive possibilities. The evidence values 0.9 and 0.6 could come from many sources, including base models trained to make independent predictions on individual random variables, domain-specialized similarity functions, or sensor readings. For this problem, any solution $y_1 \in [0.4, 0.9]$ and $y_2 = 1 - y_1$ is an optimizer. This solution set includes counterintuitive optimizers like $y_1 = 0.4$ and $y_2 = 0.6$, even though the evidence supporting y_1 is stronger. Again, squared hinge losses

ensure the optimizers better reflect the relative strength of evidence. For the problem

$$\begin{aligned} \underset{(y_1, y_2) \in [0,1]^2}{\arg\min} \quad & \left(\max\{0.9 - y_1, 0\}\right)^2 + \left(\max\{0.6 - y_2, 0\}\right)^2 \\ \text{such that} \quad & y_1 + y_2 \leq 1 \ , \end{aligned} \tag{22}$$

the only optimizer is $y_1 = 0.65$ and $y_2 = 0.35$, which is a more informative solution.

We therefore complete our generalized inference objective by allowing either hinge-loss or squared hinge-loss functions. Users of HL-MRFs have the choice of either one for each potential, depending on which is appropriate for their task.

3.2 Definition

We can now formally state the full definition of HL-MRFs. They are defined so that a MAP state is a solution to the generalized inference objective proposed in the previous subsection. We state the definition in a conditional form for later convenience, but this definition is fully general since the vector of conditioning variables may be empty.

Definition 3 *Let $\boldsymbol{y} = (y_1, \ldots, y_n)$ be a vector of n variables and $\boldsymbol{x} = (x_1, \ldots, x_{n'})$ a vector of n' variables with joint domain $\boldsymbol{D} = [0,1]^{n+n'}$. Let $\boldsymbol{\phi} = (\phi_1, \ldots, \phi_m)$ be a vector of m continuous potentials of the form*

$$\phi_j(\boldsymbol{y}, \boldsymbol{x}) = \left(\max\{\ell_j(\boldsymbol{y}, \boldsymbol{x}), 0\}\right)^{p_j} \tag{23}$$

where ℓ_j is a linear function of $\boldsymbol{y}$ and $\boldsymbol{x}$ and $p_j \in \{1, 2\}$. Let $\boldsymbol{c} = (c_1, \ldots, c_r)$ be a vector of r linear constraint functions associated with index sets denoting equality constraints $\mathcal{E}$ and inequality constraints $\mathcal{I}$, which define the feasible set

$$\tilde{\boldsymbol{D}} = \left\{ (\boldsymbol{y}, \boldsymbol{x}) \in \boldsymbol{D} \;\middle|\; \begin{array}{l} c_k(\boldsymbol{y}, \boldsymbol{x}) = 0, \forall k \in \mathcal{E} \\ c_k(\boldsymbol{y}, \boldsymbol{x}) \leq 0, \forall k \in \mathcal{I} \end{array} \right\} \ . \tag{24}$$

For $(\boldsymbol{y}, \boldsymbol{x}) \in \boldsymbol{D}$, given a vector of m nonnegative free parameters, i.e., weights, $\boldsymbol{w} = (w_1, \ldots, w_m)$, a **constrained hinge-loss energy function** *$f_{\boldsymbol{w}}$ is defined as*

$$f_{\boldsymbol{w}}(\boldsymbol{y}, \boldsymbol{x}) = \sum_{j=1}^{m} w_j \phi_j(\boldsymbol{y}, \boldsymbol{x}) \ . \tag{25}$$

We now define HL-MRFs by placing a probability density over the inputs to a constrained hinge-loss energy function. Note that we negate the hinge-loss energy function so that states with lower energy are more probable, in contrast with Definition 1. This change is made for later notational convenience.

Definition 4 *A* **hinge-loss Markov random field** *P over random variables $\boldsymbol{y}$ and conditioned on random variables $\boldsymbol{x}$ is a probability density defined as follows: if $(\boldsymbol{y}, \boldsymbol{x}) \notin \tilde{\boldsymbol{D}}$, then $P(\boldsymbol{y}|\boldsymbol{x}) = 0$; if $(\boldsymbol{y}, \boldsymbol{x}) \in \tilde{\boldsymbol{D}}$, then*

$$P(\boldsymbol{y}|\boldsymbol{x}) = \frac{1}{Z(\boldsymbol{w}, \boldsymbol{x})} \exp\left(-f_{\boldsymbol{w}}(\boldsymbol{y}, \boldsymbol{x})\right) \tag{26}$$

where

$$Z(\boldsymbol{w}, \boldsymbol{x}) = \int_{\boldsymbol{y}|(\boldsymbol{y},\boldsymbol{x})\in\tilde{\boldsymbol{D}}} \exp\left(-f_{\boldsymbol{w}}(\boldsymbol{y}, \boldsymbol{x})\right) \, d\boldsymbol{y} \ . \tag{27}$$

In the rest of this paper, we will explore how to use HL-MRFs to solve a wide range of structured machine learning problems. We first introduce a probabilistic programming language that makes HL-MRFs easy to define for large, rich domains.

4. Probabilistic Soft Logic

In this section we introduce a general-purpose probabilistic programming language, *probabilistic soft logic* (PSL). PSL allows HL-MRFs to be easily applied to a broad range of structured machine learning problems by defining *templates* for potentials and constraints. In models for structured data, there are very often repeated patterns of probabilistic dependencies. A few of the many examples include the strength of ties between similar people in social networks, the preference for triadic closure when predicting transitive relationships, and the "exactly one active" constraints on functional relationships. Often, to make graphical models both easy to define and able to generalize across different data sets, these repeated dependencies are defined using templates. Each template defines an abstract dependency, such as the form of a potential function or constraint, along with any necessary parameters, such as the weight of the potential, each of which has a single value across all dependencies defined by that template. Given input data, an undirected graphical model is constructed from a set of templates by first identifying the random variables in the data and then "grounding out" each template by introducing a potential or constraint into the graphical model for each subset of random variables to which the template applies.

A PSL program is written in a declarative, first-order syntax and defines a class of HL-MRFs that are parameterized by the input data. PSL provides a natural interface to represent hinge-loss potential templates using two types of rules: logical rules and arithmetic rules. Logical rules are based on the mapping from logical clauses to hinge-loss potentials introduced in Section 2. Arithmetic rules provide additional syntax for defining an even wider range of hinge-loss potentials and hard constraints.

4.1 Definition

In this subsection we define PSL. Our definition covers the essential functionality that should be supported by all implementations, but many extensions are possible. The PSL syntax we describe can capture a wide range of HL-MRFs, but new settings and scenarios could motivate the development of additional syntax to make the construction of different kinds of HL-MRFs more convenient.

4.1.1 Preliminaries

We begin with a high-level definition of PSL programs.

Definition 5 *A* **PSL program** *is a set of rules, each of which is a template for hinge-loss potentials or hard linear constraints. When grounded over a base of ground atoms, a PSL program induces a HL-MRF conditioned on any specified observations.*

In the PSL syntax, many components are named using *identifiers*, which are strings that begin with a letter (from the set $\{\texttt{A}, \ldots, \texttt{Z}, \texttt{a}, \ldots, \texttt{z}\}$), followed by zero or more letters, numeric digits, or underscores.

PSL programs are grounded out over data, so the universe over which to ground must be defined.

Definition 6 *A* **constant** *is a string that denotes an element in the universe over which a PSL program is grounded.*

Constants are the elements in a universe of discourse. They can be entities or attributes. For example, the constant `"person1"` can denote a person, the constant `"Adam"` can denote a person's name, and the constant `"30"` can denote a person's age. In PSL programs, constants are written as strings in double or single quotes. Constants use backslashes as escape characters, so they can be used to encode quotes within constants. It is assumed that constants are unambiguous, i.e., different constants refer to different entities and attributes.[3] Groups of constants can be represented using variables.

Definition 7 *A* **variable** *is an identifier for which constants can be substituted.*

Variables and constants are the arguments to logical predicates. Together, they are generically referred to as terms.

Definition 8 *A* **term** *is either a constant or a variable.*

Terms are connected by relationships called predicates.

Definition 9 *A* **predicate** *is a relation defined by a unique identifier and a positive integer called its arity, which denotes the number of terms it accepts as arguments. Every predicate in a PSL program must have a unique identifier as its name.*

We refer to a predicate using its identifier and arity appended with a slash. For example, the predicate `Friends/2` is a binary predicate, i.e., taking two arguments, which represents whether two constants are friends. As another example, the predicate `Name/2` can relate a person to the string that is that person's name. As a third example, the predicate `EnrolledInClass/3` can relate two entities, a student and professor, with an additional attribute, the subject of the class.

Predicates and terms are combined to create atoms.

Definition 10 *An* **atom** *is a predicate combined with a sequence of terms of length equal to the predicate's arity. This sequence is called the atom's arguments. An atom with only constants for arguments is called a ground atom.*

Ground atoms are the basic units of reasoning in PSL. Each represents an unknown or observation of interest and can take any value in $[0, 1]$. For example, the ground atom `Friends("person1", "person2")` represents whether `"person1"` and `"person2"` are friends. Atoms that are not ground are placeholders for sets of ground atoms. For example, the atom `Friends(X, Y)` stands for all ground atoms that can be obtained by substituting constants for variables `X` and `Y`.

3. Note that ambiguous references to underlying entities can be modeled by using different constants for different references and representing whether they refer to the same underlying entity as a predicate.

4.1.2 Inputs

As we have already stated, PSL defines templates for hinge-loss potentials and hard linear constraints that are grounded out over a data set to induce a HL-MRF. We now describe how that data set is represented and provided as the inputs to a PSL program. The first inputs are two sets of predicates: a set $\mathbb{C}$ of *closed* predicates, the atoms of which are completely observed, and a set $\mathbb{O}$ of *open* predicates, the atoms of which may be unobserved. The third input is the *base* $\mathcal{A}$, which is the set of all ground atoms under consideration. All atoms in $\mathcal{A}$ must have a predicate in either $\mathbb{C}$ or $\mathbb{O}$. These are the atoms that can be substituted into the rules and constraints of a PSL program, and each will later be associated with a HL-MRF random variable with domain $[0, 1]$. The final input is a function $\mathcal{O} : \mathcal{A} \to [0, 1] \cup \{\emptyset\}$ that maps the ground atoms in the base to either an observed value in $[0, 1]$ or a symbol $\emptyset$ indicating that it is unobserved. The function $\mathcal{O}$ is only valid if all atoms with a predicate in $\mathbb{C}$ are mapped to a $[0, 1]$ value. Note that this definition makes the sets $\mathbb{C}$ and $\mathbb{O}$ redundant in a sense, since they can be derived from $\mathcal{A}$ and $\mathcal{O}$, but it will be convenient later to have $\mathbb{C}$ and $\mathbb{O}$ explicitly defined.

Ultimately, the method for specifying PSL's inputs is implementation-specific, since different choices make it more or less convenient for different scenarios. In this paper, we will assume that $\mathbb{C}$, $\mathbb{O}$, $\mathcal{A}$, and $\mathcal{O}$ exist, and we remain agnostic about how they were specified. However, to make this aspect of using PSL more concrete, we will describe one possible method for defining them here.

Our example method for specifying PSL's inputs is text-based. The first section of the text input is a definition of the constants in the universe, which are grouped into types. An example universe definition follows.

```
Person = {"alexis", "bob", "claudia", "david"}
Professor = {"alexis", "bob"}
Student = {"claudia", "david"}
Subject = {"computer science", "statistics"}
```

This universe includes six constants, four with two types (`"alexis"`, `"bob"`, `"claudia"`, and `"david"`) and two with one type (`"computer science"` and `"statistics"`).

The next section of input is the definition of predicates. Each predicate includes the types of constants it takes as arguments and whether it is closed. For example, we can define predicates for an advisor-student relationship prediction task as follows:

```
Advises(Professor, Student)
Department(Person, Subject) (closed)
EnrolledInClass(Student, Subject, Professor) (closed)
```

In this case, there is one open predicate (`Advises`) and two closed predicates (`Department` and `EnrolledInClass`).

The final section of input is any associated observations. They can be specified in a list, for example:

```
Advises("alexis", "david") = 1
Department("alexis", "computer science") = 1
Department("bob", "computer science") = 1
Department("claudia", "statistics") = 1
Department("david", "statistics") = 1
```

In addition, values for atoms with the `EnrolledInClass` predicate could also be specified. If a ground atom does not have a specified value, it will have a default observed value of 0 if its predicate is closed or remain unobserved if its predicate is open.

We now describe how this text input is processed into the formal inputs $\mathbb{C}$, $\mathbb{O}$, $\mathcal{A}$, and $\mathcal{O}$. First, each predicate is added to either $\mathbb{C}$ or $\mathbb{O}$ based on whether it is annotated with the `(closed)` tag. Then, for each predicate in $\mathbb{C}$ or $\mathbb{O}$, ground atoms of that predicate are added to $\mathcal{A}$ with each sequence of constants as arguments that can be created by selecting a constant of each of the predicate's argument types. For example, assume that the input file contains a single predicate definition

```
Category(Document, Cat_Name)
```

where the universe is `Document` $= \{$`"d1"`, `"d2"`$\}$ and `Cat_Name` $= \{$`"politics"`,`"sports"`$\}$. Then,

$$\mathcal{A} = \left\{ \begin{array}{l} \texttt{Category("d1", "politics")}, \\ \texttt{Category("d1", "sports")}, \\ \texttt{Category("d2", "politics")}, \\ \texttt{Category("d2", "sports")} \end{array} \right\} . \tag{28}$$

Finally, we define the function $\mathcal{O}$. Any atom in the explicit list of observations is mapped to the given value. Then, any remaining atoms in $\mathcal{A}$ with a predicate in $\mathbb{C}$ are mapped to 0, and any with a predicate in $\mathbb{O}$ are mapped to $\emptyset$.

Before moving on, we also note that PSL implementations can support predicates and atoms that are defined functionally. Such predicates can be thought of as a type of closed predicate. Their observed values are defined as a function of their arguments. One of the most common examples is inequality, atoms of which can be represented with the shorthand infix operator `!=`. For example, the following atom has a value of 1 when two variables `A` and `B` are replaced with different constants and 0 when replaced with the same constant.

```
A != B
```

Such functionally defined predicates can be implemented without requiring their values over all arguments to be specified by the user.

4.1.3 Rules and Grounding

Before introducing the syntax and semantics of specific PSL rules, we define the grounding procedure that induces HL-MRFs in general. Given the inputs $\mathbb{C}$, $\mathbb{O}$, $\mathcal{A}$, and $\mathcal{O}$, PSL induces

a HL-MRF $P(\boldsymbol{y}|\boldsymbol{x})$ as follows. First, each ground atom $a \in \mathcal{A}$ is associated with a random variable with domain $[0, 1]$. If $\mathcal{O}(a) = \emptyset$, then the variable is included in the free variables $\boldsymbol{y}$, and otherwise it is included in the observations $\boldsymbol{x}$ with a value of $\mathcal{O}(a)$.

With the variables in the distribution defined, each rule in the PSL program is applied to the inputs and produces hinge-loss potentials or hard linear constraints, which are added to the HL-MRF. In the rest of this subsection, we describe two kinds of PSL rules: logical rules and arithmetic rules.

4.1.4 Logical Rules

The first kind of PSL rule is a logical rule, which is made up of literals.

Definition 11 *A* **literal** *is an atom or a negated atom.*

In PSL, the prefix operator `!` or `~` is used for negation. A negated atom has a value of one minus the value of the unmodified atom. For example, if `Friends("person1", "person2")` has a value of 0.7, then `!Friends("person1", "person2")` has a value of 0.3.

Definition 12 *A* **logical rule** *is a disjunctive clause of literals. Logical rules are either weighted or unweighted. If a logical rule is weighted, it is annotated with a nonnegative weight and optionally a power of two.*

Logical rules express logical dependencies in the model. As in Boolean logic, the negation, disjunction (written as `||` or `|`), and conjunction (written as `&&` or `&`) operators obey De Morgan's Laws. Also, an implication (written as `->` or `<-`) can be rewritten as the negation of the body disjuncted with the head. For example

```
   P1(A, B) && P2(A, B) -> P3(A, B) || P4(A, B)
≡  !(P1(A, B) && P2(A, B)) || P3(A, B) || P4(A, B)
≡  !P1(A, B) || !P2(A, B) || P3(A, B) || P4(A, B)
```

Therefore, any formula written as an implication with (1) a literal or conjunction of literals in the body and (2) a literal or disjunction of literals in the head is also a valid logical rule, because it is equivalent to a disjunctive clause.

There are two kinds of logical rules: weighted or unweighted. A weighted logical rule is a template for a hinge-loss potential that penalizes how far the rule is from being satisfied. A weighted logical rule begins with a nonnegative weight and optionally ends with an exponent of two (`^2`). For example, the weighted logical rule

```
1 :  Advisor(Prof, S) && Department(Prof, Sub) -> Department(S, Sub)
```

has a weight of 1 and induces potentials propagating department membership from advisors to advisees. An unweighted logical rule is a template for a hard linear constraint that requires that the rule always be satisfied. For example, the unweighted logical rule

```
Friends(X, Y) && Friends(Y, Z) -> Friends(X, Z) .
```

induces hard linear constraints enforcing the transitivity of the `Friends/2` predicate. Note the period (`.`) that is used to emphasize that this rule is always enforced and disambiguate it from weighted rules.

A logical rule is grounded out by performing all distinct substitutions from variables to constants such that the resulting ground atoms are in the base $\mathcal{A}$. This procedure produces a set of *ground rules*, which are rules containing only ground atoms. Each ground rule will then be interpreted as either a potential or hard constraint in the induced HL-MRF. For notational convenience, we assume without loss of generality that all the random variables are unobserved, i.e., $\mathcal{O}(a) = \emptyset, \forall a \in \mathcal{A}$. If the input data contain any observations, the following description still applies, except that some free variables will be replaced with observations from $\boldsymbol{x}$. The first step in interpreting a ground rule is to map its disjunctive clause to a linear constraint. This mapping is based on the unified inference objective derived in Section 2. Any ground PSL rule is a disjunction of literals, some of which are negated. Let I^+ be the set of indices of the variables that correspond to atoms that are not negated in the ground rule, when expressed as a disjunctive clause, and, likewise, let I^- be the indices of the variables corresponding to atoms that are negated. Then, the clause is mapped to the inequality

$$1 - \sum_{i \in I^+} y_i - \sum_{i \in I^-} (1 - y_i) \leq 0 \ . \tag{29}$$

If the logical rule that templated the ground rule is weighted with a weight of w and is *not* annotated with `^2`, then the potential

$$\phi(\boldsymbol{y}, \boldsymbol{x}) = \max \left\{ 1 - \sum_{i \in I^+} y_i - \sum_{i \in I^-} (1 - y_i), 0 \right\} \tag{30}$$

is added to the HL-MRF with a parameter of w. If the rule is weighted with a weight w and annotated with `^2`, then the potential

$$\phi(\boldsymbol{y}, \boldsymbol{x}) = \left(\max \left\{ 1 - \sum_{i \in I^+} y_i - \sum_{i \in I^-} (1 - y_i), 0 \right\} \right)^2 \tag{31}$$

is added to the HL-MRF with a parameter of w. If the rule is unweighted, then the function

$$c(\boldsymbol{y}, \boldsymbol{x}) = 1 - \sum_{i \in I^+} y_i - \sum_{i \in I^-} (1 - y_i) \tag{32}$$

is added to the set of constraint functions and its index is included in the set $\mathcal{I}$ to define a hard inequality constraint $c(\boldsymbol{y}, \boldsymbol{x}) \leq 0$.

As an example of the grounding process, consider the following logical rule. As part of a program for link prediction, it is often helpful to model the transitivity of a relationship.

```
3 :  Friends(A, B) && Friends(B, C) -> Friends(C, A) ^2
```

Imagine that the input data are $\mathbb{C} = \{\}$, $\mathbb{O} = \{\texttt{Friends/2}\}$,

$$\mathcal{A} = \left\{ \begin{array}{l} \texttt{Friends("p1", "p2")}, \\ \texttt{Friends("p1", "p3")}, \\ \texttt{Friends("p2", "p1")}, \\ \texttt{Friends("p2", "p3")}, \\ \texttt{Friends("p3", "p1")}, \\ \texttt{Friends("p3", "p2")} \end{array} \right\} , \tag{33}$$

and $\mathcal{O}(a) = \emptyset, \forall a \in \mathcal{A}$. Then, the rule will induce six ground rules. One such ground rule is

```
3 :  Friends("p1", "p2") && Friends("p2", "p3") -> Friends("p3", "p1") ^2
```

which is equivalent to the following.

```
3 :  !Friends("p1", "p2") || !Friends("p2", "p3") || Friends("p3", "p1") ^2
```

If the atoms `Friends("p1", "p2")`, `Friends("p2", "p3")`, and `Friends("p3", "p1")` correspond to the random variables y_1, y_2, and y_3, respectively, then this ground rule is interpreted as the weighted hinge-loss potential

$$3 \ (\max\{y_1 + y_2 - y_3 - 1, 0\})^2 \ . \tag{34}$$

Since the grounding process uses the mapping from Section 2, logical rules can be used to reason accurately and efficiently about both discrete and continuous information. They are a convenient method for constructing HL-MRFs with the unified inference objective for weighted logical knowledge bases as their MAP inference objective. They also allow the user to seamlessly incorporate some of the additional features of HL-MRFs, such as squared potentials and hard constraints. Next, we introduce an even more flexible class of PSL rules.

4.1.5 Arithmetic Rules

Arithmetic rules in PSL are more general templates for hinge-loss potentials and hard linear constraints. Like logical rules, they come in weighted and unweighted variants, but instead of using logical operators they use arithmetic operators. In general, an arithmetic rule relates two linear combinations of atoms with an inequality or an equality. A simple example enforces the mutual exclusivity of liberal and conservative ideologies.

```
Liberal(P) + Conservative(P) = 1 .
```

Just like logical rules, arithmetic rules are grounded out by performing all possible substitutions of constants for variables to make ground atoms in the base $\mathcal{A}$. In this example, each substitution for `Liberal(P)` and `Conservative(P)` is constrained to sum to 1. Since the rule is unweighted and arithmetic, it defines a hard constraint $c(\boldsymbol{y}, \boldsymbol{x})$ and its index will be included in $\mathcal{E}$ because it is an equality constraint.

To make arithmetic rules more flexible and easy to use, we define some additional syntax. The first is a generalized definition of atoms that can be substituted with sums of ground atoms, rather than just a single atom.

Definition 13 *A* **summation atom** *is an atom that takes terms and/or sum variables as arguments. A summation atom represents the summations of ground atoms that can be obtained by substituting individual constants for variables and summing over all possible constants for sum variables.*

A sum variable is represented by prepending a plus symbol (`+`) to a variable. For example, the summation atom

```
Friends(P, +F)
```

is a placeholder for the sum of all ground atoms with predicate `Friends/2` in $\mathcal{A}$ that share a first argument. Note that sum variables can be used at most once in a rule, i.e., each sum variable in a rule must have a unique identifier. Summation atoms are useful because they can describe dependencies without needing to specify the number of atoms that can participate. For example, the arithmetic rule

```
Label(X, +L) = 1 .
```

says that labels for each constant substituted for `X` should sum to one, without needing to specify how many possible labels there are.

The substitutions for sum variables can be restricted using logical clauses as filters.

Definition 14 *A* **filter clause** *is a logical clause defined for a sum variable in an arithmetic rule. The logical clause only contains atoms (1) with predicates that appear in $\mathbb{C}$ and (2) that only take as arguments (a) constants, (b) variables that appear in the arithmetic rule, and (c) the sum variable for which it is defined.*

Filter clauses restrict the substitutions for a sum variable in the corresponding arithmetic rule by only including substitutions for which the clause evaluates to true. The filters are evaluated using Boolean logic. Each ground atom a is treated as having a value of 0 if and only if $\mathcal{O}(a) = 0$. Otherwise, it is treated as having a value of 1. For example, imagine that we want to restrict the summation in the following arithmetic rule to only constants that satisfy a property `Property/1`.

```
Link(X, +Y) <= 1 .
```

Then, we can add the following filter clause.

```
{Y: Property(Y)}
```

Then, the hard linear constraints templated by the arithmetic rule will only sum over constants substituted for `Y` such that `Property(Y)` is non-zero.

In arithmetic rules, atoms can also be modified with coefficients. These coefficients can be hard-coded. As a simple example, in the rule

```
Susceptible(X) >= 0.5 Biomarker1(X) + 0.5 Biomarker2(X) .
```

the property `Susceptible/1`, which represents the degree to which a patient is susceptible to a particular disease, must be at least the average value of two biomarkers.

PSL also supports two forms of coefficient-defining syntax. The first form of coefficient syntax is a cardinality function that counts the number of terms substituted for a sum variable. Cardinality functions enable rules that depend on the number of substitutions in order to be scaled correctly, such as when averaging. Cardinality is denoted by enclosing a sum variable, without the `+`, in pipes. For example, the rule

```
1 / |Y| Friends(X, +Y) = Friendliness(X) .
```

defines the `Friendliness/1` property of a person `X` in a social network as the average strength of their outgoing friendship links. In cases in which `Friends/2` is not symmetric, we can extend this rule to sum over both outgoing and incoming links as follows.

```
1 / |Y1| |Y2| Friends(X, +Y1) + 1 / |Y1| |Y2| Friends(+Y2, X)
= Friendliness(X) .
```

The second form of coefficient syntax is built-in coefficient functions. The exact set of supported functions is implementation specific, but standard functions like maximum and minimum should be included. Coefficient functions are prepended with `@` and use square brackets instead of parentheses to distinguish them from predicates. Coefficient functions can take either scalars or cardinality functions as arguments. For example, the following rule for matching two sets of constants requires that the sum of the `Matched/2` atoms be the minimum of the sizes of the two sets.

```
Matched(+X, +Y) = @Min[|X|, |Y|] .
```

Note that PSL's coefficient syntax can also be used to define constants, as in this example.

So far we have focused on using arithmetic rules to define templates for linear constraints, but they can also be used to define hinge-loss potentials. For example, the following arithmetic rule prefers that the degree to which a person `X` is extroverted (represented with `Extroverted/1`) does not exceed the average extroversion of their friends:

```
2 :  Extroverted(X) <= 1 / |Y| Extroverted(+Y) ^2
{Y: Friends(X, Y) || Friends(Y, X)}
```

This rule is a template for weighted hinge-loss potentials of the form

$$2 \left(\max \left\{ y_{i'} - \frac{1}{|\mathcal{F}|} \sum_{i \in \mathcal{F}} y_i, 0 \right\} \right)^2 , \tag{35}$$

where $y_{i'}$ is the variable corresponding to a grounding of the atom `Extroverted(X)` and $\mathcal{F}$ is the set of the indices of the variables corresponding to `Extroverted(Y)` atoms of the friends `Y` that satisfy the rule's filter clause. Note that the weight of 2 is distinct from the coefficients in the linear constraint $\ell(\boldsymbol{y}, \boldsymbol{x}) \leq 0$ defining the hinge-loss potential. If the arithmetic rule were an equality instead of an inequality, each grounding would be two hinge-loss potentials, one using $\ell(\boldsymbol{y}, \boldsymbol{x}) \leq 0$ and one using $-\ell(\boldsymbol{y}, \boldsymbol{x}) \leq 0$. In this way, arithmetic rules can define general hinge-loss potentials.

For completeness, we state the full, formal definition of an arithmetic rule and define its grounding procedure.

Definition 15 *An* **arithmetic rule** *is an inequality or equality relating two linear combinations of summation atoms. Each sum variable in an arithmetic rule can be used once. An arithmetic rule can be annotated with filter clauses for a subset of its sum variables that restrict its groundings. Arithmetic rules are either weighted or unweighted. If an arithmetic rule is weighted, it is annotated with a nonnegative weight and optionally a power of two.*

An arithmetic rule is grounded out by performing all distinct substitutions from variables to constants such that the resulting ground atoms are in the base $\mathcal{A}$. In addition, summation atoms are replaced by the appropriate summations over ground atoms (possibly restricted by corresponding filter clauses) and the coefficient is distributed across the summands. This leads to a set of ground rules for each arithmetic rule given a set of inputs. If the arithmetic rule is an unweighted inequality, each ground rule can be algebraically manipulated to be of the form $c(\boldsymbol{y}, \boldsymbol{x}) \leq 0$. Then $c(\boldsymbol{y}, \boldsymbol{x})$ is added to the set of constraint functions and its index is added to $\mathcal{I}$. If instead the arithmetic rule is an unweighted equality, each ground rule is manipulated to $c(\boldsymbol{y}, \boldsymbol{x}) = 0$, $c(\boldsymbol{y}, \boldsymbol{x})$ is added to the set of constraint functions, and its index is added to $\mathcal{E}$. If the arithmetic rule is a weighted inequality with weight w, each ground rule is manipulated to $\ell(\boldsymbol{y}, \boldsymbol{x}) \leq 0$ and included as a potential of the form

$$\phi(\boldsymbol{y}, \boldsymbol{x}) = \max \{ \ell(\boldsymbol{y}, \boldsymbol{x}), 0 \} \tag{36}$$

with a weight of w. If the arithmetic rule is a weighted equality with weight w, each ground rule is again manipulated to $\ell(\boldsymbol{y}, \boldsymbol{x}) \leq 0$ and two potentials are included,

$$\phi_1(\boldsymbol{y}, \boldsymbol{x}) = \max \{ \ell(\boldsymbol{y}, \boldsymbol{x}), 0 \}, \quad \phi_2(\boldsymbol{y}, \boldsymbol{x}) = \max \{ -\ell(\boldsymbol{y}, \boldsymbol{x}), 0 \} , \tag{37}$$

each with a weight of w. In either case, if the weighted arithmetic rule is annotated with `^2`, then the induced potentials are squared.

4.2 Expressivity

An important question is the expressivity of PSL, which uses disjunctive clauses with positive weights for its logical rules. Other logic-based languages support different types of clauses, such as Markov logic networks (Richardson and Domingos, 2006), which support clauses with conjunctions and clauses with negative weights. As we discuss in this section, PSL's logical rules capture a general class of structural dependencies, capable of modeling arbitrary probabilistic relationships among Boolean variables, such as those defined by Markov logic networks. The advantage of PSL is that it defines HL-MRFs, which are much more scalable than discrete MRFs and often just as accurate, as we show in Section 6.4.

The expressivity of PSL is tied to the expressivity of the MAX SAT problem, since they both use the same class of weighted clauses. There are two conditions on the clauses: (1) they have nonnegative weights, and (2) they are disjunctive. We first consider the nonnegativity requirement and show that can actually be viewed as a restriction on the structure of a clause. To illustrate, consider a weighted disjunctive clause of the form

$$-w \quad : \quad \left(\bigvee_{i \in I_j^+} x_i \right) \bigvee \left(\bigvee_{i \in I_j^-} \neg x_i \right) . \tag{38}$$

If this clause were part of a generalized MAX SAT problem, in which there were no restrictions on weight sign or clause structure, but the goal were still to maximize the sum of the weights of the satisfied clauses, then this clause could be replaced with an equivalent one

without changing the optimizer:

$$w \quad : \quad \left(\bigwedge_{i \in I_j^+} \neg x_i \right) \bigwedge \left(\bigwedge_{i \in I_j^-} x_i \right) . \tag{39}$$

Note that the clause has been changed in three ways: (1) the sign of the weight has been changed, (2) the disjunctions have been replaced with conjunctions, and (3) the literals have all been negated. Due to this equivalence, the restriction on the sign of the weights is subsumed by the restriction on the structure of the clauses. In other words, any set of clauses can be converted to a set with nonnegative weights that has the same optimizer, but it might require including conjunctions in the clauses. It is also easy to verify that if Equation (38) is used to define a potential in a discrete MRF, replacing it with a potential defined by (39) leaves the distribution unchanged, due to the normalizing partition function.

We now consider the requirement that clauses be disjunctive and illustrate how conjunctive clauses can be replaced by an equivalent set of disjunctive clauses. The idea is to construct a set of disjunctive clauses such that all assignments to the variables are mapped to the same score, up to a constant. A simple example is replacing a conjunction

$$w \quad : \quad x_1 \wedge x_2 \tag{40}$$

with disjunctions

$$w \quad : \quad x_1 \vee x_2 \tag{41}$$
$$w \quad : \quad \neg x_1 \vee x_2 \tag{42}$$
$$w \quad : \quad x_1 \vee \neg x_2 \, . \tag{43}$$

Observe that the total score for all assignments to the variables remains the same, up to a constant.

This example generalizes to a procedure for encoding any Boolean MRF into a set of disjunctive clauses with nonnegative weights. Park (2002) showed that the MAP problem for any discrete Bayesian network can be represented as an instance of MAX SAT. For distributions of bounded factor size, the MAX SAT problem has size polynomial in the number of variables and factors of the distribution. We describe how any Boolean MRF can be represented with disjunctive clauses and nonnegative weights. Given a Boolean MRF with arbitrary potentials defined by mappings from joint states of subsets of the variables to scores, a new MRF is created as follows. For each potential in the original MRF, a new set of potentials defined by disjunctive clauses is created. A conjunctive clause is created corresponding to each entry in the potential's mapping with a weight equal to the score assigned by the weighted potential in the original MRF. Then, these clauses are converted to equivalent disjunctive clauses as in the example of Equations (38) and (39) by also flipping the sign of their weights and negating the literals. Once this is done for all entries of all potentials, what remains is an MRF defined by disjunctive clauses, some of which might have negative weights. We make all weights positive by adding a sufficiently large constant to all weights of all clauses, which leaves the distribution unchanged due to the normalizing partition function.

It is important to note two caveats when converting arbitrary Boolean MRFs to MRFs defined using only disjunctive clauses with nonnegative weights. First, the number of clauses required to represent a potential in the original MRF is exponential in the degree of the potential. In practice, this is rarely a significant limitation, since MRFs often contain low-degree potentials. The other important point is that the step of adding a constant to all the weights increases the total score of the MAP state. Since the bound of Goemans and Williamson (1994) is relative to this score, the bound is loosened for the original problem the larger the constant added to the weights is. This is to be expected, since even approximating MAP is NP-hard in general (Abdelbar and Hedetniemi, 1998).

We have described how general structural dependencies can be modeled with the logical rules of PSL. It is possible to represent arbitrary logical relationships with them. The process for converting general rules to PSL's logical rules can be done automatically and made transparent to the user. We have elected in this section to define PSL's logical rules without making this conversion automatic to make clear the underlying formalism.

4.3 Modeling Patterns

PSL is a flexible language, and there are some patterns of usage that come up in many applications. We illustrate some of them in this subsection with a number of examples.

4.3.1 Domain and Range Rules

In many problems, the number of relations that can be predicted among some constants is known. For binary predicates, this background knowledge can be viewed as constraints on the domain (first argument) or range (second argument) of the predicate. For example, it might be background knowledge that each entity, such as a document, has exactly one label. An arithmetic rule to express this follows.

```
Label(Document, +LabelName) = 1 .
```

The predicate `Label` is said to be *functional*.

Alternatively, sometimes it is the first argument that should be summed over. For example, imagine the task of predicting relationships among students and professors. Perhaps it is known that each student has exactly one advisor. This constraint can be written as follows.

```
Advisor(+Professor, Student) = 1 .
```

The predicate `Advisor` is said to be *inverse functional*.

Finally, imagine a scenario in which two social networks are being aligned. The goal is to predict whether each pair of people, one from each network, is the same person, which is represented with atoms of the `Same` predicate. Each person aligns with at most one person in the other network, but might not align with anyone. This can be expressed with the following two arithmetic rules.

```
Same(Person1, +Person2) <= 1 .
Same(+Person1, Person2) <= 1 .
```

The predicate `Same` is said to be both *partial functional* and *partial inverse functional*.

Many variations on these examples are possible. For example, they can be generalized to predicates with more than two arguments. Additional arguments can either be fixed or summed over in each rule. As another example, domain and range rules can incorporate multiple predicates, so that an entity can participate in a fixed number of relations counted among multiple predicates.

4.3.2 Similarity

Many problems require explicitly reasoning about similarity, rather than simply whether entities are the same or different. For example, reasoning with similarity has been explored using kernel methods, such as kFoil (Landwehr et al., 2010) that bases similarity computation on the relational structure of the data. The continuous variables of HL-MRFs make modeling similarity straightforward, and PSL's support for functionally defined predicates makes it even easier. For example, in an entity resolution task, the degree to which two entities are believed to be the same might depend on how similar their names are. A rule expressing this dependency is

```
1.0 :  Name(P1, N1) && Name(P2, N2) && Similar(N1, N2) -> Same(P1, P2)
```

This rule uses the `Similar` predicate to measure similarity. Since it is a functionally defined predicate, it can be implemented as one of many different, possibly domain specialized, string similarity functions. Any similarity function that can output values in the range $[0, 1]$ can be used.

4.3.3 Priors

If no potentials are defined over a particular atom, then it is equally probable that it has any value between zero and one. Often, however, it should be more probable that an atom has a value of zero, unless there is evidence that it has a nonzero value. Since atoms typically represent the existence of some entity, attribute, or relation, this bias promotes sparsity among the things inferred to exist. Further, if there is a potential that prefers that an atom should have a value that is at least some numeric constant, such as when reasoning with similarities as discussed in Section 4.3.2, it often should also be more probable that an atom is no higher in value than is necessary to satisfy that potential. To accomplish both these goals, simple priors can be used to state that atoms should have low values in the absence of evidence to overrules those priors. A prior in PSL can be a rule consisting of just a negative literal with a small weight. For example, in a link prediction task, imagine that this preference should apply to atoms of the `Link` predicate. A prior is then

```
0.1 :  !Link(A, B)
```

which acts as a regularizer on `Link` atoms.

4.3.4 Blocks and Canopies

In many tasks, the number of unknowns can quickly grow large, even for modest amounts of data. For example, in a link prediction task the goal is to predict relations among entities. The number of possible links grows quadratically with the number of entities (for binary

relations). If handled naively, this growth could make scaling to large data sets difficult, but this problem is often handled by constructing *blocks* (e.g., Newcombe and Kennedy, 1962) or *canopies* (McCallum et al., 2000) over the entities, so that a limited subset of all possible links are actually considered. Blocking partitions the entities so that only links among entities in the same partition element, i.e., block, are considered. Alternatively, for a finer grained pruning, a canopy is defined for each entity, which is the set of other entities to which it could possibly link. Blocks and canopies can be computed using specialized, domain-specific functions, and PSL can incorporate them by including them as atoms in the bodies of rules. Since blocks can be seen as a special case of canopies, we let the atom `InCanopy(A, B)` be 1 if `B` is in the canopy or block of `A`, and 0 if it is not. Including `InCanopy(A, B)` atoms as additional conditions in the bodies of logical rules will ensure that the dependencies only exist between the desired entities.

4.3.5 Aggregates

Another powerful feature of PSL is its ability to easily define *aggregates*, which are rules that define random variables to be deterministic functions of sets of other random variables. The advantage of aggregates is that they can be used to define dependencies that do not scale in magnitude with the number of groundings in the data. For example, consider a model for predicting interests in a social network. A fragment of a PSL program for this task follows.

```
1.0 :  Interest(P1, I) && Friends(P1, P2) -> Interest(P2, I)
1.0 :  Age(P, "20-29") && Lives(P, "California") -> Interest(P, "Surfing")
```

These two rules express the belief that interests are correlated along friendship links in the social network, and also that certain demographic information is predictive of specific interests. The question any domain expert or learning algorithm faces is how strongly each rule should be weighted relative to each other. The challenge of answering this question when using templates is that the number of groundings of the first rule varies from person to person based on the number of friends, while the groundings of the second remain constant (one per person). This inconsistent scaling of the two types of dependencies makes it difficult to find weights that accurately reflect the relative influence each type of dependency should have across people with different numbers of friends.

Using an aggregate can solve this problem of inconsistent scaling. Instead of using a separate ground rule to relate the interest of each friend, we can define a rule that is only grounded once for each person, relating an average interest across all friends to each person's own interests. A PSL fragment for this approach is

```
1.0 :  AverageFriendInterest(P, I) -> Interest(P, I)
AverageFriendInterest(P, I) = 1 / |F| Interest(+F, I) .
{F: Friends(P, F)}

/* Demographic dependencies are also included.  */
```

where the predicate `AverageFriendInterest/2` is an aggregate that is constrained to be the average amount of interest each friend of a person `P` has in an interest `I`. The weight

of the logical rule can now be scaled more appropriately relative to other types of features because there is only one grounding per person.

For a more complex example, consider the problem of determining whether two references in the data refer to the same underlying person. One useful feature to use is whether they have similar sets of friends in the social network. Again, a rule could be defined that is grounded out for each friendship pair, but this would suffer from the same scaling issues as the previous example. Instead, we can use an aggregate to directly express how similar the two references' sets of friends are. A function that measures the similarity of two sets A and B is *Jaccard similarity*:

$$J(A, B) = \frac{|A \cap B|}{|A \cup B|} .$$

Jaccard similarity is a nonlinear function, meaning that it cannot be used directly without breaking the log-concavity of HL-MRFs, but we can approximate it with a linear function. We define `SameFriends/2` as an aggregate that approximates Jaccard similarity (where `SamePerson/2` is functional and inverse functional).

```
SameFriends(A, B) = 1 / @Max[|FA|, |FB|] SamePerson(+FA, +FB) .
{FA : Friends(A, FA)}
{FB : Friends(B, FB)}
SamePerson(+P1, P2) = 1 .
SamePerson(P1, +P2) = 1 .
```

The aggregate `SameFriends/2` uses the sum of the `SamePerson/2` atoms as the intersection of the two sets, and the maximum of the sizes of the two sets of friends as a lower bound on the size of their union.

5. MAP Inference

Having defined HL-MRFs and a language for creating them, PSL, we turn to algorithms for inference and learning. The first task we consider is maximum a posteriori (MAP) inference, the problem of finding a most probable assignment to the free variables $\boldsymbol{y}$ given observations $\boldsymbol{x}$. In HL-MRFs, the normalizing function $Z(\boldsymbol{w}, \boldsymbol{x})$ is constant over $\boldsymbol{y}$ and the exponential is maximized by minimizing its negated argument, so the MAP problem is

$$\begin{aligned} \arg\max_{\boldsymbol{y}} P(\boldsymbol{y}|\boldsymbol{x}) &\equiv \arg\min_{\boldsymbol{y}|\boldsymbol{y},\boldsymbol{x}\in\tilde{\boldsymbol{D}}} f_{\boldsymbol{w}}(\boldsymbol{y}, \boldsymbol{x}) \\ &\equiv \arg\min_{\boldsymbol{y}\in[0,1]^n} \boldsymbol{w}^\top \boldsymbol{\phi}(\boldsymbol{y}, \boldsymbol{x}) \\ \text{such that} \quad & c_k(\boldsymbol{y}, \boldsymbol{x}) = 0, \quad \forall k \in \mathcal{E} \\ & c_k(\boldsymbol{y}, \boldsymbol{x}) \leq 0, \quad \forall k \in \mathcal{I} . \end{aligned} \tag{44}$$

MAP is a fundamental problem because (1) it is the method we will use to make predictions, and (2) weight learning often requires performing MAP inference many times with different weights (as we discuss in Section 6). Here, HL-MRFs have a distinct advantage over general

discrete models, since minimizing $f_{\boldsymbol{w}}$ is a convex optimization rather than a combinatorial one. There are many off-the-shelf solutions for convex optimization, the most popular of which are interior-point methods, which have worst-case polynomial time complexity in the number of variables, potentials, and constraints (Nesterov and Nemirovskii, 1994). Although in practice they perform better than their worst-case bounds (Wright, 2005), they do not scale well to large structured prediction problems (Yanover et al., 2006). We therefore introduce a new algorithm for exact MAP inference designed to scale to large HL-MRFs by leveraging the sparse connectivity structure of the potentials and hard constraints that are typical of models for real-world tasks.

5.1 Consensus Optimization Formulation

Our algorithm uses *consensus optimization*, a technique that divides an optimization problem into independent subproblems and then iterates to reach a consensus on the optimum (Boyd et al., 2011). Given a HL-MRF $P(\boldsymbol{y}|\boldsymbol{x})$, we first construct an equivalent MAP problem in which each potential and hard constraint is a function of different variables. The variables are then constrained to make the new and original MAP problems equivalent. We let $\boldsymbol{y}_{(L,j)}$ be a local copy of the variables in $\boldsymbol{y}$ that are used in the potential function ϕ_j, $j = 1, \ldots, m$ and $\boldsymbol{y}_{(L,k+m)}$ be a copy of those used in the constraint function c_k, $k = 1, \ldots, r$. We refer to the concatenation of all of these vectors as $\boldsymbol{y}_L$. We also introduce a characteristic function χ_k for each constraint function where $\chi_k \left[c_k(\boldsymbol{y}_{(L,k+m)}, \boldsymbol{x})\right] = 0$ if the constraint is satisfied and infinity if it is not. Likewise, let $\chi_{[0,1]}$ be a characteristic function that is 0 if the input is in the interval $[0, 1]$ and infinity if it is not. We drop the constraints on the domain of $\boldsymbol{y}$, letting them range in principle over $\mathbb{R}^n$ and instead use these characteristic functions to enforce the domain constraints. This formulation will make computation easier when the problem is later decomposed. Finally, let $\boldsymbol{y}_{(C,\hat{i})}$ be the variables in $\boldsymbol{y}$ that correspond to $\boldsymbol{y}_{(L,\hat{i})}$, $\hat{i} = 1, \ldots, m + r$. Operators between $\boldsymbol{y}_{(L,\hat{i})}$ and $\boldsymbol{y}_{(C,\hat{i})}$ are defined element-wise, pairing the corresponding copied variables. Consensus optimization solves the reformulated MAP problem

$$\begin{aligned} \arg\min_{(\boldsymbol{y}_L, \boldsymbol{y})} \quad & \sum_{j=1}^{m} w_j \phi_j \left(\boldsymbol{y}_{(L,j)}, \boldsymbol{x}\right) + \sum_{k=1}^{r} \chi_k \left[c_k \left(\boldsymbol{y}_{(L,k+m)}, \boldsymbol{x}\right)\right] + \sum_{i=1}^{n} \chi_{[0,1]} \left[y_i\right] \\ \text{such that} \quad & \boldsymbol{y}_{(L,\hat{i})} = \boldsymbol{y}_{(C,\hat{i})} \quad \forall \hat{i} = 1, \ldots, m + r . \end{aligned} \tag{45}$$

Inspection shows that problems (44) and (45) are equivalent.

This reformulation enables us to relax the equality constraints $\boldsymbol{y}_{(L,\hat{i})} = \boldsymbol{y}_{(C,\hat{i})}$ in order to divide problem (45) into independent subproblems that are easier to solve, using the alternating direction method of multipliers (ADMM) (Glowinski and Marrocco, 1975; Gabay and Mercier, 1976; Boyd et al., 2011). The first step is to form the *augmented Lagrangian* function for the problem. Let $\boldsymbol{\alpha} = (\boldsymbol{\alpha}_1, \ldots, \boldsymbol{\alpha}_{m+r})$ be a concatenation of vectors of Lagrange

multipliers. Then the augmented Lagrangian is

$$\mathcal{L}(\boldsymbol{y}_L, \boldsymbol{\alpha}, \boldsymbol{y}) = \sum_{j=1}^{m} w_j \phi_j \left(\boldsymbol{y}_{(L,j)}, \boldsymbol{x}\right) + \sum_{k=1}^{r} \chi_k \left[c_k \left(\boldsymbol{y}_{(L,k+m)}, \boldsymbol{x}\right)\right] + \sum_{i=1}^{n} \chi_{[0,1]}\left[y_i\right] + \sum_{\hat{i}=1}^{m+r} \boldsymbol{\alpha}_{\hat{i}}^{\top} \left(\boldsymbol{y}_{(L,\hat{i})} - \boldsymbol{y}_{(C,\hat{i})}\right) + \frac{\rho}{2} \sum_{\hat{i}=1}^{m+r} \left\|\boldsymbol{y}_{(L,\hat{i})} - \boldsymbol{y}_{(C,\hat{i})}\right\|_2^2 \quad (46)$$

using a step-size parameter $\rho > 0$. ADMM finds a saddle point of $\mathcal{L}(\boldsymbol{y}_L, \boldsymbol{\alpha}, \boldsymbol{y})$ by updating the three blocks of variables at each iteration t:

$$\boldsymbol{\alpha}_{\hat{i}}^{t} \leftarrow \boldsymbol{\alpha}_{\hat{i}}^{t-1} + \rho \left(\boldsymbol{y}_{(L,\hat{i})}^{t-1} - \boldsymbol{y}_{(C,\hat{i})}^{t-1}\right) \qquad \forall \hat{i} = 1, \ldots, m+r \quad (47)$$

$$\boldsymbol{y}_L^{t} \leftarrow \operatorname*{arg\,min}_{\boldsymbol{y}_L} \; \mathcal{L}\left(\boldsymbol{y}_L, \boldsymbol{\alpha}^t, \boldsymbol{y}^{t-1}\right) \quad (48)$$

$$\boldsymbol{y}^{t} \leftarrow \operatorname*{arg\,min}_{\boldsymbol{y}} \; \mathcal{L}\left(\boldsymbol{y}_L^t, \boldsymbol{\alpha}^t, \boldsymbol{y}\right) \quad (49)$$

The ADMM updates ensure that $\boldsymbol{y}$ converges to the global optimum $\boldsymbol{y}^\star$, the MAP state of $P(\boldsymbol{y}|\boldsymbol{x})$, assuming that there exists a feasible assignment to $\boldsymbol{y}$. We check convergence using the criteria suggested by Boyd et al. (2011), measuring the primal and dual residuals at the end of iteration t, defined as

$$\|\bar{\boldsymbol{r}}^t\|_2 \triangleq \left(\sum_{\hat{i}=1}^{m+r} \|\boldsymbol{y}_{(L,\hat{i})}^t - \boldsymbol{y}_{(C,\hat{i})}^t\|_2^2\right)^{\frac{1}{2}} \qquad \|\bar{\boldsymbol{s}}^t\|_2 \triangleq \rho \left(\sum_{i=1}^{n} \mathcal{K}_i (y_i^t - y_i^{t-1})^2\right)^{\frac{1}{2}} \quad (50)$$

where $\mathcal{K}_i$ is the number of copies made of the variable y_i, i.e., the number of different potentials and constraints in which the variable participates. The updates are terminated when both of the following conditions are satisfied

$$\|\bar{\boldsymbol{r}}^t\|_2 \leq \epsilon^{\text{abs}} \sqrt{\sum_{i=1}^{n} \mathcal{K}_i} + \epsilon^{\text{rel}} \max\left\{\left(\sum_{\hat{i}=1}^{m+r} \|\boldsymbol{y}_{(L,\hat{i})}^t\|_2^2\right)^{\frac{1}{2}}, \left(\sum_{i=1}^{n} \mathcal{K}_i (y_i^t)^2\right)^{\frac{1}{2}}\right\} \quad (51)$$

$$\|\bar{\boldsymbol{s}}^t\|_2 \leq \epsilon^{\text{abs}} \sqrt{\sum_{i=1}^{n} \mathcal{K}_i} + \epsilon^{\text{rel}} \left(\sum_{\hat{i}=1}^{m+r} \|\boldsymbol{\alpha}_{\hat{i}}^t\|_2^2\right)^{\frac{1}{2}} \quad (52)$$

using convergence parameters ϵ^{abs} and ϵ^{rel}.

5.2 Block Updates

We now describe how to implement the ADMM block updates (47), (48), and (49). Updating the Lagrange multipliers $\boldsymbol{\alpha}$ is a simple step in the gradient direction (47). Updating the local copies $\boldsymbol{y}_L$ (48) decomposes over each potential and constraint in the HL-MRF. For the

variables $\boldsymbol{y}_{(L,j)}$ for each potential ϕ_j, this requires independently optimizing the weighted potential plus a squared norm:

$$\operatorname*{arg\,min}_{\boldsymbol{y}_{(L,j)}} \; w_j \left(\max\left\{\ell_j(\boldsymbol{y}_{(L,j)}, \boldsymbol{x}), 0\right\}\right)^{p_j} + \frac{\rho}{2} \left\|\boldsymbol{y}_{(L,j)} - \boldsymbol{y}_{(C,j)} + \frac{1}{\rho}\boldsymbol{\alpha}_j\right\|_2^2 . \quad (53)$$

Although this optimization problem is convex, the presence of the hinge function complicates it. It could be solved in principle with an iterative method, such as an interior-point method, but such methods would become very expensive over many ADMM updates. Fortunately, we can reduce the problem to checking several cases and find solutions much more quickly.

There are three cases for $\boldsymbol{y}_{(L,j)}^\star$, the optimizer of problem (53), which correspond to the three regions in which the solution could lie: (1) the region $\ell(\boldsymbol{y}_{(L,j)}, \boldsymbol{x}) < 0$, (2) the region $\ell(\boldsymbol{y}_{(L,j)}, \boldsymbol{x}) > 0$, and (3) the region $\ell(\boldsymbol{y}_{(L,j)}, \boldsymbol{x}) = 0$. We check each case by replacing the potential with its value on the corresponding region, optimizing, and checking if the optimizer is in the correct region. We check the first case by replacing the potential ϕ_j with zero. Then, the optimizer of the modified problem is $\boldsymbol{y}_{(C,j)} - \boldsymbol{\alpha}_j/\rho$. If $\ell_j(\boldsymbol{y}_{(C,j)} - \boldsymbol{\alpha}_j/\rho, \boldsymbol{x}) \leq 0$, then $\boldsymbol{y}_{(L,j)}^\star = \boldsymbol{y}_{(C,j)} - \boldsymbol{\alpha}_j/\rho$, because it optimizes both the potential and the squared norm independently. If instead $\ell_j(\boldsymbol{y}_{(C,j)} - \boldsymbol{\alpha}_j/\rho, \boldsymbol{x}) > 0$, then we can conclude that $\ell_j(\boldsymbol{y}_{(L,j)}^\star, \boldsymbol{x}) \geq 0$, leading to one of the next two cases.

In the second case, we replace the maximum term with the inner linear function. Then the optimizer of the modified problem is found by taking the gradient of the objective with respect to $\boldsymbol{y}_{(L,j)}$, setting the gradient equal to the zero vector, and solving for $\boldsymbol{y}_{(L,j)}$. In other words, the optimizer is the solution for $\boldsymbol{y}_{(L,j)}$ to the equation

$$\nabla_{\boldsymbol{y}_{(L,j)}} \left[w_j \left(\ell_j(\boldsymbol{y}_{(L,j)}, \boldsymbol{x})\right)^{p_j} + \frac{\rho}{2} \left\|\boldsymbol{y}_{(L,j)} - \boldsymbol{y}_{(C,j)} + \frac{1}{\rho}\boldsymbol{\alpha}_j\right\|_2^2\right] = \boldsymbol{0} . \quad (54)$$

This condition defines a simple system of linear equations. If $p_j = 1$, then the coefficient matrix is diagonal and trivial to solve. If $p_j = 2$, then the coefficient matrix is symmetric and positive definite, and the system can be solved via Cholesky decomposition. (Since the potentials of an HL-MRF often have shared structures, perhaps templated by a PSL program, the Cholesky decompositions can be cached and shared among potentials for improved performance.) Let $\boldsymbol{y}'_{(L,j)}$ be the optimizer of the modified problem, i.e., the solution to equation (54). If $\ell_j(\boldsymbol{y}'_{(L,j)}, \boldsymbol{x}) \geq 0$, then $\boldsymbol{y}^\star_{(L,j)} = \boldsymbol{y}'_{(L,j)}$ because we know the solution lies in the region $\ell_j(\boldsymbol{y}_{(L,j)}, \boldsymbol{x}) \geq 0$ and the objective of problem (53) and the modified objective are equal on that region. In fact, if $p_j = 2$, then $\ell_j(\boldsymbol{y}'_{(L,j)}, \boldsymbol{x}) \geq 0$ whenever $\ell_j(\boldsymbol{y}_{(C,j)} - \boldsymbol{\alpha}_j/\rho, \boldsymbol{x}) \geq 0$, because the modified term is symmetric about the line $\ell_j(\boldsymbol{y}_{(L,j)}, \boldsymbol{x}) = 0$. We therefore will only reach the following third case when $p_j = 1$. If $\ell_j(\boldsymbol{y}_{(C,j)} - \boldsymbol{\alpha}_j/\rho, \boldsymbol{x}) > 0$ and $\ell_j(\boldsymbol{y}'_{(L,j)}, \boldsymbol{x}) < 0$, then we can conclude that $\boldsymbol{y}^\star_{(L,j)}$ is the projection of $\boldsymbol{y}_{(C,j)} - \boldsymbol{\alpha}_j/\rho$ onto the hyperplane $c_k(\boldsymbol{y}_{(L,j)}, \boldsymbol{x}) = 0$. This constraint must be active because it is violated by the optimizers of both modified objectives (Martins et al., 2015, Lemma 17). Since the potential has a value of zero whenever the constraint is active, solving problem (53) reduces to the projection operation.

For the local copies $\boldsymbol{y}_{(L,k+m)}$ for each constraint c_k, the subproblem is easier:

$$\underset{\boldsymbol{y}_{(L,k+m)}}{\arg\min}\ \chi_k\left[c_k(\boldsymbol{y}_{(L,k+m)},\boldsymbol{x})\right] + \frac{\rho}{2}\left\|\boldsymbol{y}_{(L,k+m)} - \boldsymbol{y}_{(C,k+m)} + \frac{1}{\rho}\boldsymbol{\alpha}_{k+m}\right\|_2^2. \tag{55}$$

Whether c_k is an equality or inequality constraint, the solution is the projection of $\boldsymbol{y}_{(C,k+m)} - \boldsymbol{\alpha}_{k+m}/\rho$ to the feasible set defined by the constraint. If c_k is an equality constraint, i.e., $k \in \mathcal{E}$, then the optimizer $\boldsymbol{y}^\star_{(L,k+m)}$ is the projection of $\boldsymbol{y}_{(C,k+m)} - \boldsymbol{\alpha}_{k+m}/\rho$ onto $c_k(\boldsymbol{y}_{(L,k+m)},\boldsymbol{x}) = 0$. If, on the other hand, c_k is an inequality constraint, i.e., $k \in \mathcal{I}$, then there are two cases. First, if $c_k(\boldsymbol{y}_{(C,k+m)} - \boldsymbol{\alpha}_{k+m}/\rho, \boldsymbol{x}) \leq 0$, then the solution is simply $\boldsymbol{y}_{(C,k+m)} - \boldsymbol{\alpha}_{k+m}/\rho$. Otherwise, it is again the projection onto $c_k(\boldsymbol{y}_{(L,k+m)},\boldsymbol{x}) = 0$.

To update the variables $\boldsymbol{y}$ (49), we solve the optimization

$$\underset{\boldsymbol{y}}{\arg\min}\ \sum_{i=1}^{n}\chi_{[0,1]}\left[y_i\right] + \frac{\rho}{2}\sum_{\hat{i}=1}^{m+r}\left\|\boldsymbol{y}_{(L,\hat{i})} - \boldsymbol{y}_{(C,\hat{i})} + \frac{1}{\rho}\boldsymbol{\alpha}_{\hat{i}}\right\|_2^2. \tag{56}$$

The optimizer is the state in which y_i is set to the average of its corresponding local copies added with their corresponding Lagrange multipliers divided by the step size ρ, and then clipped to the $[0,1]$ interval. More formally, let $\texttt{copies}(y_i)$ be the set of local copies y_c of y_i, each with a corresponding Lagrange multiplier α_c. Then, we update each y_i using

$$y_i \leftarrow \frac{1}{|\texttt{copies}(y_i)|}\sum_{y_c \in \texttt{copies}(y_i)}\left(y_c + \frac{\alpha_c}{\rho}\right) \tag{57}$$

and clip the result to $[0,1]$. Specifically, if, after update (57), $y_i > 1$, then we set y_i to 1 and likewise set it to 0 if $y_i < 0$.

Algorithm 1 shows the complete pseudocode for MAP inference. The method starts by initializing local copies of the variables that appear in each potential and constraint, along with a corresponding Lagrange multiplier for each copy. Then, until convergence, it iteratively performs the updates (47), (48), and (49). In the pseudocode, we have interleaved updates (47) and (48), updating both the Lagrange multipliers $\boldsymbol{\alpha}_{\hat{i}}$ and the local copies $\boldsymbol{y}_{(L,\hat{i})}$ together for each subproblem, because they are local operations that do not depend on other variables once $\boldsymbol{y}$ is updated in the previous iteration. This independence reveals another advantage of our inference algorithm: it is very easy to parallelize. The updates (47) and (48) can be performed in parallel, the results gathered, update (49) performed, and the updated $\boldsymbol{y}$ broadcast back to the subproblems. Parallelization makes our MAP inference algorithm even faster and more scalable.

5.3 Lazy MAP Inference

One interesting and useful property of HL-MRFs is that it is not always necessary to completely materialize the distribution in order to find a MAP state. Consider a subset $\hat{\boldsymbol{\phi}}$ of the index set $\{1,\ldots,m\}$ of the potentials $\boldsymbol{\phi}$. Observe that if a feasible assignment to $\boldsymbol{y}$ minimizes

$$\sum_{j\in\hat{\boldsymbol{\phi}}} w_j\phi_j(\boldsymbol{y},\boldsymbol{x}) \tag{58}$$

Algorithm 1 MAP Inference for HL-MRFs

Input: HL-MRF $P(\boldsymbol{y}|\boldsymbol{x})$, $\rho > 0$

Initialize $\boldsymbol{y}_{(L,j)}$ as local copies of variables $\boldsymbol{y}_{(C,j)}$ that are in ϕ_j, $j = 1,\ldots,m$

and $\phi_j(\boldsymbol{y}, \boldsymbol{x}) = 0, \forall j \notin \hat{\boldsymbol{\phi}}$, then that assignment must be a MAP state because 0 is the global minimum for any potential. Therefore, if we can identify a set of potentials that is small, such that all the other potentials are 0 in a MAP state, then we can perform MAP inference in a reduced amount of time. Of course, identifying this set is as hard as MAP inference itself, but we can iteratively grow the set by starting with an initial set, performing inference over the current set, adding any potentials that have nonzero values, and repeating.

Since the lazy inference procedure requires that the assignment be feasible, there are two ways to handle any constraints in the HL-MRF. One is to include all constraints in the inference problem from the beginning. This strategy ensures feasibility, but the idea of lazy grounding can also be extended to constraints to improve performance further. Just as we check if potentials are unsatisfied, i.e., nonzero, we can also check if constraints are unsatisfied, i.e., violated. So the algorithm now iteratively grows the set of active potentials and active constraints, adding any that are unsatisfied until the MAP state of the HL-MRF defined by the active potentials and constraints is also a feasible MAP state of the true HL-MRF.

The efficiency of lazy MAP inference can be improved heuristically by not adding all unsatisfied potentials and constraints, but instead only adding those that are unsatisfied by some threshold. This heuristic can decrease computational cost significantly, although the results are no longer guaranteed to be correct. Bounding the resulting error when possible is an important direction for future work.

5.4 Evaluation of MAP Inference

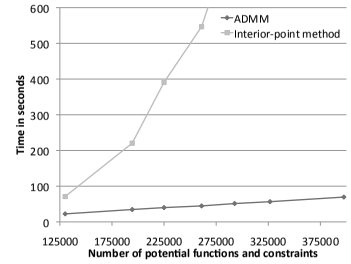
In this section we evaluate the empirical performance of our MAP inference algorithm.[4] We compare its running times against those of MOSEK,[5] a commercial convex optimization toolkit that uses interior-point methods (IPMs). We confirm the results of Yanover et al. (2006) that IPMs do not scale well to large structured-prediction problems, and we show that our MAP inference algorithm scales much better. In fact, we observe that our method scales linearly in practice with the number of potentials and constraints in the HL-MRF.

We evaluate scalability by generating social networks of varying sizes, constructing HL-MRFs over them, and measuring the running time required to find a MAP state. We compare our algorithm to MOSEK's IPM. The social networks we generate are designed to be representative of common social-network analysis tasks. We generate networks of users that are connected by different types of relationships, such as friendship and marriage, and our goal is to predict the political preferences, e.g., liberal or conservative, of each user. We also assume that we have local information about each user, representing features such as demographic information.

We generate the social networks using power-law distributions according to a procedure described by Broecheler et al. (2010b). For a target number of users N, in-degrees and out-degrees d for each edge type are sampled from the power-law distribution $D(k) \equiv \alpha k^{-\gamma}$. Incoming and outgoing edges of the same type are then matched randomly to create edges until no more matches are possible. The number of users is initially the target number

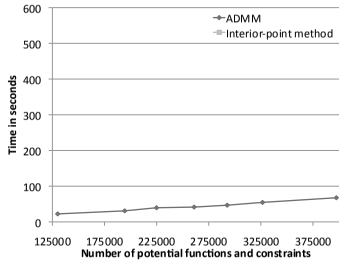
4. Code is available at `https://github.com/stephenbach/bach-jmlr17-code`.
5. http://www.mosek.com

plus the expected number of users with zero edges, and then users without any edges are removed. We use six edge types with various parameters to represent relationships in social networks with different combinations of abundance and exclusivity, choosing γ between 2 and 3, and α between 0 and 1, as suggested by Broecheler et al. We then annotate each vertex with a value in $[-1, 1]$ uniformly at random to represent local features indicating one political preference or the other.



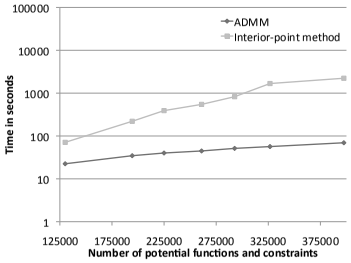
We generate social networks with between 22k and 66k vertices, which induce HL-MRFs with between 130k and 397k total potentials and constraints. In all the HL-MRFs, roughly 85% of those totals are potentials. For each social network, we create both a (log) piecewise-linear HL-MRF ($p_j = 1, \forall j = 1, \ldots, m$ in Definition 3) and a piecewise-quadratic one ($p_j = 2, \forall j = 1, \ldots, m$). We weight local features with a parameter of 0.5 and choose parameters in $[0, 1]$ for the relationship potentials representing a mix of more and less influential relationships.

We implement ADMM in Java and compare with the IPM in MOSEK (version 6) by encoding the entire MPE problem as a linear program or a second-order cone program as appropriate and passing the encoded problem via the Java native interface wrapper. All experiments are performed on a single machine with a 4-core 3.4 GHz Intel Core i7-3770 processor with 32GB of RAM. Each optimizer used a single thread, and all results are averaged over 3 runs.



We first evaluate the scalability of ADMM when solving piecewise-linear MAP problems and compare with MOSEK's interior-point method. Figures 1a (normal scale) and 1c (log scale) show the results. The running time of the IPM quickly explodes as the problem size increases. The IPM's average running time on the largest problem is about 2,200 seconds (37 minutes). This result demonstrates the limited scalability of the interior-point method. In contrast, ADMM displays excellent scalability. The average running time on the largest problem is about 70 seconds. Further, the running time appears to grow linearly in the number of potential functions and constraints in the HL-MRF, i.e., the number of subproblems that must be solved at each iteration. The line of best fit for all runs on all sizes has a coefficient of determination $R^2 = 0.9972$. Combined with Figure 1a, this shows that ADMM scales linearly with increasing problem size in this experiment. We emphasize that the implementation of ADMM is research code written in Java and the IPM is a commercial package compiled to native machine code.

We then evaluate the scalability of ADMM when solving piecewise-quadratic MAP problem and again compare with MOSEK. Figures 1b (normal scale) and 1d (log scale) show the results. Again, the running time of the interior-point method quickly explodes. We can only test it on the three smallest problems, the largest of which took an average of about 21k seconds to solve (over 6 hours). ADMM again scales linearly to the problem ($R^2 = 0.9854$). It is just as fast for quadratic problems as linear ones, taking average of about 70 seconds on the largest problem.



One of the advantages of IPMs is great numerical stability and accuracy. Consensus optimization, which treats both objective terms and constraints as subproblems, often returns solutions that are only optimal and feasible to moderate precision for non-trivially constrained problems (Boyd et al., 2011). Although this is often acceptable, we quantify the mix of infeasibility and suboptimality by repairing the infeasibility and measuring the resulting total suboptimality. We first project the solutions returned by consensus opti-

mization onto the feasible region, which took a negligible amount of computational time. Let p_{ADMM} be the value of the objective in Problem (45) at such a point and let p_{IPM} be the value of the objective at the solution returned by the IPM. Then the relative error on that problem is $(p_{\text{ADMM}} - p_{\text{IPM}})/p_{\text{IPM}}$. The relative error was consistently small; it varied between 0.2% and 0.4%, and did not trend upward as the problem size increased. This shows that ADMM was accurate, in addition to being much more scalable.

6. Weight Learning

In this section we present three weight learning methods for HL-MRFs, each with a different objective function. The first method approximately maximizes the likelihood of the training data. The second method maximizes the pseudolikelihood. The third method finds a large-margin solution, preferring weights that discriminate the ground truth from other nearby states. Since weights are often shared among many potentials defined by a template, such as all the groundings of a PSL rule, we describe these learning algorithms in terms of templated HL-MRFs. We introduce some necessary notation for HL-MRF templates. Let $\mathcal{T} = (t_1, \ldots, t_s)$ denote a vector of templates with associated weights $\boldsymbol{W} = (W_1, \ldots, W_s)$. We partition the potentials by their associated templates and let t_q also denote the set of indices of the potentials defined by that template. So, $j \in t_q$ is a shorthand for saying that the potential $\phi_j(\boldsymbol{y}, \boldsymbol{x})$ was defined by template t_q. Then, we refer to the sum of the potentials defined by a template as

$$\Phi_q(\boldsymbol{y}, \boldsymbol{x}) = \sum_{j \in t_q} \phi_j(\boldsymbol{y}, \boldsymbol{x}) \ . \tag{59}$$

In the defined HL-MRF, the weight of the j-th hinge-loss potential is set to the weight of the template from which it was derived, i.e., $w_j = W_q$, for each $j \in t_q$. Equivalently, we can rewrite the hinge-loss energy function as

$$f_{\boldsymbol{w}}(\boldsymbol{y}, \boldsymbol{x}) = \boldsymbol{W}^\top \boldsymbol{\Phi}(\boldsymbol{y}, \boldsymbol{x}) \ , \tag{60}$$

where $\boldsymbol{\Phi}(\boldsymbol{y}, \boldsymbol{x}) = (\Phi_1(\boldsymbol{y}, \boldsymbol{x}), \ldots, \Phi_s(\boldsymbol{y}, \boldsymbol{x}))$.

6.1 Structured Perceptron and Approximate Maximum Likelihood Estimation

The canonical approach for learning parameters $\boldsymbol{W}$ is to maximize the log-likelihood of training data. The partial derivative of the log-likelihood with respect to a parameter W_q is

$$\frac{\partial \log P(\boldsymbol{y}|\boldsymbol{x})}{\partial W_q} = \mathbb{E}_{\boldsymbol{W}} \left[\Phi_q(\boldsymbol{y}, \boldsymbol{x})\right] - \Phi_q(\boldsymbol{y}, \boldsymbol{x}), \tag{61}$$

where $\mathbb{E}_{\boldsymbol{W}}$ is the expectation under the distribution defined by $\boldsymbol{W}$. For a smoother ascent, it is often helpful to divide the q-th component of the gradient by the number of groundings $|t_q|$ of the q-th template (Lowd and Domingos, 2007), which we do in our experiments. Computing the expectation is intractable, so we use a common approximation (e.g., Collins, 2002; Singla and Domingos, 2005; Poon and Domingos, 2011): the values of the potentials at the most probable setting of $\boldsymbol{y}$ with the current parameters, i.e., a MAP state. Using a MAP state makes this learning approach a structured variant of voted perceptron (Collins,

2002), and we expect it to do best when the space of explored distributions has relatively low entropy. Following voted perceptron, we take steps of fixed length in the direction of the gradient, then average the points after all steps. Any step that is outside the feasible region is projected back before continuing.

6.2 Maximum Pseudolikelihood Estimation

An alternative to structured perceptron is *maximum-pseudolikelihood estimation* (MPLE) (Besag, 1975), which maximizes the likelihood of each variable conditioned on all other variables, i.e.,

$$P^*(\boldsymbol{y}|\boldsymbol{x}) = \prod_{i=1}^{n} P^*(y_i|\mathrm{MB}(y_i), \boldsymbol{x}) \tag{62}$$

$$= \prod_{i=1}^{n} \frac{1}{Z_i(\boldsymbol{W}, \boldsymbol{y}, \boldsymbol{x})} \exp\left[-f^i_{\boldsymbol{w}}(y_i, \boldsymbol{y}, \boldsymbol{x})\right]; \tag{63}$$

$$Z_i(\boldsymbol{W}, \boldsymbol{y}, \boldsymbol{x}) = \int_{y_i} \exp\left[-f^i_{\boldsymbol{w}}(y_i, \boldsymbol{y}, \boldsymbol{x})\right]; \tag{64}$$

$$f^i_{\boldsymbol{w}}(y_i, \boldsymbol{y}, \boldsymbol{x}) = \sum_{j: i \in \phi_j} w_j \phi_j\left(\{y_i \cup \boldsymbol{y}_{\setminus i}\}, \boldsymbol{x}\right). \tag{65}$$

Here, $i \in \phi_j$ means that y_i is involved in ϕ_j, and $\mathrm{MB}(y_i)$ denotes the *Markov blanket* of y_i—that is, the set of variables that co-occur with y_i in any potential function. The partial derivative of the log-pseudolikelihood with respect to W_q is

$$\frac{\partial \log P^*(\boldsymbol{y}|\boldsymbol{x})}{\partial W_q} = \sum_{i=1}^{n} \mathbb{E}_{y_i|\mathrm{MB}}\left[\sum_{j \in t_q : i \in \phi_j} \phi_j(\boldsymbol{y}, \boldsymbol{x})\right] - \Phi_q(\boldsymbol{y}, \boldsymbol{x}) \ . \tag{66}$$

Computing the pseudolikelihood gradient does not require joint inference and takes time linear in the size of $\boldsymbol{y}$. However, the integral in the above expectation does not readily admit a closed-form antiderivative, so we approximate the expectation. When a variable is unconstrained, the domain of integration is a one-dimensional interval on the real number line, so Monte Carlo integration quickly converges to an accurate estimate of the expectation.

We can also apply MPLE when the constraints are not too interdependent. For example, for linear equality constraints over disjoint groups of variables (e.g., variable sets that must sum to 1.0), we can block-sample the constrained variables by sampling uniformly from a simplex. These types of constraints are often used to represent categorical labels. We can compute accurate estimates quickly because these blocks are typically low-dimensional.

6.3 Large-Margin Estimation

A different approach to learning drops the probabilistic interpretation of the model and views HL-MRF inference as a prediction function. Large-margin estimation (LME) shifts the goal of learning from producing accurate probabilistic models to instead producing accurate MAP predictions. The learning task is then to find weights $\boldsymbol{W}$ that separate the ground truth from other nearby states by a large margin. We describe in this section

a large-margin method based on the cutting-plane approach for structural support vector machines (Joachims et al., 2009).

The intuition behind large-margin structured prediction is that the ground-truth state should have energy lower than any alternate state by a large margin. In our setting, the output space is continuous, so we parameterize this margin criterion with a continuous loss function. For any valid output state $\tilde{\boldsymbol{y}}$, a large-margin solution should satisfy

$$f_{\boldsymbol{w}}(\boldsymbol{y}, \boldsymbol{x}) \leq f_{\boldsymbol{w}}(\tilde{\boldsymbol{y}}, \boldsymbol{x}) - L(\boldsymbol{y}, \tilde{\boldsymbol{y}}), \quad \forall \tilde{\boldsymbol{y}}, \tag{67}$$

where the loss function $L(\boldsymbol{y}, \tilde{\boldsymbol{y}})$ measures the disagreement between a state $\tilde{\boldsymbol{y}}$ and the training label state $\boldsymbol{y}$. A common assumption is that the loss function decomposes over the prediction components, i.e., $L(\boldsymbol{y}, \tilde{\boldsymbol{y}}) = \sum_i L(y_i, \tilde{y}_i)$. In this work, we use the ℓ_1 distance as the loss function, so $L(\boldsymbol{y}, \tilde{\boldsymbol{y}}) = \sum_i \|y_i - \tilde{y}_i\|_1$. Since we do not expect all problems to be perfectly separable, we relax the large-margin constraint with a penalized slack ξ. We obtain a convex learning objective for a large-margin solution

$$\begin{aligned} \min_{\boldsymbol{W} \geq 0} \quad & \frac{1}{2}||\boldsymbol{W}||^2 + C\xi \\ \text{s.t.} \quad & \boldsymbol{W}^\top(\Phi(\boldsymbol{y}, \boldsymbol{x}) - \Phi(\tilde{\boldsymbol{y}}, \boldsymbol{x})) \leq -L(\boldsymbol{y}, \tilde{\boldsymbol{y}}) + \xi, \quad \forall \tilde{\boldsymbol{y}}, \end{aligned} \tag{68}$$

where $\Phi(\boldsymbol{y}, \boldsymbol{x}) = (\Phi_1(\boldsymbol{y}, \boldsymbol{x}), \ldots, \Phi_s(\boldsymbol{y}, \boldsymbol{x}))$ and $C > 0$ is a user-specified parameter. This formulation is analogous to the margin-rescaling approach by Joachims et al. (2009). Though such a structured objective is natural and intuitive, its number of constraints is the cardinality of the output space, which here is infinite. Following their approach, we optimize subject to the infinite constraint set using a *cutting-plane algorithm*: we greedily grow a set K of constraints by iteratively adding the worst-violated constraint given by a *separation oracle*, then updating $\boldsymbol{W}$ subject to the current constraints. The goal of the cutting-plane approach is to efficiently find the set of active constraints at the solution for the full objective, without having to enumerate the infinite inactive constraints. The worst-violated constraint is

$$\arg\min_{\tilde{\boldsymbol{y}}} \boldsymbol{W}^\top \Phi(\tilde{\boldsymbol{y}}, \boldsymbol{x}) - L(\boldsymbol{y}, \tilde{\boldsymbol{y}}). \tag{69}$$

The separation oracle performs loss-augmented inference by adding additional potentials to the HL-MRF. For ground truth in $\{0, 1\}$, these loss-augmenting potentials are also examples of hinge-losses, and thus adding them simply creates an augmented HL-MRF. The worst-violated constraint is then computed as standard inference on the loss-augmented HL-MRF. However, ground truth values in the interior $(0, 1)$ cause any distance-based loss to be concave, which require the separation oracle to solve a non-convex objective. In this case, we use the *difference of convex functions algorithm* (An and Tao, 2005) to find a local optimum. Since the concave portion of the loss-augmented inference objective pivots around the ground truth value, the subgradients are 1 or -1, depending on whether the current value is greater than the ground truth. We simply choose an initial direction for interior labels by rounding, and flip the direction of the subgradients for variables whose solution states are not in the interval corresponding to the subgradient direction until convergence.

Given a set K of constraints, we solve the SVM objective as in the primal form

$$\begin{aligned} \min_{\boldsymbol{W} \geq 0} \quad & \frac{1}{2}||\boldsymbol{W}||^2 + C\xi \\ \text{s.t.} \quad & K. \end{aligned} \tag{70}$$

We then iteratively invoke the separation oracle to find the worst-violated constraint. If this new constraint is not violated, or its violation is within numerical tolerance, we have found the max-margin solution. Otherwise, we add the new constraint to K, and repeat.

One fact of note is that the large-margin criterion always requires some slack for HL-MRFs with squared potentials. Since the squared hinge potential is quadratic and the loss is linear, there always exists a small enough distance from the ground truth such that an absolute (i.e., linear) distance is greater than the squared distance. In these cases, the slack parameter trades off between the peakedness of the learned quadratic energy function and the margin criterion.

6.4 Evaluation of Learning

To demonstrate the flexibility and effectiveness of learning with HL-MRFs, we test them on four diverse tasks: node labeling, link labeling, link prediction, and image completion.[6] Each of these experiments represents a problem domain that is best solved with structured-prediction approaches because their dependencies are highly structural. The experiments show that HL-MRFs perform as well as or better than canonical approaches.

For these diverse tasks, we compare against a number of competing methods. For node and link labeling, we compare HL-MRFs to discrete Markov random fields (MRFs). We construct them with Markov logic networks (MLNs) (Richardson and Domingos, 2006), which template discrete MRFs using logical rules similarly to PSL. We perform inference in discrete MRFs using Gibbs sampling, and we find approximate MAP states during learning using the search algorithm MaxWalkSat (Richardson and Domingos, 2006). For link prediction for preference prediction, a task that is inherently continuous and nontrivial to encode in discrete logic, we compare against Bayesian probabilistic matrix factorization (BPMF) (Salakhutdinov and Mnih, 2008). Finally, for image completion, we run the same experimental setup as Poon and Domingos (2011) and compare against the results they report, which include tests using sum product networks, deep belief networks (Hinton and Salakhutdinov, 2006), and deep Boltzmann machines (Salakhutdinov and Hinton, 2009).

We train HL-MRFs and discrete MRFs with all three learning methods: structured perceptron (SP), maximum pseudolikelihood estimation(MPLE), and large-margin estimation (LME). When appropriate, we evaluate statistical significance using a paired t-test with rejection threshold 0.01. We describe the HL-MRFs used for our experiments using the PSL rules that define them. To investigate the differences between linear and squared potentials we use both in our experiments. HL-MRF-L refers to a model with all linear potentials and HL-MRF-Q to one with all squared potentials. When training with SP and MPLE, we use 100 gradient steps and a step size of 1.0 (unless otherwise noted), and we average the iterates as in voted perceptron. For LME, we set $C = 0.1$. We experimented with various settings, but the scores of HL-MRFs and discrete MRFs were not sensitive to changes.

6. Code is available at `https://github.com/stephenbach/bach-jmlr17-code`.

6.4.1 Node Labeling

When classifying documents, links between those documents—such as hyperlinks, citations, or shared authorship—provide extra signal beyond the local features of individual documents. Collectively predicting document classes with these links tends to improve accuracy (Sen et al., 2008). We classify documents in citation networks using data from the Cora and Citeseer scientific paper repositories. The Cora data set contains 2,708 papers in seven categories, and 5,429 directed citation links. The Citeseer data set contains 3,312 papers in six categories, and 4,591 directed citation links. Let the predicate `Category/2` represent the category of each document and `Cites/2` represent a citation from one document to another.

The prediction task is, given a set of seed documents whose labels are observed, to infer the remaining document classes by propagating the seed information through the network. For each of 20 runs, we split the data sets 50/50 into training and testing partitions, and seed half of each set. To predict discrete categories with HL-MRFs we predict the category with the highest predicted value.

We compare HL-MRFs to discrete MRFs on this task. For prediction, we performed 2500 rounds of Gibbs sampling, 500 of which were discarded as burn-in. We construct both using the same logical rules, which simply encode the tendency for a class to propagate across citations. For each category `"C_i"`, we have the following two rules, one for each direction of citation.

```
Category(A, "C_i") && Cites(A, B) -> Category(B, "C_i")
Category(A, "C_i") && Cites(B, A) -> Category(B, "C_i")
```

We also constrain the atoms of the `Category/2` predicate to sum to 1.0 for a given document as follows.

```
Category(D, +C) = 1.0 .
```

Table 1 lists the results of this experiment. HL-MRFs are the most accurate predictors on both data sets. Both variants of HL-MRFs are also much faster than discrete MRFs. See Table 3 for average inference times over five folds.

6.4.2 Link Labeling

An emerging problem in the analysis of online social networks is the task of inferring the level of trust between individuals. Predicting the strength of trust relationships can provide useful information for viral marketing, recommendation engines, and internet security. HL-MRFs with linear potentials have been applied by Huang et al. (2013) to this task, showing superior results with models based on sociological theory. We reproduce their experimental setup using their sample of the signed Epinions trust network, orginally collected by Richardson et al. (2003), in which users indicate whether they trust or distrust other users. We perform eight-fold cross-validation. In each fold, the prediction algorithm observes the entire unsigned social network and all but 1/8 of the trust ratings. We measure prediction accuracy on the held-out 1/8. The sampled network contains 2,000 users, with 8,675 signed links. Of these links, 7,974 are positive and only 701 are negative, making it a sparse prediction task.

Table 1: Average accuracy of classification by HL-MRFs and discrete MRFs. Scores statistically equivalent to the best scoring method are typed in bold.

	Citeseer	Cora
HL-MRF-Q (SP)	**0.729**	**0.816**

MRF (SP)	0.655	0.942	0.270
MRF (MPLE)	0.725	0.963	0.298
MRF (LME)	0.795	**0.973**	**0.441**

Table 3: Average inference times (reported in seconds) of single-threaded HL-MRFs and discrete MRFs.

	Citeseer	Cora	Epinions
HL-MRF-Q	0.42	0.70	0.32
HL-MRF-L	0.46	0.50	0.28
MRF	110.96	184.32	212.36

We use a model based on the social theory of *structural balance*, which suggests that social structures are governed by a system that prefers triangles that are considered balanced. Balanced triangles have an odd number of positive trust relationships; thus, considering all possible directions of links that form a triad of users, there are sixteen logical implications of the following form.

```
Trusts(A,B) && Trusts(B,C) -> Trusts(A,C)
```

Huang et al. (2013) list all sixteen of these rules, a reciprocity rule, and a prior in their *Balance-Recip* model, which we omit to save space.

Since we expect these structural implications to vary in accuracy, learning weights for these rules provides better models. Again, we use these rules to define HL-MRFs and discrete MRFs, and we train them using various learning algorithms. For inference with discrete MRFs, we perform 5000 rounds of Gibbs sampling, of which the first 500 are burn-in. We compute three metrics: the area under the receiver operating characteristic (ROC) curve, and the areas under the precision-recall curves for positive trust and negative trust. On all three metrics, HL-MRFs with squared potentials score significantly higher. The differences among the learning methods for squared HL-MRFs are insignificant, but the differences among the models is statistically significant for the ROC metric. For area under the precision-recall curve for positive trust, discrete MRFs trained with LME are statistically tied with the best score, and both HL-MRF-L and discrete MRFs trained with LME are statistically tied with the best area under the precision-recall curve for negative trust. The results are listed in Table 2.

Though the random fold splits are not the same, using the same experimental setup, Huang et al. (2013) also scored the precision-recall area for negative trust of standard trust prediction algorithms EigenTrust (Kamvar et al., 2003) and TidalTrust (Golbeck, 2005), which scored 0.131 and 0.130, respectively. The logical models based on structural balance that we run here are significantly more accurate, and HL-MRFs more than discrete MRFs.

In addition to comparing favorably with regard to predictive accuracy, inference in HL-MRFs is also much faster than in discrete MRFs. Table 3 lists average inference times on five folds of three prediction tasks: Cora, Citeseer, and Epinions. This illustrates an important difference between performing structured prediction via convex inference versus sampling in a discrete prediction space: convex inference can be much faster.

6.4.3 Link Prediction

Preference prediction is the task of inferring user attitudes (often quantified by ratings) toward a set of items. This problem is naturally structured, since a user's preferences are often interdependent, as are an item's ratings. *Collaborative filtering* is the task of predicting unknown ratings using only a subset of observed ratings. Methods for this task range from simple nearest-neighbor classifiers to complex latent factor models. More generally, this problem is an instance of link prediction, since the goal is to predict links indicating preference between users and content. Since preferences are ordered rather than Boolean, it is natural to represent them with the continuous variables of HL-MRFs, with higher values indicating greater preference. To illustrate the versatility of HL-MRFs, we design a simple, interpretable collaborative filtering model for predicting humor preferences. We test this model on the Jester dataset, a repository of ratings from 24,983 users on a set of 100 jokes (Goldberg et al., 2001). Each joke is rated on a scale of $[-10, +10]$, which we normalize to $[0, 1]$. We sample a random 2,000 users from the set of those who rated all 100 jokes, which we then split into 1,000 train and 1,000 test users. From each train and test matrix, we sample a random 50% to use as the observed features $\boldsymbol{x}$; the remaining ratings are treated as the variables $\boldsymbol{y}$.

Our HL-MRF model uses an item-item similarity rule:

```
SimRating(J1, J2) && Likes(U, J1) -> Likes(U, J2)
```

where `J1` and `J2` are jokes and `U` is a user; the predicate `Likes/2` indicates the degree of preference (i.e., rating value); and `SimRating/2` is a closed predicate that measures the mean-adjusted cosine similarity between the observed ratings of two jokes. We also include the following rules to enforce that `Likes(U,J)` concentrates around the observed average rating of user `U` (represented with the predicate `AvgUserRating/1`) and item `J` (represented with the predicate `AvgJokeRating/1`), and the global average (represented with the predicate `AvgRating/1`).

```
AvgUserRating(U) -> Likes(U, J)
Likes(U, J) -> AvgUserRating(U)
AvgJokeRating(J) -> Likes(U, J)
Likes(U, J) -> AvgJokeRating(J)
AvgRating("constant") -> Likes(U, J)
Likes(U, J) -> AvgRating("constant")
```

The atom `AvgRating("constant")` takes a placeholder constant as an argument, since there is only one grounding of it for the entire HL-MRF. Again, all three of these predicates are closed and computed using averages of observed ratings. In all cases, the observed ratings are taken only from the training data for learning (to avoid leaking information about the test data) and only from the test data during testing.

We compare our HL-MRF model to a canonical latent factor model, *Bayesian probabilistic matrix factorization* (BPMF) (Salakhutdinov and Mnih, 2008). BPMF is a fully Bayesian treatment and is therefore considered "parameter-free;" the only parameter that must be specified is the rank of the decomposition. Based on settings used by Xiong et al.

Table 4: Normalized mean squared/absolute errors (NMSE/NMAE) for preference prediction using the Jester dataset. The lowest errors are typed in bold.

	NMSE	NMAE
HL-MRF-Q (SP)	0.0554	0.1974
HL-MRF-Q (MPLE)	0.0549	0.1953
HL-MRF-Q (LME)	0.0738	0.2297
HL-MRF-L (SP)	0.0578	0.2021
HL-MRF-L (MPLE)	0.0535	0.1885
HL-MRF-L (LME)	0.0544	**0.1875**
BPMF	**0.0501**	**0.1832**

Table 5: Mean squared errors per pixel for image completion. HL-MRFs produce the most accurate completions on the Caltech101 and the left-half Olivetti faces, and only sum-product networks produce better completions on Olivetti bottom-half faces. Scores for other methods are reported in Poon and Domingos (2011).

	HL-MRF-Q (SP)	SPN	DBM	DBN	PCA	NN
Caltech-Left	1741	1815	2998	4960	2851	2327
Caltech-Bottom	1910	1924	2656	3447	1944	2575
Olivetti-Left	927	942	1866	2386	1076	1527
Olivetti-Bottom	1226	918	2401	1931	1265	1793

(2010), we set the rank of the decomposition to 30 and use 100 iterations of burn in and 100 iterations of sampling. For our experiments, we use the code of Xiong et al. (2010). Since BPMF does not train a model, we allow BPMF to use all of the training matrix during the prediction phase.

Table 4 lists the normalized mean squared error (NMSE) and normalized mean absolute error (NMAE), averaged over 10 random splits. Though BPMF produces the best scores, the improvement over HL-MRF-L (LME) is not significant in NMAE.

6.4.4 Image Completion

Digital image completion requires models that understand how pixels relate to each other, such that when some pixels are unobserved, the model can infer their values from parts of the image that are observed. We construct pixel-grid HL-MRFs for image completion. We test these models using the experimental setup of Poon and Domingos (2011): we reconstruct images from the Olivetti face data set and the Caltech101 face category. The Olivetti data set contains 400 images, 64 pixels wide and tall, and the Caltech101 face category contains 435 examples of faces, which we crop to the center 64 by 64 patch, as was done by Poon

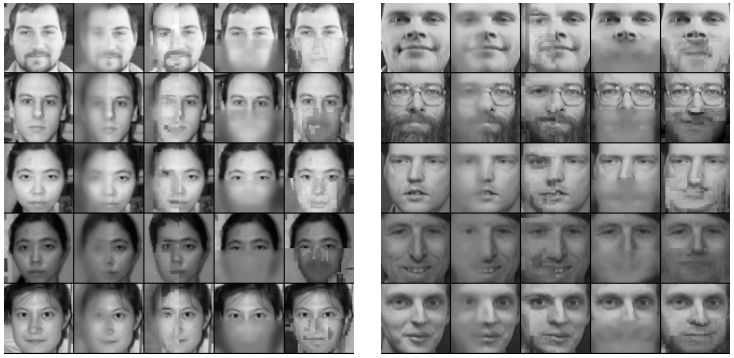

Figure 2: Example results on image completion of Caltech101 (left) and Olivetti (right) faces. From left to right in each column: (1) true face, left side predictions by (2) HL-MRFs and (3) SPNs, and bottom half predictions by (4) HL-MRFs and (5) SPNs. SPN completions are downloaded from Poon and Domingos (2011).

and Domingos (2011). Following their experimental setup, we hold out the last fifty images and predict either the left half of the image or the bottom half.

The HL-MRFs in this experiment are much more complex than the ones in our other experiments because we allow each pixel to have its own weight for the following rules, which encode agreement or disagreement between neighboring pixels:

```
Bright("P_ij", I) && North("P_ij", Q) -> Bright(Q, I)
Bright("P_ij", I) && North("P_ij", Q) -> !Bright(Q, I)
!Bright("P_ij", I) && North("P_ij", Q) -> Bright(Q, I)
!Bright("P_ij", I) && North("P_ij", Q) -> !Bright(Q, I)
```

where `Bright("P_ij", I)` is the normalized brightness of pixel `"P_ij"` in image `I`, and `North("P_ij", Q)` indicates that `Q` is the north neighbor of `"P_ij"`. We similarly include analogous rules for the south, east, and west neighbors, as well as the pixels mirrored across the horizontal and vertical axes. This setup results in up to 24 rules per pixel, (boundary pixels may not have north, south, east, or west neighbors) which, in a 64 by 64 image, produces 80,896 PSL rules.

We train these HL-MRFs using SP with a 5.0 step size on the first 200 images of each data set and test on the last fifty. For training, we maximize the data log-likelihood of uniformly random held-out pixels for each training image, allowing for generalization throughout the image. Table 5 lists our results and others reported by Poon and Domingos (2011) for sum-product networks (SPN), deep Boltzmann machines (DBM), deep belief networks (DBN), principal component analysis (PCA), and nearest neighbor (NN). HL-MRFs produce the best mean squared error on the left- and bottom-half settings for the Caltech101 set and the left-half setting in the Olivetti set. Only sum product networks produce lower error

on the Olivetti bottom-half faces. Some reconstructed faces are displayed in Figure 2, where the shallow, pixel-based HL-MRFs produce comparably convincing images to sum-product networks, especially in the left-half setting, where HL-MRFs can learn which pixels are likely to mimic their horizontal mirror. While neither method is particularly good at reconstructing the bottom half of faces, the qualitative difference between the deep SPN and the shallow HL-MRF completions is that SPNs seem to hallucinate different faces, often with some artifacts, while HL-MRFs predict blurry shapes roughly the same pixel intensity as the observed, top half of the face. The tendency to better match pixel intensity helps HL-MRFs score better quantitatively on the Caltech101 faces, where the lighting conditions are more varied than in Olivetti faces.

Training and predicting with these HL-MRFs takes little time. In our experiments, training each model takes about 45 minutes on a 12-core machine, while predicting takes under a second per image. While Poon and Domingos (2011) report faster training with SPNs, both HL-MRFs and SPNs clearly belong to a class of faster models when compared to DBNs and DBMs, which can take days to train on modern hardware.

7. Related Work

Researchers in artificial intelligence and machine learning have long been interested in predicting interdependent unknowns using structural dependencies. Some of the earliest work in this area is inductive logic programming (ILP) (Muggleton and De Raedt, 1994), in which structural dependencies are described with first-order logic. Using first-order logic has several advantages. First, it can capture many types of dependencies among variables, such as correlations, anti-correlations, and implications. Second, it can compactly specify dependencies that hold across many different sets of propositions by using variables as wild-cards that match entities in the data. These features enable the construction of intuitive, general-purpose models that are easily applicable or adapted to different domains. Inference for ILP finds the propositions that satisfy a query, consistent with a relational knowledge base. However, ILP is limited by its difficulty in coping with uncertainty. Standard ILP approaches only model dependencies which hold universally, and such dependencies are rare in real-world data.

Another broad area of research, probabilistic methods, directly models uncertainty over unknowns. Probabilistic graphical models (PGMs) (Koller and Friedman, 2009) are a family of formalisms for specifying joint distributions over interdependent unknowns through graphical structures. The graphical structure of a PGM generally represents conditional independence relationships among random variables. Explicitly representing conditional independence relationships allows a distribution to be more compactly parametrized. For example, in the worst case, a discrete distribution could be represented by an exponentially large table over joint assignments to the random variables. However, describing the distribution in smaller, conditionally independent pieces can be much more compact. Similar benefits apply to continuous distributions. Algorithms for probabilistic inference and learning can also operate over the conditionally independent pieces described by the graph structure. They are therefore straightforward to apply to a wide variety of distributions. Categories of PGMs include Markov random fields (MRFs), Bayesian networks (BNs), and

dependency networks (DNs). Constructing PGMs often requires careful design, and models are usually constructed for single tasks and data sets.

More recently, researchers have sought to combine the advantages of relational and probabilistic approaches, creating the field of *statistical relational learning* (SRL) (Getoor and Taskar, 2007). SRL techniques build probabilistic models of relational data, i.e., data composed of entities and relationships connecting them. Relational data is most often described using a relational calculus, but SRL techniques are also equally applicable to similar categories of data that go by other names, such as graph data or network data. Modeling relational data is inherently complicated by the large number of interconnected and overlapping structural dependencies that are typically present. This complication has motivated two directions of work. The first direction is algorithmic, seeking inference and learning methods that scale up to high dimensional models. The other direction is both user-oriented and—as a growing body of evidence shows—supported by learning theory, seeking formalisms for compactly specifying entire groups of dependencies in the model that share both form and parameters. Specifying these grouped dependencies, often in the form of templates via a domain-specific language, is convenient for users. Most often in relational data the structural dependencies hold without regard to the identities of entities, instead being induced by an entity's class (or classes) and the structure of its relationships with other entities. Therefore, many SRL models and languages give users the ability to specify dependencies in this abstract form and ground out models over specific data sets based on these definitions. In addition to convenience, recent work in learning theory says that repeated dependencies with tied parameters can be the key to generalizing from a few—or even one—large, structured training example(s) (London et al., 2016).

A related field to SRL is *structured prediction* (SP) (Bakir et al., 2007; Nowozin et al., 2016), which generalizes the tasks of classification and regression to the task of predicting structured objects. The loss function used during learning is generalized to a task-appropriate loss function that scores disagreement between predictions and the true structures. Often, models for structured prediction take the form of energy functions that are linear in their parameters. Therefore, prediction with such models is equivalent to MAP inference for MRFs. A distinct branch of SP is learn-to-search methods, in which the problem is decomposed into a series of one-dimension prediction problems. The challenge is to learn a good order in which to predict the components of the structure, so that each one-dimension prediction problem can be conditioned on the most useful information. Examples of learn-to-search methods include incremental structured perceptron (Collins and Roark, 2004), SEARN (Daumé III et al., 2009), DAgger (Ross et al., 2011), and AggreVaTe (Ross and Bagnell, 2014).

In this paper we focus on SP methods that perform joint prediction directly. Better understanding the differences and relative advantages of joint-prediction methods and learn-to-search methods is an important direction for future work. In the rest of this section we survey models and domain-specific languages for SP and SRL (Section 7.1), inference methods (Section 7.2), and learning methods (Section 7.3).

7.1 Models and Languages

SP and SRL encompass many approaches. One broad area of work—of which PSL is a part—uses first-order logic and other relational formalisms to specify templates for PGMs. Probabilistic relational models (Friedman et al., 1999) define templates for BNs in terms of a database schema, and they can be grounded out over instances of that schema to create BNs. Relational dependency networks (Neville and Jensen, 2007) template RNs using structured query language (SQL) queries over a relational schema. Markov logic networks (MLNs) (Richardson and Domingos, 2006) use first-order logic to define Boolean MRFs. Each logical clause in a first-order knowledge base is a template for a set of potentials when the MLN is grounded out over a set of propositions. Whether each proposition is true is a Boolean random variable, and the potential has a value of one when the corresponding ground clause is satisfied by the propositions and zero when it is not. (MLNs are formulated such that higher values of the energy function are more probable.) Clauses can either be weighted, in which case the potential has the weight of the clause that templated it, or unweighted, in which case in must hold universally, as in ILP. In these ways, MLNs are similar to PSL. Whereas MLNs are defined over Boolean variables, PSL is a templating language for HL-MRFs, which are defined over continuous variables. However, these continuous variables can be used to model discrete quantities. See Section 2 for more information on the relationships between HL-MRFs and discrete MRFs, and Section 6.4 for empirical comparisons between the two. As we show, HL-MRFs and PSL scale much better while retaining the rich expressivity and accuracy of their discrete counterparts. In addition, HL-MRFs and PSL can reason directly about continuous data.

PSL is part of a broad family of probabilistic programming languages (Gordon et al., 2014). The goals of probabilistic programming and SRL often overlap. Probabilistic programming seeks to make constructing probabilistic models easy for the end user, and separate model specification from the development of inference and learning algorithms. If algorithms can be developed for the entire space of models covered by a language, then it is easy for users to experiment with including and excluding different model components. It also makes it easy for existing models to benefit from improved algorithms. Separation of model specification and algorithms is also useful in SRL for the same reasons. In this paper we emphasize designing algorithms that are flexible enough to support the full class of HL-MRFs. Examples of probabilistic programming languages include IBAL (Pfeffer, 2001), BLOG (Milch et al., 2005), Markov logic (Richardson and Domingos, 2006), ProbLog (De Raedt et al., 2007), Church (Goodman et al., 2008), Figaro (Pfeffer, 2009), FACTORIE (McCallum et al., 2009), Anglican (Wood et al., 2014), and Edward (Tran et al., 2016).

Other formalisms have also been proposed for probabilistic reasoning over continuous domains and other domains equipped with semirings. Hybrid Markov logic networks (Wang and Domingos, 2008) mix discrete and continuous variables. In addition to the dependencies over discrete variables supported by MLNs, they support soft equality constraints between two variables of the same form as those defined by squared arithmetic rules in PSL, as well as linear potentials of the form $y_1 - y_2$ for a soft inequality constraint $y_1 > y_2$. Inference in hybrid MLNs is intractable. Wang and Domingos (2008) propose a random walk algorithm for approximate MAP inference. Another related formalism is aProbLog (Kimmig et al., 2011), which generalizes ProbLog to allow clauses to be annotated with elements from a

semiring, generalizing ProbLog's support for clauses annotated with probabilities. Many common inference tasks can be generalized from this perspective as algebraic model counting (Kimmig et al., 2016). The PITA system (Riguzzi and Swift, 2011) for probabilistic logic programming can also be viewe as implementing inference over various semirings.

7.2 Inference

Whether viewed as MAP inference for an MRF or SP without probabilistic semantics, searching over a structured space to find the optimal prediction is an important but difficult task. It is NP-hard in general (Shimony, 1994), so much work has focused on approximations and identifying classes of problems for which it is tractable. A well-studied approximation technique is local consistency relaxation (LCR) (Wainwright and Jordan, 2008). Inference is first viewed as an equivalent optimization over the realizable expected values of the potentials, called the marginal polytope. When the variables are discrete and each potential is an indicator that a subset of variables is in a certain state, this optimization becomes a linear program. Each variable in the program is the marginal probability that a variable is a particular state or the variables associated with a potential are in a particular joint state. The marginal polytope is then the set of marginal probabilities that are globally consistent. The number of linear constraints required to define the marginal polytope is exponential in the size of the problem, however, so the linear program has to be relaxed in order to be tractable. In a local consistency relaxation, the marginal polytope is relaxed to the local polytope, in which the marginals over variables and potential states are only locally consistent in the sense that each marginal over potential states sums to the marginal distributions over the associated variables.

A large body of work has focused on solving the LCR objective quickly. Typically, off-the-shelf convex optimization methods do not scale well for large graphical models and structured predictors (Yanover et al., 2006), so a large branch of research has investigated highly scalable message-passing algorithms. One approach is dual decomposition (DD) (Sontag et al., 2011), which solves a problem dual to the LCR objective. Many DD algorithms use coordinate descent, such as TRW-S (Kolmogorov, 2006), MSD (Werner, 2007), MPLP (Globerson and Jaakkola, 2007), and ADLP (Meshi and Globerson, 2011). Other DD algorithms use subgradient-based approaches (e.g., Jojic et al., 2010; Komodakis et al., 2011; Schwing et al., 2012).

Another approach to solving the LCR objective uses message-passing algorithms to solve the problem directly in its primal form. One well-known algorithm is that of Ravikumar et al. (2010a), which uses proximal optimization, a general approach that iteratively improves the solution by searching for nearby improvements. The authors also provide rounding guarantees for when the relaxed solution is integral, i.e., the relaxation is tight, allowing the algorithm to converge faster. Another message-passing algorithm that solves the primal objective is AD^3 (Martins et al., 2015), which uses the alternating direction method of multipliers (ADMM). AD^3 optimizes objective (10) for binary, pairwise MRFs and supports the addition of certain deterministic constraints on the variables. A third example of a primal message-passing algorithm is APLP (Meshi and Globerson, 2011), which is the primal analog of ADLP. Like AD^3, it uses ADMM to optimize the objective.

Other approaches to approximate inference include tighter linear programming relaxations (Sontag et al., 2008, 2012). These tighter relaxations enforce local consistency on variable subsets that are larger than individual variables, which makes them *higher-order local consistency relaxations*. Mezuman et al. (2013) developed techniques for special cases of higher-order relaxations, such as when the MRF contains cardinality potentials, in which the probability of a configuration depends on the number of variables in a particular state. Researchers have also explored nonlinear convex programming relaxations, e.g., Ravikumar and Lafferty (2006) and Kumar et al. (2006).

Previous analyses have identified particular subclasses whose local consistency relaxations are tight, i.e., the maximum of the relaxed program is exactly the maximum of the original problem. These special classes include graphical models with tree-structured dependencies, models with submodular potential functions, models encoding bipartite matching problems, and those with *nand* potentials and perfect graph structures (Wainwright and Jordan, 2008; Schrijver, 2003; Jebara, 2009; Foulds et al., 2011). Researchers have also studied performance guarantees of other subclasses of the first-order local consistency relaxation. Kleinberg and Tardos (2002) and Chekuri et al. (2005) considered the metric labeling problem. Feldman et al. (2005) used the local consistency relaxation to decode binary linear codes.

In this paper we examine the classic problem of MAX SAT—finding a joint Boolean assignment to a set of propositions that maximizes the sum of a set of weighted clauses that are satisfied—as an instance of SP. Researchers have also considered approaches to solving MAX SAT other than the one one we study, the randomized algorithm of Goemans and Williamson (1994). One line of work focusing on convex programming relaxations has obtained stronger rounding guarantees than Goemans and Williamson (1994) by using nonlinear programming, e.g., Asano and Williamson (2002) and references therein. Other work does not use the probabilistic method but instead searches for discrete solutions directly, e.g., Mills and Tsang (2000), Larrosa et al. (2008), and Choi et al. (2009). We note that one such approach, that of Wah and Shang (1997), is essentially a type of DD formulated for MAX SAT. A more recent approach blends convex programming and discrete search via mixed integer programming (Davies and Bacchus, 2013). Additionally, Huynh and Mooney (2009) introduced a linear programming relaxation for MLNs inspired by MAX SAT relaxations, but the relaxation of general Markov logic provides no known guarantees on the quality of solutions.

Finally, *lifted inference* takes advantage of symmetries in probability distributions to reduce the amount of work required for inference. Some of the earliest approaches identified repeated dependency structures in PGMs to avoid repeated computations (Koller and Pfeffer, 1997; Pfeffer et al., 1999). Lifted inference has been widely applied in SRL because the templates that are commonly used to define PGMs often induce symmetries. Various inference techniques for discrete MRFs have been extended to a lifted approach, including belief propagation (Jaimovich et al., 2007; Singla and Domingos, 2008; Kersting et al., 2009) and Gibbs sampling (Venugopal and Gogate, 2012). Approaches to lifted convex optimization (Mladenov et al., 2012) might be extended to HL-MRFs. See de Salvo Braz et al. (2007), Kersting (2012), and Kimmig et al. (2015) for more information on lifted inference.

7.3 Learning

Taskar et al. (2004) connected SP and PGMs by showing how to train MRFs with large-margin estimation, a generalization of the large-margin objective for binary classification used to train support vector machines (Vapnik, 2000). Large-margin learning is a well-studied approach to train structured predictors because it directly incorporates the structured loss function into a convex upper bound on the true objective: the regularized expected risk. The learning objective is to find the parameters with smallest norm such that a linear combination of feature functions assign a better score to the training data than all other possible predictions. The amount by which the score of the correct prediction must exceed the score of other predictions is scaled using the structured loss function. The objective is therefore encoded as a norm minimization problem subject to many linear constraints, one for each possible prediction in the structured space.

Structured SVMs (Tsochantaridis et al., 2005) extend large-margin estimation to a broad class of structured predictors and admit a tractable cutting-plane learning algorithm. This algorithm will terminate in a number of iterations linear in the size of the problem, and so the computational challenge of large-margin learning for structured prediction comes down to the task of finding the most violated constraint in the learning objective. This can be accomplished by optimizing the energy function plus the loss function. In other words, the task is to find the structure that is the best combination of being favored by the energy function but unfavored by the loss function. Often, the loss function decomposes over the components of the prediction space, so the combined energy function and loss function can often be viewed as simply the energy function of another structured predictor that is equally challenging or easy to optimize, such as when the space of structures is a set of discrete vectors and the loss function is the Hamming distance.

It is common during large-margin estimation that no setting of the parameters can predict all the training data without error. In this case, the training data is said to not be separable, again generalizing the notion of linear separability in the feature space from binary classification. The solution to this problem is to add slack variables to the constraints that require the training data to be assigned the best score. The magnitude of the slack variables are penalized in the learning objective, so estimation must trade off between the norm of the parameters and violating the constraints. Joachims et al. (2009) extend this formulation to a "one slack" formulation, in which a single slack variable is used for all the constraints across all training examples, which is more efficient. We use this framework for large-margin estimation for HL-MRFs in Section 6.3.

The repeated inferences required for large-margin learning, one to find the most-violated constraint at each iteration, can become computationally expensive. Therefore researchers have explored speeding up learning by interleaving the inference problem with the learning problem. In the cutting-plane formulation discussed above, the objective is equivalently a saddle-point problem, with the solution at the minimum with respect to the parameters and the maximum with respect to the inference variables. Taskar et al. (2005) proposed dualizing the inner inference problem to form a joint minimization. For SP problems with a tight duality gap, i.e., the dual problem has the same optimal value as the primal problem, this approach leads to an equivalent, convex optimization that can be solved for all variables simultaneously. In other words, the learning and most-violated constraint problems are

solved simultaneously, greatly reducing training time. For problems with non-tight duality gaps, e.g., MAP inference in general, discrete MRFs, Meshi et al. (2010) showed that the same principle can be applied by using approximate inference algorithms like dual decomposition to bound the primal objective.

A related problem to parameter learning is *structure learning*, i.e., identifying an accurate dependency structure for a model. A common SRL approach is searching over the space of templates for PGMs. For probabilistic relational models, Friedman et al. (1999) learned structures described in the vocabulary of relational schemas. For models that are templated with first-order-logic-like languages, such as PSL and MLNs, these approaches take the form of rule learning. Based on rule-learning techniques from inductive logic programming (e.g., Richards and Mooney, 1992; De Raedt and Dehaspe, 1996) a series of approaches have sought to learn MLN rules from relational data. Initially, Kok and Domingos (2005) learned rules by generating candidates and performing a beam search to identify rules that improved a weighted pseudolikelihood objective. Then, Mihalkova and Mooney (2007) observed that the previous approach generated candidate rules without regard to the data, so they introduced an approach that used the data to guide the proposal of rules via *relational pathfinding*. Kok and Domingos (2010) improved on that by first performing graph clustering to find common *motifs*, which are common subgraphs, to guide rule proposal. They observed that modifying a rule set one clause at a time often got stuck in poor local optima, and by using the motifs as refinement operators instead, they were able to converge to better optima. Other approaches to structure learning search directly over grounded PGMs, including ℓ_1-regularized pseudolikelihood maximization (Ravikumar et al., 2010b) and grafting (Perkins et al., 2003; Zhu et al., 2010). These methods can all be extended to HL-MRFs and PSL.

8. Conclusion

In this paper we introduced HL-MRFs, a new class of probabilistic graphical models that unite and generalize several approaches to modeling relational and structured data: Boolean logic, probabilistic graphical models, and fuzzy logic. HL-MRFs can capture relaxed, probabilistic inference with Boolean logic and exact, probabilistic inference with fuzzy logic, making them useful models for both discrete and continuous data. HL-MRFs also generalize these inference techniques with additional expressivity, allowing for even more flexibility. HL-MRFs are a significant addition to the the library of machine learning tools because they embody a useful point in the spectrum of models that trade off between scalability and expressivity. As we showed, they can be easily applied to a wide range of structured problems in machine learning and achieve high-quality predictive performance, competitive with or surpassing the performance of canonical approaches. However, these other models either do not scale as well, like discrete MRFs, or are not as versatile in their ability to capture a wide range of problems, like Bayesian probabilistic matrix factorization.

We also introduced PSL, a probabilistic programming language for HL-MRFs. PSL makes HL-MRFs easy to design, allowing users to encode their ideas for structural dependencies using an intuitive syntax based on first-order logic. PSL also helps accelerate a time-consuming aspect of the modeling process: refining a model. In contrast with other types of models that require specialized inference and learning algorithms depending on

which structural dependencies are included, HL-MRFs can encode many types of dependencies and scale well with the same inference and learning algorithms. PSL makes it easy to quickly add, remove, and modify dependencies in the model and rerun inference and learning, allowing users to quickly improve the quality of their models. Finally, because PSL uses a first-order syntax, each PSL program actually specifies an entire class of HL-MRFs, parameterized by the particular data set over which it is grounded. Therefore, a model or components of a model refined for one data set can easily be applied to others.

Next, we introduced inference and learning algorithms that scale to large problems. The MAP inference algorithm is far more scalable than standard tools for convex optimization because it leverages the sparsity that is so common to the dependencies in structured prediction. The supervised learning algorithms extend standard learning objectives to HL-MRFs. Together, this combination of an expressive formalism, a user-friendly probabilistic programming language, and highly scalable algorithms enables researchers and practitioners to easily build large-scale, accurate models of relational and structured data.[7]

This paper also lays the foundation for many lines of future work. Our analysis of local consistency relaxation (LCR) as a hierarchical optimization is a general proof technique, and it could be used to derive compact forms for other LCR objectives. As in the case of MRFs defined using logical clauses, such compact forms can simplify analysis and could lead to a greater understanding of LCR for other classes of MRFs. Another important line of work is understanding what guarantees apply to the MAP states of HL-MRFs. Can anything be said about their ability to approximate MAP inference in discrete models that go beyond the models already covered by the known rounding guarantees? Future directions also include developing new algorithms for HL-MRFs. One important direction is marginal inference for HL-MRFs and algorithms for sampling from them. Unlike marginal inference for discrete distributions, which computes the marginal probability that a variable is in a particular state, marginal inference for HL-MRFs requires finding the marginal probability that a variable is in a particular range. One option for doing so, as well as generating samples from HL-MRFs, is to extend the hit-and-run sampling scheme of Broecheler and Getoor (2010). This method was developed for continuous constrained MRFs with piecewise-linear potentials. There are also many new domains to which HL-MRFs and PSL can be applied. With these modeling tools, researchers can design and apply new solutions to structured prediction problems.

Appendix A. Proof of Theorem 2

In this appendix, we prove the equivalence of objectives (7) and (10). Our proof analyzes the local consistency relaxation to derive an equivalent, more compact optimization over only the variable pseudomarginals $\boldsymbol{\mu}$ that is identical to the MAX SAT relaxation. Since the variables are Boolean, we refer to each pseudomarginal $\mu_i(1)$ as simply μ_i. Let $\boldsymbol{x}_j^F$ denote the unique setting such that $\phi_j(\boldsymbol{x}_j^F) = 0$. (I.e., $\boldsymbol{x}_j^F$ is the setting in which each literal in the clause C_j is false.)

We begin by reformulating the local consistency relaxation as a hierarchical optimization, first over the variable pseudomarginals $\boldsymbol{\mu}$ and then over the factor pseudomarginals $\boldsymbol{\theta}$. Due to the structure of local polytope $\mathbb{L}$, the pseudomarginals $\boldsymbol{\mu}$ parameterize inner linear programs that decompose over the structure of the MRF, such that—given fixed $\boldsymbol{\mu}$—there is an independent linear program $\hat{\phi}_j(\boldsymbol{\mu})$ over $\boldsymbol{\theta}_j$ for each clause C_j. We rewrite objective (10) as

$$\operatorname*{arg\,max}_{\boldsymbol{\mu} \in [0,1]^n} \sum_{C_j \in \boldsymbol{C}} \hat{\phi}_j(\boldsymbol{\mu}), \tag{71}$$

where

$$\hat{\phi}_j(\boldsymbol{\mu}) = \max_{\boldsymbol{\theta}_j} \; w_j \sum_{\boldsymbol{x}_j | \boldsymbol{x}_j \neq \boldsymbol{x}_j^F} \theta_j(\boldsymbol{x}_j) \tag{72}$$

$$\text{such that} \sum_{\boldsymbol{x}_j | x_j(i)=1} \theta_j(\boldsymbol{x}_j) = \mu_i \qquad \forall i \in I_j^+ \tag{73}$$

$$\sum_{\boldsymbol{x}_j | x_j(i)=0} \theta_j(\boldsymbol{x}_j) = 1 - \mu_i \qquad \forall i \in I_j^- \tag{74}$$

$$\sum_{\boldsymbol{x}_j} \theta_j(\boldsymbol{x}_j) = 1 \tag{75}$$

$$\theta_j(\boldsymbol{x}_j) \geq 0 \qquad \forall \boldsymbol{x}_j \; . \tag{76}$$

It is straightforward to verify that objectives (10) and (71) are equivalent for MRFs with disjunctive clauses for potentials. All constraints defining $\mathbb{L}$ can be derived from the constraint $\boldsymbol{\mu} \in [0,1]^n$ and the constraints in the definition of $\hat{\phi}_j(\boldsymbol{\mu})$. We have omitted redundant constraints to simplify analysis.

To make this optimization more compact, we replace each inner linear program $\hat{\phi}_j(\boldsymbol{\mu})$ with an expression that gives its optimal value for any setting of $\boldsymbol{\mu}$. Deriving this expression requires reasoning about any maximizer $\boldsymbol{\theta}_j^\star$ of $\hat{\phi}_j(\boldsymbol{\mu})$, which is guaranteed to exist because problem (72) is bounded and feasible[8] for any parameters $\boldsymbol{\mu} \in [0,1]^n$ and w_j.

We first derive a sufficient condition for the linear program to not be fully satisfiable, in the sense that it cannot achieve a value of w_j, the maximum value of the weighted potential

8. Setting $\theta_j(\boldsymbol{x}_j)$ to the probability defined by $\boldsymbol{\mu}$ under the assumption that the elements of $\boldsymbol{x}_j$ are independent, i.e., the product of the pseudomarginals, is always feasible.

$w_j \phi_j(\boldsymbol{x})$. Observe that, by the objective (72) and the simplex constraint (75), showing that $\hat{\phi}_j(\boldsymbol{\mu})$ is not fully satisfiable is equivalent to showing that $\theta^\star_j(\boldsymbol{x}^F_j) > 0$.

Lemma 16 *If*

$$\sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i) < 1 \ ,$$

then $\theta^\star_j(\boldsymbol{x}^F_j) > 0$.

Proof By the simplex constraint (75),

$$\sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i) < \sum_{\boldsymbol{x}_j} \theta^\star_j(\boldsymbol{x}_j) \ .$$

Also, by summing all the constraints (73) and (74),

$$\sum_{\boldsymbol{x}_j | \boldsymbol{x}_j \neq \boldsymbol{x}^F_j} \theta^\star_j(\boldsymbol{x}_j) \leq \sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i) \ ,$$

because all the components of $\boldsymbol{\theta}^\star$ are nonnegative, and—except for $\theta^\star_j(\boldsymbol{x}^F_j)$—they all appear at least once in constraints (73) and (74). These bounds imply

$$\sum_{\boldsymbol{x}_j | \boldsymbol{x}_j \neq \boldsymbol{x}^F_j} \theta^\star_j(\boldsymbol{x}_j) < \sum_{\boldsymbol{x}_j} \theta^\star_j(\boldsymbol{x}_j) \ ,$$

which means $\theta^\star_j(\boldsymbol{x}^F_j) > 0$, completing the proof. ■

We next show that if $\hat{\phi}_j(\boldsymbol{\mu})$ is parameterized such that it is not fully satisfiable, as in Lemma 16, then its optimum always takes a particular value defined by $\boldsymbol{\mu}$.

Lemma 17 *If* $w_j > 0$ *and* $\theta^\star_j(\boldsymbol{x}^F_j) > 0$*, then*

$$\sum_{\boldsymbol{x}_j | \boldsymbol{x}_j \neq \boldsymbol{x}^F_j} \theta^\star_j(\boldsymbol{x}_j) = \sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i) \ .$$

Proof We prove the lemma via the Karush-Kuhn-Tucker (KKT) conditions (Karush, 1939; Kuhn and Tucker, 1951). Since problem (72) is a maximization of a linear function subject to linear constraints, the KKT conditions are necessary and sufficient for any optimum $\boldsymbol{\theta}^\star_j$.

Before writing the relevant KKT conditions, we introduce some necessary notation. For a state $\boldsymbol{x}_j$, we need to reason about the variables that disagree with the unsatisfied state $\boldsymbol{x}^F_j$. Let

$$d(\boldsymbol{x}_j) \triangleq \left\{ i \in I_j^+ \cup I_j^- | \boldsymbol{x}_j(i) \neq \boldsymbol{x}^F_j(i) \right\}$$

be the set of indices for the variables that do not have the same value in the two states $\boldsymbol{x}_j$ and $\boldsymbol{x}^F_j$.

We now write the relevant KKT conditions for $\boldsymbol{\theta}^\star_j$. Let $\boldsymbol{\lambda}, \boldsymbol{\alpha}$ be real-valued vectors where $|\boldsymbol{\lambda}| = |I_j^+| + |I_j^-| + 1$ and $|\boldsymbol{\alpha}| = |\boldsymbol{\theta}_j|$. Let each λ_i correspond to a constraint (73) or (74)

for $i \in I_j^+ \cup I_j^-$, and let λ_Δ correspond to the simplex constraint (75). Also, let each $\alpha_{\boldsymbol{x}_j}$ correspond to a constraint (76) for each $\boldsymbol{x}_j$. Then, the following KKT conditions hold:

$$\alpha_{\boldsymbol{x}_j} \geq 0 \qquad \forall \boldsymbol{x}_j \tag{77}$$

$$\alpha_{\boldsymbol{x}_j} \theta^\star_j(\boldsymbol{x}_j) = 0 \qquad \forall \boldsymbol{x}_j \tag{78}$$

$$\lambda_\Delta + \alpha_{\boldsymbol{x}^F_j} = 0 \tag{79}$$

$$w_j + \sum_{i \in d(\boldsymbol{x}_j)} \lambda_i + \lambda_\Delta + \alpha_{\boldsymbol{x}_j} = 0 \qquad \forall \boldsymbol{x}_j \neq \boldsymbol{x}^F_j \ . \tag{80}$$

Since $\theta^\star_j(\boldsymbol{x}^F_j) > 0$, by condition (78), $\alpha_{\boldsymbol{x}^F_j} = 0$. By condition (79), then $\lambda_\Delta = 0$. From here we can bound the other elements of $\boldsymbol{\lambda}$. Observe that for every $i \in I_j^+ \cup I_j^-$, there exists a state $\boldsymbol{x}_j$ such that $d(\boldsymbol{x}_j) = \{i\}$. Then, it follows from condition (80) that there exists $\boldsymbol{x}_j$ such that, for every $i \in I_j^+ \cup I_j^-$,

$$w_j + \lambda_i + \lambda_\Delta + \alpha_{\boldsymbol{x}_j} = 0 \ .$$

Since $\alpha_{\boldsymbol{x}_j} \geq 0$ by condition (77) and $\lambda_\Delta = 0$, it follows that $\lambda_i \leq -w_j$. With these bounds, we show that, for any state $\boldsymbol{x}_j$, if $|d(\boldsymbol{x}_j)| \geq 2$, then $\theta^\star_j(\boldsymbol{x}_j) = 0$. Assume that for some state $\boldsymbol{x}_j$, $|d(\boldsymbol{x}_j)| \geq 2$. By condition (80) and the derived constraints on $\boldsymbol{\lambda}$,

$$\alpha_{\boldsymbol{x}_j} \geq (|d(\boldsymbol{x}_j)| - 1) w_j > 0 \ .$$

With condition (78), $\theta^\star_j(\boldsymbol{x}_j) = 0$. Next, observe that for all $i \in I_j^+$ (resp. $i \in I_j^-$) and for any state $\boldsymbol{x}_j$, if $d(\boldsymbol{x}_j) = \{i\}$, then $x_j(i) = 1$ (resp. $x_j(i) = 0$), and for any other state $\boldsymbol{x}'_j$ such that $x'_j(i) = 1$ (resp. $x'_j(i) = 0$), $d(\boldsymbol{x}'_j) \geq 2$. By constraint (73) (resp. constraint (74)), $\theta^\star(\boldsymbol{x}_j) = \mu_i$ (resp. $\theta^\star(\boldsymbol{x}_j) = 1 - \mu_i$).

We have shown that if $\theta^\star_j(\boldsymbol{x}^F_j) > 0$, then for all states $\boldsymbol{x}_j$, if $d(\boldsymbol{x}_j) = \{i\}$ and $i \in I_j^+$ (resp. $i \in I_j^-$), then $\theta^\star_j(\boldsymbol{x}_j) = \mu_i$ (resp. $\theta^\star_j(\boldsymbol{x}_j) = 1 - \mu_i$), and if $|d(\boldsymbol{x}_j)| \geq 2$, then $\theta^\star_j(\boldsymbol{x}_j) = 0$. This completes the proof. ■

Lemma 16 says if $\sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i) < 1$, then $\hat{\phi}_j(\boldsymbol{\mu})$ is not fully satisfiable, and Lemma 17 provides its optimal value. We now reason about the other case, when $\sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i) \geq 1$, and we show that this condition is sufficient to ensure that $\hat{\phi}_j(\boldsymbol{\mu})$ is fully satisfiable.

Lemma 18 *If* $w_j > 0$ *and*

$$\sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i) \geq 1 \ ,$$

then $\theta^\star_j(\boldsymbol{x}^F_j) = 0$.

Proof We prove the lemma by contradiction. Assume that $w_j > 0$, $\sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i) \geq 1$, and that the lemma is false, $\theta^\star_j(\boldsymbol{x}^F_j) > 0$. Then, by Lemma 17,

$$\sum_{\boldsymbol{x}_j | \boldsymbol{x}_j \neq \boldsymbol{x}^F_j} \theta^\star_j(\boldsymbol{x}_j) \geq 1 \ .$$

The assumption that $\theta_j^\star(\boldsymbol{x}_j^F) > 0$ implies

$$\sum_{\boldsymbol{x}_j} \theta_j^\star(\boldsymbol{x}_j) > 1,$$

which is a contradiction, since it violates the simplex constraint (75). The possibility that $\theta_j^\star(\boldsymbol{x}_j^F) < 0$ is excluded by the nonnegativity constraints (76). ■

For completeness and later convenience, we also state the value of $\hat{\phi}_j(\boldsymbol{\mu})$ when it is fully satisfiable.

Lemma 19 *If $\theta_j^\star(\boldsymbol{x}_j^F) = 0$, then*

$$\sum_{\boldsymbol{x}_j | \boldsymbol{x}_j \neq \boldsymbol{x}_j^F} \theta_j^\star(\boldsymbol{x}_j) = 1 \ .$$

Proof The lemma follows from the simplex constraint (75). ■

We can now combine the previous lemmas into a single expression for the value of $\hat{\phi}_j(\boldsymbol{\mu})$.

Lemma 20 *For any feasible setting of $\boldsymbol{\mu}$,*

$$\hat{\phi}_j(\boldsymbol{\mu}) = w_j \min\left\{\sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i), 1\right\} \ .$$

Proof The lemma is trivially true if $w_j = 0$ since any assignment will yield zero value. If $w_j > 0$, then we consider two cases. In the first case, if $\sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i) < 1$, then, by Lemmas 16 and 17,

$$\hat{\phi}_j(\boldsymbol{\mu}) = w_j \left(\sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i)\right) \ .$$

In the second case, if $\sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i) \geq 1$, then, by Lemmas 18 and 19,

$$\hat{\phi}_j(\boldsymbol{\mu}) = w_j \ .$$

By factoring out w_j, we can rewrite this piecewise definition of $\hat{\phi}_j(\boldsymbol{\mu})$ as w_j multiplied by the minimum of $\sum_{i \in I_j^+} \mu_i + \sum_{i \in I_j^-} (1 - \mu_i)$ and 1, completing the proof. ■

This leads to our final equivalence result.

Theorem 2 *For an MRF with potentials corresponding to disjunctive logical clauses and associated nonnegative weights, the first-order local consistency relaxation of MAP inference is equivalent to the MAX SAT relaxation of Goemans and Williamson (1994). Specifically, any partial optimum $\boldsymbol{\mu}^\star$ of objective (10) is an optimum $\hat{\boldsymbol{y}}^\star$ of objective (7), and vice versa.*

Proof Substituting the solution of the inner optimization from Lemma 20 into the local consistency relaxation objective (71) gives a projected optimization over only $\boldsymbol{\mu}$ which is identical to the MAX SAT relaxation objective (7). ■
