The Journal of Machine Learning Research
Print-Archive Edition
Volume 18 (papers from 2017)
Issues 74–149

The Journal of Machine Learning Research (JMLR) is an open access journal. All articles published in JMLR are freely available via electronic distribution. This Print-Archive Edition is published annually as a means of archiving the contents of the journal in perpetuity. The contents of this edition are articles published electronically in JMLR in 2017.

JMLR is abstracted in ACM Computing Reviews, INSPEC, and Psychological Abstracts/PsycINFO.

JMLR is a publication of Journal of Machine Learning Research, Inc. For further information regarding JMLR, including open access to articles, visit http://www.jmlr.org/.

JMLR Print-Archive Edition is a publication of Microtome Publishing under agreement with Journal of Machine Learning Research, Inc. For further information regarding the Print-Archive Edition, including subscription and distribution information and background on open-access print archiving, visit Microtome Publishing at http://www.mtome.com/.

Collection copyright © 2017 The Journal of Machine Learning Research, Inc. and Microtome Publishing.
Individual articles copyright © 2017 by their respective authors and distributed under a Creative Commons Attribution 4.0 International License.

ISSN 1532-4435 (print)
ISSN 1533-7928 (online)

JMLR Editorial Board

Editor-in-Chief
Bernhard Schölkopf, MPI for Intelligent Systems, Germany

Editor-in-Chief
Kevin Murphy, Google Research, USA

Managing Editor
Aron Culotta, Illinois Institute of Technology, USA

Production Editor
Charles Sutton, University of Edinburgh, UK

JMLR Web Master
Chiyuan Zhang, Massachusetts Institute of Technology, USA

JMLR Action Editors
Ryan Adams, Princeton University, USA. **Shivani Agarwal**, University of Pennsylvania, USA. **Edoardo M. Airoldi**, Harvard University, USA. **Anima Anandkumar**, California Institute of Technology, USA. **Peter Auer**, University of Leoben, Austria. **David Barber**, University College London, UK. **Samy Bengio**, Google Research, USA. **Yoshua Bengio**, Université de Montréal, Canada. **Jeff Bilmes**, University of Washington, USA. **Karsten Borgwardt**, ETH Zurich, Switzerland. **Léon Bottou**, Facebook AI Research. **François Caron**, University of Oxford, United Kingdom. **Miguel A. Carreira-Perpinan**, University of California, Merced, USA. **Alexander Clark**, King's College London, UK. **Corinna Cortes**, Google Research, USA. **Koby Crammer**, Technion, Israel. **Sanjoy Dasgupta**, University of California, San Diego, USA. **Inderjit S. Dhillon**, University of Texas, Austin, USA. **Jennifer Dy**, Northeastern University, USA. **Gal Elidan**, Hebrew University, Israel. **Charles Elkan**, University of California at San Diego, USA. **Barbara Engelhardt**, Princeton University, USA. **Rob Fergus**, New York University, USA. **Kenji Fukumizu**, The Institute of Statistical Mathematics, Japan **Amir Globerson**, Tel Aviv University, Israel **Moises Goldszmidt**, Microsoft Research, USA. **Russ Greiner**, University of Alberta, Canada. **Arthur Gretton**, University College London, UK. **Maya Gupta**, Google Research, USA. **Isabelle Guyon**, ClopiNet, USA. **Moritz Hardt**, Google Research, USA. **Thomas Hofmann**, ETH Zurich, Switzerland **Bert Huang**, Virginia Tech, USA. **Aapo Hyvärinen**, University of Helsinki, Finland **Alex Ihler**, University of California, Irvine, USA. **Tommi Jaakkola**, Massachusetts Institute of Technology, USA. **Samuel Kaski**, Aalto University, Finland **Sathiya Keerthi**, Microsoft Research, USA. **Emtiyaz Khan**, RIKEN Center for Advanced Intelligence, Japan **George Konidaris**, Duke University, USA. **Andreas Krause**, ETH Zurich, Switzerland **Sanjiv Kumar**, Google Research, USA. **Christoph Lampert**, Institute of Science and Technology, Austria **Daniel Lee**, University of Pennsylvania, USA. **Qiang Liu**, Dartmouth College, USA. **Gábor Lugosi**, Pompeu Fabra University, Spain **Michael Mahoney**, University of California at Berkeley, USA. **Shie Mannor**, Technion, Israel **Jon McAuliffe**, University of California at Berkeley, USA. **Robert E. McCulloch**, University of Chicago, USA. **Chris Meek**, Microsoft Research, USA. **Qiaozhu Mei**, University of Michigan, USA. **Vahab Mirrokni**, Google Research, USA. **Mehryar Mohri**, New York University, USA. **Joris Mooij**, University of Amsterdam, Netherlands **Boaz Nadler**, Weizmann Institute of Science, Israel. **Long Nguyen**, University of Michigan, USA. **Sebastian Nowozin**, Microsoft Research, Cambridge, UK **Una-May O'Reilly**, Massachusetts Institute of Technology, USA. **Manfred**

Opper, Technical University of Berlin, Germany **Laurent Orseau**, Google Deepmind, USA. **Luis Ortiz**, University of Michigan - Dearborn, USA. **Jie Peng**, University of California, Davis, USA. **Jan Peters**, Technische Universitaet Darmstadt, Germany **Avi Pfeffer**, Charles River Analytics, USA. **Joelle Pineau**, McGill University, Canada. **Massimiliano Pontil**, Istituto Italiano di Tecnologia (Italy), University College London (UK) **Luc de Raedt**, Katholieke Universiteit Leuven, Belgium **Alexander Rakhlin**, University of Pennsylvania, USA. **Ben Recht**, University of California, Berkeley, USA. **Lorenzo Rosasco**, Massachusetts Institute of Technology, USA. **Saharon Rosset**, Tel Aviv University, Israel **Ruslan Salakhutdinov**, University of Toronto, Canada. **Sujay Sanghavi**, University of Texas, Austin, USA. **Mark Schmidt**, University of British Columbia, Canada. **Marc Schoenauer**, INRIA Saclay, France **John Shawe-Taylor**, University College London, UK **Xiaotong Shen**, University of Minnesota, USA. **David Sontag**, New York University, USA. **Peter Spirtes**, Carnegie Mellon University, USA. **Nathan Srebro**, Toyota Technical Institute at Chicago, USA. **Ingo Steinwart**, University of Stuttgart, Germany **Amos Storkey**, University of Edinburgh, UK **Csaba Szepesvari**, University of Alberta, Canada. **Olivier Teytaud**, INRIA Saclay, France **Ivan Titov**, University of Amsterdam, Netherlands **Ryan Tibshirani**, Carnegie Mellon University **Ryota Tomioka**, Microsoft Research Cambridge, UK **Koji Tsuda**, National Institute of Advanced Industrial Science and Technology, Japan **Zhuowen Tu**, University of California at San Diego, USA. **Nicolas Vayatis**, ENS Cachan, France **S V N Vishwanathan**, Purdue University, USA. **Manfred Warmuth**, University of California at Santa Cruz, USA. **Kilian Weinberger**, Cornell University, USA. **David Wipf**, Microsoft Research Asia, China **Daniela Witten**, University of Washington. **Stefan Wrobel**, Fraunhofer IAIS and University of Bonn, Germany **Eric Xing**, Carnegie Mellon University, USA. **Tong Zhang**, Baidu Inc, China **Zhihua Zhang**, Peking University, China **Hui Zou**, University of Minnesota, USA.

JMLR MLOSS Editors

Alexandre Gramfort, INRIA, Université Paris-Saclay, France **Antti Honkela**, University of Helsinki, Finland **Balázs Kégl**, CNRS / Université Paris-Saclay, France **Cheng Soon Ong**, Australian National University, Australia

Journal of Machine Learning Research

Volume 18 (papers from 2017)
Volume year 2018

Part A

18(1):1–29 **Averaged Collapsed Variational Bayes Inference**
Katsuhiko Ishiguro, Issei Sato, Naonori Ueda

18(2):1–45 **Scalable Influence Maximization for Multiple Products in Continuous-Time Diffusion Networks**
Nan Du, Yingyu Liang, Maria-Florina Balcan, Manuel Gomez-Rodriguez, Hongyuan Zha, Le Song

18(3):1–35 **Local algorithms for interactive clustering**
Pranjal Awasthi, Maria Florina Balcan, Konstantin Voevodski

18(4):1–5 **SnapVX: A Network-Based Convex Optimization Solver**
David Hallac, Christopher Wong, Steven Diamond, Abhijit Sharang, Rok Sosič, Stephen Boyd, Jure Leskovec

18(5):1–30 **Communication-efficient Sparse Regression**
Jason D. Lee, Qiang Liu, Yuekai Sun, Jonathan E. Taylor

18(6):1–36 **Improving Variational Methods via Pairwise Linear Response Identities**
Jack Raymond, Federico Ricci-Tersenghi

18(7):1–37 **Distributed Sequence Memory of Multidimensional Inputs in Recurrent Networks**
Adam S. Charles, Dong Yin, Christopher J. Rozell

18(8):1–35 **Persistence Images: A Stable Vector Representation of Persistent Homology**
Henry Adams, Tegan Emerson, Michael Kirby, Rachel Neville, Chris Peterson, Patrick Shipman, Sofya Chepushtanova, Eric Hanson, Francis Motta, Lori Ziegelmeier

18(9):1–57 **Spectral Clustering Based on Local PCA**
Ery Arias-Castro, Gilad Lerman, Teng Zhang

18(10):1–33 **On Perturbed Proximal Gradient Algorithms**
Yves F. Atchadé, Gersende Fort, Eric Moulines

18(11):1–39 **Differential Privacy for Bayesian Inference through Posterior Sampling**
Christos Dimitrakakis, Blaine Nelson, Zuhe Zhang, Aikaterini Mitrokotsa, Benjamin I. P. Rubinstein

18(12):1–5 **Refinery: An Open Source Topic Modeling Web Platform**
Daeil Kim, Benjamin F. Swanson, Michael C. Hughes, Erik B. Sudderth

18(13):1–43 **Using Conceptors to Manage Neural Long-Term Memories for Temporal Patterns**
Herbert Jaeger

18(14):1–45 **Automatic Differentiation Variational Inference**
Alp Kucukelbir, Dustin Tran, Rajesh Ranganath, Andrew Gelman, David M. Blei

18(15):1–35 **Empirical Evaluation of Resampling Procedures for Optimising SVM Hyperparameters**
Jacques Wainer, Gavin Cawley

18(16):1–49 **A Unified Formulation and Fast Accelerated Proximal Gradient Method for Classification**
Naoki Ito, Akiko Takeda, Kim-Chuan Toh

18(17):1–5 **Imbalanced-learn: A Python Toolbox to Tackle the Curse of Imbalanced Datasets in Machine Learning**
Guillaume Lemaître, Fernando Nogueira, Christos K. Aridas

18(18):1–65 **Information-Geometric Optimization Algorithms: A Unifying Picture via Invariance Principles**
Yann Ollivier, Ludovic Arnold, Anne Auger, Nikolaus Hansen

18(19):1–53 **Breaking the Curse of Dimensionality with Convex Neural Networks**
Francis Bach

18(20):1–32 **Memory Efficient Kernel Approximation**
Si Si, Cho-Jui Hsieh, Inderjit S. Dhillon

18(21):1–38 **On the Equivalence between Kernel Quadrature Rules and Random Feature Expansions**
Francis Bach

18(22):1–40 **Analyzing Tensor Power Method Dynamics in Overcomplete Regime**
Animashree Anandkumar, Rong Ge, Majid Janzamin

18(23):1–5 **JSAT: Java Statistical Analysis Tool, a Library for Machine Learning**
Edward Raff

18(24):1–29 **Identifying a Minimal Class of Models for High–dimensional Data**
Daniel Nevo, Ya'acov Ritov

18(25):1–5 **Auto-WEKA 2.0: Automatic model selection and hyperparameter optimization in WEKA**
Lars Kotthoff, Chris Thornton, Holger H. Hoos, Frank Hutter, Kevin Leyton-Brown

18(26):1–5 **POMDPs.jl: A Framework for Sequential Decision Making under Uncertainty**
Maxim Egorov, Zachary N. Sunberg, Edward Balaban, Tim A. Wheeler, Jayesh K. Gupta, Mykel J. Kochenderfer

18(27):1–32 **Generalized Pólya Urn for Time-Varying Pitman-Yor Processes**
François Caron, Willie Neiswanger, Frank Wood, Arnaud Doucet, Manuel Davy

18(28):1–39 **Particle Gibbs Split-Merge Sampling for Bayesian Inference in Mixture Models**
Alexandre Bouchard-Côté, Arnaud Doucet, Andrew Roth

18(29):1–53 **Certifiably Optimal Low Rank Factor Analysis**
Dimitris Bertsimas, Martin S. Copenhaver, Rahul Mazumder

18(30):1–52 **Group Sparse Optimization via lp,q Regularization**
Yaohua Hu, Chong Li, Kaiwen Meng, Jing Qin, Xiaoqi Yang

18(31):1–32 **Preference-based Teaching**
Ziyuan Gao, Christoph Ries, Hans U. Simon, Sandra Zilles

18(32):1–40 **Nonparametric Risk Bounds for Time-Series Forecasting**
Daniel J. McDonald, Cosma Rohilla Shalizi, Mark Schervish

18(33):1–39 **Online Bayesian Passive-Aggressive Learning**
Tianlin Shi, Jun Zhu

18(34):1–41 **Asymptotic Analysis of Objectives Based on Fisher Information in Active Learning**
Jamshid Sourati, Murat Akcakaya, Todd K. Leen, Deniz Erdogmus, Jennifer G. Dy

18(35):1–39 **A Spectral Algorithm for Inference in Hidden semi-Markov Models**
Igor Melnyk, Arindam Banerjee

18(36):1–30 **Simplifying Probabilistic Expressions in Causal Inference**
Santtu Tikka, Juha Karvanen

18(37):1–22 **Nearly optimal classification for semimetrics**
Lee-Ad Gottlieb, Aryeh Kontorovich, Pinhas Nisnevitch

18(38):1–39 **Bridging Supervised Learning and Test-Based Co-optimization**
Elena Popovici

18(39):1–5 **GFA: Exploratory Analysis of Multiple Data Sources with Group Factor Analysis**
Eemeli Leppäaho, Muhammad Ammad-ud-din, Samuel Kaski

18(40):1–6 **GPflow: A Gaussian Process Library using TensorFlow**
Alexander G. de G. Matthews, Mark van der Wilk, Tom Nickson, Keisuke Fujii, Alexis Boukouvalas, Pablo León-Villagrá, Zoubin Ghahramani, James Hensman

18(41):1–49 **COEVOLVE: A Joint Point Process Model for Information Diffusion and Network Evolution**
Mehrdad Farajtabar, Yichen Wang, Manuel Gomez-Rodriguez, Shuang Li, Hongyuan Zha, Le Song

18(42):1–60 **Learning Local Dependence In Ordered Data**
Guo Yu, Jacob Bien

18(43):1–29 **Bayesian Learning of Dynamic Multilayer Networks**
Daniele Durante, Nabanita Mukherjee, Rebecca C. Steorts

18(44):1–29 **Time-Accuracy Tradeoffs in Kernel Prediction: Controlling Prediction Quality**
Samory Kpotufe, Nakul Verma

18(45):1–21 **Asymptotic behavior of Support Vector Machine for spiked population model**
Hanwen Huang

18(46):1–22 **Distributed Semi-supervised Learning with Kernel Ridge Regression**
Xiangyu Chang, Shao-Bo Lin, Ding-Xuan Zhou

18(47):1–43 **On Markov chain Monte Carlo methods for tall data**
Rémi Bardenet, Arnaud Doucet, Chris Holmes

18(48):1–33 **Explaining the Success of AdaBoost and Random Forests as Interpolating Classifiers**
Abraham J. Wyner, Matthew Olson, Justin Bleich, David Mease

18(49):1–47 **Clustering from General Pairwise Observations with Applications to Time-varying Graphs**
Shiau Hong Lim, Yudong Chen, Huan Xu

18(50):1–41 **Uniform Hypergraph Partitioning: Provable Tensor Methods and Sampling Techniques**
Debarghya Ghoshdastidar, Ambedkar Dukkipati

18(51):1–24 **Reconstructing Undirected Graphs from Eigenspaces**
Yohann De Castro, Thibault Espinasse, Paul Rochet

18(52):1–11 **An Optimal Algorithm for Bandit and Zero-Order Convex Optimization with Two-Point Feedback**
Ohad Shamir

18(53):1–31 **Perishability of Data: Dynamic Pricing under Varying-Coefficient Models**
Adel Javanmard

18(54):1–24 **Two New Approaches to Compressed Sensing Exhibiting Both Robust Sparse Recovery and the Grouping Effect**
Mehmet Eren Ahsen, Niharika Challapalli, Mathukumalli Vidyasagar

18(55):1–35 **On the Consistency of Ordinal Regression Methods**
Fabian Pedregosa, Francis Bach, Alexandre Gramfort

18(56):1–26 **Statistical Inference with Unnormalized Discrete Models and Localized Homogeneous Divergences**
Takashi Takenouchi, Takafumi Kanamori

18(57):1–59 **Density Estimation in Infinite Dimensional Exponential Families**
Bharath Sriperumbudur, Kenji Fukumizu, Arthur Gretton, Aapo Hyvärinen, Revant Kumar

18(58):1–52 **Lens Depth Function and k-Relative Neighborhood Graph: Versatile Tools for Ordinal Data Analysis**
Matthäus Kleindessner, Ulrike von Luxburg

18(59):1–39 **Joint Label Inference in Networks**
Deepayan Chakrabarti, Stanislav Funiak, Jonathan Chang, Sofus A. Macskassy

18(60):1–45 **Achieving Optimal Misclassification Proportion in Stochastic Block Models**
Chao Gao, Zongming Ma, Anderson Y. Zhang, Harrison H. Zhou

18(61):1–33 **On the Propagation of Low-Rate Measurement Error to Subgraph Counts in Large Networks**
Prakash Balachandran, Eric D. Kolaczyk, Weston D. Viles

18(62):1–58 **Dense Distributions from Sparse Samples: Improved Gibbs Sampling Parameter Estimators for LDA**
Yannis Papanikolaou, James R. Foulds, Timothy N. Rubin, Grigorios Tsoumakas

18(63):1–29 **Fundamental Conditions for Low-CP-Rank Tensor Completion**
Morteza Ashraphijuo, Xiaodong Wang

18(64):1–34 **Parallel Symmetric Class Expression Learning**
An C. Tran, Jens Dietrich, Hans W. Guesgen, Stephen Marsland

18(65):1–35 **Learning Partial Policies to Speedup MDP Tree Search via Reduction to I.I.D. Learning**
Jervis Pinto, Alan Fern

18(66):1–42 **Hierarchically Compositional Kernels for Scalable Nonparametric Learning**
Jie Chen, Haim Avron, Vikas Sindhwani

18(67):1–29 **Sharp Oracle Inequalities for Square Root Regularization**
Benjamin Stucky, Sara van de Geer

18(68):1–43 **Soft Margin Support Vector Classification as Buffered Probability Minimization**
Matthew Norton, Alexander Mafusalov, Stan Uryasev

18(69):1–29 **Variational Particle Approximations**
Ardavan Saeedi, Tejas D. Kulkarni, Vikash K. Mansinghka, Samuel J. Gershman

18(70):1–37 **A Bayesian Framework for Learning Rule Sets for Interpretable Classification**
Tong Wang, Cynthia Rudin, Finale Doshi-Velez, Yimin Liu, Erica Klampfl, Perry MacNeille

18(71):1–46 **A Robust-Equitable Measure for Feature Ranking and Selection**
A. Adam Ding, Jennifer G. Dy, Yi Li, Yale Chang

18(72):1–32 **Multiscale Strategies for Computing Optimal Transport**
Samuel Gerber, Mauro Maggioni

18(73):1–46 **Non-parametric Policy Search with Limited Information Loss**
Herke van Hoof, Gerhard Neumann, Jan Peters

Part B

18(74):1–40 **Tests of Mutual or Serial Independence of Random Vectors with Applications**
Martin Bilodeau, Aurélien Guetsop Nangue

18(75):1–34 **Recovering PCA and Sparse PCA via Hybrid-(l1,l2) Sparse Sampling of Data Elements**
Abhisek Kundu, Petros Drineas, Malik Magdon-Ismail

18(76):1–61 **Quantifying the Informativeness of Similarity Measurements**
Austin J. Brockmeier, Tingting Mu, Sophia Ananiadou, John Y. Goulermas

18(77):1–36 **Time for a Change: a Tutorial for Comparing Multiple Classifiers Through Bayesian Analysis**
Alessio Benavoli, Giorgio Corani, Janez Demšar, Marco Zaffalon

18(78):1–44 **Relational Reinforcement Learning for Planning with Exogenous Effects**
David Martínez, Guillem Alenyà, Tony Ribeiro, Katsumi Inoue, Carme Torras

18(79):1–31 **Bayesian Tensor Regression**
Rajarshi Guhaniyogi, Shaan Qamar, David B. Dunson

18(80):1–50 **Robust Discriminative Clustering with Sparse Regularizers**
Nicolas Flammarion, Balamurugan Palaniappan, Francis Bach

18(81):1–36 **Making Decision Trees Feasible in Ultrahigh Feature and Label Dimensions**
Weiwei Liu, Ivor W. Tsang

18(82):1–37 **Learning Scalable Deep Kernels with Recurrent Structure**
Maruan Al-Shedivat, Andrew Gordon Wilson, Yunus Saatchi, Zhiting Hu, Eric P. Xing

18(83):1–52 **Convolutional Neural Networks Analyzed via Convolutional Sparse Coding**
Vardan Papyan, Yaniv Romano, Michael Elad

18(84):1–42 **Stochastic Primal-Dual Coordinate Method for Regularized Empirical Risk Minimization**
Yuchen Zhang, Lin Xiao

18(85):1–21 **Angle-based Multicategory Distance-weighted SVM**
Hui Sun, Bruce A. Craig, Lingsong Zhang

18(86):1–47 **Minimax Estimation of Kernel Mean Embeddings**
Ilya Tolstikhin, Bharath K. Sriperumbudur, Krikamol Muandet

18(87):1–28 **The Impact of Random Models on Clustering Similarity**
Alexander J. Gates, Yong-Yeol Ahn

18(88):1–35 **Hierarchical Clustering via Spreading Metrics**
Aurko Roy, Sebastian Pokutta

18(89):1–5 **The MADP Toolbox: An Open Source Library for Planning and Learning in (Multi-)Agent Systems**
Frans A. Oliehoek, Matthijs T. J. Spaan, Bas Terwijn, Philipp Robbel, João V. Messias

18(90):1–50 **A survey of Algorithms and Analysis for Adaptive Online Learning**
H. Brendan McMahan

18(91):1–35 **A distributed block coordinate descent method for training l1 regularized linear classifiers**
Dhruv Mahajan, S. Sathiya Keerthi, S. Sundararajan

18(92):1–31 **Distributed Learning with Regularized Least Squares**
Shao-Bo Lin, Xin Guo, Ding-Xuan Zhou

18(93):1–67 **Identifying Unreliable and Adversarial Workers in Crowdsourced Labeling Tasks**
Srikanth Jagabathula, Lakshminarayanan Subramanian, Ashwin Venkataraman

18(94):1–38 **An Easy-to-hard Learning Paradigm for Multiple Classes and Multiple Labels**
Weiwei Liu, Ivor W. Tsang, Klaus-Robert Müller

18(95):1–32 **Fisher Consistency for Prior Probability Shift**
Dirk Tasche

18(96):1–5 **openXBOW – Introducing the Passau Open-Source Crossmodal Bag-of-Words Toolkit**
Maximilian Schmitt, Björn Schuller

18(97):1–47 **Optimal Rates for Multi-pass Stochastic Gradient Methods**
Junhong Lin, Lorenzo Rosasco

18(98):1–29 **Rank Determination for Low-Rank Data Completion**
Morteza Ashraphijuo, Xiaodong Wang, Vaneet Aggarwal

18(99):1–32 **Bayesian Network Learning via Topological Order**
Young Woong Park, Diego Klabjan

18(100):1–37 **Stability of Controllers for Gaussian Process Dynamics**
Julia Vinogradska, Bastian Bischoff, Duy Nguyen-Tuong, Jan Peters

18(101):1–51 **Harder, Better, Faster, Stronger Convergence Rates for Least-Squares Regression**
Aymeric Dieuleveut, Nicolas Flammarion, Francis Bach

18(102):1–28 **Confidence Sets with Expected Sizes for Multiclass Classification**
Christophe Denis, Mohamed Hebiri

18(103):1–50 **Online Learning to Rank with Top-k Feedback**
Sougata Chaudhuri, Ambuj Tewari

18(104):1–72 **A Unifying Framework for Gaussian Process Pseudo-Point Approximations using Power Expectation Propagation**
Thang D. Bui, Josiah Yan, Richard E. Turner

18(105):1–23 **Accelerating Stochastic Composition Optimization**
Mengdi Wang, Ji Liu, Ethan X. Fang

18(106):1–37 **Distributed Bayesian Learning with Stochastic Natural Gradient Expectation Propagation and the Posterior Server**
Leonard Hasenclever, Stefan Webb, Thibaut Lienart, Sebastian Vollmer, Balaji Lakshminarayanan, Charles Blundell, Yee Whye Teh

18(107):1–28 **Optimal Dictionary for Least Squares Representation**
Mohammed Rayyan Sheriff, Debasish Chatterjee

18(108):1–37 **Computational Limits of A Distributed Algorithm for Smoothing Spline**
Zuofeng Shang, Guang Cheng

18(109):1–67 **Hinge-Loss Markov Random Fields and Probabilistic Soft Logic**
Stephen H. Bach, Matthias Broecheler, Bert Huang, Lise Getoor

18(110):1–49 **Clustering with Hidden Markov Model on Variable Blocks**
Lin Lin, Jia Li

18(111):1–55 **Approximation Vector Machines for Large-scale Online Learning**
Trung Le, Tu Dinh Nguyen, Vu Nguyen, Dinh Phung

18(112):1–29 **Efficient Sampling from Time-Varying Log-Concave Distributions**
Hariharan Narayanan, Alexander Rakhlin

18(113):1–24 **Document Neural Autoregressive Distribution Estimation**
Stanislas Lauly, Yin Zheng, Alexandre Allauzen, Hugo Larochelle

18(114):1–26 **Target Curricula via Selection of Minimum Feature Sets: a Case Study in Boolean Networks**
Shannon Fenn, Pablo Moscato

18(115):1–52 **A General Distributed Dual Coordinate Optimization Framework for Regularized Loss Minimization**
Shun Zheng, Jialei Wang, Fen Xia, Wei Xu, Tong Zhang

18(116):1–40 **Second-Order Stochastic Optimization for Machine Learning in Linear Time**
Naman Agarwal, Brian Bullins, Elad Hazan

18(117):1–49 **Regularized Estimation and Testing for High-Dimensional Multi-Block Vector-Autoregressive Models**
Jiahe Lin, George Michailidis

18(118):1–25 **Learning Theory of Distributed Regression with Bias Corrected Regularization Kernel Network**
Zheng-Chu Guo, Lei Shi, Qiang Wu

18(119):1–59 **Probabilistic Line Searches for Stochastic Optimization**
Maren Mahsereci, Philipp Hennig

18(120):1–49 **Learning Instrumental Variables with Structural and Non-Gaussianity Assumptions**
Ricardo Silva, Shohei Shimizu

18(121):1–34 **Classification of Time Sequences using Graphs of Temporal Constraints**
Mathieu Guillame-Bert, Artur Dubrawski

18(122):1–43 **Distributed Stochastic Variance Reduced Gradient Methods by Sampling Extra Data with Replacement**
Jason D. Lee, Qihang Lin, Tengyu Ma, Tianbao Yang

18(123):1–41 **Kernel Partial Least Squares for Stationary Data**
Marco Singer, Tatyana Krivobokova, Axel Munk

18(124):1–40 **Robust and Scalable Bayes via a Median of Subset Posterior Measures**
Stanislav Minsker, Sanvesh Srivastava, Lizhen Lin, David B. Dunson

18(125):1–53 **Statistical and Computational Guarantees for the Baum-Welch Algorithm**
Fanny Yang, Sivaraman Balakrishnan, Martin J. Wainwright

18(126):1–45 **Online but Accurate Inference for Latent Variable Models with Local Gibbs Sampling**
Christophe Dupuy, Francis Bach

18(127):1–45 **Poisson Random Fields for Dynamic Feature Models**
Valerio Perrone, Paul A. Jenkins, Dario Spanò, Yee Whye Teh

18(128):1–33 **Gap Safe Screening Rules for Sparsity Enforcing Penalties**
Eugene Ndiaye, Olivier Fercoq, Alexandre Gramfort, Joseph Salmon

18(129):1–31 **Minimax Filter: Learning to Preserve Privacy from Inference Attacks**
Jihun Hamm

18(130):1–38 **Knowledge Graph Completion via Complex Tensor Factorization**

Abstract

The problem of testing mutual independence between many random vectors is addressed. The closely related problem of testing serial independence of a multivariate stationary sequence is also considered. The Möbius transformation of characteristic functions is used to characterize independence. A generalization to p vectors of distance covariance and Hilbert-Schmidt independence criterion ($HSIC$) tests with the translation invariant kernel of a stable probability distribution is proposed. Both test statistics can be expressed in a simple form as a sum over all elements of a componentwise product of p doubly-centered matrices. It is shown that an $HSIC$ statistic with sufficiently small scale parameters is equivalent to a distance covariance statistic. Consistency and weak convergence of both types of statistics are established. Approximation of p-values is made by randomization tests without recomputing interpoint distances for each randomized sample. The dependogram is adapted to the proposed tests for the graphical identification of sources of dependencies. Empirical rejection rates obtained through extensive simulations confirm both the applicability of the testing procedures in small samples and the high level of competitiveness in terms of power. Applications to meteorological and financial data provide some interesting interpretations of dependencies revealed by dependograms.

Keywords: Distance covariance, Hilbert-Schmidt independence criterion, Möbius transformation, mutual independence, serial independence

1. Introduction

The problem of testing for independence between p components of a random vector has attracted considerable attention in statistics. Many nonparametric procedures exist in the literature. A natural approach is to consider a functional of the difference between the empirical joint distribution and the product of the empirical marginal distributions. This same approach can also use empirical characteristic functions. When the functional of the difference is above a certain threshold, the components are declared dependent. Csörgő (1985), Kankainen (1995), Sejdinovic et al. (2013b) and Fan et al. (2017) considered mutual tests of independence based on empirical characteristic functions. However, when dependence is declared, it is not possible to identify, with their proposed tests, subsets of variables responsible for the dependence. This limitation is similar to that of a global F-test in an analysis of variance model with one fixed factor, as opposed to multiple comparisons procedures, or that of a global chi-square test of independence in a multi-way contingency table, as opposed to log-linear models with interaction terms. For tests of independence, a useful method is the Möbius transformation.

The Möbius transformation defined in (1) of Section 2 has a long history in statistics. The Möbius transformation of distribution functions was first proposed in Blum et al. (1961) for $p = 3$. The general case was treated in Deheuvels (1981), Ghoudi et al. (2001), Genest and Rémillard (2004), Kojadinovic and Holmes (2009), Kojadinovic and Yan (2011), and Duchesne et al. (2012). It can also be defined with characteristic functions as in Bilodeau and Lafaye de Micheaux (2005), with half-space probabilities as in Beran et al. (2007), or with cell probabilities in a contingency table as in Bilodeau and Lafaye de Micheaux (2009). The first appearance of a Möbius transformation, although not stated explicitly, goes back to the work of Lancaster (1951) on contingency tables as explained in Bilodeau and Lafaye de Micheaux (2009). The machine learning community (Sejdinovic et al., 2013a) proposed kernel nonparametric tests for Lancaster three-variable interaction. This test is in fact a test based on the empirical version of the Möbius transformation of the characteristic function when $p = 3$. The general Möbius transformation considered in this paper can be used to build tests for general interactions of any order, as well as tests of mutual and serial independence.

The paper is organized as follows. Section 2 introduces the Möbius transformation of characteristic functions. It presents a characterization of the mutual independence between p random vectors by the Möbius transformation. In Section 3, new tests based on the Möbius transformation of empirical characteristic functions are introduced. They generalize the Hilbert-Schmidt independence criterion ($HSIC$) test (Gretton et al., 2005, 2008) and the distance covariance test (Székely et al., 2007) to the case $p > 2$. This work addresses the case of finite-dimensional Euclidean spaces. $HSIC$ was originally defined more generally using any semimetric space of negative type (as in the distance covariance), or any Borel measurable space on which a kernel is defined (Sejdinovic et al., 2013b). For example, in Gretton et al. (2008), dependence was detected between text in different languages using kernels on strings. On the other hand, this manuscript proposes a criterion that is more general than $HSIC$ in a different respect, via subsets of components in the Möbius transformation, where the criterion coincides with $HSIC$ when the latter is specialized to Euclidean spaces and $p = 2$. The new test statistics have a common form as a sum of elements of a componentwise product of p doubly-centered matrices. An equivalence is established between an $HSIC$ statistic with infinitesimal scale parameters and a distance covariance statistic. The weak convergence of the empirical processes based on the Möbius transformation is proved. The consistency and weak convergence of the $HSIC$ and distance covariance functionals are also established. A difficulty encountered in establishing the asymptotic independence of the collection of distance covariance functionals, over all subsets of components, is described. Other competing nonparametric tests of independence are reviewed in Section 4.

Rather than relying on the limiting distribution to conduct tests, Section 5 describes randomization tests as an approximation to permutation tests. In Section 6, p-values obtained by randomization tests for all possible subsets of components are combined using

the methods of Fisher (1950, pp. 99-101) or Tippett (1952) to obtain a global test of mutual independence. Section 7 describes the dependogram, a graphical device of Genest and Rémillard (2004), in the context of $HSIC$ and distance covariance tests. Section 8 adapts all the results described for the mutual independence situation to the problem of testing for the serial independence of a multivariate stationary sequence. Computational costs are given in Section 9 together with a short description of `R` (R Core Team, 2015) packages for nonparametric independence tests. Simulated models are considered in Section 10 to verify that the proposed tests have empirical significance levels close to the nominal level in small samples and comparable or higher powers in many situations when compared to existing tests such as those of Csörgő (1985), Kojadinovic and Holmes (2009) or Kojadinovic and Yan (2011).

Finally, Section 11 contains an application to real data on variables related to air temperature, soil temperature, humidity, wind, and evaporation. $HSIC$ or distance covariance tests should be preferred to the Gaussian likelihood ratio test since a multivariate Gaussian model is rejected by the test of Henze and Zirkler (1990). According to these tests, wind does not exhibit any dependence with all other variables considered. Another application finds significant serial dependencies in the S&P/TSX composite, DOW JONES, and S&P500 daily percent increasing rates ranging from January 2, 2014 to March 2, 2016. The strongest dependency observed at a lag of 4 days by a distance covariance test is interpreted using a broken line regression model as the tendency of stock markets to recover in the days following a sharp decline.

2. Möbius Transformation

The Möbius transformation of characteristic functions is a powerful tool for the characterization of mutual independence between p random vectors $Z^{(1)}, \ldots, Z^{(p)}$. The dimension of the vector $Z^{(j)}$ is d_j, for $j = 1, \ldots, p$. Let f be the joint characteristic function of these p vectors, and let $f^{(j)}$ be the marginal characteristic function of $Z^{(j)}$. Mutual independence is characterized by the factorization

$$f(t^{(1)}, \ldots, t^{(p)}) = \prod_{j=1}^{p} f^{(j)}(t^{(j)}),$$

for all $t^{(1)}, \ldots, t^{(p)}$. It may also be characterized by the Möbius transformation which is defined as follows. Let $\mathcal{I}_p$ be the family of subsets B of $\{1, \ldots, p\}$ of cardinality $|B| > 1$. The set $\mathcal{I}_p$ has $2^p - p - 1$ elements since the empty set is excluded, as well as all p singletons. For any $B \in \mathcal{I}_p$ and any $t^{(1)}, \ldots, t^{(p)}$, define $t^{(B)} = (t^{(j)} : \ j \in B)$. Similarly, $Z^{(B)} = (Z^{(j)} : j \in B)$, and $f^{(B)}$ is the joint characteristic function of $Z^{(B)}$. The Möbius transformation of the characteristic function f for the set $B \in \mathcal{I}_p$ is given by

$$\mu_B(t^{(B)}) = \sum_{C \subseteq B} (-1)^{|B \setminus C|} f^{(C)}(t^{(C)}) \prod_{j \in B \setminus C} f^{(j)}(t^{(j)}). \tag{1}$$

By convention, for $C = \emptyset$, both $f^{(C)}(t^{(C)})$ and $\prod_{j \in C} f^{(j)}(t^{(j)})$ are equal to one. The following characterization holds: $Z^{(1)}, \ldots, Z^{(p)}$ are mutually independent if and only if, $\mu_B(t^{(B)}) = 0$,

for all $B \in \mathcal{I}_p$, and all vectors $t^{(B)}$. A proof by induction of this characterization using distribution functions is given in Ghoudi et al. (2001) and is immediately applicable to characteristic functions.

3. Dependence Statistics

Consider $Z_k = (Z_k^{(1)}, \ldots, Z_k^{(p)})$, $k = 1, \ldots, n$, an independent and identically distributed sample of size n. The Möbius processes corresponding to μ_B, $B \in \mathcal{I}_p$, are defined as

$$R_{nB}(t^{(B)}) = \sqrt{n} \sum_{C \subseteq B} (-1)^{|B \setminus C|} f_n^{(C)}(t^{(C)}) \prod_{j \in B \setminus C} f_n^{(j)}(t^{(j)}), \tag{2}$$

where

$$f_n^{(C)}(t^{(C)}) = \frac{1}{n} \sum_{k=1}^{n} e^{i \langle t^{(C)}, Z_k^{(C)} \rangle} \tag{3}$$

is the empirical characteristic function. When $C = \{j\}$ is a singleton, the notation used for $f_n^{(C)}$ is simply $f_n^{(j)}$. The empirical processes R_{nB}, for all $B \in \mathcal{I}_p$, are illustrated when $p = 3$ in Table 1. The processes R_{nB} are identical to the empirical characteristic independence processes

$$S_{nB}(t^{(B)}) = \sqrt{n} \left[f_n^{(B)}(t^{(B)}) - \prod_{j \in B} f_n^{(j)}(t^{(j)}) \right]$$

in Csörgő (1985) only for subsets B of cardinality 2. The process S_{nB} appears later in the test statistic $\mathcal{J}_n^2$ in (17) used for testing the hypothesis of mutual independence. For $B = \{1, 2, 3\}$, the process

$$S_{nB}(t^{(B)}) = \sqrt{n} \left[f_n^{(1,2,3)}(t^{(1)}, t^{(2)}, t^{(3)}) - f_n^{(1)}(t^{(1)}) f_n^{(2)}(t^{(2)}) f_n^{(3)}(t^{(3)}) \right]$$

can be contrasted with the process R_{nB} in Table 1. Although, at first sight, R_{nB} may look more complicated than S_{nB} and both processes converge weakly to Gaussian processes, the processes R_{nB} have major advantages which are enunciated in Section 4.

B	$R_{nB}(t^{(B)})/\sqrt{n}$
$\{1,2\}$	$f_n^{(1,2)}(t^{(1)}, t^{(2)}) - f_n^{(1)}(t^{(1)}) f_n^{(2)}(t^{(2)})$
$\{1,3\}$	$f_n^{(1,3)}(t^{(1)}, t^{(3)}) - f_n^{(1)}(t^{(1)}) f_n^{(3)}(t^{(3)})$
$\{2,3\}$	$f_n^{(2,3)}(t^{(2)}, t^{(3)}) - f_n^{(2)}(t^{(2)}) f_n^{(3)}(t^{(3)})$
$\{1,2,3\}$	$-f_n^{(1,2,3)}(t^{(1)}, t^{(2)}, t^{(3)}) + f_n^{(1,2)}(t^{(1)}, t^{(2)}) f_n^{(3)}(t^{(3)}) + f_n^{(1,3)}(t^{(1)}, t^{(3)}) f_n^{(2)}(t^{(2)})$ $+f_n^{(2,3)}(t^{(2)}, t^{(3)}) f_n^{(1)}(t^{(1)}) - 2 f_n^{(1)}(t^{(1)}) f_n^{(2)}(t^{(2)}) f_n^{(3)}(t^{(3)})$

Table 1: Empirical processes R_{nB}, $B \in \mathcal{I}_3$.

The dependence statistic for the subset B is now defined as the Cramér-von Mises functional

$$W_{nB} = \frac{1}{n} \int |R_{nB}(t^{(B)})|^2 dw_B(t^{(B)}), \tag{4}$$

where $dw_B(t^{(B)}) = \prod_{j\in B} dw^{(j)}(t^{(j)})$ is a product measure. The evaluation of this integral is facilitated using another representation of the process. First, recall the multinomial formula (Ghoudi et al., 2001)

$$\sum_{C\subseteq B}\left(\prod_{i\in C} u^{(i)}\right)\left(\prod_{j\in B\setminus C} v^{(j)}\right) = \prod_{i\in B}\left(u^{(i)}+v^{(i)}\right). \tag{5}$$

Then, the empirical process (2) can be written as

$$R_{nB}(t^{(B)}) = \frac{1}{\sqrt{n}}\sum_{k=1}^{n}\prod_{j\in B}\left[e^{i\langle t^{(j)},Z_k^{(j)}\rangle} - f_n^{(j)}(t^{(j)})\right]. \tag{6}$$

The representation (6) is obtained after replacing the expression (3) for the empirical characteristic function in (2) and by applying the multinomial formula (5). The representation given by (6) allows the integral (4) to be evaluated explicitly in some cases and simplifies the proof of theorems to come. Two important cases are now presented.

3.1 Hilbert-Schmidt Independence Criterion

Assume that the measure $dw_B(t^{(B)}) = \prod_{j\in B} dG^{(j)}(t^{(j)})$ is a product of symmetric (around the origin) probability measures. The population Hilbert-Schmidt independence criterion is

$$\mathcal{H}_B^2 = \int |\mu_B(t^{(B)})|^2 \prod_{j\in B} dG^{(j)}(t^{(j)}) \tag{7}$$

which is well defined since the function μ_B is bounded. For the sample version, let $\varphi^{(j)}$ be the (real) characteristic function of $G^{(j)}$. The sample version of the Hilbert-Schmidt independence criterion (7) is denoted $\mathcal{H}_{nB}^2$ and has the following explicit expression.

Theorem 1 *For any $B \in \mathcal{I}_p$, the dependence statistic $\mathcal{H}_{nB}^2$ is given by*

$$\mathcal{H}_{nB}^2 = \frac{1}{n^2}\sum_{k=1}^{n}\sum_{l=1}^{n}\prod_{j\in B} A_{kl}^{(j)}, \tag{8}$$

where

$$\begin{aligned} a_{kl}^{(j)} &= \varphi^{(j)}(Z_k^{(j)} - Z_l^{(j)}), \\ A_{kl}^{(j)} &= a_{kl}^{(j)} - \bar{a}_{k.}^{(j)} - \bar{a}_{.l}^{(j)} + \bar{a}_{..}^{(j)}, \\ \bar{a}_{k.}^{(j)} &= \frac{1}{n}\sum_{l=1}^{n} a_{kl}^{(j)},\ \bar{a}_{.l}^{(j)} = \frac{1}{n}\sum_{k=1}^{n} a_{kl}^{(j)},\ \bar{a}_{..}^{(j)} = \frac{1}{n^2}\sum_{k,l=1}^{n} a_{kl}^{(j)}. \end{aligned} \tag{9}$$

By definition, matrices $A^{(j)} = (A_{kl}^{(j)})$, $j = 1,\ldots,p$, are doubly-centered, *i.e.* rows and columns of these matrices sum up to zero. In the special case $p = 2$ of testing the independence between two vectors, the statistic $\mathcal{H}_{nB}^2$, for $B = \{1,2\}$, is the Hilbert-Schmidt independence criterion, or $HSIC$, with translation invariant kernels $\varphi^{(j)}(Z_k^{(j)} - Z_l^{(j)})$, $j = 1,2$. A proof of Theorem 1 for $p = 3$ was provided by Sejdinovic et al. (2013a).

An important special case is when $G^{(j)}$ is the stable distribution of index $\alpha \in (0,2]$ with scale parameter $\beta_j > 0$ first studied by Lévy (1925). Then, the translation invariant kernel is

$$a_{kl}^{(j)} = e^{-\beta_j^{\alpha}|Z_k^{(j)} - Z_l^{(j)}|_{d_j}^{\alpha}}, \tag{10}$$

where $|\cdot|_{d_j}$ is the Euclidean norm in dimension d_j. The corresponding dependence statistic is then denoted $\mathcal{H}_{nB}^{2(\alpha)}$. The case $\alpha = 2$ is the Gaussian kernel, and $\alpha = 1$ is the Cauchy kernel, often referred to as the Laplace kernel in machine learning (Gretton et al., 2005, 2009) because of its similarity to a Laplace density in dimension one.

The following result establishes the consistency of the Hilbert-Schmidt independence criterion $\mathcal{H}_{nB}^2$.

Theorem 2

(i) $\mathcal{H}_{nB}^2 \overset{a.s.}{\to} \mathcal{H}_B^2$, *as* $n \to \infty$.

(ii) *If* $\mu_B(t^{(B)}) \neq 0$ *for some vector* $t^{(B)}$, *then* $n\mathcal{H}_{nB}^2 \overset{a.s.}{\to} \infty$, *as* $n \to \infty$.

3.2 Distance Covariance

Assume that the measure $dw_B(t^{(B)}) = \prod_{j\in B} dw^{(j)}(t^{(j)})$ is a product of non integrable measures. The measure $dw^{(j)}$ of index $0 < \alpha < 2$ is defined as

$$dw^{(j)}(t^{(j)}) = \left[C(d_j,\alpha)|t^{(j)}|_{d_j}^{d_j+\alpha}\right]^{-1} dt^{(j)},$$

with the normalizing constant

$$C(d,\alpha) = 2\pi^{d/2}\Gamma(1-\alpha/2)/\left[\alpha 2^{\alpha}\Gamma((d+\alpha)/2)\right].$$

A similar representation as in (8) also holds. The corresponding dependence statistic is denoted $\mathcal{V}_{nB}^{2(\alpha)}$, which is the usual notation for distance covariance of index α.

Theorem 3 *Let $0 < \alpha < 2$. Then, for any $B \in \mathcal{I}_p$, the dependence statistic $\mathcal{V}_{nB}^{2(\alpha)}$ has the same form as in (8) of Theorem 1 with*

$$a_{kl}^{(j)} = -|Z_k^{(j)} - Z_l^{(j)}|_{d_j}^{\alpha}. \tag{11}$$

In the special case $|B| = 2$, the statistic $\mathcal{V}_{nB}^{2(\alpha)}$ reduces to the distance covariance of index α in Feuerverger (1993) for the case $d_1 = d_2 = 1$, and later generalized by Székely et al. (2007) to the case $d_1 \geq 1$, $d_2 \geq 1$. A very special case requiring a separate analysis is when $|B| = 2$ and $\alpha = 2$. In this case, $\mathcal{V}_{nB}^{2(2)}$ is the numerator of the RV coefficient of Escoufier (1973) as noticed by Josse and Holmes (2016) when $d_1 \geq 1$ and $d_2 \geq 1$, and earlier by Székely et al. (2007) only when $d_1 = d_2 = 1$. It should be noted that the case $\alpha = 2$ leads only to a test of non correlation but not of independence, unless the joint distribution is Gaussian. For this reason, the value $\alpha = 2$ will not be considered for distance covariance in the sequel.

Székely et al. (2007) showed the consistency of distance covariance for $0 < \alpha < 2$ and $|B| = 2$. Consistency of distance covariance for $|B| > 2$ is now established. Only when necessary, the notation $\mathbb{E}_3$ is for the expectation with respect to Z_3, treating the other variable as a constant to avoid using conditional expectations.

Theorem 4 *Let $0 < \alpha < 2$. Assume*

$$\mathbb{E}\prod_{j\in B}|Z_1^{(j)} - Z_2^{(j)}|_{d_j}^{\alpha} < \infty. \tag{12}$$

Define

$$\mathcal{V}_B^{2(\alpha)} = \mathbb{E}\prod_{j\in B}\left[-|Z_1^{(j)} - Z_2^{(j)}|_{d_j}^{\alpha} + \mathbb{E}_3|Z_1^{(j)} - Z_3^{(j)}|_{d_j}^{\alpha} + \mathbb{E}_3|Z_2^{(j)} - Z_3^{(j)}|_{d_j}^{\alpha} - \mathbb{E}|Z_3^{(j)} - Z_4^{(j)}|_{d_j}^{\alpha}\right].$$

Then,

(i) $\mathcal{V}_B^{2(\alpha)} = \int |\mu_B(t^{(B)})|^2 dw_B(t^{(B)}) < \infty$.

(ii) *If $\mu_B(t^{(B)}) \neq 0$ for some vector $t^{(B)}$, then $n\mathcal{V}_{nB}^{2(\alpha)} \overset{a.s.}{\to} \infty$, as $n \to \infty$.*

For $0 < \alpha < 2$, the following limit establishes that $\mathcal{V}_{nB}^{2(\alpha)}$ is, for all practical purpose, equivalent to $\mathcal{H}_{nB}^{2(\alpha)}$ when scale parameters β_j, $j \in B$, are sufficiently small:

$$\lim_{\beta_j\to 0, \forall j\in B} \mathcal{H}_{nB}^{2(\alpha)} / \prod_{j\in B}\beta_j^{\alpha} = \mathcal{V}_{nB}^{2(\alpha)}. \tag{13}$$

This result, proved in the appendix, implies that $\mathcal{H}_{nB}^{2(\alpha)}$, properly normalized with sufficiently small scale parameters, can be as close as desired to $\mathcal{V}_{nB}^{2(\alpha)}$ and thus, $\mathcal{H}_{nB}^{2(\alpha)}$ will have a power function indistinguishable from that of $\mathcal{V}_{nB}^{2(\alpha)}$. For semimetrics generated by kernels, Sejdinovic et al. (2013b, Theorem 24) established an equivalence between distance covariance and $HSIC$. However, for distance covariance defined in terms of a weighted distance between characteristic functions, one can not find a continuous translation invariant kernel for which $HSIC$ coincide with distance covariance (Sejdinovic et al., 2013b, Section 5.3). Nevertheless, (13) provides an equivalence of a different nature: for α-stable distributions, appropriately normalized $HSIC$ and distance covariance are equivalent in the limit, as the scale parameters converge to zero.

As simple as it may seem, this equivalence, for the simplest case $|B| = 2$, has gone unnoticed in the discussions of distance covariance (Székely and Rizzo, 2009; Gretton et al., 2009). In Section 8.2 of Sejdinovic et al. (2013b), for $|B| = 2$, the $HSIC$ test based on $\mathcal{H}_{nB}^{2(2)}$ with Gaussian kernels with scale parameters set at the inverse of median of interpoint distances is compared to distance covariance tests of varying index α. It was found in the independent component analysis benchmark example that $\mathcal{V}_{nB}^{2(1/3)}$ is more powerful than $\mathcal{H}_{nB}^{2(2)}$. From (13), the $HSIC$ test based on $\mathcal{H}_{nB}^{2(1/3)}$, with translation invariant kernels of the stable distribution of index $\alpha = 1/3$ and very small scale parameters, would have a power function indistinguishable from that of $\mathcal{V}_{nB}^{2(1/3)}$. In another example with sinusoidally dependent data, the $HSIC$ test based on $\mathcal{H}_{nB}^{2(2)}$ has a very poor power function compared to $\mathcal{V}_{nB}^{2(1/6)}$. Sejdinovic et al. (2013b) explained: "the exponent in the distance-induced kernel plays a similar role as the bandwidth of the Gaussian kernel, and smaller exponents are able to detect dependencies at smaller lengthscales. Poor performance of the Gaussian kernel with median bandwidth in this example is a consequence of the mismatch between the overall

lengthscale of the marginal distributions (captured by the median interpoint distances) and the lengthscales at which dependencies are present". In fact, the exponent in the distance-induced kernel of a distance covariance test plays the same role as the index of the translation invariant kernel of a stable distribution in an $HSIC$ test. Indistinguishable power functions can be obtained by choosing sufficiently small scale parameters in the translation invariant kernel. This all means that $HSIC$ with sufficiently small scale parameters always match distance covariance in terms of power. But $HSIC$ with scale parameters appropriately selected may, in some cases, improve on distance covariance.

3.3 Asymptotic Distribution

Empirical processes as in (2) have been recently very useful at tackling problems related to mutual independence because of the simplicity of the asymptotic distribution. Let $d_B = \sum_{j\in B} d_j$. Each process R_{nB} is defined on the space $C(\mathbb{R}^{d_B}, \mathbb{C})$ of complex-valued continuous functions defined on $\mathbb{R}^{d_B}$. Let $d = \sum_{j=1}^{p} d_j$ and $t = (t_1, \ldots, t_d) \in \mathbb{R}^d$. The following mild tail condition (Csörgő, 1981, 1985) is assumed

$$\int_0^1 \frac{\bar{\psi}(h)}{h\left(\log\frac{1}{h}\right)^{1/2}} dh < \infty, \tag{14}$$

where

$$\bar{\psi}(h) = \sup\left\{y:\ 0 \le y \le 1,\ \lambda_d\left\{t:\ |t|_\infty < \frac{1}{2},\ \psi(t) < y\right\} < h\right\},$$

with λ_d standing for the Lebesgue measure in $\mathbb{R}^d$ and $|t|_\infty = \max(|t_1|, \ldots, |t_d|)$, is the nondecreasing rearrangement of the function $\psi(t) = [1 - Ref(t)]^{1/2}$. Weak convergence of the collection of processes R_{nB} is now established. For details concerning the metrics on the spaces in Theorem 5, the reader is referred to the appendix. The symbol $\Rightarrow$ stands for weak convergence.

Theorem 5 *If $Z^{(1)}, \ldots, Z^{(p)}$ are mutually independent, then the process $R_{nB} \Rightarrow R_B$ in $C(\mathbb{R}^{d_B}, \mathbb{C})$, where R_B is a zero mean complex Gaussian process with $\bar{R}_B(t^{(B)}) = R_B(-t^{(B)})$ and complex covariance function*

$$\mathbb{E}\left[R_B(t^{(B)})\bar{R}_B(s^{(B)})\right] = \prod_{j\in B}[f^{(j)}(t^{(j)} - s^{(j)}) - f^{(j)}(t^{(j)})f^{(j)}(-s^{(j)})].$$

Moreover, the collection of processes $(R_{nB}:\ B \in \mathcal{I}_p) \Rightarrow (R_B:\ B \in \mathcal{I}_p)$ on the product of spaces $\underset{B\in\mathcal{I}_p}{\times} C(\mathbb{R}^{d_B}, \mathbb{C})$ to a zero mean Gaussian process such that the marginal processes R_B, $B \in \mathcal{I}_p$, are mutually independent.

The convergence of functionals (4) also holds even though they are not defined on the whole space $C(\mathbb{R}^{d_B}, \mathbb{C})$, but only on the space of squared integrable functions. In the next theorem, the asymptotic distribution of $n\mathcal{H}_{nB}^2$ is described. In particular, it provides the asymptotic distribution of $n\mathcal{H}_{nB}^{2(\alpha)}$, for any $\alpha \in (0, 2]$.

Theorem 6 *Let $W_{nB} = \mathcal{H}_{nB}^2$. If $Z^{(1)}, \ldots, Z^{(p)}$ are mutually independent, then $nW_{nB} \Rightarrow W_B$ for each $B \in \mathcal{I}_p$, where $W_B = \int |R_B(t^{(B)})|^2 \prod_{j\in B} dG^{(j)}(t^{(j)})$. Moreover, the collection*

of variables $(nW_{nB} : \ B \in \mathcal{I}_p) \Rightarrow (W_B : \ B \in \mathcal{I}_p)$*, where the variables* W_B*,* $B \in \mathcal{I}_p$*, are mutually independent.*

Theorem 6 holds without moment conditions for $\mathcal{H}^2_{nB}$ since in this case dw_B is a probability measure. Theorems 5 and 6 were proved when $p = 2$ by Zhang et al. (2011). The case for $p = 3$ was covered in Appendix E of Sejdinovic et al. (2013a). The distribution of W_B can be represented using the Karhunen-Loève expansion. Without loss of generality, let $B = \{1, \ldots, k\}$. Then, W_B is distributed as

$$\sum_{i_1=1}^{\infty} \cdots \sum_{i_k=1}^{\infty} \lambda^{(1)}_{i_1} \ldots \lambda^{(k)}_{i_k} Z^2_{i_1 \ldots i_k}, \tag{15}$$

where $Z_{i_1 \ldots i_k}$ are independent standard normal variables, and for $j = 1, \ldots, k$, $\lambda^{(j)}_1, \lambda^{(j)}_2, \ldots$ are eigenvalues depending only on the probability measure $P^{(j)}$ of $Z^{(j)}$ and the weighting probability measure $dG^{(j)}$. From arguments as in Sejdinovic et al. (2013a) and Sejdinovic et al. (2013b), the eigenvalues $\lambda^{(j)}_1, \lambda^{(j)}_2, \ldots$ are those of the integral operator

$$S_{\tilde{k}^{(j)}} g(s^{(j)}) = \int_{\mathbb{R}^{d_j}} \tilde{k}^{(j)}(s^{(j)}, t^{(j)}) g(t^{(j)}) dP^{(j)}(t^{(j)}),$$

where $k^{(j)}(s^{(j)}, t^{(j)}) = \varphi^{(j)}(t^{(j)} - s^{(j)})$ is the translation invariant kernel (9) and

$$\tilde{k}^{(j)}(s^{(j)}, t^{(j)}) = k^{(j)}(s^{(j)}, t^{(j)}) - \mathbb{E}k^{(j)}(Z^{(j)}_1, t^{(j)}) - \mathbb{E}k^{(j)}(s^{(j)}, Z^{(j)}_2) + \mathbb{E}k^{(j)}(Z^{(j)}_1, Z^{(j)}_2), \tag{16}$$

for $Z^{(j)}_1$, $Z^{(j)}_2$ independent and distributed according to $P^{(j)}$, is the corresponding doubly-centered kernel.

The same type of results for $|B| = 2$ have been obtained by Székely et al. (2007) for distance covariance, see also Lyons (2013, Corollary 2.8 and Remark 2.9) for the product structure of eigenvalues. For $|B| > 2$, provided that $\mathbb{E} \prod_{j \in B} |Z^{(j)}_1 - Z^{(j)}_2|^{2\alpha}_{d_j}$ is finite, the V-statistic structure of $W_{nB} = \mathcal{V}^{2(\alpha)}_{nB}$ can be used as in Lyons (2013, Theorem 2.7) or Sejdinovic et al. (2013a) to show that $nW_{nB} \Rightarrow W_B$, where W_B is of the same form as in (15). However, this V-statistic argument does not establish the asymptotic independence of the collection of variables $(W_B : \ B \in \mathcal{I}_p)$. It can not be proven either as in Theorem 6 since the generalization of a result of Kellermeier (1980) used in the proof no longer holds since it is based on Jensen's inequality which is valid only for probability measures. The asymptotic independence of the collection could be concluded if the collection of processes $(R_{nB} : \ B \in \mathcal{I}_p)$ were independent for each n, unfortunately this is not the case. For distance covariance, the asymptotic independence of the collection remains unanswered.

In Section 6, p-values of global tests, such as tests of Fisher in (18) or Tippett in (19), computed by combining individual p-values for each $B \in \mathcal{I}_p$ must be approximated. Simple approximations assume that individual p-values are mutually independent. However, in finite samples with sample size as small as 100, an approximation relying on randomization tests which does not rely on the independence of individual p-values was found to yield better conformity of global p-values to the nominal significance level of 0.05.

4. Other Functionals

The test of Kojadinovic and Holmes (2009, Proposition 13) is based on the Möbius decomposition of the independence empirical copula process and is defined as the Cramér-von Mises functional (4) in which the process R_{nB} in (2) defined with empirical characteristic functions is replaced by an analogous process defined with empirical copulas. Also, the integrating measure dw_B is replaced by the uniform distribution over the hypercube. The dependence statistics W_{nB} thus obtained will be denoted KH^2_{nB}. The statistics KH^2_{nB} can also be represented in the form (8) with appropriately defined terms $a^{(j)}_{kl}$.

The test of Beran et al. (2007) uses the Möbius decomposition of the independence empirical half-space process and is defined as the Kolmogorov statistic obtained by taking the supnorm of the processes. The Kolmogorov statistics do not have an explicit form as in (8). They must be computed by solving a costly optimization problem over discretized unit spheres of dimensions d_j and p-values are approximated by the bootstrap. Distance covariance and $HSIC$ tests are only orthogonally invariant, whereas the test of Beran et al. (2007) is invariant to the general linear group. The heavy computational cost of this test makes it unsuitable for large scale simulations of power functions. For this reason, it will not be considered in the simulations of Section 10.

A global test of mutual independence can also be constructed directly from the empirical characteristic independence process (Csörgő, 1985; Kankainen, 1995; Sejdinovic et al., 2013a; Fan et al., 2017),

$$\begin{aligned} \mathcal{J}^2_n &= \int \left| f_n(t^{(1)}, \ldots, t^{(p)}) - \prod_{j=1}^{p} f^{(j)}_n(t^{(j)}) \right|^2 \prod_{j=1}^{p} dG^{(j)}(t^{(j)}) \\ &= \frac{1}{n^2} \sum_{k=1}^{n} \sum_{l=1}^{n} \prod_{j=1}^{p} a^{(j)}_{kl} - \frac{2}{n^{p+1}} \sum_{k=1}^{n} \prod_{j=1}^{p} \sum_{l=1}^{n} a^{(j)}_{kl} + \frac{1}{n^{2p}} \prod_{j=1}^{p} \sum_{k=1}^{n} \sum_{l=1}^{n} a^{(j)}_{kl}, \end{aligned} \tag{17}$$

where $dG^{(j)}$, $j = 1, \ldots, p$, are probability measures and $a^{(j)}_{kl}$ is defined in (9). The special case of the stable distribution of index α with $a^{(j)}_{kl}$ defined in (10) yields a statistic denoted as $\mathcal{J}^{2(\alpha)}_n$. This choice of weight function, except for $\alpha = 2$, seems to have been overlooked in the literature and no reference to this choice appears in the recent paper by (Fan et al., 2017). In the more general context of random variables taking values in separable metric spaces, Pfister et al. (2017) embedded the joint distribution and the product of the marginals in a reproducing kernel Hilbert space and defined the p-component Hilbert-Schmidt independence criterion as the squared distance between the embeddings. This framework provides a global test of mutual independence which contains (17) as a special case. Also, similar tests to (17) based on empirical distribution functions have been proposed by Blum et al. (1961), Cotterill and Csörgő (1982), and Cotterill and Csörgő (1985) in the univariate case, *i.e.* $d_j = 1$ for $j = 1, \ldots, p$. Kojadinovic and Holmes (2009, Proposition 10) also considered in the multivariate case a test similar to (17) based on empirical copulas.

Simulations in Section 10 will compare $HSIC$ tests $\mathcal{H}^{2(\alpha)}_{nB}$ and distance covariance tests $\mathcal{V}^{2(\alpha)}_{nB}$ to the tests KH^2_{nB} and $\mathcal{J}^{2(2)}_n$. Dependence statistics resulting from the Möbius decomposition have the following advantages over statistics of the type $\mathcal{J}^2_n$ in (17).

1. The statistic W_{nB} in (8) has a simpler structure than that of $\mathcal{J}_n^2$ in (17). The integral operator defining the eigenvalues associated with $\mathcal{J}_n^2$ is an integral of dimension $d = \sum_{j=1}^p d_j$ which can not be written as a product of integral operators as soon as $p > 2$. The integral operator for W_{nB} is always a product of $|B|$ integral operators in smaller dimensions d_j, $j \in B$.

2. The p-values of W_{nB}, $B \in \mathcal{I}_p$, can be combined (see Section 6) to get a global test of mutual independence with a predetermined global significance level.

3. When a global test in item 2 rejects the mutual independence hypothesis, subsets $B \in \mathcal{I}_p$ yielding small p-values can be identified as the possible source of dependence using a dependogram described in Section 7.

5. Approximate p-values

Ways to approximate the null distribution of test statistics are now discussed.

5.1 Spectral Approach

The asymptotic distribution of $n\mathcal{J}_n^2$ in (17) is also an infinite linear combination of chi-squared variables with one degree of freedom with coefficients which are eigenvalues of an integral operator (Fan et al., 2017). Using estimated eigenvalues, they resorted to the algorithm of Imhof (1961), see Duchesne and Lafaye De Micheaux (2010), to compute the cumulative distribution function by a numerical inversion of the characteristic function. For $p = 2$, the spectral approach is also proposed by Zhang et al. (2017). After estimation of eigenvalues, rather than using the algorithm of Imhof (1961), they simulated a large number of values of (15) by generating independent random $N(0, 1)$ variables. The spectral approach to approximate (15) is appropriate for large sample sizes and kernels with an eigenspectrum which decays very rapidly such as the Gaussian kernel. For slowly decaying kernels, the number $(N_\lambda)^k$ of terms in (15), where N_λ is the number of eigenvalues considered, may be too large to apply such methods. The spectral approach for the very simple RV coefficient of Escoufier (1973) is appropriate only in large samples (Josse and Holmes, 2016).

5.2 Resampling Techniques

Another approximation is the *permutation test* which recomputes the statistics for all $(n!)^{p-1}$ permutations. From a theoretical point of view (Hoeffding, 1952), permutation tests are well known to guarantee a non asymptotic control of the significance level (by permutation invariance of the test statistic under the null hypothesis, that is mutual independence here). Since this is not feasible, even for moderate sample sizes, the strategy is to rely on resampling techniques. As an approximation to the permutation test, the *randomization test* simulates the null distribution by permuting (resample without replacement) the observations $Z_1^{(j)}, \ldots, Z_n^{(j)}$, independently for each component, a large number of, say, 1000 permutations. Sejdinovic et al. (2013a) proposed to approximate the null distribution of $n\mathcal{J}_n^2$ in (17) by a randomization test. Another technique is to resample with replacement, independently for each component, a large number of times which is a *bootstrap test*. Bootstrap tests and randomization tests are asymptotically equivalent in the sense that

the resulting critical values and power functions are appropriately close (Romano, 1989; van der Vaart and Wellner, 1996). General references for permutation tests are Efron and Tibshirani (1993), Good (2000), and Pesarin and Salmaso (2010).

5.3 Methods of Moments

Other approximations are based on the method of moments. The distribution obtained by recomputing a statistic for all $(n!)^{p-1}$ permutations is called the permutation distribution of the statistic. The exact first three moments of the permutation distribution of statistics of the general form (8) were obtained by Kazi-Aoual et al. (1995) when $p = 2$ and generalized by Guetsop Nangue (2016) to the case $p \geq 2$. The Pearson type III approximation is a shifted gamma distribution with the same first three moments as the permutation distribution. The Pearson type III distribution is part of the original system of distributions devised by Pearson (1895) in an effort to model visibly skewed observations. The first published paper in which a Pearson type III distribution is used as an approximation to a permutation test is Mielke et al. (1981). For an historical account of the Pearson type III distribution in the context of permutation tests, the reader is referred to Berry et al. (2016, Section 1.2.2). For $p = 2$, Gretton et al. (2008) proposed the approximation by a gamma distribution with the same first two moments as those of the asymptotic distribution, not the permutation distribution, in (15). These first two moments depend on unknown eigenvalues but can be estimated using traces of matrices involving the doubly-centered matrices $A^{(j)} = (A_{kl}^{(j)})$ without having to compute eigenvalues. An empirical failure mode of the gamma approximation was demonstrated in Gretton and Györfi (2010, Figure 1). More recently, Guetsop Nangue (2016, Table 2.9) simulated empirical significance levels of $HSIC$ for meta-Gaussian distributions in the case $p = 2$. The kernel was Gaussian with scaling set at the median of distances. For sample sizes $n = 15$, 25, 50, and 100, the Pearson type III approximation gave rates close to the nominal rate of 0.05 for dimensions up to $d_1 = d_2 = 50$, whereas the gamma approximation gave rates close or equal to 0 as the dimensions were increased. Although the exact permutation test guarantees a non asymptotic control of the significance level, it should be stressed that neither the Pearson type III nor the gamma approximations guarantee an asymptotic control of the significance level. Although p-values of individual statistics W_{nB} can be accurately approximated by the Pearson type III approximation for small samples, the independence of these p-values, guaranteed by the asymptotic distribution, holds to a satisfying degree only in large samples. This is particularly the case as soon as $p > 4$ and $d_j > 1$. Solely for this reason, p-values of global tests which combine individual p-values of tests for sub-hypotheses will be assessed by randomization tests.

5.4 Randomization Tests

Randomization tests are now described to approximate p-values of individual test statistics. Randomization tests for global tests which combine individual p-values are deferred to Section 6. Let Q_n be any test statistic such as $\mathcal{J}_n^2$, $\mathcal{V}_{nB}^{2(\alpha)}$ or $\mathcal{H}_{nB}^{2(\alpha)}$, $B \in \mathcal{I}_p$. Denote a permutation of $\{1, \ldots, n\}$ by $\sigma = (\sigma(1), \ldots, \sigma(n))$. Consider independent random permutations $\sigma_1, \ldots, \sigma_p$ of $\{1, \ldots, n\}$. For $j = 1, \ldots, p$, the permutation σ_j permutes the observations

$(Z_1^{(j)}, \ldots, Z_n^{(j)})$ to yield the permuted data $(Z_{\sigma_j(1)}^{(j)}, \ldots, Z_{\sigma_j(n)}^{(j)})$ of the component j. The statistic Q_n is then recomputed on the permuted data. To this end, note that one need not recompute the elements $a_{kl}^{(j)}$ in (10) or (11). For $\mathcal{J}_n^2$ in (17), one simply permutes according to σ_j the rows and corresponding columns of the $n \times n$ matrix $a^{(j)} = (a_{kl}^{(j)})$. For $\mathcal{V}_{nB}^{2(\alpha)}$ or $\mathcal{H}_{nB}^{2(\alpha)}$, this same argument applies to the matrix $A^{(j)} = (A_{kl}^{(j)})$ in (1).

Approximate p-values are now obtained by recomputing the test statistic N times. Generate Np independent random permutations $\sigma_{i,j}$, $i = 1, \ldots, N$, $j = 1, \ldots, p$.[1] For $i = 1, \ldots, N$, let $Q_{n,i}$ be the test statistic computed from the permuted data $(Z_{\sigma_{i,j}(1)}^{(j)}, \ldots, Z_{\sigma_{i,j}(n)}^{(j)})$, $j = 1, \ldots, p$. An approximate p-value is then obtained as follows.

(1) Let $Q_{n,0}$ be the test statistic computed from the original data.

(2) Generate N randomized samples from the original data and compute $Q_{n,i}$ for $i = 1, \ldots, N$.

(3) An approximate p-value is then given by

$$\frac{1}{N+1}\left[1 + \sum_{i=1}^{N} \mathbb{I}\left\{Q_{n,i} \geq Q_{n,0}\right\}\right].$$

This approximate p-value of the randomization test guaranties (by virtue of exchangeability of the variables $Q_{n,i}$, $i = 0, \ldots, N$) a non-asymptotic control of type I error rates for each individual test (Romano and Wolf, 2005, Lemma 1). The N randomized samples can also be used to compute an approximate quantile of the test statistic Q_n. Let $Q_{n,(1)}, \ldots, Q_{n,(N)}$ be the order statistics of $Q_{n,1}, \ldots, Q_{n,N}$, an approximate π-quantile of Q_n is the order statistic $Q_{n,(\lfloor N\pi \rfloor)}$. The finite sample control of the significance level of randomization tests will be assessed by simulations in Section 10.

6. Combining p-values

If the exact distribution function F_{nB} of W_{nB} was known, then $1 - F_{nB}(W_{nB})$ would be the exact p-value. Since F_{nB} is continuous, this p-value would be exactly uniformly distributed over the interval $(0, 1)$. Moreover, exact p-values obtained by varying B would also be approximately independent in large samples. This holds due to the asymptotic mutual independence of statistics W_{nB} in Theorem 6.

As an approximation, a p-value $\hat{p}_{nB}$ is computed for every dependence statistic W_{nB}, $B \in \mathcal{I}_p$, using randomization tests as in Section 5. Under the mutual independence hypothesis, these $2^p - p - 1$ p-values are, for large samples, approximately independent and also approximately uniformly distributed on $(0, 1)$. The quantity $-2 \log \hat{p}_{nB}$ thus has approximately a χ_2^2 null distribution. Fisher's global test statistic rejects the mutual independence when $-2 \sum_{B \in \mathcal{I}_p} \log \hat{p}_{nB}$ is large. It reports a global p-value of

$$\hat{p}_n = P\left(\chi_\nu^2 > -2 \sum_{B \in \mathcal{I}_p} \log \hat{p}_{nB}\right), \text{ where } \nu = 2(2^p - p - 1). \tag{18}$$

1. Since observations in one component can be held fixed, $N(p-1)$ permutations would suffice. However, treating all components the same way is convenient for purposes of notation and software development.

The number of subsets may be too large for some p or only low order interaction terms may be of interest. In this case, p-values of a test of mutual independence of order q, where $2 \leq q \leq p$, are computed as

$$\hat{p}_n = P\left(\chi_\nu^2 > -2 \sum_{B \in \mathcal{I}_p, |B| \leq q} \log \hat{p}_{nB}\right), \text{ where } \nu = 2 \sum_{i=2}^{q} \binom{p}{i}.$$

Another way of combining independent p-values leads to Tippett's global test with a rejection region consisting of small values of $\min_{B \in \mathcal{I}_p} \hat{p}_{nB}$. Tippett's test of mutual independence of order q reports a combined p-value of

$$\hat{p}_n = 1 - \left(1 - \min_{B \in \mathcal{I}_p, |B| \leq q} \hat{p}_{nB}\right)^r, \text{ where } r = \sum_{i=2}^{q} \binom{p}{i}. \tag{19}$$

In the simulations of Section 10, although each individual p-value is well approximated by a uniform variable on $(0, 1)$, the global p-values obtained by Fisher's (18) or Tippett's (19) method sometimes lead to a global test of significance level which exceeds the nominal level. This was observed especially for $p > 4$ and some $d_j > 1$ and can be attributed to the lack of independence between statistics W_{nB} in finite samples. For a test of mutual independence of order q, $2 \leq q \leq p$, it is preferable to obtain the global p-values using randomized samples as follows (Kojadinovic and Holmes, 2009).

(1) Compute the statistics $W_{nB,0}$, $B \in \mathcal{I}_p$ and $|B| \leq q$, from the original data.

(2) Generate N randomized samples from the original data and let $W_{nB,i}$ be the statistics from the ith randomized sample.

(3) An approximate p-value for the statistic $W_{nB,j}$ based on Romano and Wolf (2005) [2] is

$$\psi(W_{nB,j}) = \frac{1}{N+1}\left[1 + \sum_{i \in \{0,\ldots,N\} \setminus \{j\}} \mathbb{I}\left\{W_{nB,i} \geq W_{nB,j}\right\}\right], \; j = 0, 1, \ldots, N.$$

(4) For $i = 0, 1, \ldots, N$, compute Fisher's and Tippett's statistics

$$F_{n,i} = -2 \sum_{B \in \mathcal{I}_p, |B| \leq q} \log[\psi(W_{nB,i})] \text{ and } T_{n,i} = \min_{B \in \mathcal{I}_p, |B| \leq q} \psi(W_{nB,i}).$$

(5) Approximate p-values for the global tests of Fisher and Tippett are given respectively by

$$\frac{1}{N+1}\left[1 + \sum_{i=1}^{N} \mathbb{I}\left\{F_{n,i} \geq F_{n,0}\right\}\right] \text{ and } \frac{1}{N+1}\left[1 + \sum_{i=1}^{N} \mathbb{I}\left\{T_{n,i} \leq T_{n,0}\right\}\right].$$

2. The non-asymptotic control of type I error rates can not be concluded from the expression $\psi(W_{nB,j}) = \frac{1}{N+1}\left[\frac{1}{2} + \sum_{i=1}^{N} \mathbb{I}\left\{W_{nB,i} \geq W_{nB,j}\right\}\right]$ in Kojadinovic and Holmes (2009, p. 1152).

Note that variables $F_{n,i}$ (and $T_{n,i}$), $i = 0, \ldots, N$, are exchangeable since this is the case of variables $W_{nB,j}$, and thus also $\psi(W_{nB,j})$, $j = 0, \ldots, N$, for each fixed B. The p-values of the global tests of Fisher and Tippett in item (5) thus lead to a non-asymptotic control of type I global error rates (Romano and Wolf, 2005, Lemma 1).

Neither of the two methods is generally more powerful than the other. When only a few of the individual hypotheses are strongly false, Tippett's method is preferable. To detect alternatives for which many of the individual hypotheses are equally false, Fisher's method is likely to be preferable (Westberg, 1985; Loughin, 2004).

7. Dependogram

The dependogram is described for test statistics W_{nB}, $B \in \mathcal{I}_p$, which can be either $\mathcal{V}_{nB}^{2(\alpha)}$ or $\mathcal{H}_{nB}^{2(\alpha)}$. Genest and Rémillard (2004) introduced the dependogram which is a graphical tool, with subsets ordered by size on the horizontal axis, and corresponding values W_{nB} represented by vertical bars on the vertical axis. For each subset $B \in \mathcal{I}_p$, statistics W_{nB} are computed together with corresponding critical values given by the π-quantile, $c_{\pi B}$, obtained from N randomized samples as in Section 5. Critical values are represented by dashes. Dependence in a subset is declared when the vertical bar extends beyond the dash. If the number of subsets is large, a dependogram of order q, $2 \leq q \leq p$, can be constructed by considering only subsets of maximum cardinality q. Assuming statistics W_{nB} are independent, the choice $\pi = (1-\alpha')^{1/r}$ with $r = \sum_{i=2}^{q} \binom{p}{i}$ leads to a global significance level α'. Indeed, under the mutual independence hypothesis

$$P(W_{nB} \leq c_{\pi B} : \ |B| \leq q) = \prod_{|B| \leq q} P(W_{nB} \leq c_{\pi B}) = \pi^r = 1 - \alpha'.$$

The dependogram should be seen as an exploratory tool that can be used when a global test rejects the mutual independence hypothesis. It helps to identify the dependency structures present in the data as in Figure 4. A dependogram built from $HSIC$ statistics will be normalized as in (13) so that, for small scale parameters, it has roughly the same order of magnitude as the dependogram based on distance covariance statistics.

A difficulty in interpreting a dependogram is now illustrated with an example. Consider a model with three dependent variables $Z^{(1)}$, $Z^{(2)}$ and $Z^{(3)}$, where $Z^{(1)}$ and $Z^{(2)}$ are dependent, but the pair $(Z^{(1)}, Z^{(2)})$ is independent of $Z^{(3)}$. Looking at Table 1 with the true characteristic functions, one can verify that $\mu_{12} \not\equiv 0$, $\mu_{13} \equiv 0$, $\mu_{23} \equiv 0$, and $\mu_{123} \equiv 0$. Therefore, only the test for the subset $\{1, 2\}$ is expected to be significant. The test for the subset $\{1, 2, 3\}$ is not expected to be significant even though the three variables are dependent. Of course, the global test is expected to be significant as it will combine tests for all subsets.

8. Tests of Serial Independence

The problem of testing for serial independence of a multivariate stationary ergodic sequence is now addressed. The test statistic in the serial context is very similar. Consider a stationary ergodic sequence $Y_1, Y_2, \ldots$ in $\mathbb{R}^{d_1}$, where Y_1 is distributed according to the characteristic function $f^{(1)}$. Let $p \geq 2$ be a fixed integer. For a sequence of length m, let $n = m - p + 1$

and

$$Z_k = (Z_k^{(1)}, \ldots, Z_k^{(p)}) = (Y_k, Y_{k+1}, \ldots, Y_{k+p-1}), \ k = 1, \ldots, n, \tag{20}$$

where $Z_k^{(j)} = Y_{k+j-1}$, $j = 1, \ldots, p$. Let $f(t^{(1)}, \ldots, t^{(p)})$ be the joint characteristic function of $Z_1 = (Y_1, \ldots, Y_p)$ and $f^{(B)}$ be the joint characteristic function of $Z_1^{(B)} = (Y_j : \ j \in B)$. For example, if $p = 4$ and the indices in the subset $B = \{1, 2, 3\}$ are translated by one to yield $C = B + 1 = \{2, 3, 4\}$ then, $f^{(B)}$ and $f^{(C)}$ are the same characteristic function since the process is stationary. In the serial context, a subset B and its translate, say $B + k$, can be treated as the same subset. The set $\mathcal{I}_p$ is thus reduced to $\mathcal{B}_p = \{B \in \mathcal{I}_p : 1 \in B\}$ and has now cardinality $2^{p-1} - 1$. For a given $B \in \mathcal{B}_p$, the Möbius transformation of the characteristic function f for the set B is given by

$$\mu_{B,s}(t^{(B)}) = \sum_{C \subseteq B} (-1)^{|B \setminus C|} f^{(C)}(t^{(C)}) \prod_{j \in B \setminus C} f^{(1)}(t^{(j)}).$$

The subscript s stands for serial. The Möbius transformation characterizes the serial independence: $Y_1, \ldots, Y_p$ are mutually independent if and only if, $\mu_{B,s}(t^{(B)}) = 0$, for all $B \in \mathcal{B}_p$, and all vectors $t^{(B)}$.

The corresponding process in the serial case is denoted $R_{nB,s}$ and is defined exactly as in (2). Here, the index set of the process $R_{nB,s}$ is the Euclidean space $\mathbb{R}^{d_B}$, where $d_B = d_1|B|$. Note that all the empirical characteristic functions $f_n^{(j)}$, $j = 1, \ldots, p$, are now essentially the same estimate of the unknown characteristic function $f^{(1)}$. They are not replaced by a single estimate based on all n observations to preserve the representation of the functional (8) in terms of doubly-centered matrices. The dependence statistic for the subset B is now defined as the functional

$$W_{nB,s} = \frac{1}{n} \int |R_{nB,s}(t^{(B)})|^2 \prod_{j \in B} dw(t^{(j)}).$$

It can be computed as before in (8). Due to the stationarity, it should be noted that the same kernel is used to define the elements $a_{kl}^{(j)}$, for all $j \in B$. Two types of weighting measures are considered.

1. For $HSIC$, $dw(t^{(j)}) = dG(t^{(j)})$ is a probability measure with characteristic function φ in which case

$$a_{kl}^{(j)} = \varphi(Z_k^{(j)} - Z_l^{(j)}). \tag{21}$$

The dependence statistic is denoted $W_{nB,s} = \mathcal{H}_{nB,s}^2$. As in Theorem 2, the population Hilbert-Schmidt independence criterion

$$\mathcal{H}_{B,s}^2 = \int |\mu_{B,s}(t^{(B)})|^2 \prod_{j \in B} dG(t^{(j)})$$

is consistently estimated by $\mathcal{H}_{nB,s}^2$. The proof is omitted since it can be proven as Theorem 2 using the ergodic theorem. The special case when $dG(t^{(j)})$ is the probability measure of the stable distribution of index α is denoted $\mathcal{H}_{nB,s}^{2(\alpha)}$, for $\alpha \in (0, 2]$.

2. For distance covariance, $dw(t^{(j)}) = \left[C(d_1,\alpha)|t^{(j)}|_{d_1}^{d_1+\alpha}\right]^{-1}$, in which case $a_{kl}^{(j)} = -|Z_k^{(j)} - Z_l^{(j)}|_{d_1}^{\alpha}$. Under an appropriate moment condition as in Theorem 4, the consistency and weak convergence of the functional, which is denoted $W_{nB,s} = \mathcal{V}_{nB,s}^{2(\alpha)}$ for $\alpha \in (0,2)$, should hold.

Pinkse (1998) proposed a non parametric test based on characteristic functions of serial independence against serial dependence of fixed lag k that is consistent against all such alternatives. It is based on a consistent estimator for an upper bound of $\mathcal{H}_{B,s}^2$ for the subset $B = \{1, 1+k\}$. The control of the global significance level when multiple tests are done for several values of k is not addressed by this author. Diks and Panchenko (2007) constructed a test based on divergence measures between distributions using kernel-based quadratic forms to detect dependence at lag k using the subset $B = \{1, 1+k, \ldots, 1+(c-1)k\}$ of given cardinality c. Their criterion is written as $Q = Q_{11} - 2Q_{12} + Q_{22}$. They used U-statistics as estimates for each term. Unfortunately, an error in the estimates of the last two terms on p. 85 leads to an erroneous statistic. If V-statistics are used instead, it is not hard to verify that their test statistic is of the exact form (17).

Under the hypothesis of serial independence, the vectors $Z_k = (Y_k, Y_{k+1}, \ldots, Y_{k+p-1})$, $k = 1, \ldots, n$, are dependent due to some overlapping Y's. The proof of Theorem 5 is not directly applicable. Nevertheless, a very similar weak convergence theorem still holds.

Theorem 7 *Let $Y_1, Y_2, \ldots$ be independent and identically distributed. Then, for any fixed p, the process $R_{nB,s} \Rightarrow S_B$ in $C(\mathbb{R}^{d_B}, \mathbb{C})$ to a zero mean complex Gaussian processes S_B with complex covariance function*

$$\mathbb{E}\left[S_B(t^{(B)})\bar{S}_B(s^{(B)})\right] = \prod_{j\in B}\left[f^{(1)}(t^{(j)} - s^{(j)}) - f^{(1)}(t^{(j)})f^{(1)}(-s^{(j)})\right].$$

Moreover, the collection of processes $(R_{nB,s} : B \in \mathcal{B}_p) \Rightarrow (S_B : B \in \mathcal{B}_p)$ on the product of spaces $\underset{B\in\mathcal{B}_p}{\times} C(\mathbb{R}^{d_B}, \mathbb{C})$ to a zero mean Gaussian process such that the marginal processes S_B, $B \in \mathcal{B}_p$, are mutually independent.

In the next theorem, the asymptotic distribution of $n\mathcal{H}_{nB,s}^2$ is described. The proof is omitted since it is the same as for Theorem 6.

Theorem 8 *Let $W_{nB,s} = \mathcal{H}_{nB,s}^2$. If $Y_1, Y_2, \ldots$ are independent and identically distributed, then $nW_{nB,s} \Rightarrow W_{B,s}$ for each $B \in \mathcal{B}_p$, where $W_{B,s} = \int |S_B(t^{(B)})|^2 \prod_{j\in B} dG(t^{(j)})$. Moreover, the collection of variables $(nW_{nB,s} : B \in \mathcal{B}_p) \Rightarrow (W_{B,s} : B \in \mathcal{B}_p)$, where the variables $W_{B,s}$, $B \in \mathcal{B}_p$, are mutually independent.*

The distribution of $W_{B,s}$ can be also represented using the Karhunen-Loève expansion. Without loss of generality, let $B = \{1, \ldots, k\}$. Then, $W_{B,s}$ is distributed as in (15), where the eigenvalues $\lambda_1^{(j)}, \lambda_2^{(j)}, \ldots$ no longer depend on j, but only on the probability measure $P^{(1)}$ of Y_1 and the weighting probability measure $dG(t^{(1)})$. The eigenvalues $\lambda_1, \lambda_2, \ldots$ are those of the integral operator

$$S_{\tilde{k}}g(s^{(1)}) = \int_{\mathbb{R}^{d_1}} \tilde{k}(s^{(1)}, t^{(1)})g(t^{(1)})dP(t^{(1)}),$$

where $k(s^{(1)}, t^{(1)}) = \varphi(t^{(1)} - s^{(1)})$ is the translation invariant kernel (21) and

$$\tilde{k}(s^{(1)}, t^{(1)}) = k(s^{(1)}, t^{(1)}) - \mathbb{E}k(Y_1, t^{(1)}) - \mathbb{E}k(s^{(1)}, Y_2) + \mathbb{E}k(Y_1, Y_2),$$

for Y_1, Y_2 independent and distributed according to $P^{(1)}$, is the corresponding doubly-centered kernel.

Computations of p-values of individual tests and global tests in Sections 5 and 6 can also be used for testing for serial independence. Subsets B are now restricted to $B \in \mathcal{B}_p$. A modification to the dependogram is necessary since the null distributions of statistics of the same cardinality are now identical. The critical values $c_{\pi B}$ of Section 7 for all B of the same cardinality are replaced by a single critical value as in Figure 6. Since there are $\binom{p-1}{\omega-1}$ subsets B containing 1 and of cardinality ω, the single critical value is taken as the π-quantile of the amalgamated $N\binom{p-1}{\omega-1}$ statistics $W_{nB,i}$, for $i = 1, \ldots, N$ and $|B| = \omega$.

It has been shown how distance covariance and $HSIC$ tests can be adapted for testing for serial independence. The global test $\mathcal{J}_n^2$ in (17) can also be used for serial independence by defining subsequences of length p as in (20).

9. Computational Aspects

The complexity cost of all randomization tests based on the Möbius decomposition in this paper are of the order $O(n^2 rN)$, where n is the sample size, $r = \sum_{i=2}^{q}\binom{p}{i}$ is the number of subsets considered in a global test of order q, and N is the number of randomized samples. Even for the smallest value $q = 2$, the number of subsets of the order $r = O(p^2)$ increases quadratically with p. These tests thus become rapidly infeasible as n or p increases. The serial statistics in Section 8 have a lower complexity cost since in this case $r = \sum_{i=2}^{q}\binom{p-1}{i-1}$ yields a number of subsets of the order $r = O(p)$ increasing linearly with p when $q = 2$.

The statistics $\mathcal{H}_{nB}^{2(\alpha)}$ and $\mathcal{V}_{nB}^{2(\alpha)}$ are combined as in Section 6 to yield global statistics $\mathcal{H}_n^{2(\alpha)}$ and $\mathcal{V}_n^{2(\alpha)}$, respectively. Scale parameters β_j in (10) must be selected for $\mathcal{H}_{nB}^{2(\alpha)}$. They are set to

$$\beta_j = c_j/\text{med}_{k<l}|Z_k^{(j)} - Z_l^{(j)}|_{d_j},\ j = 1, \ldots, p. \tag{22}$$

The choice $c_j = 1$ leads to the so-called heuristic method suggested by Gretton et al. (2008). Selection of very small constants c_j allows to check the equivalence between distance covariance and $HSIC$ tests as described in (13). Unless stated otherwise, the heuristic method will be used for $HSIC$ tests. Distance covariance and $HSIC$ tests will be compared to two other tests: the test of Kojadinovic and Holmes (2009) denoted KH_n^2 for the mutual independence case, or Kojadinovic and Yan (2011) denoted KY_n^2 for the serial case, and the test $\mathcal{J}_n^{2(2)}$ in (17) with heuristic scale parameters (22) as in Sejdinovic et al. (2013a).

When $d_j = 1$ for all $j = 1, \ldots, p$, the statistics KH_n^2 (or KY_n^2) are replaced by the equivalent statistic of Genest and Rémillard (2004) denoted GR_n^2. KH_n^2 differs from GR_n^2 only in the approximation used for p-values. The former uses a randomization test, whereas the latter takes advantage of the fact that for $d_j = 1$, the test is distribution free implying that critical values can be obtained by simulating the null distribution for given values of n and p. Thus, a single set of critical values can be used for all replicates.

The `copula R` package (Kojadinovic and Yan, 2010) functions `multIndepTest` and `multSerialIndepTest` were used for tests based on KH_n^2 and KY_n^2, respectively. Inci-

dentally, the implementation of KH_n^2 unnecessarily recomputes the doubly-centered matrices $A^{(j)}$ for every permutation in their `C` subroutine `bootstrap_MA_I`. The same package also contains the functions `indepTest` and `serialIndepTest` for GR_n^2. An `R` function for distance covariance and $HSIC$ tests proposed in this paper for $p \geq 2$ is available at `dms.umontreal.ca/~bilodeau`. For $p = 2$, it produces, up to a factor of $1/n$ depending on the definitions of statistics, the same result as the function `dcov.test` of the `energy` package (Rizzo and Szekely, 2016). Computations in Section 10 were done on an Intel(R) Core(TM) i7 with a CPU of 3.20 GHz.

10. Simulated Models

All empirical significance levels and empirical powers in this section are evaluated with 1000 tests (replicates) conducted at a global significance level $\alpha' = 0.05$. The p-values of all randomization tests are based on 1000 permutations (the default). Power results are summarized by graphics with a tick mark at 0.05 on the power axis to check for the conformity of empirical significance levels to the nominal level. Six tests are compared: distance covariance tests $\mathcal{V}_n^{2(1/2)}$ and $\mathcal{V}_n^{2(1)}$, $HSIC$ tests $\mathcal{H}_n^{2(1/2)}$ and $\mathcal{H}_n^{2(1)}$, the test KH_n^2 of Kojadinovic and Holmes (2009) and the test $\mathcal{J}_n^{2(2)}$ in (17). When all $d_j = 1$, the test KH_n^2 is replaced by GR_n^2 as explained in Section 9. Also, for the serial case, the test KH_n^2 is replaced by the test KY_n^2 of Kojadinovic and Yan (2011). Unless stated otherwise, p-values of tests based on the Möbius decomposition are combined using the method of Fisher.

10.1 Copula Models

Power comparisons are made for the Gaussian, Student, Frank and Clayton copulas. A general reference for copulas is the book by Nelsen (2006).

10.1.1 Gaussian and Student Copulas with Bivariate Marginals

As in Kojadinovic and Holmes (2009), a correlation matrix is constructed of the form

$$R = \begin{pmatrix} (1-\rho_w)I_2 + \rho_w J_2 J_2' & \rho_b J_2 J_2' & \rho_b J_2 J_2' \\ \rho_b J_2 J_2' & (1-\rho_w)I_2 + \rho_w J_2 J_2' & \rho_b J_2 J_2' \\ \rho_b J_2 J_2' & \rho_b J_2 J_2' & (1-\rho_w)I_2 + \rho_w J_2 J_2' \end{pmatrix}, \tag{23}$$

where I_2 is the identity matrix of dimension 2 and J_2 is the vector of ones of dimension 2. Notations w and b stand for within and between, respectively. Samples of size $n = 100$ are generated from a multivariate distribution of dimension 6 (Gaussian or Student with 2 degrees of freedom) with correlation matrix R in (23). Probability transforms are then applied so that all 6 variables are uniformly distributed on the interval $(0, 1)$. The resulting vector is partitioned into three two-dimensional vectors. The value of ρ_w is set to 0.5. For the Gaussian model, Figure 1 shows that the best test is KH_n^2 followed closely by $\mathcal{V}_n^{2(1)}$. However, for the Student model, KH_n^2 performs poorly compared to all the other tests, the most powerful test being $\mathcal{H}_n^{2(1/2)}$. For the Student model, the three components are always dependent even when $\rho_b = 0$ which explains the power at $\rho_b = 0$ in the right panel of Figure 1. In fact, the only elliptical distribution for which uncorrelatedness implies independence is the Gaussian distribution (Bilodeau and Brenner, 1999, Proposition 4.11).

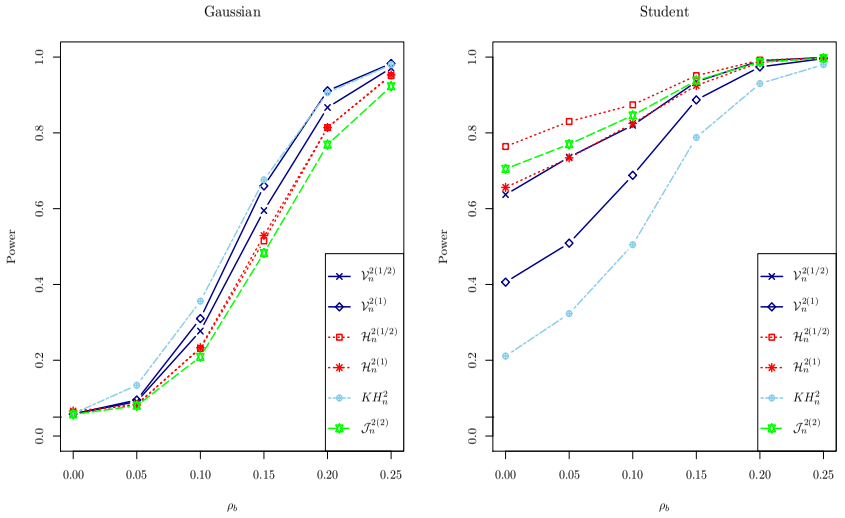

Figure 1: Empirical powers for the Gaussian (left panel) and Student (right panel) copulas with bivariate marginals of Section 10.1.1.

10.1.2 Frank and Clayton Copulas with Univariate Marginals

The Frank and Clayton copulas are now considered for $n = 100$, $p = 3$ and $d_j = 1$ for $j = 1, 2, 3$. These two copulas have a parameter θ with the value $\theta = 0$ corresponding to the independence copula. For the Frank copula, independence is obtained as the limiting case $\theta \to 0$. Figure 2 shows that for both copulas, the tests GR_n^2 and $\mathcal{V}_n^{2(1)}$ have very similar powers and are the most powerful. The least powerful test is $\mathcal{J}_n^{2(2)}$. The $HSIC$ tests are less powerful than their distance covariance counterparts, but their powers could be increased to those of distance covariance by selecting smaller scale parameters as predicted by (13).

10.1.3 Frank Copula with Bivariate Marginals

The Frank copula model is now considered for $p = 3$ and $d_j = 2$ for $j = 1, 2, 3$. The sample size is still 100. A random vector is generated from the Frank copula of dimension six with parameter θ and it is partitioned into three vectors of dimension two. The most powerful test in Figure 3 is $\mathcal{V}_n^{2(1)}$ and the least powerful is KH_n^2.

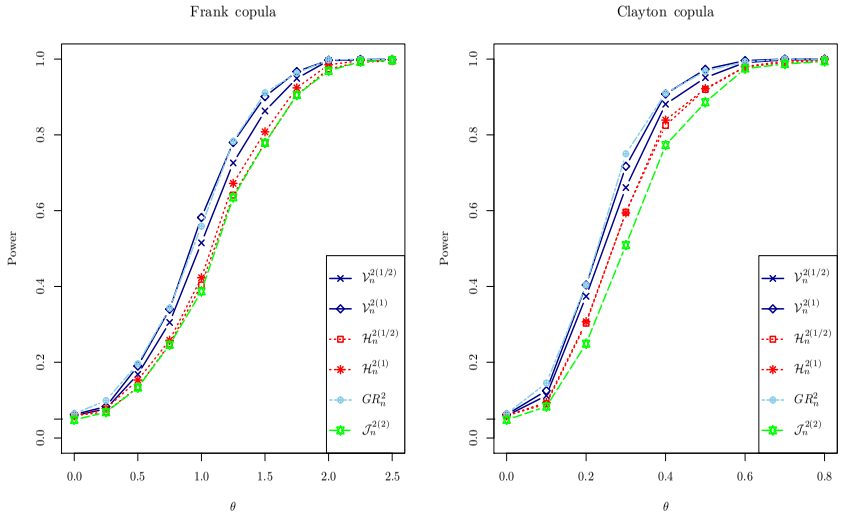

Figure 2: Empirical powers for the Frank (left panel) and Clayton (right panel) copulas with univariate marginals of Section 10.1.2.

10.2 Model of Romano and Siegel

The original model is taken from Kojadinovic and Holmes (2009) which extends an example in Genest and Rémillard (2004). Samples of size $n = 100$ are generated from the distribution of a 12-dimensional random vector as follows.

1. Generate a two-dimensional Gaussian vector $X^{(1)} = (X_1^{(1)}, X_2^{(1)})$ with means 0, variances 1, and covariance 0.5.

2. Generate two independent copies $Z^{(2)}$ and $Z^{(3)}$ of $X^{(1)}$.

3. Define $Z^{(1)} = (Z_1^{(1)}, Z_2^{(1)})$ by $Z_i^{(1)} = |X_i^{(1)}|\text{sign}(Z_1^{(2)} Z_1^{(3)})$, $i = 1, 2$.

4. Generate a three-dimensional Gaussian vector $Z^{(4)}$ with means 0, variances 1, and covariances 0.3.

5. Generate an independent copy $X^{(5)}$ of $Z^{(4)}$.

6. Define $Z^{(5)} = Z^{(4)} + X^{(5)}$.

Following Romano and Siegel (1986), the three two-dimensional vectors $(Z^{(1)}, Z^{(2)}, Z^{(3)})$ are pairwise independent, but not jointly independent. This vector is independent of $(Z^{(4)}, Z^{(5)})$

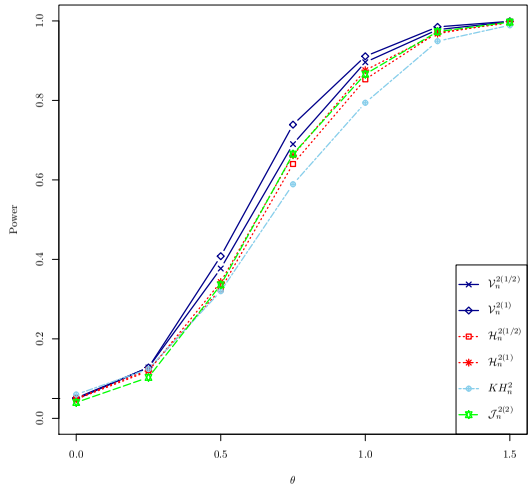

Figure 3: Empirical powers for the Frank copula with bivariate marginals of Section 10.1.3.

in which the two three-dimensional vectors $Z^{(4)}$ and $Z^{(5)}$ are dependent. One can check that the only non null terms μ_B are for the subsets $\{4,5\}$, $\{1,2,3\}$, and $\{1,2,3,4,5\}$.

In order to compare the powers of various tests, a modified model with weaker dependence is introduced. Items 3 and 6 are modified to

3'. Define $Z^{(1)} = (Z_1^{(1)}, Z_2^{(1)})$ by $Z_i^{(1)} = (1-\theta)|X_i^{(1)}| + \theta|X_i^{(1)}|\text{sign}(Z_1^{(2)} Z_1^{(3)})$, $i = 1, 2$,

6'. Define $Z^{(5)} = \theta Z^{(4)} + X^{(5)}$,

for some $\theta \in [0, 0.4]$. Mutual independence now holds among the 5 components for $\theta = 0$ and the dependence increases with θ. The value $\theta = 1$ leading to the original model is not considered since it yields a dependence too easily detected.

Figure 4 is the dependogram based on one simulated sample with $\theta = 0.4$. The statistics computed are $\mathcal{V}_{nB}^{2(1)}$ and $\mathcal{H}_{nB}^{2(1)}$ with very small constants $c_j = .0001$ in (22). It illustrates the equivalence for small scale parameters between $\mathcal{V}_{nB}^{2(\alpha)}$ and $\mathcal{H}_{nB}^{2(\alpha)}$ described precisely in (13). Both dependograms are identical apart from small variations between critical values due to the permutations generated by the randomization tests. The dependence among $Z^{(4)}$ and $Z^{(5)}$, represented by the subset $\{4,5\}$, is significant. Moreover, the third order dependence between $Z^{(1)}$, $Z^{(2)}$ and $Z^{(3)}$, represented by the subset $\{1,2,3\}$, is also significant. The dependence for the subset $\{1,2,3,4,5\}$ is not significant. This can be explained by the powers of tests for false sub-hypotheses corresponding to subsets of small cardinality which

are generally higher because the presence of noise is less important than in subsets of large cardinality. Tests based on the Möbius decomposition combine p-values according to the

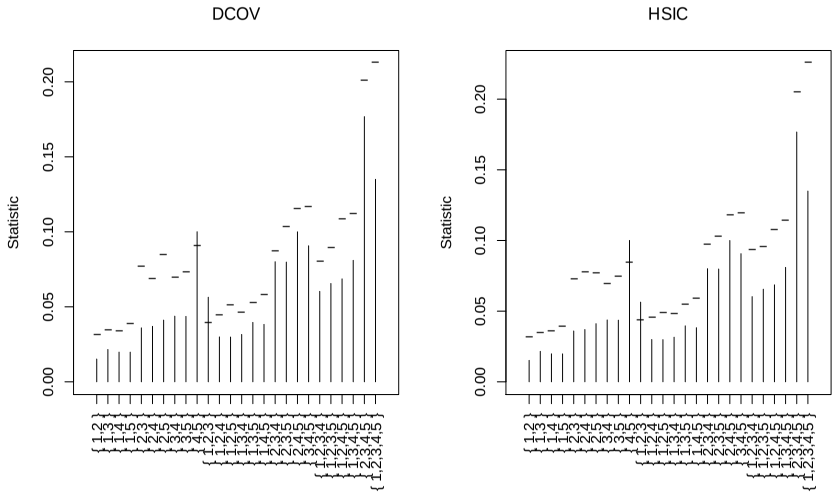

Figure 4: Dependograms for one sample of size $n = 100$ from the modified model of Romano and Siegel with $\theta = 0.4$ in Section 10.2 based on $\mathcal{V}_{nB}^{2(1)}$ (left panel) and $\mathcal{H}_{nB}^{2(1)}$ (right panel) with small constants $c_j = .0001$ in (22).

methods of Tippett and Fisher. Figure 5 shows that KH_n^2 is more powerful than distance covariance and $HSIC$ tests when using the method of Fisher. However, the method of Tippett is markedly more powerful than that of Fisher. This finding should not come as a surprise since only 3 of the 26 sub-hypotheses are false. Using the method of Tippett the most powerful test $\mathcal{V}_n^{2(1)}$ is markedly better than $\mathcal{J}_n^{2(2)}$ and KH_n^2. The popular belief that the method of Fisher is more powerful than that of Tippett should not be given too much consideration. The preferred test depends on the model under consideration.

10.3 Bivariate AR(1) Model

The model considered is the bivariate AR(1) model defined by $Y_k = AY_{k-1} + \epsilon_k$, where the innovations ϵ_k are independently distributed as bivariate Gaussian with mean vector 0 and covariance matrix C. The final specification is made by defining

$$A = \begin{pmatrix} 0 & \theta \\ \theta & 0 \end{pmatrix} \text{ and } C = \begin{pmatrix} 1 & 0.5 \\ 0.5 & 1 \end{pmatrix}.$$

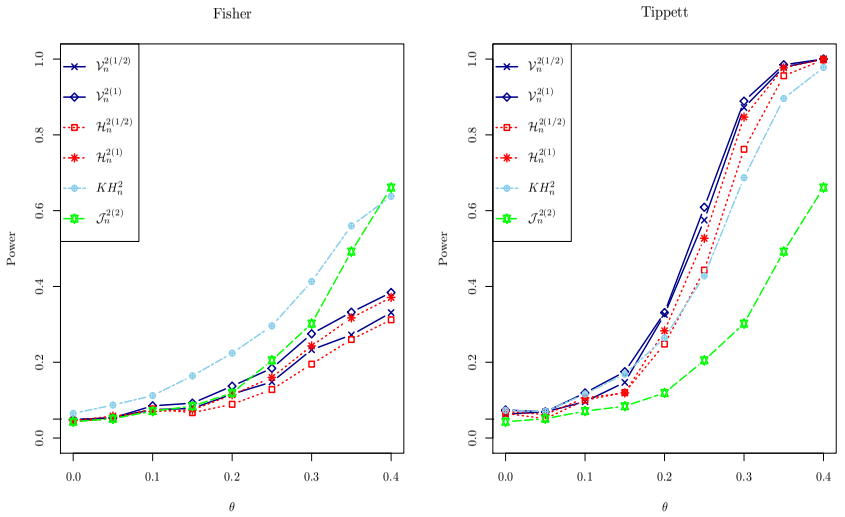

Figure 5: Empirical powers for the modified model of Romano and Siegel in Section 10.2. The methods of Fisher (left panel) and Tippett (right panel) are used to combine p-values.

The serial dependence of the sequence increases with θ and serial independence holds for $\theta = 0$. Tests of Tippett and Fisher are compared. The value $p = 3$ chosen arbitrarily can detect dependencies among three successive observations. In particular, it can detect dependencies at lags one or two. Sequences of length $m = 100$ are generated using the `mAr.sim` function of the `R` package `mAr` (Barbosa, 2012). The dependogram in Figure 6 shows a significant dependence at lag one. It shortly fails to detect the weaker dependence at lag 2 with the short sequence length of 100. Power functions in Figure 7 reveal $\mathcal{V}_n^{2(1)}$ as the most powerful test. Comparisons between Fisher and Tippett tests show comparable powers with a slight advantage for Tippett. Higher powers of $\mathcal{J}_n^{2(2)}$ locally around $\theta = 0$ can be attributed to the higher empirical significance level of this test.

11. Applications

Applications to meteorological and financial data are now provided in the following two sections.

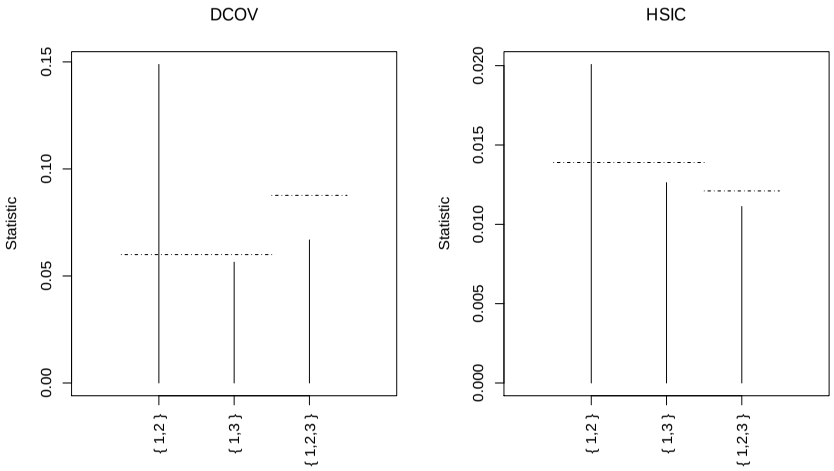

Figure 6: Dependograms for one sequence of length $m = 100$ for the AR(1) model with $\theta = 0.4$ of Section 10.3 based on $\mathcal{V}_{nB}^{2(1)}$ (left panel) and $\mathcal{H}_{nB}^{2(1)}$ (right panel).

11.1 Testing Mutual Independence Between Air Temperature, Soil Temperature, Humidity, Wind and Evaporation

These meteorological data are from Rencher (1995, p. 294). Table 2 describes the data with 46 observations on 11 variables. When a data set consists of variables measured on different scales, the scaling of variables often helps to enhance the appearance of the dependogram. In this application, variables were scaled to zero mean and unit variance. The `R` package `MVN` (Korkmaz et al., 2014) contains the function `hzTest` to perform the test for multivariate normality of Henze and Zirkler (1990). This test applied to the joint distribution of all 11 variables rejected a multivariate Gaussian model with a p-value of 0. Now, five groups of variables are considered as in Table 2. The Gaussian likelihood ratio test found a significant mutual dependence between the five groups. However, this test should not be relied on since it was found that data are not jointly Gaussian and it is well known that Gaussian likelihood ratio tests are not robust (Tyler, 1983; Bilodeau and Brenner, 1999). Mutual independence between these five groups is tested with distance covariance and $HSIC$ tests, both of index 1. Figure 8 contains dependograms only for subsets B of order up to 3. Both dependograms are very similar and lead to the same conclusions. It reveals that air temperature, soil temperature, relative humidity and evaporation are pairwise dependent.

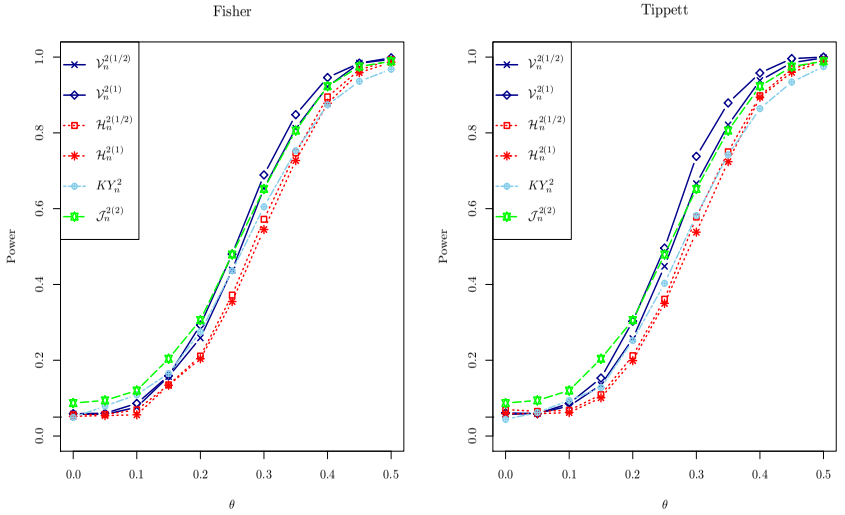

Figure 7: Empirical powers for the AR(1) model of Section 10.3. The methods of Fisher (left panel) and Tippett (right panel) are used to combine p-values.

However, wind does not exhibit any dependence of order 2 or 3 with any of the other 4 groups of variables.

11.2 Testing Serial Independence for Financial Data

Tests of serial independence of the three dimensional sequence formed by the daily percent increasing rates (DPIR) of indices from three stock markets: S&P/TSX composite (TSX), DOW JONES and S&P500. The values of indices are taken at closure. The series of length 534 range from January 2, 2014 to March 2, 2016. Note that five index values are observed weekly since the stock exchanges are not opened on weekends. The top row of Figure 9 shows that the financial series considered are not stationary. It is more appropriate to consider DPIR values. In the bottom row, one may see that DPIR values are more stationary, although still not perfectly stationary.

Tests of serial independence KY_{nB}^2, $\mathcal{V}_{nB}^{2(1)}$, and the test of non serial correlation $\mathcal{V}_{nB}^{2(2)}$ are conducted on the 3 joint series. The value of $p = 10$ allows a maximum lag of 9 days. Figure 10 reveals dependencies at small lags of 1, 2, and 4 in the dependogram of $\mathcal{V}_{nB}^{2(1)}$. The dependogram of KY_{nB}^2 was produced with the `copula` package and does not include critical values. Nevertheless, KY_{nB}^2 and $\mathcal{V}_{nB}^{2(1)}$ agree on the strongest dependency observed

Variables	Labels
$Z^{(1)}$	maximum daily air temperature minimum daily air temperature integrated area under daily air temperature curve
$Z^{(2)}$	maximum daily soil temperature minimum daily soil temperature integrated area under soil temperature
$Z^{(3)}$	maximum daily relative humidity minimum daily relative humidity integrated area under daily humidity curve
$Z^{(4)}$	total wind, measured in miles per day
$Z^{(5)}$	evaporation

Table 2: Variables related to air temperature, soil temperature, humidity, wind and evaporation.

at lag 4. The distance covariance $\mathcal{V}_{nB}^{2(2)}$ of index 2 was also performed on the sequence. One should recall that $\mathcal{V}_{nB}^{2(2)}$ is no longer a test of serial independence, but merely of non serial correlation. Interestingly, this test did not reveal any significant serial correlation. In an attempt to unravel the most significant dependency at lag 4 declared by $\mathcal{V}_{nB}^{2(1)}$, Figure 11 is a scatterplot of DPIR values observed on day k and $k+4$ for the TSX market. The Pearson (p-value of 0.11) and the Kendall (p-value of 0.14) correlation tests applied to this scatterplot are not significant. The test $\mathcal{V}_{nB}^{2(1)}$ for $B = \{1, 5\}$ on the single TSX market is very significant (p-value less than 0.001). A broken line regression with a change point at the origin was fitted to this scatterplot to account for different regimes according to whether DPIR is negative or positive. This regression model has three parameters for the intercept and slopes at the left and right of the origin. The left slope is very significant (p-value of 0.000015) contrary to the right slope (p-value of 0.021). The very significant left slope could be interpreted by the tendency of the TSX market to recover in the days following a decline. The sharper the market declines, the stronger it recovers. Among days such that $\text{DPIR}_k < \xi$, the percentage of days with $\text{DPIR}_{k+4} > 0$ is 60.7% for $\xi = -0.5$. This percentage goes up to 63.4% for $\xi = -1$ and to 68.2% for $\xi = -1.5$. Similar conclusions were found for the DOW JONES and S&P500 stock markets.

12. Conclusion

Generalizations of distance covariance and $HSIC$ tests were done successfully. For both mutual and serial independence hypotheses, the dependence statistics related to distance covariance and $HSIC$ were defined using the Möbius transformation. Simple and explicit expressions for dependence statistics were derived in the explicit form (8) as a sum over all elements of a componentwise product of doubly-centered matrices $A^{(j)} = (A_{kl}^{(j)})$. Computationally efficient approximation of p-values by randomization tests is made possible by this

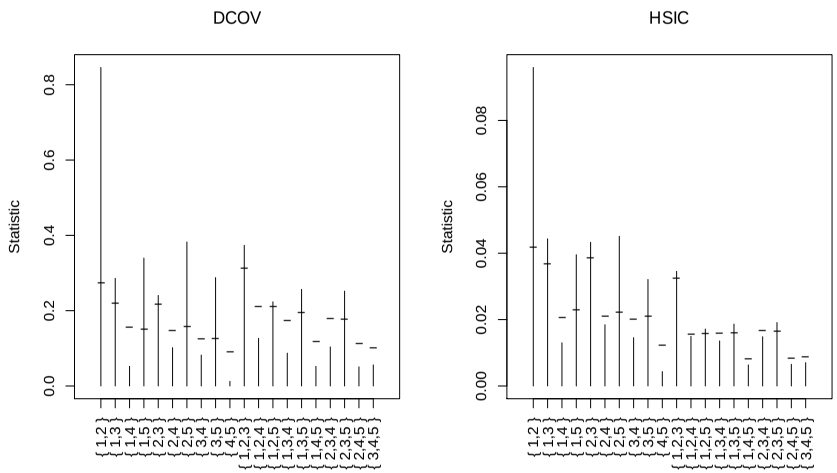

Figure 8: Dependograms of order $q = 3$ of air temperature, soil temperature, relative humidity, wind and evaporation for the meteorological data in Section 11.1 based on $\mathcal{V}_{nB}^{2(1)}$ (left panel) and $\mathcal{H}_{nB}^{2(1)}$ (right panel).

explicit form. Indeed, distances in $A^{(j)}$ do not have to be recomputed since it suffices to permute rows and corresponding columns of $A^{(j)}$ for every randomized sample. The method of combining individual p-values was put forward to construct global tests whose p-values evaluated by randomization tests yielded global significance levels close to the nominal level of 0.05 in all simulated models considered.

Distance covariance tests yielded powers generally very competitive with other tests considered. This paper has presented some advances to the problem of testing independence but some questions remain unanswered. The index α of distance covariance tests has a major influence on power functions. The adaptive selection of this index is a major difficulty which should be the object of future investigations. At the same time, it offers more flexibility and possibilities than tests based on copulas for which the only integrating measure is uniform. $HSIC$ tests can always achieve the same power function as distance covariance tests with the same index simply by selecting very small scale parameters. The additional adaptive selection of scale parameters could possibly yield tests which in certain cases would be more powerful than distance covariance tests. For $p = 2$, Guetsop Nangue (2016) selected the scale parameters which maximize the variance of the permutation distribution. This yielded $HSIC$ tests more powerful than distance covariance tests in two

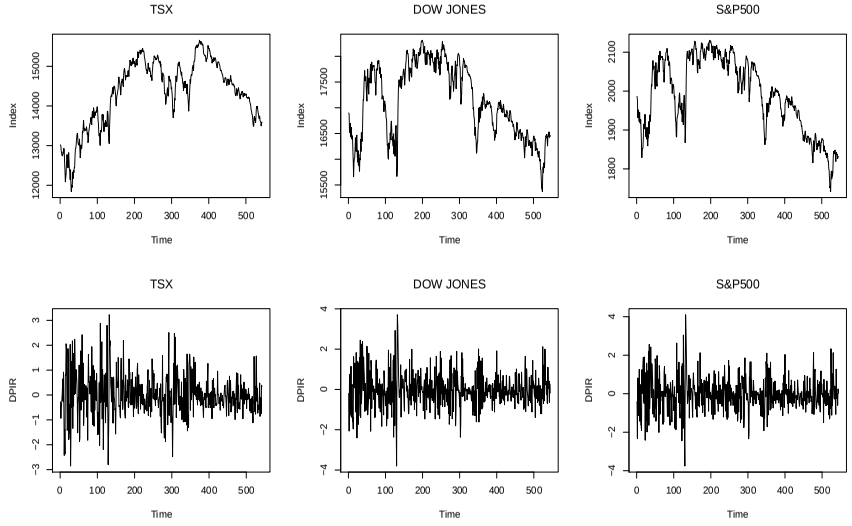

Figure 9: Daily evolution of the S&P/TSX composite (TSX), DOW JONES and S&P500 stock markets. The period of observation ranges from January 2, 2014 to March 2, 2016.

examples form the machine learning community considered in Sejdinovic et al. (2013b): the Independent Component Analysis (ICA) benchmark densities of Bach and Jordan (2002) and the sinusoidally dependent data. The adaptive selection of scale parameters for $p > 2$ is more challenging and is worthy of future research.

Acknowledgments

The authors would like to thank Arthur Gretton and three referees for their careful reading and constructive comments and suggestions which enhanced the quality of the paper. Financial support by the Faculté des arts et des sciences of Université de Montréal during the graduate thesis of the second author was greatly appreciated. This research was done without the financial support from the Natural Sciences and Engineering Research Council of Canada.

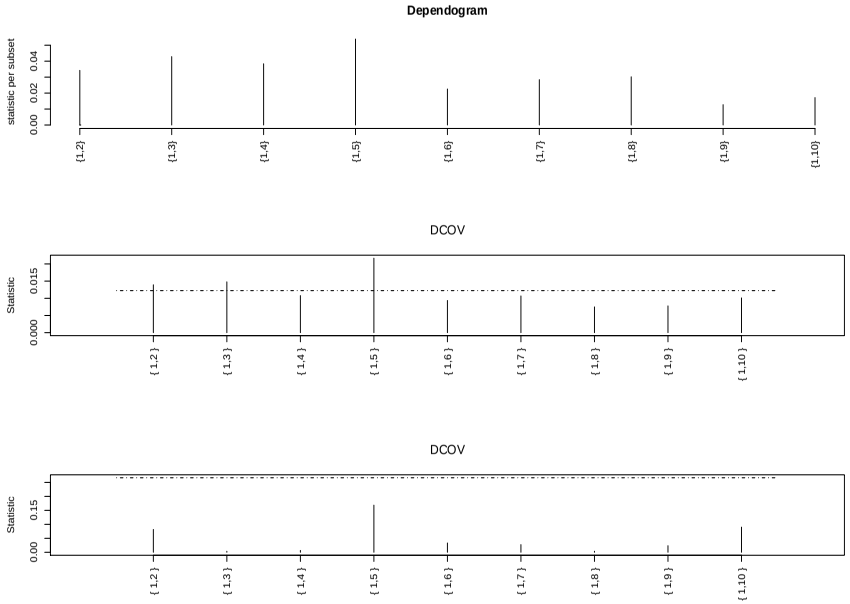

Figure 10: Dependograms for joint DPIR of S&P/TSX composite, DOW JONES, and S&P500. For $p = 10$, the maximum lag is 9. From top to bottom, three tests are considered: KY^2_{nB}, $\mathcal{V}^{2(1)}_{nB}$, and $\mathcal{V}^{2(2)}_{nB}$.

Appendix A: Proofs

Proof [Theorem 1] Upon using the representation (6) of the process,

$$\begin{aligned}\int |R_{nB}(t^{(B)})|^2 \prod_{j\in B} dG^{(j)}(t^{(j)}) &= \frac{1}{n}\sum_{k=1}^{n}\sum_{l=1}^{n}\prod_{j\in B}\int \left[e^{i\langle t^{(j)}, Z_k^{(j)} - Z_l^{(j)}\rangle} - \frac{1}{n}\sum_{v=1}^{n} e^{i\langle t^{(j)}, Z_k^{(j)} - Z_v^{(j)}\rangle}\right. \\ &- \left.\frac{1}{n}\sum_{u=1}^{n} e^{i\langle t^{(j)}, Z_u^{(j)} - Z_l^{(j)}\rangle} + \frac{1}{n^2}\sum_{u=1}^{n}\sum_{v=1}^{n} e^{i\langle t^{(j)}, Z_u^{(j)} - Z_v^{(j)}\rangle}\right] dG^{(j)}(t^{(j)}) \\ &= \frac{1}{n}\sum_{k=1}^{n}\sum_{l=1}^{n}\prod_{j\in B}[a_{kl}^{(j)} - \bar{a}_{k\cdot}^{(j)} - \bar{a}_{\cdot l}^{(j)} + \bar{a}_{\cdot\cdot}^{(j)}],\end{aligned} \tag{24}$$

where $a_{kl}^{(j)} = \varphi^{(j)}(Z_k^{(j)} - Z_l^{(j)})$ and $\varphi^{(j)}$ is the characteristic function of $G^{(j)}$. ■

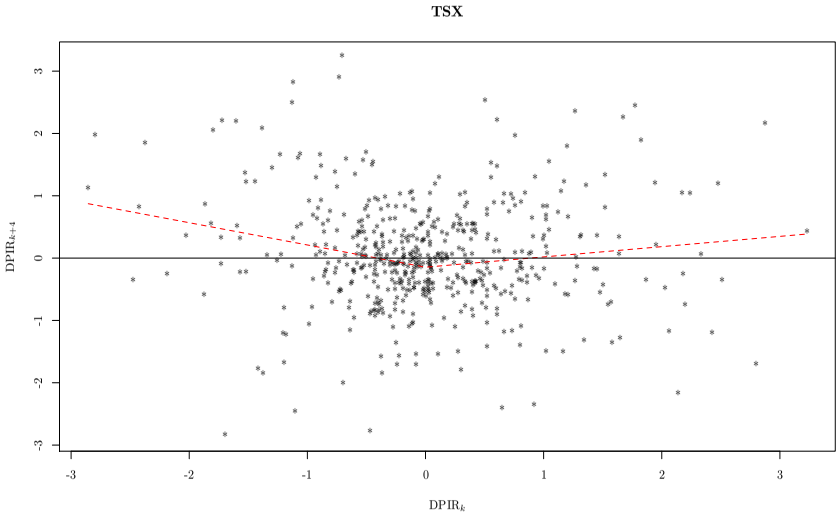

Figure 11: For the TSX market, broken line regression of DPIR on a given day on DPIR four days earlier with a change point at the origin.

Proof [Theorem 2] From (2) and the strong law of large numbers, $R_{nB}(t^{(B)})/\sqrt{n} \overset{a.s.}{\to} \mu_B(t^{(B)})$. Since the number of subsets of B is $2^{|B|}$, it is also clear that $|R_{nB}(t^{(B)})/\sqrt{n}| \leq 2^{|B|}$. Any constant being integrable with respect to the probability measure $\prod_{j\in B} dG^{(j)}(t^{(j)})$, it follows from the dominated convergence theorem that

$$\frac{1}{n}\int |R_{nB}(t^{(B)})|^2 \prod_{j\in B} dG^{(j)}(t^{(j)}) \overset{a.s.}{\to} \int |\mu_B(t^{(B)})|^2 \prod_{j\in B} dG^{(j)}(t^{(j)}),$$

i.e. $\mathcal{H}^2_{nB} \overset{a.s.}{\to} \mathcal{H}^2_B$. This proves (i). To prove (ii), since $\mu_B(t^{(B)}) \neq 0$ and the function μ_B is continuous, it follows that $\mathcal{H}^2_B > 0$. Therefore, $n\mathcal{H}^2_{nB} \overset{a.s.}{\to} \infty$. ■

Proof [Theorem 3] Because of double-centering, the expression between brackets in (24) is unchanged if one is subtracted from all four exponential functions. Then, it suffices in the proof of Theorem 1, for the weight function defining $\mathcal{V}^{2(\alpha)}_{nB}$, to evaluate

$$\int e^{i\langle t^{(j)}, Z^{(j)}\rangle} - 1 dw^{(j)}(t^{(j)}) = -|Z^{(j)}|^\alpha_{d_j} \tag{25}$$

using Lemma 1 of Székely et al. (2007, p. 2771). ■

The representation (6) of the process was unexploited in Székely et al. (2007). It simplifies greatly their derivations.

Proof [Theorem 4] The notation $\mathbb{E}_3$ is for the expectation with respect to Z_3, treating the other variable as a constant to avoid using for conditional expectations. The notation $\mathbb{E}_{12}$ and $\mathbb{E}_{34}$ are defined similarly. Condition (12) implies that

$$\mathbb{E}_{12}\prod_{j\in B}\left||Z_1^{(j)} - Z_2^{(j)}|^\alpha_{d_j} - \mathbb{E}_3|Z_1^{(j)} - Z_3^{(j)}|^\alpha_{d_j} - \mathbb{E}_3|Z_2^{(j)} - Z_3^{(j)}|^\alpha_{d_j} + \mathbb{E}_{34}|Z_3^{(j)} - Z_4^{(j)}|^\alpha_{d_j}\right| < \infty.$$

and that $\mathcal{V}^{2(\alpha)}_B$ is well defined. The integral (25) yields

$$\begin{aligned}
\mathcal{V}^{2(\alpha)}_B &= \mathbb{E}_{12}\prod_{j\in B}\Big[\int e^{i\langle t^{(j)}, Z_1^{(j)} - Z_2^{(j)}\rangle} - 1 dw^{(j)}(t^{(j)}) + \mathbb{E}_3\int 1 - e^{i\langle t^{(j)}, Z_1^{(j)} - Z_3^{(j)}\rangle} dw^{(j)}(t^{(j)}) \\
&\quad + \mathbb{E}_3\int 1 - e^{i\langle t^{(j)}, Z_3^{(j)} - Z_2^{(j)}\rangle} dw^{(j)}(t^{(j)}) + \mathbb{E}_{34}\int e^{i\langle t^{(j)}, Z_3^{(j)} - Z_4^{(j)}\rangle} - 1 dw^{(j)}(t^{(j)})\Big] \\
&= \mathbb{E}_{12}\prod_{j\in B}\mathbb{E}_{34}\int \Big[e^{i\langle t^{(j)}, Z_1^{(j)} - Z_2^{(j)}\rangle} - e^{i\langle t^{(j)}, Z_1^{(j)} - Z_3^{(j)}\rangle} \\
&\quad - e^{i\langle t^{(j)}, Z_3^{(j)} - Z_2^{(j)}\rangle} + e^{i\langle t^{(j)}, Z_3^{(j)} - Z_4^{(j)}\rangle}\Big] dw^{(j)}(t^{(j)}).
\end{aligned}$$

The theorem of Fubini yields

$$\begin{aligned}
\mathcal{V}^{2(\alpha)}_B &= \mathbb{E}_{12}\prod_{j\in B}\int \mathbb{E}_{34}\Big[e^{i\langle t^{(j)}, Z_1^{(j)} - Z_2^{(j)}\rangle} - e^{i\langle t^{(j)}, Z_1^{(j)} - Z_3^{(j)}\rangle} \\
&\quad - e^{i\langle t^{(j)}, Z_3^{(j)} - Z_2^{(j)}\rangle} + e^{i\langle t^{(j)}, Z_3^{(j)} - Z_4^{(j)}\rangle}\Big] dw^{(j)}(t^{(j)}) \\
&= \mathbb{E}_{12}\prod_{j\in B}\int \Big[e^{i\langle t^{(j)}, Z_1^{(j)} - Z_2^{(j)}\rangle} - e^{i\langle t^{(j)}, Z_1^{(j)}\rangle} f^{(j)}(-t^{(j)}) \\
&\quad - e^{-i\langle t^{(j)}, Z_2^{(j)}\rangle} f^{(j)}(t^{(j)}) + f^{(j)}(t^{(j)}) f^{(j)}(-t^{(j)})\Big] dw^{(j)}(t^{(j)}) \\
&= \mathbb{E}_{12}\int \prod_{j\in B}\Big[e^{i\langle t^{(j)}, Z_1^{(j)}\rangle} - f^{(j)}(t^{(j)})\Big]\Big[e^{-i\langle t^{(j)}, Z_2^{(j)}\rangle} - f^{(j)}(-t^{(j)})\Big] dw_B(t^{(B)}) \\
&= \int \mathbb{E}_1\prod_{j\in B}\Big[e^{i\langle t^{(j)}, Z_1^{(j)}\rangle} - f^{(j)}(t^{(j)})\Big]\mathbb{E}_2\prod_{j\in B}\Big[e^{-i\langle t^{(j)}, Z_2^{(j)}\rangle} - f^{(j)}(-t^{(j)})\Big] dw_B(t^{(B)}).
\end{aligned}$$

By a similar development leading to (6),

$$\mu_B(t^{(B)}) = \mathbb{E}_1\prod_{j\in B}\Big[e^{i\langle t^{(j)}, Z_1^{(j)}\rangle} - f^{(j)}(t^{(j)})\Big].$$

Hence, $\mathcal{V}^{2(\alpha)}_B = \int |\mu_B(t^{(B)})|^2 dw_B(t^{(B)})$. This proves (i). For (ii), if $\mu_B(t^{(B)}) \neq 0$, then necessarily $t^{(B)} \neq 0$. Consider a compact ball $\mathfrak{B}$ not containing 0 and but containing the point $t^{(B)}$. The measure dw_B is integrable on $\mathfrak{B}$. Then, arguing as in the proof of Theorem 2

$$\mathcal{V}^{2(\alpha)}_{nB} \geq \frac{1}{n}\int_{\mathfrak{B}} |R_n(t^{(B)})|^2 dw_B(t^{(B)}) \overset{a.s.}{\to} \int_{\mathfrak{B}} |\mu_B(t^{(B)})|^2 dw_B(t^{(B)}) > 0$$

and therefore, $n\mathcal{V}_{nB}^{2(\alpha)} \xrightarrow{a.s.} \infty$. ■

Proof [Equation (13)] The result follows using the invariance by translation, $a_{kl}^{(j)} \mapsto a_{kl}^{(j)} - 1$, and the following limit,

$$\lim_{\beta_j \to 0} \frac{e^{-\beta_j^\alpha |Z_k^{(j)} - Z_l^{(j)}|_{d_j}^\alpha} - 1}{\beta_j^\alpha} = -|Z_k^{(j)} - Z_l^{(j)}|_{d_j}^\alpha.$$

■

Let $d_B = \sum_{j \in B} d_j$. Define the metric (Whitt, 1970)

$$\rho_B(x, y) = \sum_{s=1}^{\infty} 2^{-s} \frac{\rho_{sB}(x, y)}{1 + \rho_{sB}(x, y)},$$

where

$$\rho_{sB}(x, y) = \sup_{|t^{(B)}|_{d_B} \leq s} |x(t^{(B)}) - y(t^{(B)})|,$$

on the linear complete metric space of continuous functions $\mathcal{C}(\mathbb{R}^{d_B}, \mathbb{C})$. The Borel σ-field in $\mathcal{C}(\mathbb{R}^{d_B}, \mathbb{C})$ is generated by the coordinate projections, *i.e.* it is the smallest σ-field with respect to which all coordinate projections are measurable. Weak convergence of random variables in $\mathcal{C}(\mathbb{R}^{d_B}, \mathbb{C})$ is equivalent to weak convergence on any compact subset; see Whitt (1970, Theorem 5) or Kallenberg (2002, Proposition 16.6). Moreover, weak converge of a sequence on a compact subset is equivalent to finite dimensional weak convergence and tightness of that sequence. The metric defined on the product of spaces $\underset{B \in \mathcal{I}_p}{\times} C(\mathbb{R}^{d_B}, \mathbb{C})$ (Whitt, 1970) is

$$\rho\left((x_B,\ B \in \mathcal{I}_p), (y_B,\ B \in \mathcal{I}_p)\right) = \max_{B \in \mathcal{I}_p} \rho_B(x_B, y_B).$$

From Whitt (1970, Corollary 7), weak convergence on this product of spaces is equivalent to finite dimensional weak convergence of the joint process and tightness on compacta of each individual process.

Proof [Theorem 5] The process $R_{nB}(t)$ in (6) is closely related to the process

$$\breve{R}_{nB}(t) = \frac{1}{\sqrt{n}} \sum_{k=1}^{n} \prod_{j \in B} \left[e^{i\langle t^{(j)}, Z_k^{(j)} \rangle} - f^{(j)}(t^{(j)}) \right]. \tag{26}$$

in which marginal characteristic functions are not estimated. The process $\breve{R}_{nB}$ in (26) is a sum of independent and identically distributed random variables. Bilodeau and Lafaye de Micheaux (2005, Theorem 2.1) proved that the collection of processes $\breve{R}_{nB}$ converges as stated in Theorem 5 under the weak condition (14). The independence of the asymptotic processes for $B \neq C$ is verified

$$\mathbb{E}\left[R_B(t^{(B)}) \bar{R}_C(s^{(C)}) \right] = \mathbb{E}\left\{ \prod_{j \in B} \left[e^{i\langle t^{(j)}, Z_k^{(j)} \rangle} - f^{(j)}(t^{(j)}) \right] \prod_{j \in C} \left[e^{i\langle s^{(j)}, -Z_k^{(j)} \rangle} - f^{(j)}(-s^{(j)}) \right] \right\}$$

$$= 0,$$

because there is an index j in B, but not in C, or the converse, for which the corresponding term has expectation zero. Then, it suffices to show $\rho_{sB}(R_{nB}, \breve{R}_{nB}) \xrightarrow{P} 0$, for all $s \geq 1$ and $B \in \mathcal{I}_p$. The representation in Ghoudi et al. (2001, p. 212) holds for characteristic functions

$$R_{nB}(t) = \sum_{C \subseteq B} (-1)^{|C|} \prod_{j \in C} [f_n^{(j)}(t^{(j)}) - f^{(j)}(t^{(j)})] \breve{R}_{n,B\setminus C}(t^{(B\setminus C)}). \tag{27}$$

From (27), it follows that

$$|R_{nB}(t^{(B)}) - \breve{R}_{nB}(t^{(B)})| \leq \sum_{C \subseteq B, C \neq \emptyset} \prod_{j \in C} |f_n^{(j)}(t^{(j)}) - f^{(j)}(t^{(j)})| |\breve{R}_{n,B\setminus C}(t^{(B\setminus C)})|, \tag{28}$$

where the sum has only a finite number of terms. Using the Glivenko-Cantelli convergence in Csörgő (1981, Theorem 2.1) and the fact that the processes $\breve{R}_{n,B\setminus C}$ are tight, it follows that, for any $s \geq 1$, $\rho_s(R_{nB}, \breve{R}_{nB}) \xrightarrow{P} 0$. ■

Proof [Theorem 6] Let

$$|[R_{nB}(t^{(B)})]|^2 = \int |R_{nB}(t^{(B)})|^2 \prod_{j \in B} dG^{(j)}(t^{(j)})$$

be the squared L_2 norm, on the space of squared integrable functions, of the process R_{nB}. Then, $nW_{nB} = |[R_{nB}]|^2$ and $n\breve{T}_{nB} = |[\breve{R}_{nB}]|^2$. Use $\int \tilde{k}(t^{(B)}, t^{(B)}) \prod_{j \in B} dG^{(j)}(t^{(j)}) < \infty$, where $\tilde{k}$ is defined in (16), and Tonelli's theorem to conclude that $W_B := |[R_B]|^2$ is finite almost surely. The proof consists in showing the following two results (Henze and Wagner, 1997): (i) $|[\breve{R}_{nB}]|^2 \Rightarrow |[R_B]|^2$ and (ii) $|[R_{nB} - \breve{R}_{nB}]|^2 \xrightarrow{P} 0$. Note that from (i) and the continuous mapping theorem, $|[\breve{R}_{nB}]| \Rightarrow |[R_B]|$, which, with the triangle inequality $\Big|\, |[R_{nB}]| - |[\breve{R}_{nB}]| \,\Big| \leq |[R_{nB} - \breve{R}_{nB}]|$ and (ii), implies $|[R_{nB}]| \Rightarrow |[R_B]|$ and, thus $|[R_{nB}]|^2 \Rightarrow |[R_B]|^2$. Using a slight generalization of Kellermeier (1980, Theorem 3.3), it suffices for (i) to show the following uniform integrability condition:

$$\lim_{N \to \infty} \limsup_{n \to \infty} \int_{\{|t^{(j)}|_{d_j} > N, \forall j \in B\}} \mathbb{E}|\breve{R}_{nB}(t^{(B)})|^2 \prod_{j \in B} dG^{(j)}(t^{(j)}) = 0. \tag{29}$$

It can be verified that $\mathbb{E}|\breve{R}_{nB}(t^{(B)})|^2 = \prod_{j \in B} \left[1 - |f^{(j)}(t^{(j)})|^2\right]$ does not depend on n. Now, for each $j \in B$,

$$\int 1 - |f^{(j)}(t^{(j)})|^2 dG^{(j)}(t^{(j)}) < \infty$$

since the integrand is bounded. This proves (29). For (ii), since all processes $\breve{R}_{n,B\setminus C}$ are tight, it suffices from (28) to show that for all $j \in B$,

$$\int |f_n^{(j)}(t^{(j)}) - f^{(j)}(t^{(j)})|^2 dG^{(j)}(t^{(j)}) \xrightarrow{P} 0.$$

This follows from the dominated convergence theorem, since $f_n^{(j)}(t^{(j)}) \overset{a.s.}{\to} f^{(j)}(t^{(j)})$ and the integrand is bounded by 4. The weak convergence of the collection $(|[R_{nB}]|^2,\ B \in \mathcal{I}_p)$ follows by the same argument above from (i') $(|[\breve{R}_{nB}]|^2,\ B \in \mathcal{I}_p) \Rightarrow (|[R_B]|^2,\ B \in \mathcal{I}_p)$ and (ii) $|[R_{nB} - \breve{R}_{nB}]|^2 \overset{P}{\to} 0$, for each $B \in \mathcal{I}_p$. Thus, it remains to establish (i'). From Theorem 5 and the continuous mapping theorem, $\sum_{B\in\mathcal{I}_p} c_B|\breve{R}_{nB}(t^{(B)})|^2 \Rightarrow \sum_{B\in\mathcal{I}_p} c_B|R_B(t^{(B)})|^2$, for all constants c_B, $B \in \mathcal{I}_p$. Also, $\sum_{B\in\mathcal{I}_p} c_B|[\breve{R}_{nB}]|^2 \Rightarrow \sum_{B\in\mathcal{I}_p} c_B|[R_B]|^2$ because the following uniform integrability condition

$$\lim_{N\to\infty} \limsup_{n\to\infty} \int_{\{|t^{(j)}|_{d_j}>N, j=1,\ldots,p\}} \mathbb{E}\left|\sum_{B\in\mathcal{I}_p} c_B|\breve{R}_{nB}(t^{(B)})|^2\right| \prod_{j=1}^{p} dG^{(j)}(t^{(j)})$$
$$\leq \sum_{B\in\mathcal{I}_p} |c_B| \lim_{N\to\infty} \limsup_{n\to\infty} \int_{\{|t^{(j)}|_{d_j}>N, \forall j\in B\}} \mathbb{E}|\breve{R}_{nB}(t^{(B)})|^2 \prod_{j\in B} dG^{(j)}(t^{(j)}) = 0$$

is satisfied from (29). Finally, (i') follows from the Cramér-Wold theorem. The mutual independence of $(|[R_B]|^2,\ B \in \mathcal{I}_p)$ follows from that of $(R_B,\ B \in \mathcal{I}_p)$ in Theorem 5. ■

Proof [Theorem 7] Consider the processes

$$\breve{R}_{nB,s}(t^{(B)}) = \frac{1}{\sqrt{n}} \sum_{k=1}^{n} \prod_{j\in B} \left[e^{i\langle t^{(j)}, Z_k^{(j)}\rangle} - f^{(1)}(t^{(j)})\right],\ B \in \mathcal{B}_p.$$

Finite dimensional weak convergence of the processes is proved. Because of overlapping of Y's in consecutive Z_k's, the Z_k's form an $(p-1)$-dependent sequence, see Ferguson (1996, p. 69). Thus, the central limit theorem for such dependent sequences establishes that $\breve{R}_{nB,s}(t^{(B)})$ and $\breve{R}_{nC,s}(s^{(C)})$ are asymptotically and jointly normal with asymptotic covariance $\sigma_{0,0} + 2\sigma_{0,1} + \cdots + 2\sigma_{0,p-1}$, where

$$\sigma_{0,u} = \mathbb{E}\left\{\prod_{j\in B}\left[e^{i\langle t^{(j)}, Z_k^{(j)}\rangle} - f^{(1)}(t^{(j)})\right] \prod_{j\in C}\left[e^{i\langle s^{(j)}, -Z_{k+u}^{(j)}\rangle} - f^{(1)}(-s^{(j)})\right]\right\}.$$

All of the above expectations are null unless $B = C$ (both in $\mathcal{B}_p$) and $u = 0$. Next, to establish weak convergence of the process on any compact, assume without loss of generality that n is a multiple of p, say $n = rp$. This amounts to neglecting at most $p-1$ terms in the sequence. Rewrite the sequence $Z_1, Z_2, \ldots$ as an array with p rows, each consisting of r independent and identically distributed vectors,

$$\begin{array}{cccc} Z_1 & Z_{1+p} & \cdots & Z_{1+(r-1)p} \\ Z_2 & Z_{2+p} & \cdots & Z_{2+(r-1)p} \\ \vdots & \vdots & \ddots & \vdots \\ Z_p & Z_{p+p} & \cdots & Z_{p+(r-1)p}. \end{array}$$

Then, the expression

$$\breve{R}_{nB,s}(t^{(B)}) = \frac{1}{\sqrt{p}} \sum_{h=1}^{p} \sum_{C\subseteq B} (-1)^{|B\setminus C|} \prod_{j\in B\setminus C} f^{(1)}(t^{(j)}) \cdot \frac{1}{\sqrt{r}} \sum_{i=0}^{r-1} \left[e^{i\langle t^{(C)}, Z_{pi+h}^{(C)}\rangle} - \prod_{j\in C} f^{(1)}(t^{(j)})\right]$$

establishes weak convergence since for each pair (h, C) in finite number, the last sum over i is an empirical characteristic function process over a compact. Finally, $R_{nB,s}$ and $\breve{R}_{nB,s}$ are equivalent processes follows from the inequality

$$|R_{nB,s}(t^{(B)}) - \breve{R}_{nB,s}(t^{(B)})| \leq \sum_{C\subseteq B, C\neq\emptyset} \prod_{j\in C} |f_n^{(j)}(t^{(j)}) - f^{(1)}(t^{(j)})||\breve{R}_{nB\setminus C,s}(t^{(B\setminus C)})|,$$

and the same arguments following (28). ■

Abstract

This paper addresses how well we can recover a data matrix when only given a few of its elements. We present a randomized algorithm that element-wise sparsifies the data, retaining only a few of its entries. Our new algorithm independently samples the data using probabilities that depend on both squares (ℓ_2 sampling) and absolute values (ℓ_1 sampling) of the entries. We prove that this hybrid algorithm (i) achieves a near-PCA reconstruction of the data, and (ii) recovers sparse principal components of the data, from a sketch formed by a sublinear sample size. Hybrid-(ℓ_1, ℓ_2) inherits the ℓ_2-ability to sample the important elements, as well as the regularization properties of ℓ_1 sampling, and maintains strictly better quality than either ℓ_1 or ℓ_2 on their own. Extensive experimental results on synthetic, image, text, biological, and financial data show that not only are we able to recover PCA and sparse PCA from incomplete data, but we can speed up such computations significantly using our sparse sketch .

Keywords: element-wise sampling, sparse representation, pca, sparse pca, hybrid-(ℓ_1, ℓ_2)

1. Introduction

We address two fundamental data science problems, namely, (i) a near-PCA reconstruction of the data, and (ii) recovering sparse principal components of the data, in a setting where we can use only a few of the data entries (*element-wise matrix sparsification* problem was pioneered by Achlioptas and McSherry 2001, 2007). This is a situation that one is confronted with all too often in machine learning (say, we have a small sample of data points and those data points have missing features). For example, with user-recommendation data, one does not have all the ratings of any given user. Or in a privacy preserving setting, a client may not want to give us all entries in the data matrix. In such a setting, our goal is to show that if the samples that we get are chosen carefully, the top-k PCA and sparse PCA features of the data can be recovered within some provable error bounds. In fact, we show that solutions of a large class of optimization problems, irrespective of whether they are efficiently solvable (e.g. PCA) or NP-hard (e.g. sparse PCA), can be approximated provably by such element-wise sparse representation of the data.

More formally, the data matrix is $\mathbf{A} \in \mathbb{R}^{m\times n}$ (m data points in n dimensions). Often, real data matrices have low effective rank, so let $\mathbf{A}_k$ be the best rank-k approximation to $\mathbf{A}$ with $\|\mathbf{A} - \mathbf{A}_k\|_2$ being small, where $\|\mathbf{X}\|_2$ is the spectral norm of matrix $\mathbf{X}$. $\mathbf{A}_k$ is obtained by projecting $\mathbf{A}$ onto the subspace spanned by its top-k principal components. In order to approximate this top-k principal subspace, we adopt the following strategy. Select a small number, s, of elements from $\mathbf{A}$ and produce a sparse sketch $\tilde{\mathbf{A}}$; use $\tilde{\mathbf{A}}$ to approximate the top-k principal subspace. Note that both PCA and the sparse PCA problem have the same objective, i.e., to maximize the variance of the data; however, the sparse PCA problem has an additional sparsity constraint on each principal component (and this makes it NP-hard). Sections 2.1 and 2.2 contains the formulations of PCA and sparse PCA, respectively. We give the details of Algorithm 2 to approximate the top-k principal subspace and the corresponding theoretical guarantees in Theorem 3. Theorem 4 shows the quality of approximation for the sparse PCA problem (and this error bound is applicable to a large class of optimization problems as long as the objective function satisfies a generalized notion of Lipschitz continuity to be discussed later). The key quantity that we must control to recover a close approximation to PCA and sparse PCA is how well the sparse sketch approximates the data *in the operator norm*. That is, if $\|\mathbf{A} - \tilde{\mathbf{A}}\|_2$ is small then we can recover PCA and sparse PCA effectively from a small number of samples.

Problem: Element-wise Matrix Sparsification

Given $\mathbf{A} \in \mathbb{R}^{m\times n}$ and $\epsilon > 0$, sample s elements to obtain a sparse sketch $\tilde{\mathbf{A}}$ for which

$$\|\mathbf{A} - \tilde{\mathbf{A}}\|_2 \leq \epsilon \quad \text{and} \quad \|\tilde{\mathbf{A}}\|_0 \leq s. \tag{1}$$

See SECTION 1.1 for notations. Our main result addresses the problem above. In a nutshell, with only partially observed data whose elements have been carefully selected, one can recover an approximation to the top-k principal subspace. An additional benefit is that our approximation to the top-k subspace using iterated matrix multiplication (e.g., power iterations) can benefit computationally from sparsity. To construct $\tilde{\mathbf{A}}$, we use a general randomized approach which independently samples (and rescales) s elements from $\mathbf{A}$ using probability p_{ij} to sample element $\mathbf{A}_{ij}$. We analyze in detail the case $p_{ij} \propto \alpha|\mathbf{A}_{ij}| + (1-\alpha)|\mathbf{A}_{ij}|^2$ to get a bound on $\|\mathbf{A} - \tilde{\mathbf{A}}\|_2$. We now make our discussion precise, starting with our notation.

1.1 Notation

We use bold uppercase (e.g., $\mathbf{X}$) for matrices and bold lowercase (e.g., $\mathbf{x}$) for column vectors. The i-th row of $\mathbf{X}$ is $\mathbf{X}_{(i)}$, and the i-th column of $\mathbf{X}$ is $\mathbf{X}^{(i)}$. Let $[n]$ denote the set $\{1, 2, ..., n\}$. $\mathbb{E}(X)$ is the expectation of a random variable X; for a matrix, $\mathbb{E}(\mathbf{X})$ denotes the element-wise expectation. For a matrix $\mathbf{X} \in \mathbb{R}^{m\times n}$, the Frobenius norm $\|\mathbf{X}\|_F$ is $\|\mathbf{X}\|_F^2 = \sum_{i,j=1}^{m,n} \mathbf{X}_{ij}^2$, and the spectral (operator) norm $\|\mathbf{X}\|_2$ is $\|\mathbf{X}\|_2 = \max_{\|\mathbf{y}\|_2=1} \|\mathbf{X}\mathbf{y}\|_2$. We also have the ℓ_1 and ℓ_0 norms: $\|\mathbf{X}\|_1 = \sum_{i,j=1}^{m,n} |\mathbf{X}_{ij}|$ and $\|\mathbf{X}\|_0$ is the number of non-zero entries in $\mathbf{X}$. The k-th largest singular value of $\mathbf{X}$ is $\sigma_k(\mathbf{X})$. For symmetric matrices $\mathbf{X}$ and $\mathbf{Y}$, $\mathbf{Y} \succeq \mathbf{X}$ if and only if $\mathbf{Y} - \mathbf{X}$ is positive semi-definite. $\mathbf{I}_n$ is the $n \times n$ identity and $\ln x$ is the natural logarithm of x. We use $\mathbf{e}_i$ to denote standard basis vectors whose dimensions will be clear from the context.

Two popular sampling probabilities are ℓ_1, where $p_{ij} = |\mathbf{A}_{ij}|/\|\mathbf{A}\|_1$ (Achlioptas and McSherry 2001; Achlioptas et al. 2013a), and ℓ_2, where $p_{ij} = \mathbf{A}_{ij}^2/\|\mathbf{A}\|_F^2$ (Achlioptas and McSherry 2001; Drineas and Zouzias 2011). We construct $\tilde{\mathbf{A}}$ as follows: $\tilde{\mathbf{A}}_{ij} = 0$ if (i,j)-th entry is not sampled; sampled elements $\mathbf{A}_{ij}$ are rescaled to $\tilde{\mathbf{A}}_{ij} = \mathbf{A}_{ij}/p_{ij}$ which makes the sketch $\tilde{\mathbf{A}}$ an unbiased estimator of $\mathbf{A}$, so $\mathbb{E}[\tilde{\mathbf{A}}] = \mathbf{A}$. The sketch is *sparse* if the number of sampled elements is sublinear in mn, i.e., $s = o(mn)$. Sampling according to element magnitudes is natural in many applications, for example in a recommendation system users tend to rate a product they like (high positive) or dislike (high negative).

Our main sparsification algorithm (Algorithm 1) receives as input a matrix $\mathbf{A}$ and an accuracy parameter $\epsilon > 0$, and samples s elements from $\mathbf{A}$ in s independent, identically distributed trials with replacement, according to a hybrid-(ℓ_1, ℓ_2) probability distribution specified in Equation (3). The algorithm returns $\tilde{\mathbf{A}} \in \mathbb{R}^{m\times n}$, a sparse and unbiased estimator of $\mathbf{A}$, as a solution to (1).

1.2 Prior Work on Element Sampling

Achlioptas and McSherry (2001, 2007) pioneered the idea of ℓ_2 sampling for element-wise sparsification. However, ℓ_2 sampling on its own is insufficient for provably accurate bounds on $\|\mathbf{A} - \tilde{\mathbf{A}}\|_2$. As a matter of fact Achlioptas and McSherry (2001, 2007) observed that "small" entries need to be sampled with probabilities that depend on their absolute values only, thus also introducing the notion of ℓ_1 sampling. The underlying reason for the need of ℓ_1 sampling is the fact that if a small element is sampled and rescaled using ℓ_2 sampling, this would result in a huge entry in $\tilde{\mathbf{A}}$ (because of the rescaling). As a result, the variance of ℓ_2 sampling is quite high, resulting in poor theoretical and experimental behavior. ℓ_1 sampling of small entries rectifies this issue by reducing the variance of the overall approach. Arora et al. (2006) proposed a sparsification algorithm that deterministically keeps large entries, i.e., entries of $\mathbf{A}$ such that $|\mathbf{A}_{ij}| \geq \epsilon/\sqrt{n}$ and randomly rounds the remaining entries using ℓ_1 sampling. Formally, entries of $\mathbf{A}$ that are smaller than $\epsilon\sqrt{n}$ are set to sign $(\mathbf{A}_{ij})\,\epsilon/\sqrt{n}$ with probability $p_{ij} = \sqrt{n}\,|\mathbf{A}_{ij}|/\epsilon$ and to zero otherwise. They used an ϵ-net argument to show that $\|\mathbf{A} - \tilde{\mathbf{A}}\|_2$ was bounded with high probability. Drineas and Zouzias (2011) bypassed the need for ℓ_1 sampling by zeroing-out the small entries of $\mathbf{A}$ (e.g., all entries such that $|\mathbf{A}_{ij}| < \epsilon/2n$ for a matrix $\mathbf{A} \in \mathbb{R}^{n\times n}$) and then use ℓ_2 sampling on the remaining entries in order to sparsify the matrix. This simple modification improves Achlioptas and McSherry (2007) and Arora et al. (2006), and comes with an elegant proof using the matrix-Bernstein inequality of Recht (2011). Note that all these approaches need truncation of small entries. Recently, Achlioptas et al. (2013a) showed that ℓ_1 sampling in isolation could be done without any truncation, and argued that (under certain assumptions) ℓ_1 sampling would be better than ℓ_2 sampling, even using the truncation. Their proof is also based on the matrix-valued Bernstein inequality of Recht (2011). Finally, the result that is closest to ours is due to Achlioptas et al. (2013b), where the proposed distribution is

$$p_{ij} = \rho_i \cdot |\mathbf{A}_{ij}|\,/\|\mathbf{A}_{(i)}\|_1 \quad \text{(Bernstein distribution)} \tag{2}$$

where, ρ_i is a distribution over the rows, i.e., $\sum_i \rho_i = 1$. This distribution is derived using matrix-Bernstein inequality for a fixed sampling budget s, and under some assumptions it is shown to be near-optimal in the sense that the error $\|\mathbf{A} - \tilde{\mathbf{A}}\|_2$ it produces is within a constant factor of the smallest error produced by an optimal distribution over elements $\mathbf{A}_{ij}$. Similar to this distribution we also use a convex combination of probabilities. However, our proposed hybrid distribution only relies on ℓ_1 and ℓ_2 probabilities, thus requiring considerably less prior information about the data

$\mathbf{A}$ comparing to Bernstein distribution (Achlioptas et al. 2013b), while also being more faithful to how matrices in practice are sampled locally based on element properties, and not based on global properties of a matrix.

1.3 Our Contributions

We introduce an intuitive hybrid approach to element-wise matrix sparsification, by combining ℓ_1 and ℓ_2 sampling. We propose to use sampling probabilities of the form

$$p_{ij} = \alpha \cdot \frac{|\mathbf{A}_{ij}|}{\|\mathbf{A}\|_1} + (1-\alpha)\frac{\mathbf{A}_{ij}^2}{\|\mathbf{A}\|_F^2}, \quad \alpha \in (0,1] \tag{3}$$

for all i, j . We retain the good properties of ℓ_2 sampling that bias us towards data elements in the presence of small noise, while *regularizing* smaller entries using ℓ_1 sampling. We summarize the main contributions below.

• We give a parameterized sampling distribution in the variable $\alpha \in (0,1]$ that controls the balance between ℓ_2 sampling and ℓ_1 regularization. This greater flexibility allows us to achieve better accuracy than both ℓ_1 and ℓ_2. Further, we derive the optimal hybrid-(ℓ_1, ℓ_2) distribution, using Lemma 1 for any given $\mathbf{A}$, by computing the optimal parameter α^* which achieves the desired accuracy with the smallest sample size using our theoretical bound.

Setting $\alpha = 1$ in our bounds we reproduce the result of Achlioptas et al. (2013a) who claim that ℓ_1 is typically better than ℓ_2. Moreover, our result shows that $\alpha^* < 1$ which means that the hybrid approach is better than ℓ_1 (and ℓ_2). Thus, our result generalizes the result of Achlioptas et al. (2013a). Note that the Bernstein distribution of Achlioptas et al. (2013b) (for a given s) is a convex combination of 'intra-row' weights $|\mathbf{A}_{ij}|\,/\|\mathbf{A}\|_1$, where as, our distribution (for a given ϵ) is a much simpler and intuitive convex combination of ℓ_1 and ℓ_2 probabilities.

• We propose Algorithm 2 to provably recover PCA by constructing a sparse unbiased sketch of (centered) data from a limited number of samples. Moreover, we show how we can effectively approximate the sparse PCA problem (NP-hard) from incomplete data. In fact, we prove how sampling based sketches can approximate the solutions for a large class of optimization problems (irrespective of their computational hardness) from limited number of observed data points.

For the above problems we want to derive probabilities using little or no global information about the data. The Bernstein distribution in Achlioptas et al. (2013b) requires additional information about row norms $\|\mathbf{A}_{(i)}\|_1$, as well as, optimal convex combinations ρ_i, for each row. In contrast, our distribution assumes only one real number α^*. This makes our optimal hybrid distribution more convenient for the above problems in practice.

• Finally, we propose Algorithm 3 to provably implement hybrid sampling using *only one pass* over the data. This is particularly useful in streaming setting where we receive data as a stream of numbers and we have only limited memory to store them. Note that Bernstein sampling of Achlioptas et al. (2013b) can be implemented in streaming setting as well; however, they need information (or estimates) of those global quantities beforehand. In contrast, we need no prior knowledge of parameter α which governs the sampling distribution. Surprisingly, we can set α^* (or its estimate) at a later stage of the sampling process when the stream terminates.

Extensive experimental results on image, text, biological, and financial data show that sketches using our optimal hybrid-(ℓ_1, ℓ_2) sampling achieve better quality of approximation to PCA and sparse PCA problems than either ℓ_1 or ℓ_2 sampling on their own. Moreover, we can speed up such

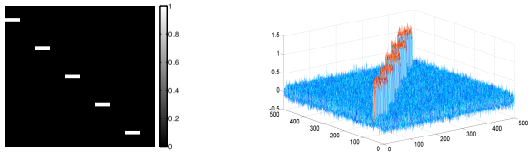

Figure 1: (left) Synthetic 500×500 binary data $\mathbf{D}$; (right) mesh view of noisy data $\mathbf{A}_{0.1}$.

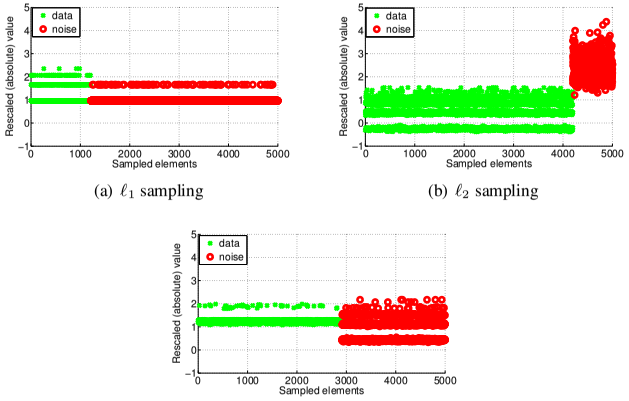
computations significantly using our sparse sketch. Finally, our results are comparable (if not better) than those of Achlioptas et al. (2013b) despite using significantly less information about the data.



1.4 A Motivating Example for Hybrid Sampling

The main motivation for introducing the idea of hybrid-(ℓ_1, ℓ_2) sampling comes from achieving a tighter bound on s using a simple and intuitive probability distribution on elements of $\mathbf{A}$. For this, we observe certain good properties of both ℓ_1 and ℓ_2 sampling for sparsification of noisy data (in practice, we experience data that are noisy, and it is perhaps impossible to separate "true" data from noise). We illustrate the behavior of ℓ_1 and ℓ_2 sampling on noisy data using the following synthetic example. We construct a 500×500 binary data $\mathbf{D}$ (FIGURE 1), and then perturb it by a random Gaussian matrix $\mathbf{N}$ whose elements $\mathbf{N}_{ij}$ follow Gaussian distribution with mean zero and standard deviation 0.1. We denote this perturbed data matrix by $\mathbf{A}_{0.1}$. First, we note that ℓ_1 and ℓ_2 sampling work *identically* on binary data $\mathbf{D}$. However, FIGURE 2 depicts the change in behavior of ℓ_1 and ℓ_2 sampling to sparsify $\mathbf{A}_{0.1}$. Data elements and noise in $\mathbf{A}_{0.1}$ are the elements with non-zero and zero values in $\mathbf{D}$, respectively. We sample $s = 5000$ indices in i.i.d. trials according to ℓ_1 and ℓ_2 probabilities separately to produce sparse sketch $\tilde{\mathbf{A}}$. FIGURE 2 shows that elements of $\tilde{\mathbf{A}}$, produced by ℓ_1 sampling, have controlled variance but most of them are noise. On the other hand, ℓ_2 sampling is biased towards data elements, although small number of sampled noisy elements create large variance due to rescaling. Such large magnitude noisy elements become outliers in $\tilde{\mathbf{A}}$; consequently, PCA on $\tilde{\mathbf{A}}$ becomes a poor approximation to the true PCA of $\mathbf{A}$. Our hybrid-(ℓ_1, ℓ_2) sampling benefits from this bias of ℓ_2 towards data elements to sample large number of true data. Additionally, the regularization property of ℓ_1 component prevents noisy elements to become outliers in $\tilde{\mathbf{A}}$ helping us to achieve near-PCA reconstruction.

We parameterize our distribution using the variable $\alpha \in (0, 1]$ that controls the balance between ℓ_2 sampling and ℓ_1 regularization. One can view α as a regularization parameter. We derive an expression to compute α^*, the optimal α, corresponding to the smallest sample size that we need to achieve an accuracy ϵ in (1). When $\alpha = 1$ we reproduce the result of Achlioptas et al. (2013a). However, α^* may be smaller than 1, and the bound on sample size, using α^*, is guaranteed to be tighter than that of Achlioptas et al. (2013a) and ℓ_2.

2. Main Results

We present the quality-of-approximation result of our main sampling algorithm (Algorithm 1). We sample some of the non-zero elements of the fixed matrix $\mathbf{A} \in \mathbb{R}^{m \times n}$ (and rescale them) to form a sparse matrix $\tilde{\mathbf{A}}$ that is close to $\mathbf{A}$ in spectral norm. It would be useful to interpret the sampling

(a) ℓ_1 sampling (b) ℓ_2 sampling

(c) Hybrid-(ℓ_1, ℓ_2) sampling

Figure 2: Elements of sparse sketch $\tilde{\mathbf{A}}$ produced from $\mathbf{A}_{0.1}$ by (a) ℓ_1, (b) ℓ_2, and (c) hybrid-(ℓ_1, ℓ_2), $\alpha = 0.7$ sampling. In each plot, x-axis is the number of sampled indices $s = 5000$, including both data and noise. y-axis plots the rescaled absolute values (in $\ln$ scale) of $\tilde{\mathbf{A}}$ corresponding to the sampled indices. ℓ_1 sampling produces elements with controlled variance but it mostly samples noise, whereas ℓ_2 samples a lot of data although producing large variance of rescaled elements. Hybrid-(ℓ_1, ℓ_2) sampling uses ℓ_1 as a regularizer while sampling fairly large number of data that helps to preserve the spectral structure of original data. Data and noisy elements are shown as clusters for better visualization.

of elements from $\mathbf{A}$ as follows. We can express $\mathbf{A}$ as a sum of matrices each having at most one non-zero element.

$$\mathbf{A} = \sum_{i,j=1}^{m,n} \mathbf{A}_{ij} \mathbf{e}_i \mathbf{e}_j^T, \quad \forall (i,j) \in [m] \times [n] \tag{4}$$

We sample (in i.i.d. trials) some of the terms in (4) according to some probability distribution $\{p_{ij}\}_{i,j=1}^{m,n}$ defined over the elements of $\mathbf{A}$ to form a (weighted) partial sum that represents our sparse sketch $\tilde{\mathbf{A}}$ of $\mathbf{A}$. More formally, we define the following sampling operator $\mathcal{S}_\Omega : \mathbb{R}^{m \times n} \to \mathbb{R}^{m \times n}$ in (5) that extracts some of the terms from (4). Let $\Omega \subset [m] \times [n]$ be a multi-set of sampled indices (i_t, j_t), for $t = 1, ..., s$. Then,

$$\tilde{\mathbf{A}} = \mathcal{S}_\Omega(\mathbf{A}) = \frac{1}{s} \sum_{t=1}^{s} \frac{\mathbf{A}_{i_t j_t}}{p_{i_t j_t}} \mathbf{e}_{i_t} \mathbf{e}_{j_t}^T, \quad (i_t, j_t) \in \Omega \tag{5}$$

Clearly, $\tilde{\mathbf{A}}$ in (5) is a sparse (at most s non-zero elements), unbiased estimator of $\mathbf{A}$. We use the sampling operator in (5) in Algorithm 1 to randomly sample (in i.i.d. trials) s elements of $\mathbf{A}$,

according to p_{ij}'s as in equation (3). In order to bound $\|\mathbf{A}-\tilde{\mathbf{A}}\|_2$ we first express $\mathbf{A}-\tilde{\mathbf{A}}$ as a sum of zero-mean, independent, random matrices, and then use the following matrix-Bernstein inequality in Lemma 1 (due to Recht 2011) that bounds the deviation of spectral norms of such matrices.

Lemma 1 *[Theorem 3.2 of Recht 2011] Let $\mathbf{M}_1, \mathbf{M}_2, ..., \mathbf{M}_s$ be independent, zero-mean random matrices in $\mathbb{R}^{m\times n}$. Suppose $\max_{t\in[s]}\left\{\|\mathbb{E}(\mathbf{M}_t\mathbf{M}_t^T)\|_2, \|\mathbb{E}(\mathbf{M}_t^T\mathbf{M}_t)\|_2\right\} \leq \rho^2$, and $\|\mathbf{M}_t\|_2 \leq \gamma$ for all $t \in [s]$. Then, for any $\epsilon > 0$, $\left\|\frac{1}{s}\sum_{t=1}^{s}\mathbf{M}_t\right\|_2 \leq \epsilon$ holds, subject to a failure probability at most $(m+n)\exp\left(\frac{-s\epsilon^2/2}{\rho^2+\gamma\epsilon/3}\right)$.*

A popular construction of $\mathbf{M}_t \in \mathbb{R}^{m\times n}$, $t \in [s]$, in Lemma 1 is $\mathbf{M}_t = \frac{\mathbf{A}_{i_tj_t}}{p_{i_tj_t}}\mathbf{e}_{i_t}\mathbf{e}_{j_t}^T - \mathbf{A}$ for $p_{i_tj_t} \neq 0$. Clearly, $\frac{1}{s}\sum_{t=1}^{s}\mathbf{M}_t = \tilde{\mathbf{A}} - \mathbf{A}$. We can see that ρ^2 and γ of Lemma 1 are now dependent on p_{ij} (Lemmas 8 and 9), i.e., different choices of p_{ij} lead to different bounds on ρ^2 and γ. Now, upper bounding the failure probability in Lemma 1 by $\delta > 0$, we can express the sample size s as a function of the key quantities ρ^2 and γ, and consequently as a function of p_{ij}:

$$s \geq \frac{2}{\epsilon^2}\cdot(\rho^2 + \gamma\epsilon/3)\cdot\ln((m+n)/\delta).$$

Since our choice of p_{ij} in (3) is a function of distribution parameter α, we essentially parameterize ρ^2 and γ by α, and express s as a function of α. Let us define $f(\alpha)$ as follows.

$$f(\alpha) = \rho^2(\alpha) + \gamma(\alpha)\epsilon\|\mathbf{A}\|_2/3,$$

where

$$\gamma(\alpha) = \max_{\substack{i,j,\\ \mathbf{A}_{ij}\neq 0}}\left\{\frac{\|\mathbf{A}\|_1}{\alpha + (1-\alpha)\frac{\|\mathbf{A}\|_1\cdot|\mathbf{A}_{ij}|}{\|\mathbf{A}\|_F^2}}\right\} + \|\mathbf{A}\|_2, \tag{6}$$

$$\rho^2(\alpha) = \max\left\{\max_i\sum_{j=1}^{n}\xi_{ij}(\alpha), \max_j\sum_{i=1}^{m}\xi_{ij}(\alpha)\right\} - \sigma_{min}^2, \tag{7}$$

$$\xi_{ij}(\alpha) = \|\mathbf{A}\|_F^2/\Big(\frac{\alpha\cdot\|\mathbf{A}\|_F^2}{|\mathbf{A}_{ij}|\cdot\|\mathbf{A}\|_1} + (1-\alpha)\Big), \mathbf{A}_{ij} \neq 0, \tag{8}$$

σ_{min} is the smallest singular value of $\mathbf{A}$. Such parameterization gives us a flexibility to express the sample size as a function of α: $s(\alpha) \propto f(\alpha)$. Naturally, we want to find $\alpha \in (0, 1]$ that results in the smallest $s(\alpha)$. The optimal α may be less than 1, and setting $\alpha = 1$ (in which case equation 3 coincides with ℓ_1 probabilities of Achlioptas et al. 2013a) may not produce the smallest s.

We can see that $\gamma(\alpha)$ prevents $f(\alpha)$ from blowing up (in case of sampling a tiny element of $\mathbf{A}$) by setting α away from 0 (this is a regularization step). Thus, $\rho^2(\alpha)$ becomes the dominating term in $f(\alpha)$ as $\gamma(\alpha)$ is multiplied by a small constant ϵ. We take a closer look at $\xi_{ij}(\alpha)$ as it is the key quantity in $\rho^2(\alpha)$ which is approximately the larger of the largest row sum or the largest column sum of $\xi_{ij}(\alpha)$. While minimizing $f(\alpha)$, α maintains a trade-off between the two terms $\frac{\alpha\cdot\|\mathbf{A}\|_F^2}{|\mathbf{A}_{ij}|\cdot\|\mathbf{A}\|_1}$ and $(1-\alpha)$ such that the maximum row sum or column sum of $\xi_{ij}(\alpha)$ gets smaller. Along row i or column j, for smaller $|\mathbf{A}_{ij}|$, we typically have $|\mathbf{A}_{ij}|\cdot\|\mathbf{A}\|_1 < \|\mathbf{A}\|_F^2$, and consequently $\alpha \to 1$ reduces $\rho^2(\alpha)$. On the other hand, for larger $|\mathbf{A}_{ij}|$ we have $|\mathbf{A}_{ij}|\cdot\|\mathbf{A}\|_1 > \|\mathbf{A}\|_F^2$ and α away from 1 is preferred to reduce $\rho^2(\alpha)$. Thus α plays an intricate role to reduce the overall sample size

Algorithm 1 Element-wise Matrix Sparsification

1: **Input:** $\mathbf{A} \in \mathbb{R}^{m\times n}$, accuracy $\epsilon > 0$.
2: **Set** s as in eq. (11).
3: **For** $t = 1 \ldots s$ (i.i.d. trials with replacement) **randomly sample** pairs of indices $(i_t, j_t) \in [m] \times [n]$ with $\mathbb{P}\left[(i_t, j_t) = (i, j)\right] = p_{ij}$, where p_{ij} are as in (3), using α as in (10).
4: **Output:** $\mathcal{S}_\Omega(\mathbf{A}) = \frac{1}{s}\sum_{t=1}^{s}\frac{\mathbf{A}_{i_tj_t}}{p_{i_tj_t}}\mathbf{e}_{i_t}\mathbf{e}_{j_t}^T$.

depending on the structure of the data. Note that for $\alpha = 1$ (as in Achlioptas et al. 2013a) we have $\xi_{ij}(\alpha) = |\mathbf{A}_{ij}|\cdot\|\mathbf{A}\|_1$. Therefore, for larger $|\mathbf{A}_{ij}|$ (true data points), maximum row sum or column sum of $\xi_{ij}(\alpha)$ lose the benefit of the delicate role played by $\alpha < 1$ to reduce those quantities, and they become larger than that for $\alpha < 1$. Thus, parameterization and optimization with α gives us a strictly smaller sample size than that of ℓ_1 or ℓ_2 sampling for the problem in (1).

Our main algorithm Algorithm 1 leads us to the following theorem.

Theorem 2 *Let $\mathbf{A} \in \mathbb{R}^{m\times n}$ and let $\epsilon > 0$ be an accuracy parameter. Let $\mathcal{S}_\Omega$ be the sampling operator defined in (5), and assume that the multi-set Ω is generated using sampling probabilities $\{p_{ij}\}_{i,j=1}^{m,n}$ as in (3). Then, with probability at least $1-\delta$, $\|\mathcal{S}_\Omega(\mathbf{A}) - \mathbf{A}\|_2 \leq \epsilon\|\mathbf{A}\|_2$, if*

$$s \geq \frac{2}{(\epsilon\|\mathbf{A}\|_2)^2}\cdot f(\alpha)\cdot\ln((m+n)/\delta). \tag{9}$$

Furthermore, we can find α^* (optimal α corresponding to the smallest s) by solving (10):

$$\alpha^* = \min_{\alpha\in(0,1]} f(\alpha), \tag{10}$$

and the corresponding optimal sample size is

$$s^* = \frac{2}{(\epsilon\|\mathbf{A}\|_2)^2}\cdot f(\alpha^*)\cdot\ln((m+n)/\delta). \tag{11}$$

For a given matrix $\mathbf{A}$, we can easily compute $\rho^2(\alpha)$ and $\gamma(\alpha)$ for various values of α. Given an accuracy ϵ and failure probability δ, we can compute α^* corresponding to the tightest bound on s. Note that, for $\alpha = 1$ we reproduce the results of Achlioptas et al. (2013a) (which was expressed using various matrix metrics). However, α^* may be smaller than 1, and is guaranteed to produce tighter s comparing to extreme choices of α (e.g. $\alpha = 1$ for ℓ_1). We illustrate this in FIGURE 3. We give a proof of Theorem 2 in APPENDIX A.

2.1 Approximation of PCA via Element Sampling

The top-k principal components of centered data $\mathbf{A} \in \mathbb{R}^{m\times n}$ (m data points in n dimensions), denoted by $\mathbf{V}_k \in \mathbb{R}^{n\times k}$, can be formulated as the solution to the variance maximization problem:

$$\mathbf{V}_k = \operatorname*{argmax}_{\mathbf{V}\in\mathbb{R}^{n\times k}, \mathbf{V}^T\mathbf{V}=\mathbf{I}} \operatorname{trace}(\mathbf{V}^T\mathbf{A}^T\mathbf{A}\mathbf{V}). \tag{12}$$

The maximum variance achievable using $\mathbf{V}_k$, denoted by OPT_k, is the sum of squares of the top-k singular values of $\mathbf{A}$. Note that in (12) the optimal solution is computed using the full data $\mathbf{A}$ (which is typically dense).

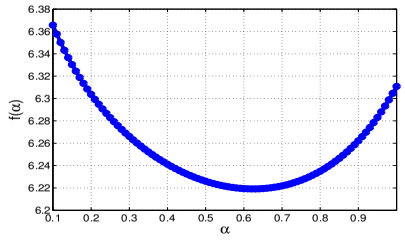


Figure 3: Plot of $f(\alpha)$ in eqn. (10) for data $\mathbf{A}_{0.1}$. We use $\epsilon = 0.05$ and $\delta = 0.1$. x-axis plots α and y-axis is in log scale.

Algorithm 2 Approximation of PCA from Data Samples

1: **Input:** Centered data $\mathbf{A} \in \mathbb{R}^{m\times n}$, sparsity parameter $s > 0$, and rank parameter k.
2: Produce sparse unbiased sketch $\tilde{\mathbf{A}}$ from $\mathbf{A}$, in s i.i.d. trials using Algorithm 1[1].
3: Perform rank truncated SVD on matrix $\tilde{\mathbf{A}}$, i.e., $[\tilde{\mathbf{U}}_k, \tilde{\mathbf{D}}_k, \tilde{\mathbf{V}}_k]$ = SVD($\tilde{\mathbf{A}}$, k).
4: **Output:** $\tilde{\mathbf{V}}_k$ (columns of $\tilde{\mathbf{V}}_k$ are the ordered principal components).

Here we discuss a provable algorithm (Algorithm 2) to approximate PCA by applying element-wise sampling. We produce a sparse unbiased estimator $\tilde{\mathbf{A}}$ of centered data $\mathbf{A}$ by sampling s elements in i.i.d. trials according to our hybrid-(ℓ_1, ℓ_2) distribution in (3). We use this $\tilde{\mathbf{A}}$ instead of $\mathbf{A}$ in (12) to compute the new optimal solution $\tilde{\mathbf{V}}_k$

$$\tilde{\mathbf{V}}_k = \underset{\mathbf{V}\in\mathbb{R}^{n\times k}, \mathbf{V}^T\mathbf{V}=\mathbf{I}}{\text{argmax}} \text{trace}(\mathbf{V}^T\tilde{\mathbf{A}}^T\tilde{\mathbf{A}}\mathbf{V}). \tag{13}$$

The computation of rank-truncated SVD on sparse data requires fewer floating point operations (therefore can be fast), and we consider the right singular vectors $\tilde{\mathbf{V}}_k$ of $\tilde{\mathbf{A}}$ as the approximate principal components of $\mathbf{A}$. Naturally, more samples produce better approximation. However, this reduces sparsity, consequently we may lose the speed advantage. Theorem 3 shows the quality of approximation of principal components produced by Algorithm 2.

Theorem 3 *Let $\mathbf{A} \in \mathbb{R}^{m\times n}$ be a given matrix, and $\tilde{\mathbf{A}}$ be a sparse sketch produced by Algorithm 1. Let $\tilde{\mathbf{V}}_k$ be the PCA's of $\tilde{\mathbf{A}}$ computed in step 3 of Algorithm 2. Then*

1) $\|\mathbf{A} - \mathbf{A}\tilde{\mathbf{V}}_k\tilde{\mathbf{V}}_k{}^T\|_F^2 \le \|\mathbf{A} - \mathbf{A}_k\|_F^2 + 4\|\mathbf{A}_k\|_F^2 \cdot \|\mathbf{A} - \tilde{\mathbf{A}}\|_2/\sigma_k(\mathbf{A})$,
2) $\|\mathbf{A}_k - \tilde{\mathbf{A}}_k\|_F \le \sqrt{8k}\cdot(\|\mathbf{A} - \mathbf{A}_k\|_2 + \|\mathbf{A} - \tilde{\mathbf{A}}\|_2)$,
3) $\|\mathbf{A} - \tilde{\mathbf{A}}_k\|_F \le \|\mathbf{A} - \mathbf{A}_k\|_F + \sqrt{8k}\cdot(\|\mathbf{A} - \mathbf{A}_k\|_2 + \|\mathbf{A} - \tilde{\mathbf{A}}\|_2)$.

1. Here we avoid computing $\|\mathbf{A}\|_2$ directly and instead upper bound it by $\|\mathbf{A}\|_F$ in $\gamma(\alpha)$ in Lemma 8. In (10) $\rho^2(\alpha)$ is the dominating term (we ignore $\sigma_{\min}$ as it is typically very small) and $\gamma(\alpha)$ is multiplied by a small constant ϵ; thus in reality such relaxation of $\gamma(\alpha)$ and $\rho^2(\alpha)$ has little effect on α^* (we verified it experimentally). However, we refer to the α that we get using the above as near-optimal.

The first inequality of Theorem 3 bounds the approximation of projected data onto the space spanned by top k approximate principal components. The second and third inequalities measure the quality of $\tilde{\mathbf{A}}_k$ as a surrogate for $\mathbf{A}_k$ and the quality of projection of sparsified data onto approximate principal components, respectively. The proofs of first two inequalities of Theorem 3 follow from Theorem 5 and Theorem 8 of Achlioptas and McSherry (2001), respectively. The last inequality follows from the triangle inequality. The last two inequalities above are particularly useful in cases where $\mathbf{A}$ is inherently low-rank and we choose an appropriate k for which $\|\mathbf{A} - \mathbf{A}_k\|_2$ is small.

2.2 Approximating Sparse PCA from Incomplete Data

PCA constructs a low dimensional subspace of the data such that projection of the data onto this subspace preserves as much information as possible. However a shortcoming of PCA is the interpretation of the principal components (or factors) as they can be linear combinations of *all* the original variables. In many cases the original variables have direct physical significance (e.g. genes in biological applications or assets in financial applications). In such cases it is desirable to have factors which have loadings on only a small number of the original variables. These interpretable factors are sparse principal components (SPCA). To derive sparse principal components, we add a sparsity constraint to the optimization problem (see equation 14): every column of $\mathbf{V}$ should have at most r non-zero entries (r is an input parameter),

$$\mathbf{S}_k = \underset{\mathbf{V}\in\mathbb{R}^{n\times k}, \mathbf{V}^T\mathbf{V}=\mathbf{I}, \|\mathbf{V}^{(i)}\|_0\le r}{\text{argmax}} \text{trace}(\mathbf{V}^T\mathbf{A}^T\mathbf{A}\mathbf{V}). \tag{14}$$

The sparse PCA problem is not only NP-hard, but also inapproximable (Magdon-Ismail 2017). There are many heuristics for obtaining sparse factors (Cadima and Jolliffe, 1995; Trendafilov et al., 2003; Zou et al., 2006; d'Aspremont et al., 2007, 2008; Moghaddam et al., 2006; Shen and Huang, 2008) including some approximation algorithms with provable guarantees Asteris et al. (2014). The existing research typically addresses the task of getting just the top principal component ($k = 1$) (some exceptions are Ma 2013; Cai et al. 2013; Wang et al. 2014; Lei and Vu 2015). While the sparse PCA problem is hard and interesting, it is *not* the focus of this work.

We address the question: What if we do not know $\mathbf{A}$, but only have a sparse sampling of some of the entries in $\mathbf{A}$ (incomplete data)? The sparse sampling is used to construct a *sketch* of $\mathbf{A}$, denoted $\tilde{\mathbf{A}}$. There is not much else to do but solve the sparse PCA problem with the sketch $\tilde{\mathbf{A}}$ instead of the full data $\mathbf{A}$ to get $\tilde{\mathbf{S}}_k$,

$$\tilde{\mathbf{S}}_k = \underset{\mathbf{V}\in\mathbb{R}^{n\times k}, \mathbf{V}^T\mathbf{V}=\mathbf{I}, \|\mathbf{V}^{(i)}\|_0\le r}{\text{argmax}} \text{trace}(\mathbf{V}^T\tilde{\mathbf{A}}^T\tilde{\mathbf{A}}\mathbf{V}). \tag{15}$$

We study how $\tilde{\mathbf{S}}_k$ performs as an approximation to $\mathbf{S}_k$ with respective to the objective that we are trying to optimize, namely trace($\mathbf{S}^T\mathbf{A}^T\mathbf{A}\mathbf{S}$) — the quality of approximation is measured with respect to the true $\mathbf{A}$. We show that the quality of approximation is controlled by how well $\tilde{\mathbf{A}}^T\tilde{\mathbf{A}}$ approximates $\mathbf{A}^T\mathbf{A}$ as measured by the spectral norm of the deviation $\mathbf{A}^T\mathbf{A} - \tilde{\mathbf{A}}^T\tilde{\mathbf{A}}$. This is a general result that does not rely on how one constructs the sketch $\tilde{\mathbf{A}}$.

Lemma 4 (Sparse PCA from a Sketch) *Let $\mathbf{S}_k$ be a solution to the sparse PCA problem that solves (14), and $\tilde{\mathbf{S}}_k$ a solution to the sparse PCA problem for the sketch $\tilde{\mathbf{A}}$ which solves (15). Then,*

$$\textit{trace}(\tilde{\mathbf{S}}_k{}^T\mathbf{A}^T\mathbf{A}\tilde{\mathbf{S}}_k) \ge \textit{trace}(\mathbf{S}_k{}^T\mathbf{A}^T\mathbf{A}\mathbf{S}_k) - 2k\|\mathbf{A}^T\mathbf{A} - \tilde{\mathbf{A}}^T\tilde{\mathbf{A}}\|_2.$$

Lemma 4 says that if we can closely approximate $\mathbf{A}$ with $\tilde{\mathbf{A}}$, then we can compute, from $\tilde{\mathbf{A}}$, sparse components which capture almost as much variance as the optimal sparse components computed from the full data $\mathbf{A}$. We prove that Lemma 4 follows as a corollary of a more general result given in Theorem 10.

In our setting, the sketch $\tilde{\mathbf{A}}$ is computed from a sparse sampling of the data elements in $\mathbf{A}$ (incomplete data). We use probabilities of the form in (3) to determine which elements to sample and how to form the sketch such that the error $\|\mathbf{A}^T\mathbf{A} - \tilde{\mathbf{A}}^T\tilde{\mathbf{A}}\|_2$ is small. We can simplify this quantity in terms of $\|\mathbf{A} - \tilde{\mathbf{A}}\|_2$ as follows. Let $\Delta = \mathbf{A} - \tilde{\mathbf{A}}$.

$$\|\mathbf{A}^T\mathbf{A} - \tilde{\mathbf{A}}^T\tilde{\mathbf{A}}\|_2 = \|\mathbf{A}^T\Delta + \Delta^T\mathbf{A} - \Delta^T\Delta\|_2 \leq 2\|\mathbf{A}\|_2\|\Delta\|_2 + \|\Delta\|_2^2. \tag{16}$$

We combine the bound on $\|\mathbf{A} - \tilde{\mathbf{A}}\|_2$ for given accuracy ϵ/k from Theorem 2 with Lemma 4 to derive $k\|\mathbf{A}^T\mathbf{A} - \tilde{\mathbf{A}}^T\tilde{\mathbf{A}}\|_2 \leq \epsilon(2 + \epsilon/k)\|\mathbf{A}\|_2^2$ with a sample size $s = k^2 \cdot s^*$ where s^* as in (11). However, we simplify this bound for a better interpretation of s in terms matrix dimensions m and n and stable rank $\tilde{k} = \|\mathbf{A}\|_F^2/\|\mathbf{A}\|_2^2$. Note that $\|\mathbf{A}\|_1 \leq \sqrt{mn}\|\mathbf{A}\|_F$ from Cauchy-Schwartz. Then,

$$\gamma(\alpha)/\|\mathbf{A}\|_2 \leq 1 + \|\mathbf{A}\|_1/(\alpha\|\mathbf{A}\|_2) \leq 1 + \sqrt{mn\tilde{k}}/\alpha = \hat{\gamma}. \tag{17}$$

Also, from $|\mathbf{A}_{ij}| \leq \|\mathbf{A}\|_2$, $\rho^2(\alpha)$ in (7) can be simplified as

$$\xi_{ij}(\alpha) \leq \|\mathbf{A}\|_F^2\Big(\alpha\tilde{k}\|\mathbf{A}\|_2/\|\mathbf{A}\|_1 + (1-\alpha)\Big)^{-1}, \tag{18}$$

$$\rho^2(\alpha)/\|\mathbf{A}\|_2^2 \leq \max\{m,n\}\tilde{k}\Big(\alpha\tilde{k}\|\mathbf{A}\|_2/\|\mathbf{A}\|_1 + (1-\alpha)\Big)^{-1} = \hat{\rho}^2. \tag{19}$$

Using the above relaxations we have the following theorem on sample size complexity.

Theorem 5 (Sampling Complexity for Sparse PCA) *Sample s data-elements from $\mathbf{A} \in \mathbb{R}^{m\times n}$ to form the sparse sketch $\tilde{\mathbf{A}}$ using Algorithm 1. Let $\mathbf{S}_k$ be a solution to the sparse PCA problem that solves (14), and let $\tilde{\mathbf{S}}_k$, which solves (15), be a solution to the sparse PCA problem for the sketch $\tilde{\mathbf{A}}$ formed from the s sampled data elements. Suppose the number of samples s satisfies*

$$s \geq 2k^2\epsilon^{-2}(\hat{\rho}^2 + \epsilon\hat{\gamma}/(3k))\log((m+n)/\delta),$$

($\hat{\rho}^2$ and $\hat{\gamma}$ are dimensionless quantities that depend only on $\mathbf{A}$). Then, with probability at least $1-\delta$

$$\mathit{trace}(\tilde{\mathbf{S}}_k{}^T\mathbf{A}^T\mathbf{A}\tilde{\mathbf{S}}_k) \geq \mathit{trace}(\mathbf{S}_k{}^T\mathbf{A}^T\mathbf{A}\mathbf{S}_k) - 2\epsilon(2+\epsilon/k)\|\mathbf{A}\|_2^2.$$

The dependence of $\hat{\rho}^2$ and $\hat{\gamma}$ on $\mathbf{A}$ are given in (17) and (19), respectively. Roughly speaking, we can ignore the term with $\hat{\gamma}$ since it is multiplied by ϵ/k, and we have $\hat{\rho}^2 = O(\tilde{k}\max\{m,n\})$. To paraphrase Theorem 5, when the stable rank $\tilde{k}$ is a small constant, with $O(k^2\max\{m,n\})$ samples, one can recover almost as good sparse principal components as with all data (a possible price being a small fraction of the optimal variance, since $OPT_k \geq \|\mathbf{A}\|_2^2$). As far as we know, the only prior work related to the problem we consider here is Lounici (2013) which proposed a specific method to construct sparse PCA from incomplete data. However, we develop a general tool that can be used with any existing sparse PCA heuristic. Moreover, we derive much simpler bounds (Theorems 4 and 5) using matrix concentration inequalities, as opposed to ϵ-net arguments in Lounici (2013).

2.2.1 SPARSE SKETCH USING GREEDY THRESHOLD

We also give an application of Lemma 4 to run sparse PCA after "denoising" the data using a greedy thresholding algorithm that sets the small elements to zero (see Theorem 6). Such denoising is appropriate when the observed matrix has been element-wise perturbed by small noise, and the uncontaminated data matrix is sparse and contains large elements. We show that if an appropriate fraction of the (noisy) data is set to zero, one can still recover sparse principal components. This gives a principled approach to regularizing sparse PCA in the presence of small noise when the data is sparse.

We give the simplest scenario of incomplete data where Lemma 4 gives some reassurance that one can compute good sparse principal components. Suppose the smallest data elements have been set to zero. This can happen, for example, if only the largest elements are measured, or in a noisy setting if the small elements are treated as noise and set to zero. So

$$\tilde{\mathbf{A}}_{ij} = \begin{cases} \mathbf{A}_{ij} & |\mathbf{A}_{ij}| \geq \delta, \\ 0 & |\mathbf{A}_{ij}| < \delta. \end{cases}$$

Recall $\tilde{k} = \|\mathbf{A}\|_F^2/\|\mathbf{A}\|_2^2$ (stable rank of $\mathbf{A}$), and define $\|\mathbf{A}_\delta\|_F^2 = \sum_{|\mathbf{A}_{ij}|<\delta}\mathbf{A}_{ij}^2$. Let $\Delta = \mathbf{A} - \tilde{\mathbf{A}}$. By construction, $\|\Delta\|_F^2 = \|\mathbf{A}_\delta\|_F^2$ and $\|\mathbf{A}^T\mathbf{A} - \tilde{\mathbf{A}}^T\tilde{\mathbf{A}}\|_2 \leq 2\|\mathbf{A}\|_2\|\Delta\|_2 + \|\Delta\|_2^2$ from (16). Suppose the zeroing of elements only loses a fraction of the energy in $\mathbf{A}$, i.e. δ is selected so that $\|\mathbf{A}_\delta\|_F^2 \leq \epsilon^2\|\mathbf{A}\|_F^2/\tilde{k}$; that is an $\epsilon/\tilde{k}$ fraction of the total variance in $\mathbf{A}$ has been lost in the unmeasured (or zero) data. Then $\|\Delta\|_2 \leq \|\Delta\|_F \leq \epsilon\|\mathbf{A}\|_F/\sqrt{\tilde{k}} = \epsilon\|\mathbf{A}\|_2$.

Theorem 6 *Suppose that $\tilde{\mathbf{A}}$ is created from $\mathbf{A}$ by zeroing all elements that are less than δ, and δ is such that the truncated norm satisfies $\|\mathbf{A}_\delta\|_2^2 \leq \epsilon^2\|\mathbf{A}\|_F^2/\tilde{k}$. Then the sparse PCA solution $\tilde{\mathbf{V}}^*$ satisfies*

$$\mathit{trace}(\tilde{\mathbf{V}}^{*T}\mathbf{A}\mathbf{A}\tilde{\mathbf{V}}^*) \geq \mathit{trace}(\mathbf{V}^{*T}\mathbf{A}\mathbf{A}^T\mathbf{V}^*) - 2k\epsilon\|\mathbf{A}\|_2^2(2+\epsilon).$$

Theorem 6 shows that it is possible to recover sparse PCA after setting small elements to zero. This is appropriate when most of the elements in $\mathbf{A}$ are small noise and a few of the elements in $\mathbf{A}$ contain large data elements. For example if the data consists of sparse $O(\sqrt{nm})$ large elements (of magnitude, say 1) and many $nm - O(\sqrt{nm})$ small elements whose magnitude is $o(1/\sqrt{nm})$ (high signal-to-noise setting), then $\|\mathbf{A}_\delta\|_2^2/\|\mathbf{A}\|_2^2 \to 0$ and with just a sparse sampling of the $O(\sqrt{nm})$ large elements (very incomplete data), we recover near optimal sparse PCA.

Not only do our algorithms preserve the quality of the sparse principal components, but iterative algorithms for sparse PCA, whose running time is proportional to the number of non-zero entries in the input matrix, benefit from the sparsity of $\tilde{\mathbf{A}}$. Our experiments show about five-fold speed gains while producing near-comparable sparse components using less than 10% of the data.

2.3 One-pass Hybrid-(ℓ_1, ℓ_2) Sampling

Here we discuss the implementation of hybrid-(ℓ_1, ℓ_2) sampling in one pass over the input matrix $\mathbf{A}$ using $O(s)$ memory, e.g., a streaming model. Here we propose an algorithm, Algorithm 3, to implement a one-pass version of the hybrid sampling *without a priori knowledge of the regularization parameter* α.

We use SELECT-s algorithm (Algorithm 5 in APPENDIX F) to implement one-pass ℓ_1 and ℓ_2 sampling. We note that steps 2-3 of Algorithm 3 access the elements of $\mathbf{A}$ only once, in parallel,

Algorithm 3 One-pass hybrid sampling

1: **Input:** $\mathbf{A}_{ij}$ for all $(i,j) \in [m] \times [n]$, arbitrarily ordered, and sample size s.
2: Apply SELECT-s algorithm (Algorithm 5) using ℓ_1 probabilities to sample s independent indices (i_{t_1}, j_{t_1}) and corresponding values $\mathbf{A}_{i_{t_1} j_{t_1}}$ to form random multiset S_1 of triples $(i_{t_1}, j_{t_1}, \mathbf{A}_{i_{t_1} j_{t_1}})$, for $t_1 = 1, ..., s$.
3: Apply SELECT-s algorithm using ℓ_2 probabilities to sample s independent indices (i_{t_2}, j_{t_2}) and corresponding values $\mathbf{A}_{i_{t_2} j_{t_2}}$ to form random multiset S_2 of triples $(i_{t_2}, j_{t_2}, \mathbf{A}_{i_{t_2} j_{t_2}})$, for $t_2 = 1, ..., s$.
4: Store $\|\mathbf{A}\|_F^2$ and $\|\mathbf{A}\|_1$ /* these are already computed in SELECT-s algorithms above */
5: /* stream terminates */
6: Set the value of $\alpha \in (0, 1]$ (say, using Algorithm 4).
7: Create empty multiset of triples S.
8: $\mathbf{X} \leftarrow \mathbf{0}_{m \times n}$.
9: **For** $t = 1 \dots s$
10: Generate a uniform random number $x \in [0, 1]$.
11: if $x \leq \alpha$, $S(t) \leftarrow S_1(t)$; otherwise, $S(t) \leftarrow S_2(t)$.
12: $(i_t, j_t) \leftarrow S(t, 1:2)$.
13: $p \leftarrow \alpha \cdot \frac{|S(t,3)|}{\|\mathbf{A}\|_1} + (1-\alpha) \cdot \frac{|S(t,3)|^2}{\|\mathbf{A}\|_F^2}$
14: $\mathbf{X} \leftarrow \mathbf{X} + \frac{S(t,3)}{p \cdot s} e_{i_t} e_{j_t}^T$.
15: **End**
16: **Output:** random multiset S, and sparse matrix $\mathbf{X}$.

to form independent multisets S_1 and S_2. We store $\|\mathbf{A}\|_F^2$ and $\|\mathbf{A}\|_1$ already computed in steps 2-3. Subsequent steps do not need further access to $\mathbf{A}$. Interestingly, we set α in step 6 when the data stream terminates. Steps 9-15 sample s elements from S_1 and S_2 using the α in step 6, and produces a sparse matrix $\mathbf{X}$ using the sampled entries in multiset S. Theorem 7 proves that Algorithm 3 indeed samples elements of $\mathbf{A}$ according to the hybrid-(ℓ_1, ℓ_2) probabilities in (3).

Theorem 7 *Using the same notations as in Algorithm 3, for $\alpha \in (0, 1]$, $t = 1, ..., s$,*

$$P\left[S(t) = (i, j, \mathbf{A}_{ij})\right] = \alpha \cdot \frac{|\mathbf{A}_{ij}|}{\|\mathbf{A}\|_1} + (1-\alpha) \cdot \frac{\mathbf{A}_{ij}^2}{\|\mathbf{A}\|_F^2}.$$

See proof in APPENDIX E. Note that, Theorem 7 holds for any arbitrary $\alpha \in (0, 1]$ in line 7 of Algorithm 3, i.e., Algorithm 4 is not essential for correctness of Theorem 7. We only need α to be independent of the elements of S_1 and S_2. However, we can use Algorithm 4 to get a good estimate of α^* (SECTION 2.3.1). In this case, we need additional independent samples from $\mathbf{A}$ to 'learn' the parameter α^*.

2.3.1 ESTIMATE OF α^* FROM SAMPLES

Here we discuss Algorithm 4, to estimate α^* from samples of $\mathbf{A}$ and few other quantities, such as, $\|\mathbf{A}\|_F$, $\|\mathbf{A}\|_1$, and $\mathbf{A}_{min}$, where $\mathbf{A}_{min}$ is defined as

$$\mathbf{A}_{min} = \min_{\substack{i,j: \\ \mathbf{A}_{ij} \neq 0}} |\mathbf{A}_{ij}|.$$

Algorithm 4 Estimating α^* from Samples

1: **Input:** Ω, the set of triples $\{(i, j, \mathbf{A}_{ij})\}$ where each $\mathbf{A}_{ij}$ is sampled with probability p_{ij} (say $p_{ij} = |\mathbf{A}_{ij}| / \|\mathbf{A}\|_1$), accuracy ε, $\mathbf{A}_{min}$, $\|\mathbf{A}\|_F^2$, $\|\mathbf{A}\|_1$, and matrix dimensions m and n.
2: Compute $\tilde{\gamma}(\alpha)$ as in equation (20) and $\tilde{\xi}_{ij}(\alpha)$ as in equation (21), for a given α.
3: **Output:** $\tilde{\alpha}$ in equation (23).

Let Ω be a set of sampled triples $\{(i, j, \mathbf{A}_{ij})\}$ where each $\mathbf{A}_{ij}$ is sampled with probability p_{ij} (e.g., $p_{ij} = |\mathbf{A}_{ij}| / \|\mathbf{A}\|_1$). Let us define, for a fixed α,

$$\tilde{\gamma}(\alpha) = \max_{\substack{i,j: \\ \mathbf{A}_{ij} \neq 0}} \left\{ \frac{\|\mathbf{A}\|_1}{\alpha + (1-\alpha) \frac{\|\mathbf{A}\|_1 \cdot |\mathbf{A}_{ij}|}{\|\mathbf{A}\|_F^2}} \right\} + \|\mathbf{A}\|_F = \frac{\|\mathbf{A}\|_1}{\alpha + (1-\alpha) \frac{\|\mathbf{A}\|_1}{\|\mathbf{A}\|_F^2} \cdot \mathbf{A}_{min}} + \|\mathbf{A}\|_F. \quad (20)$$

Note that, $\tilde{\gamma}(\alpha)$ can be computed using only one pass over the data. Further, we define the following random variable (parameterized by α)

$$\tilde{\xi}_{ij}(\alpha) \;=\; \frac{\|\mathbf{A}\|_F^2}{\frac{\alpha \cdot \|\mathbf{A}\|_F^2}{|\mathbf{A}_{ij}| \cdot \|\mathbf{A}\|_1} + (1-\alpha)} \cdot \delta_{ij}, \quad (21)$$

where δ_{ij} is an indicator function defined as $\delta_{ij} := \mathbb{I}((i, j, \mathbf{A}_{ij}) \in \Omega)$. Note that, $\delta_{ij} = 1$ w.p. p_{ij}, and 0 otherwise. For a given column j, we define the following random variable $\tilde{Y}_j(\alpha)$:

$$\tilde{Y}_j(\alpha) = \sum_{i=1}^{m} \tilde{\xi}_{ij}(\alpha).$$

Similarly, for a given row i, we define $\tilde{Y}_i(\alpha) = \sum_{j=1}^{n} \tilde{\xi}_{ij}(\alpha)$. Finally, we define

$$\tilde{\rho}^2(\alpha) = \max\{\max_j \tilde{Y}_j(\alpha), \max_i \tilde{Y}_i(\alpha)\}. \quad (22)$$

Using the above quantities we solve the optimization problem in (23) and use the solution as an estimate for α^*.

$$\tilde{\alpha} : \min_{\alpha \in (0,1]} \quad \tilde{\rho}^2(\alpha) + \tilde{\gamma}(\alpha)\varepsilon/3. \quad (23)$$

Note that, $\tilde{\gamma}(\alpha)$ in equation (20) closely approximates $\gamma(\alpha)$ in equation (6), where the error of approximation is $\|\mathbf{A}\|_F - \|\mathbf{A}\|_2$. This error becomes small in equation (23) as $\tilde{\gamma}(\alpha)$ is multiplied by a small quantity $\varepsilon/3$. Next we analyze how well $\tilde{\xi}_{ij}(\alpha)$ approximates $\xi_{ij}(\alpha)$ using a simplified data model. For this we assume $|\mathbf{A}_{ij}| \in \{L, \epsilon, 0\}$, where $L \gg \epsilon > 0$, and let s_L and s_ϵ be the number of elements with magnitudes L and ϵ, respectively. Also, let the minimum singular value $\sigma_{\min} \approx 0$. For $(i, j, \mathbf{A}_{ij}) \in \Omega$ and $|\mathbf{A}_{ij}| = \epsilon$ (which is unlikely), $|\mathbf{A}_{ij}| \cdot \|\mathbf{A}\|_1 \ll \|\mathbf{A}\|_F^2$; consequently $\tilde{\xi}_{ij}(\alpha)$ is small and does not contribute much to $\tilde{Y}_j(\alpha)$ (or $\tilde{Y}_i(\alpha)$). On the other hand, for $(i, j, \mathbf{A}_{ij}) \in \Omega$ and $|\mathbf{A}_{ij}| = L$ (which is very likely), $|\mathbf{A}_{ij}| \cdot \|\mathbf{A}\|_1 \gg \|\mathbf{A}\|_F^2$, and consequently $\tilde{\xi}_{ij}(\alpha)$ contributes significantly to $\tilde{Y}_j(\alpha)$ (or $\tilde{Y}_i(\alpha)$). So, if we sample s_L number of such large elements $\tilde{\rho}^2(\alpha)$ is close to $\rho^2(\alpha)$, and $\tilde{\alpha} \approx \alpha^*$. Finally, note that Algorithm 4 can be implemented using only one-pass over the data. Experimental results on real data validate the quality of Algorithm 4.

3. Experiments

We perform various element-wise sampling on synthetic and real data to show how well the sparse sketches preserve the structure of the original data, in spectral norm. Also, we show results on the quality and computation time of the principal components and sparse principal components derived from sparse sketches.

3.1 Algorithms for Sparse Sketches

Algorithm 1 is our prototypical algorithm to produce (unbiased) sparse sketches $\tilde{\mathbf{A}}$ from a given matrix via various sampling methods. We construct our sparse sketch using our optimal hybrid-(ℓ_1, ℓ_2) probabilities, and compare its quality with other sketches produced via ℓ_1 and ℓ_2 sampling. We borrow same definitions from (Achlioptas et al. 2013a) for comparing our results with ℓ_1 sampling.

$$\mathrm{nd}(\mathbf{A}) := \frac{\|\mathbf{A}\|_1^2}{\|\mathbf{A}\|_F^2}, \quad \mathrm{rs}_0(\mathbf{A}) := \frac{\max_i \|\mathbf{A}_{(i)}\|_0}{\|\mathbf{A}\|_0/m}, \quad \mathrm{rs}_1(\mathbf{A}) := \frac{\max_i \|\mathbf{A}_{(i)}\|_1}{\|\mathbf{A}\|_1/m},$$

where nd is numeric density and rs is row density skewness. Achlioptas et al. (2013a) argues that ℓ_1 outperforms ℓ_2 sampling when $\mathrm{rs}_0 > \mathrm{rs}_1$. We compute the theoretical optimal mixing parameter α^* by solving (10) for various datasets [2], and compare this α^* with the theoretical condition derived by Achlioptas et al. (2013a). Further, we verify the accuracy of α^* by measuring $\mathcal{E} = \|\mathbf{A} - \tilde{\mathbf{A}}\|_2 / \|\mathbf{A}\|_2$ for distributions corresponding to various α, for a given sample size s [3]. We expect $\mathcal{E}$ to be the smallest for $\alpha \approx \alpha^*$ rather than $\alpha = 1$ (ℓ_1) or $\alpha \approx 0$ (ℓ_2).

3.2 Algorithms for PCA from Sparse Sketches

We first compare three algorithms for computing PCA of the centered data $\mathbf{A}$. Let the actual PCA of the original data be $\mathcal{A}$. We use Algorithm 2 to compute approximate PCA from random samples via our optimal hybrid-(ℓ_1, ℓ_2) sampling. Let us denote this approximate PCA by $\mathcal{H}$. Also, we compute PCA of a Gaussian random projection of the original data to compare its quality with $\mathcal{H}$. Let $\mathbf{A}_G = \mathbf{G}\mathbf{A} \in \mathbb{R}^{r \times n}$, where $\mathbf{A} \in \mathbb{R}^{m \times n}$ is the original data, and $\mathbf{G}$ is a $r \times m$ standard Gaussian matrix. Let the PCA of this random projection $\mathbf{A}_G$ be $\mathcal{G}$. The quality of various PCA is determined by measuring how much variance of the data they can capture (as in equation 12). For this, let σ_k, σ_h, and σ_g denote the variance preserved by $\mathcal{A}$, $\mathcal{H}$, and $\mathcal{G}$, respectively. Note that, $\mathcal{A}$ and $\mathcal{G}$ require access to the full data, while $\mathcal{H}$ is computed from only few samples of $\mathbf{A}$. Also, we compare the computation time (in milliseconds) t_a, t_h, and t_G for $\mathcal{A}$, $\mathcal{H}$, and $\mathcal{G}$, respectively.

Finally, we compare the quality of our optimal hybrid sampling with ℓ_1 sampling and Bernstein sampling (Achlioptas et al. 2013b) by quantifying the variance, σ_{ℓ_1} and σ_b, preserved by the corresponding sparse sketches.

3.3 Algorithms for Approximate Sparse PCA from Sketches

We show the experimental results for sparse PCA from a sketch using several real data matrices. As we mentioned, sparse PCA is NP-Hard, and so we use heuristics. These heuristics are discussed next, followed by the data, the experimental design and finally the results.

2. we find α^* from the plot of $f(\alpha)$ for $\alpha \in [0.1, 1]$.
3. here we use $\mathbf{A}$, s, and α as input to Algorithm 1 to form $\tilde{\mathbf{A}}$ by s i.i.d samples from p_{ij} in (3) for given α.

Let $\mathcal{G}$ (ground truth) denote the algorithm which computes the principal components (which may not be sparse) of the full data matrix $\mathbf{A}$; the optimal variance is OPT_k. We consider six heuristics for getting sparse principal components.

$\mathcal{G}_{\mathrm{max},r}$	The r largest-magnitude entries in each principal component generated by $\mathcal{G}$.
$\mathcal{G}_{\mathrm{sp},r}$	r-sparse components using the *Spasm* toolbox of Sjstrand et al. (2012) with $\mathbf{A}$.
$\mathcal{H}_{\mathrm{max},r}$	The r largest entries of the principal components for the (ℓ_1, ℓ_2)-sampled sketch $\tilde{\mathbf{A}}$.
$\mathcal{H}_{\mathrm{sp},r}$	r-sparse components using *Spasm* with the (ℓ_1, ℓ_2)-sampled sketch $\tilde{\mathbf{A}}$.
$\mathcal{U}_{\mathrm{max},r}$	The r largest entries of the principal components for the *uniformly* sampled sketch $\tilde{\mathbf{A}}$.
$\mathcal{U}_{\mathrm{sp},r}$	r-sparse components using *Spasm* with the uniformly sampled sketch $\tilde{\mathbf{A}}$.

Output of an algorithm $\mathcal{Z}$ is sparse principal components $\mathbf{V}$, and we consider the metric $f(\mathcal{Z}) = \mathrm{trace}(\mathbf{V}^T\mathbf{A}^T\mathbf{A}\mathbf{V})$, where $\mathbf{A}$ is the original centered data. We consider the following statistics.

$\frac{f(\mathcal{G}_{\mathrm{max},r})}{f(\mathcal{G}_{\mathrm{sp},r})}$	Relative loss of greedy thresholding versus *Spasm*, illustrating the value of a good sparse PCA algorithm. Our sketch based algorithms *do not* address this loss.
$\frac{f(\mathcal{H}_{\mathrm{max/sp},r})}{f(\mathcal{G}_{\mathrm{max/sp},r})}$	Relative loss of using the (ℓ_1, ℓ_2)-sketch $\tilde{\mathbf{A}}$ instead of complete data $\mathbf{A}$. A ratio close to 1 is desired.
$\frac{f(\mathcal{U}_{\mathrm{max/sp},r})}{f(\mathcal{G}_{\mathrm{max/sp},r})}$	Relative loss of using the uniform sketch $\tilde{\mathbf{A}}$ instead of complete data $\mathbf{A}$. A benchmark to highlight the value of a good sketch.

We also report the computation time for the algorithms. We show results to confirm that sparse PCA algorithms using the (ℓ_1, ℓ_2)-sketch are nearly comparable to those same algorithms on the complete data; and, gain in computation time from sparse sketch is proportional to the sparsity.

Also, we evaluate the quality of Algorithm 4 to estimate α^* from a small number of samples from various data.

3.4 Other Sketching Probabilities

We consider p_{ij} proportional to the sum of row and column *leverage scores* of $\mathbf{A}$ (Chen et al. 2014) to produce sparse sketch $\tilde{\mathbf{A}}$ using Algorithm 1. Let $\mathbf{A}$ be an $m \times n$ matrix of rank ϱ, and its SVD is given by $\mathbf{A} = \mathbf{U}\mathbf{\Sigma}\mathbf{V}^T$, where $\mathbf{U}$ and $\mathbf{V}$ contains ϱ orthonormal left and right singular vectors, respectively, and $\mathbf{\Sigma}$ is the diagonal matrix of singular values. We define leverage scores as follows (as in Mahoney and Drineas 2009)

$$\begin{aligned} \text{(row leverage)} \quad \mu_i &= \|\mathbf{U}_{(i)}\|_2^2, \quad \forall i \in [m] \\ \text{(column leverage)} \quad \nu_j &= \|\mathbf{V}_{(j)}\|_2^2, \quad \forall j \in [n] \end{aligned}$$

and element-wise leverage score (similar to Chen et al. 2014)

$$p_{lev} = \frac{1}{2}\frac{\mu_i + \nu_j}{(m+n)\varrho} + \frac{1}{2mn}, \quad i \in [m], j \in [n].$$

Note that p_{lev} is a probability distribution on the elements of $\mathbf{A}$. At a high level, the leverage scores of an element (i, j) is proportional to the squared norms of the i-th row of the left singular matrix and the j-th row of the right singular matrix. The constant term in p_{lev} prevents the rescaled values from blowing up in case of sampling an element with tiny leverage score. Such leverage score sampling is distinct from uniform sampling only for *low-rank* matrices or *low-rank approximations* to matrices. So, we consider sparsification of low-rank and rank-truncated data, and compare the quality of sparse sketches produced from such low-rank matrices using our optimal hybrid sampling with that of using p_{lev}.

	m	n	$\|\mathbf{A}\|_0$	nd	$\text{rs}_0 > \text{rs}_1$	α^*
$\mathbf{A}_{0.1}$	500	500	2.5e+5	9.2e+4	no	.63
TTC1	139	15170	37831	12204	yes	1
TTC2	138	11859	29334	9299	yes	1
TTC3	125	15485	47304	14201	yes	1
TTC4	125	14392	35018	10252	yes	1
Digit	2313	256	5.9e+5	5.1e+5	no	.20
Stock	1218	7956	5.5e+6	6.5e+3	no	.74
Gene	107	22215	2.4e+6	2.25e+6	yes	.99

Table 1: α^* for various $m \times n$ data sets ($\epsilon = .05$ is the desired relative-error accuracy). $\text{rs}_0 > \text{rs}_1$ implies ℓ_1 is better than ℓ_2 (Achlioptas et al. 2013a), and we reproduce this ($\alpha^* = 1$). But, for $\text{rs}_0 \leq \text{rs}_1$, $\alpha^* < 1$ and our hybrid sampling is strictly better than both ℓ_1 and ℓ_2.

3.5 Description of Data

Synthetic Data: $\mathbf{A}_{0.1}$ as described in SECTION 1.4 (FIGURE 1).

TechTC Datasets (TTC): (Gabrilovich and Markovitch 2004) These datasets are bag-of-words features for document-term data describing two topics (ids). We choose four such datasets. Rows represent documents and columns are the words. We preprocessed the data by removing all the words of length four or smaller, and then divide each row by its Frobenius norm.

Digit Data: (Hull 1994) A data set of three handwritten digits: six (664 samples), nine (644 samples), and one (1005 samples). Pixels are treated as features, and pixel values are normalized in [-1,1]. Each 16×16 digit image is encoded to form a row in the data matrix (2313 rows and 256 columns).

Stock Data (S&P): We use a temporal data containing 1218 stocks (rows) collected between 1983 and 2011. This temporal data set has with 7056 snapshots (columns) of prices.

Gene Expression Data: We use GSE10072 gene expression data for lung cancer from NCBI Gene Expression Omnibus database. There are 107 samples (58 lung tumor cases and 49 normal lung controls) forming the rows of the matrix, with 22,215 probes (features) from GPL96 platform annotation table.

3.6 Results

All the random results are based on mean of several independent trials (small variance observed).

3.6.1 QUALITY OF SPARSE SKETCH

Table 1 summarizes α^* for various data sets. Achlioptas et al. (2013a) argued that, for $\text{rs}_0 > \text{rs}_1$, ℓ_1 sampling is better than ℓ_2 (even with truncation). Our results on α^* in Table 1 reproduce this condition ($\alpha^* = 1$ implies ℓ_1). Moreover, our method can derive the right blend of ℓ_1 and ℓ_2 sampling even when the above condition fails. In this sense, we generalize the results of Achlioptas et al. (2013a).

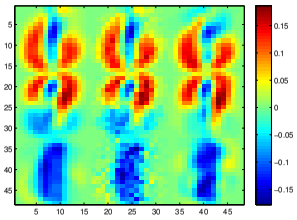
	$s/(k(m+n))$	$\hat{\alpha}$
$\mathbf{A}_{0.1}$, $k = 5$	2	0.7
	3	0.7
Digit, $k = 3$	3	0.3
	5	0.3
Stock, $k = 1$	2	0.7
	3	0.7

Table 2: $\hat{\alpha}$ corresponding to the minimum relative error $\|\mathbf{A} - \tilde{\mathbf{A}}\|_2 / \|\mathbf{A}\|_2$, for a fixed budget of samples size s. $\hat{\alpha} \approx \alpha^*$ in Table 1, indicating that our optimal hybrid sampling produces strictly better sparse sketch than both ℓ_1 and ℓ_2. $k \approx \|\mathbf{A}\|_F^2 / \|\mathbf{A}\|_2^2$ (stable rank).

Also, we note the value of α [4] for the minimum relative error $\frac{\|\mathbf{A}-\tilde{\mathbf{A}}\|_2}{\|\mathbf{A}\|_2}$, for a fixed sample size s in Table 2. Table 2 shows that the quality of the sparse sketch produced by our optimal hybrid sampling is strictly better than that of both ℓ_1 and ℓ_2.

• *Comparison with ℓ_2-with-truncation:* We also compare our optimal hybrid sampling with ℓ_2 sampling with truncation. We use two predetermined truncation parameters, $\varepsilon = 0.1$ and $\varepsilon = 0.01$. First, ℓ_2 sampling without truncation turns out to produce the worst quality sparse sketches for all datasets. For real datasets, hybrid-(ℓ_1, ℓ_2) sampling using α^* outperforms ℓ_2 with truncation $\varepsilon = 0.1$ and $\varepsilon = 0.01$. For $\mathbf{A}_{0.1}$, ℓ_2 with $\varepsilon = 0.01$ appears to produce $\tilde{\mathbf{A}}$ that is as bad as ℓ_2 without truncation. However, ℓ_2 with $\varepsilon = 0.1$ shows better quality than optimal hybrid sampling (for $\mathbf{A}_{0.1}$ only) as this ε filters out the noisy elements. We should point out that we know a good ε for $\mathbf{A}_{0.1}$ as we control the noise in this case. However, in reality, we have no control over the noise, and choosing the right ε with no prior knowledge of the data, is an improbable outcome.

3.6.2 QUALITY OF PCA FROM SPARSE SKETCHES



We investigate the quality of Algorithm 2 for Digit data and $\mathbf{A}_{0.1}$. We set $r = 30k$ for the random projection matrix $\mathbf{A}_G$ to achieve a comparable runtime of $\mathcal{G}$ with $\mathcal{H}$ (k is 3 and 5 for Digit and $\mathbf{A}_{0.1}$, respectively). FIGURE 4 shows that $\mathcal{H}$ has better quality than $\mathcal{G}$ for Digit data. Also, Table 3 lists the gain in computation time for Algorithm 2 due to sparsification (using hybrid sampling with α^*). Finally, our optimal hybrid sampling outperforms ℓ_1 and Bernstein sampling (Achlioptas et al. 2013b) by preserving more variance of data via PCA (Table 4).

3.6.3 QUALITY OF SPARSE PCA ALGORITHMS

We report results for primarily the top principal component ($k = 1$) which is the case most considered in the literature. When $k > 1$, our results do not qualitatively change. We note the optimal mixing parameter α^* using Algorithm 1 for various datasets in Table 5.

Handwritten Digits. We sample approximately 7% of the elements from the centered data using (ℓ_1, ℓ_2)-sampling, as well as uniform sampling. The quality of solution for small r is shown in Table 5, including the running time τ. For this data, $f(\mathcal{G}_{\text{max},r})/f(\mathcal{G}_{\text{sp},r}) \approx 0.23$ ($r = 10$), so it is important to use a good sparse PCA algorithm. We see from Table 5 that the (ℓ_1, ℓ_2)-sketch

4. We vary α from 0.1 to 1 with step size 0.1.

Hybrid-(ℓ_1, ℓ_2) σ_h/σ_k	Random Projection σ_g/σ_k
97.94%	96.89%

Figure 4: [Digit data] Approximation quality of PCA (Algorithm 2) from samples of data. (Left) Visualization of principal components as 16×16 image. Principal components are ordered from the top row to the bottom. First column of PCA's are exact ($\mathcal{A}$). Second column of PCA's ($\mathcal{H}$) are computed on sparse sketch with 7% non-zeros of all the elements via hybrid sampling using optimal α. Third column of PCA's ($\mathcal{G}$) are computed on $\mathbf{A}_G$. (Right) Variance preserved by PCA algorithms. Hybrid sampling based PCA, despite using less information, is better than PCA of random projection.

	Sparsified Digit	Sparsified $\mathbf{A}_{0.1}$
# non-zeros	7%	6%
$t_a/t_h/t_G$	151/30/36	73/18/36

Table 3: Computational gain of Algorithm 2 comparing to exact PCA. We report the computation time of MATLAB function 'svds($\mathbf{A}$,k)' for actual data $\mathbf{A}$ (t_a), sparsified data $\tilde{\mathbf{A}}$ (t_h), and random projection data $\mathbf{A}_G$ (t_G). We use only 7% and 6% of all the elements of Digit data and $\mathbf{A}_{0.1}$, respectively, to construct respective sparse sketches. $k = 3$ for Digit and $k = 5$ for $\mathbf{A}_{0.1}$.

significantly outperforms the uniform sketch. A more extensive comparison of recovered variance is given in FIGURE 6(a). We also observe a speed-up of a factor of about 6 for the (ℓ_1, ℓ_2)-sketch. We point out that the uniform sketch is reasonable for the digits data because most data elements are close to either $+1$ or -1, since the pixels are either black or white.

We show a visualization of the principal components in FIGURE 5. We observe that the sparse components from the (ℓ_1, ℓ_2)-sketch are almost identical to that of from the complete data.

TechTC Data. We sample approximately 5% of the elements from the centered data using our (ℓ_1, ℓ_2)-sampling, as well as uniform sampling. For this data, $f(\mathcal{G}_{\text{max},r})/f(\mathcal{G}_{\text{sp},r}) \approx 0.84$ ($r = 10$). We observe a very significant quality difference between the (ℓ_1, ℓ_2)-sketch and uniform sketch. A more extensive comparison of recovered variance is given in FIGURE 6(b). We also observe a speed-up of a factor of about 6 for the (ℓ_1, ℓ_2)-sketch. Unlike the digits data which is uniformly near ± 1, the text data is "spikey" and now it is important to sample with a bias toward larger elements, which is why the uniform-sketch performs very poorly.

	ℓ_1 σ_{ℓ_1}/σ_k	Bernstein σ_b/σ_k	Hybrid-(ℓ_1, ℓ_2) σ_h/σ_k
Digit ($\alpha^* = 0.42$)	98.47 %	98.46 %	**98.51**%
Stock ($\alpha^* = 0.1$)	85.09 %	95.61 %	**97.07**%

Table 4: Variance preserved by PCA of various sparse sketches. Our optimal hybrid sampling outperforms other sampling methods including Bernstein sampling (Achlioptas et al. 2013b). We sample 9% non-zeros from digit data and 2% non-zeros from stock data.

Centered Data	α^*	r	$\frac{f(\mathcal{H}_{\text{max/ sp},r})}{f(\mathcal{G}_{\text{max/ sp},r})}$	$\frac{\tau(\mathcal{G})}{\tau(\mathcal{H})}$	$\frac{f(\mathcal{U}_{\text{max/ sp},r})}{f(\mathcal{G}_{\text{max/ sp},r})}$	$\frac{\tau(\mathcal{G})}{\tau(\mathcal{U})}$
Digit	.42	40	0.99/ 0.90	6.21	1.01/ 0.70	5.33
TTC1	1	40	0.94/ 0.99	5.70	0.41/ 0.38	5.96
Stock	.10	40	1.00/ 1.00	3.72	0.66/ 0.66	4.76
Gene	.82	40	0.82/ 0.88	3.61	0.65/ 0.15	2.53

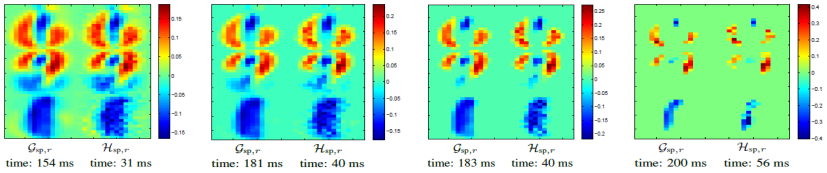


Table 5: Comparison of sparse principal components from the (ℓ_1, ℓ_2)-sketch and uniform sketch. Recall, $\mathcal{G}$ is the ground truth.

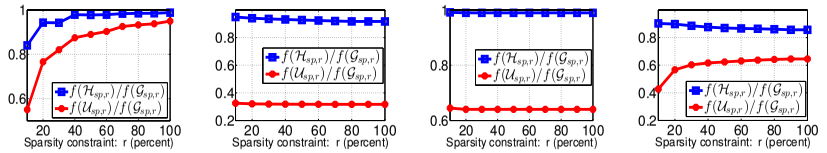
As a final comparison, we look at the actual sparse top component with sparsity parameter $r = 10$. The topic IDs in the TechTC data are 10567="*US: Indiana: Evansville*" and 11346="*US: Florida*". The top-10 features (words) in the full PCA on the complete data are shown in Table 6. In Table 7 we show which words appear in the top sparse principal component with sparsity $r = 10$ using various sparse PCA algorithms. We observe that the sparse PCA from the (ℓ_1, ℓ_2)-sketch with only 5% of the data sampled matches quite closely with the same sparse PCA algorithm using the complete data ($\mathcal{G}_{\text{max/sp},r}$ matches $\mathcal{H}_{\text{max/sp},r}$).

Stock Data. We sample about 2% of the non-zero elements from the centered data using the (ℓ_1, ℓ_2)-sampling, as well as uniform sampling. For this data, $f(\mathcal{G}_{\text{max},r})/f(\mathcal{G}_{\text{sp},r}) \approx 0.96$ ($r = 10$). We observe a very significant quality difference between the (ℓ_1, ℓ_2)-sketch and uniform sketch. A more extensive comparison of recovered variance is given in FIGURE 6(c). We also observe a speed-up of a factor of about 4 for the (ℓ_1, ℓ_2)-sketch. Similar to TechTC data this data set is also "spikey", so biased sampling toward larger elements significantly outperforms the uniform-sketch.



We now look at the actual sparse top component with sparsity parameter $r = 10$. The top-10 features (stocks) in the full PCA on the complete data are shown in Table 8. In Table 9 we show which stocks appear in the top sparse principal component using various sparse PCA algorithms. We observe that the sparse PCA from the (ℓ_1, ℓ_2)-sketch with only 2% of the non-zero elements sampled matches quite closely with the same sparse PCA algorithm using the complete data ($\mathcal{G}_{\text{max/sp},r}$ matches $\mathcal{H}_{\text{max/sp},r}$).

Gene Expression Data. We sample about 9% of the elements from the centered data using the (ℓ_1, ℓ_2)-sampling, as well as uniform sampling. For this data, $f(\mathcal{G}_{\text{max},r})/f(\mathcal{G}_{\text{sp},r}) \approx 0.05$ ($r = 10$) which means a good sparse PCA algorithm is imperative. We observe a very significant quality difference between the (ℓ_1, ℓ_2)-sketch and uniform sketch. A more extensive comparison of re-

(a) $r = 100\%$ (b) $r = 50\%$ (c) $r = 30\%$ (d) $r = 10\%$

Figure 5: [Digits] Visualization of top-3 sparse principal components. In each figure, left panel shows $\mathcal{G}_{\text{sp},r}$ and right panel shows $\mathcal{H}_{\text{sp},r}$. r is the maximum number of non-zeros allowed.

(a) Digit (b) TechTC (c) Stock (d) Gene

Figure 6: Quality of sparse PCA for (ℓ_1, ℓ_2)-sketch and uniform sketch over an extensive range for the sparsity constraint r. The variance preserved by the uniform sketch is significantly lower, highlighting the importance of a good sketch.

covered variance is given in FIGURE 6(d). We also observe a speed-up of a factor of about 4 for the (ℓ_1, ℓ_2)-sketch. Similar to TechTC data this data set is also "spikey", and consequently biased sampling toward larger elements significantly outperforms the uniform-sketch.

Also, we look at the actual sparse top component with sparsity parameter $r = 10$. The top-10 features (probes) in the full PCA on the complete data are shown in Table 10. In Table 11 we show which probes appear in the top sparse principal component with sparsity $r = 10$ using various sparse PCA algorithms. We observe that the sparse PCA from the (ℓ_1, ℓ_2)-sketch with only 9% of the elements sampled matches reasonably with the same sparse PCA algorithm using the complete data ($\mathcal{G}_{\text{max/sp},r}$ matches $\mathcal{H}_{\text{max/sp},r}$).

Finally, we validate the genes corresponding to the top probes in the context of lung cancer. Table 12 lists the top twelve gene symbols in Table 10. Note that a gene can occur multiple times in principal component as genes can be associated with different probes. Genes like SFTPC, AGER, WIF1, and FABP4 are down-regulated in lung cancer, while SPP1 is up-regulated (see the functional gene grouping: `www.sabiosciences.com/rt_pcr_product/HTML/PAHS-134Z.html`). Co-expression analysis on the set of eight genes for $\mathcal{H}_{\text{max},r}$ and $\mathcal{H}_{\text{sp},r}$ using the tool ToppFun (`toppgene.cchmc.org/`) shows that all eight genes appear in a list of selected probes characterizing non-small-cell lung carcinoma (NSCLC) in (Hou et al., 2010, Table

S1). Further, AGER and FAM107A appear in the *top five* highly discriminative genes in (Hou et al., 2010, Table S3). Additionally, AGER, FCN3, SPP1, and ADH1B appear among the 162 most differentiating genes across two subtypes of NSCLC and normal lung cancer in (Dracheva et al., 2007, Supplemental Table 1). Such findings show that our method can identify, from incomplete data, important genes for complex diseases like cancer. Also, notice that our sampling-based method is able to identify additional important genes, such as, FCN3 and FAM107A in top ten genes.

• *Quality of Other Sketches:* We briefly report on other options for sketching $\mathbf{A}$. We consider suboptimal α (not α^* from (10) to construct a suboptimal hybrid distribution, and use this in proto-Algorithm 1 to construct a sparse sketch. FIGURE 7 reveals that a good sketch using the α^* is important.

3.6.4 ESTIMATE OF α^* FROM SAMPLES

Table 13 shows the quality of estimated α^* computed by Algorithm 4 using a small number of observed data elements. Note that most of the elements of Digit data have magnitude close to 1; consequently we need more samples to estimate α^* accurately.

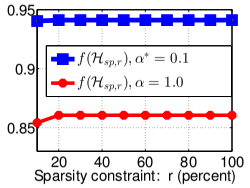

Figure 7: [Stock data] Quality of sketch using *suboptimal* α to illustrate the importance of the optimal mixing parameter α^*.

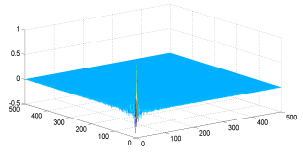
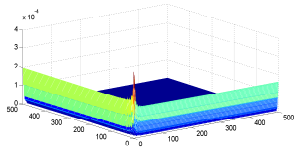
	Non-zeros sampled	Estimated α^*
Digit, $\alpha^* = 0.42$	6 %	0.80
	19 %	0.67
Stock, $\alpha^* = 0.1$	2 %	0.1
	10 %	0.1

Table 13: Estimated α^* using Algorithm 4 from small number of non-zeros of Digit and Stock data. Most of elements of Digit data are close to either $+1$ or -1, thus requiring more samples to accurately estimate α^*.



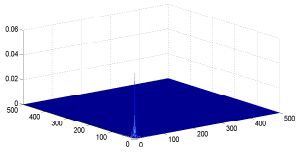
3.6.5 OTHER SKETCHING PROBABILITIES

We compare the quality of sparse sketches produced from low-rank and rank-truncated synthetic and real data using our optimal hybrid sampling with p_{lev}.



• *Power-law Matrix:* First, we construct a 500×500 low-rank *power-law* matrix, similar to Chen et al. (2014), as follows: $\mathbf{A}_{pow} = \mathbf{D}\mathbf{X}\mathbf{Y}^T\mathbf{D}$, where, matrices $\mathbf{X}$ and $\mathbf{Y}$ are 500×5 i.i.d. Gaussian $\mathcal{N}(0,1)$ and $\mathbf{D}$ is a diagonal matrix with power-law decay, $\mathbf{D}_{ii} = i^{-\gamma}$, $1 \le i \le 500$. The parameter γ controls the 'incoherence' of the matrix (larger γ makes the data more 'spiky').

Further, we construct low-rank approximation by projecting a data set onto a low dimensional subspace. We notice that the datasets projected onto the space spanned by top few principal components preserve the linear structure of the data. For example, Digit data show good separation of digits when projected onto the top three principal components. For TechTC and Gene data the top two respective principal components are good enough to form a low-dimensional subspace where the datasets show reasonable separation of two classes of samples. For the stock data we use top three PCAs because the stable rank is close to 2.



Quality of Sparse Sketch: We measure $\|\mathbf{A} - \tilde{\mathbf{A}}\|_2 / \|\mathbf{A}\|_2$ ($\mathbf{A}$ is the low-rank data) for the above-mentioned two sampling methods using various sample size. Table 14 lists the quality of sparse sketches produced from $\mathbf{A}_{pow}$ via the two sampling methods. Similarly, for all other datasets our optimal hybrid sampling (with α^*) outperforms the leverage score sampling (Table 15) for (low-rank) matrix sparsification.

(a) Low-rank data $\mathbf{A}_{pow}$

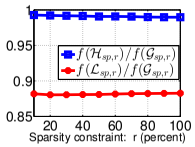
(b) Element-wise leverage scores for $\mathbf{A}_{pow}$

(c) Optimal hybrid distribution for $\mathbf{A}_{pow}$

Figure 8: Comparing optimal hybrid-(ℓ_1, ℓ_2) distribution with leverage scores p_{lev} for data $\mathbf{A}_{pow}$ for $\gamma = 1.0$. (a) Structure of $\mathbf{A}_{pow}$, (b) distribution p_{lev}, (c) optimal hybrid-(ℓ_1, ℓ_2) distribution. Our optimal hybrid distribution is more aligned with the structure of the data, requiring much smaller sample size to achieve a given accuracy of sparsification. This is supported by Table 14.

	$\frac{s}{k(m+n)}$	hybrid-(ℓ_1, ℓ_2)	p_{lev}
$\gamma = 0.5$	3	42%	58%
	5	31%	43%
$\gamma = 0.8$	3	15%	43%
	5	12%	40%
$\gamma = 1.0$	3	8%	42%
	5	6%	39%

Table 14: Sparsification quality $\|\mathbf{A}_{pow} - \tilde{\mathbf{A}}_{pow}\|_2 / \|\mathbf{A}_{pow}\|_2$ for low-rank 'power-law' matrix $\mathbf{A}_{pow}$ $(k = 5)$. We compare the quality of hybrid-(ℓ_1, ℓ_2) sampling and leverage score sampling for two sample size. We note (mean) α^* of hybrid-(ℓ_1, ℓ_2) distribution for data $\mathbf{A}_{pow}$ using $\epsilon = 0.05, \delta = 0.1$. For $\gamma = 0.5, 0.8, 1.0$, we have mean $\alpha^* = 0.11, 0.72, 0.8$, respectively, with very small variance.



We notice that with increasing γ leverage scores get more aligned with the structure of the data $\mathbf{A}_{pow}$ resulting in gradually improving approximation quality, for the same sample size. Larger γ produces more variance in data elements. ℓ_2 component of our hybrid distribution bias us towards the larger data elements, while ℓ_1 works as a regularizer to maintain the variance of the sampled

	$\frac{s}{k(m+n)}$	Hybrid-(ℓ_1, ℓ_2)	p_{lev}
Digit, $k = 3$	3	44%	61%
	5	34%	47%
$\mathbf{A}_{0.1}$, $k = 5$	3	25%	80%
	5	21%	62%

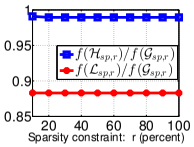


Table 15: Sparsification of rank-truncated data. We compare the quality of $\|\mathbf{A} - \tilde{\mathbf{A}}\|_2 / \|\mathbf{A}\|_2$ for hybrid-(ℓ_1, ℓ_2) sampling and leverage score sampling using two different sample size.

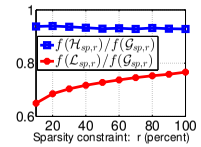

(a) Digit (rank 3)

(b) TechTC (rank 2)

(c) Stock (rank 3)

(d) Gene (rank 2)

Figure 9: [Low-rank data] Quality of sparse PCA of low-rank data for optimal (ℓ_1, ℓ_2)-sketch and leverage score sketch over an extensive range for the sparsity constraint r. The quality of the optimal hybrid sketch is considerably better highlighting the importance of a good sketch.

(and rescaled) elements. With increasing γ we need more regularization to counter the problem of rescaling. Interestingly, our optimal parameter α^* adapts itself with this changing structure of data, e.g. for $\gamma = 0.5, 0.8, 1.0$, we have $\alpha^* = 0.11, 0.72, 0.8$, respectively. This shows the benefit of our parameterized hybrid distribution to achieve a superior approximation quality. FIGURE 8 shows the structure of the data $\mathbf{A}_{pow}$ for $\gamma = 1.0$ along with the optimal hybrid-(ℓ_1, ℓ_2) distribution and leverage score distribution p_{lev}. The figure suggests our optimal hybrid distribution is better aligned with the structure of the data, resulting in a superior sparse sketch of the data. Similar results are observed for other datasets as well.

Quality of Sparse PCA: Let $\mathcal{L}_{\text{sp},r}$ be the r-sparse components using *Spasm* for the leverage score sampled sketch $\tilde{\mathbf{A}}$. FIGURE 9 shows that leverage score sampling is not as effective as the optimal hybrid (ℓ_1, ℓ_2)-sampling for sparse PCA of low-rank data.

3.7 Conclusion

It is possible to use a sparse sketch (incomplete data) to recover nearly as good principal components and sparse principal components as one would have gotten with the complete data. We mention that, while $\mathcal{G}_{\text{max}}$ which uses the largest weights in the unconstrained PCA does not perform well with respect to the variance, it does identify good features. A simple enhancement to $\mathcal{G}_{\text{max}}$ is to recalibrate the sparse component after identifying the features - this is an unconstrained PCA problem on just

the columns of the data matrix corresponding to the features. This method of recalibrating can be used to improve any sparse PCA algorithm.

Our algorithms are simple and efficient, and many interesting avenues for further research remain. Can the sampling complexity for the top-k sparse PCA be reduced from $O(k^2)$ to $O(k)$. We suspect that this should be possible by getting a better bound on $\sum_{i=1}^{k} \sigma_i(\mathbf{A}^T\mathbf{A} - \tilde{\mathbf{A}}^T\tilde{\mathbf{A}})$; we used the crude bound $k\|\mathbf{A}^T\mathbf{A} - \tilde{\mathbf{A}}^T\tilde{\mathbf{A}}\|_2$. We also presented a general surrogate optimization bound which may be of interest in other applications. In particular, it is pointed out in Magdon-Ismail and Boutsidis (2016) that though PCA optimizes variance, a more natural way to look at PCA is as the linear projection of the data that minimizes the *information loss*. Magdon-Ismail and Boutsidis (2016) gives efficient algorithms to find sparse linear dimension reduction that minimizes information loss – the information loss of sparse PCA can be considerably higher than optimal. To minimize information loss, the objective to maximize is $f(\mathbf{V}) = \text{trace}(\mathbf{A}^T\mathbf{A}\mathbf{V}(\mathbf{A}\mathbf{V})^\dagger\mathbf{A})$. It would be interesting to see whether one can recover sparse low-information-loss linear projectors from incomplete data.

Overall, the experimental results demonstrate the quality of the algorithms presented here, indicating the superiority of our approach to other extreme choices of element-wise sampling methods, such as, ℓ_1 and ℓ_2 sampling. Also, we demonstrate the theoretical and practical usefulness of hybrid-(ℓ_1, ℓ_2) sampling for fundamental data analysis tasks such as recovering PCA and sparse PCA from sketches. Finally, our sampling scheme outperforms element-wise leverage scores for the sparsification of various *low-rank* synthetic and real data.

Appendix A. Proof of Theorem 2

In this section we provide a proof of Theorem 2 following the proof outline of Drineas and Zouzias (2011); Achlioptas et al. (2013a). We use Lemma 1 as our main tool. For all $t \in [s]$ we define the matrix $\mathbf{M}_t \in \mathbb{R}^{m\times n}$ as follows:

$$\mathbf{M}_t = \frac{\mathbf{A}_{i_t j_t}}{p_{i_t j_t}} \mathbf{e}_{i_t}\mathbf{e}_{j_t}^T - \mathbf{A}.$$

It now follows that $\frac{1}{s}\sum_{t=1}^{s} \mathbf{M}_t = S_\Omega(\mathbf{A}) - \mathbf{A}$. We can bound $\|\mathbf{M}_t\|_2$ for all $t \in [s]$. We define the following quantity:

$$\lambda = \frac{\|\mathbf{A}\|_1 \cdot |\mathbf{A}_{ij}|}{\|\mathbf{A}\|_F^2}, \text{ for } \mathbf{A}_{ij} \neq 0 \tag{24}$$

Lemma 8 *Using our notation, and using probabilities of the form (3), for all $t \in [s]$,*

$$\|\mathbf{M}_t\|_2 \leq \max_{\substack{i,j:\\ \mathbf{A}_{ij}\neq 0}} \frac{\|\mathbf{A}\|_1}{\alpha + (1-\alpha)\lambda} + \|\mathbf{A}\|_2.$$

Proof Using probabilities of the form (3), and because $\mathbf{A}_{ij} = 0$ is never sampled,

$$\begin{aligned}\|\mathbf{M}_t\|_2 &= \|(\mathbf{A}_{i_t j_t}/p_{i_t j_t})\mathbf{e}_{i_t}\mathbf{e}_{j_t}^T - \mathbf{A}\|_2 \\ &\leq \max_{\substack{i,j:\\ \mathbf{A}_{ij}\neq 0}} \left\{ \left(\frac{\alpha}{\|\mathbf{A}\|_1} + \frac{(1-\alpha)\cdot|\mathbf{A}_{ij}|}{\|\mathbf{A}\|_F^2} \right)^{-1} \right\} + \|\mathbf{A}\|_2,\end{aligned}$$

Using (24), we obtain the bound. ■

Next we bound the spectral norm of the expectation of $\mathbf{M}_t\mathbf{M}_t^T$.

Lemma 9 *Using our notation, and using probabilities of the form (3), for all $t \in [s]$,*

$$\|\mathbb{E}(\mathbf{M}_t\mathbf{M}_t^T)\|_2 \leq \|\mathbf{A}\|_F^2\beta_1 - \sigma^2,$$

$$\beta_1 = \max_i \sum_{j=1}^{n} \left(\frac{\alpha\cdot\|\mathbf{A}\|_F^2}{|\mathbf{A}_{ij}|\cdot\|\mathbf{A}\|_1} + (1-\alpha) \right)^{-1},$$

for $\mathbf{A}_{ij} \neq 0$.

Proof Recall that $\mathbf{A} = \sum_{i,j=1}^{m,n} \mathbf{A}_{ij}\mathbf{e}_i\mathbf{e}_j^T$ and $\mathbf{M}_t = \frac{\mathbf{A}_{i_t j_t}}{p_{i_t j_t}}\mathbf{e}_{i_t}\mathbf{e}_{j_t}^T - \mathbf{A}$. We derive

$$\mathbb{E}[\mathbf{M}_t\mathbf{M}_t^T] = \sum_{i,j=1}^{m,n} (\mathbf{A}_{ij}^2/p_{ij})\mathbf{e}_i\mathbf{e}_i^T - \mathbf{A}\mathbf{A}^T.$$

Sampling according to probabilities of (3), and because $\mathbf{A}_{ij} = 0$ is never sampled, we get,

$$\begin{aligned}\sum_{i,j=1}^{m,n} \frac{\mathbf{A}_{ij}^2}{p_{ij}} &= \|\mathbf{A}\|_F^2 \sum_{i,j=1}^{m,n} \left(\frac{\alpha\cdot\|\mathbf{A}\|_F^2}{|\mathbf{A}_{ij}|\cdot\|\mathbf{A}\|_1} + (1-\alpha) \right)^{-1}, \\ &\leq \|\mathbf{A}\|_F^2 \sum_{i=1}^{m} \max_i \sum_{j=1}^{n} \left(\frac{\alpha\cdot\|\mathbf{A}\|_F^2}{|\mathbf{A}_{ij}|\cdot\|\mathbf{A}\|_1} + (1-\alpha) \right)^{-1}.\end{aligned}$$

for $\mathbf{A}_{ij} \neq 0$. Thus,

$$\mathbb{E}[\mathbf{M}_t \mathbf{M}_t^T] \;\preceq\; \|\mathbf{A}\|_F^2 \beta_1 \sum_{i=1}^{m} \mathbf{e}_i \mathbf{e}_i^T - \mathbf{A}\mathbf{A}^T = \|\mathbf{A}\|_F^2 \beta_1 \mathbf{I}_m - \mathbf{A}\mathbf{A}^T.$$

Note that, $\|\mathbf{A}\|_F^2 \beta_1 \mathbf{I}_m$ is diagonal with all entries non-negative, and $\mathbf{A}\mathbf{A}^T$ is postive semi-definite. Therefore,

$$\|\mathbb{E}[\mathbf{M}_t \mathbf{M}_t^T]\|_2 \leq \|\mathbf{A}\|_F^2 \beta_1 - \sigma^2.$$

■

Similarly, we can obtain

$$\left\|\mathbb{E}[\mathbf{M}_t^T \mathbf{M}_t]\right\|_2 \leq \|\mathbf{A}\|_F^2 \beta_2 - \sigma^2,$$

where, for $\mathbf{A}_{ij} \neq 0$,

$$\beta_2 = \max_j \sum_{i=1}^{m} \left(\frac{\alpha \cdot \|\mathbf{A}\|_F^2}{|\mathbf{A}_{ij}| \cdot \|\mathbf{A}\|_1} + (1-\alpha) \right)^{-1}.$$

We can now apply Lemma 1 with

$$\rho^2(\alpha) = \|\mathbf{A}\|_F^2 \max\{\beta_1, \beta_2\} - \sigma^2,$$

and

$$\gamma(\alpha) = \frac{\|\mathbf{A}\|_1}{\alpha + (1-\alpha)\lambda} + \|\mathbf{A}\|_2,$$

to conclude that $\|\mathcal{S}_\Omega(\mathbf{A}) - \mathbf{A}\|_2 \leq \varepsilon$ holds subject to a failure probability at most

$$(m+n) \exp\left(\frac{-s\varepsilon^2/2}{\rho^2(\alpha) + \gamma(\alpha)\varepsilon/3} \right).$$

Bounding the failure probability by δ, and setting $\varepsilon = \epsilon \cdot \|\mathbf{A}\|_2$, we complete the proof.

Appendix B. Proof of Lemma 4

Lemma 4 will be a corollary of a more general result, for a class of optimization problems involving a Lipschitz-like objective function over an arbitrary (not necessarily convex) domain. Let $f(\mathbf{V}, \mathbf{X})$ be a function that is defined for a matrix variable $\mathbf{V}$ and a matrix parameter $\mathbf{X}$. The optimization variable $\mathbf{V}$ is in some feasible set $\mathcal{S}$ which is arbitrary. The parameter $\mathbf{X}$ is also arbitrary. We assume that f is locally Lipschitz in $\mathbf{X}$, that is

$$|f(\mathbf{V}, \mathbf{X}) - f(\mathbf{V}, \tilde{\mathbf{X}})| \leq \gamma(\mathbf{X}) \|\mathbf{X} - \tilde{\mathbf{X}}\|_2, \qquad \forall \mathbf{V} \in \mathcal{S}.$$

(Note we allow the "Lipschitz constant" to depend on the fixed matrix $\mathbf{X}$ but not the variables $\mathbf{V}, \tilde{\mathbf{X}}$; this is more general than a globally Lipshitz objective) The next lemma is the key tool we need to prove Lemma 4 and it may be of independent interest in other optimization settings. We are interested in maximizing $f(\mathbf{V}, \mathbf{X})$ with respect to $\mathbf{V}$ to obtain $\mathbf{V}^*$. But, we only have an approximation $\tilde{\mathbf{X}}$ for $\mathbf{X}$, and so we maximize $f(\mathbf{V}, \tilde{\mathbf{X}})$ to obtain $\tilde{\mathbf{V}}^*$, which will be a suboptimal solution with respect to $\mathbf{X}$. We wish to bound $f(\mathbf{V}^*, \mathbf{X}) - f(\tilde{\mathbf{V}}^*, \mathbf{X})$ which quantifies how suboptimal $\tilde{\mathbf{V}}^*$ is with respect to $\mathbf{X}$.

Lemma 10 (Surrogate optimization bound) *Let $f(\mathbf{V}, \mathbf{X})$ be γ-locally Lipschitz w.r.t. $\mathbf{X}$ over the domain $\mathbf{V} \in \mathcal{S}$. Define* $\mathbf{V}^* = \arg\max_{\mathbf{V} \in \mathcal{S}} f(\mathbf{V}, \mathbf{X})$; $\tilde{\mathbf{V}}^* = \arg\max_{\mathbf{V} \in \mathcal{S}} f(\mathbf{V}, \tilde{\mathbf{X}})$. *Then,*

$$f(\mathbf{V}^*, \mathbf{X}) - f(\tilde{\mathbf{V}}^*, \mathbf{X}) \leq 2\gamma(\mathbf{X}) \|\mathbf{X} - \tilde{\mathbf{X}}\|_2.$$

In the lemma, the function f and the domain $\mathcal{S}$ are arbitrary. In our setting, $\mathbf{X} \in \mathbb{R}^{n \times n}$, the domain $\mathcal{S} = \{\mathbf{V} \in \mathbb{R}^{n \times k}; \mathbf{V}^T\mathbf{V} = \mathbf{I}_k; \|\mathbf{V}^{(j)}\|_0 \leq r\}$, and $f(\mathbf{V}, \mathbf{X}) = \text{trace}(\mathbf{V}^T\mathbf{X}\mathbf{V})$. We first show that f is Lipschitz w.r.t. $\mathbf{X}$ with $\gamma = k$ (a constant independent of $\mathbf{X}$). Let the representation of $\mathbf{V}$ by its columns be $\mathbf{V} = [\mathbf{v}_1, \ldots, \mathbf{v}_k]$. Then,

$$|\text{trace}(\mathbf{V}^T\mathbf{X}\mathbf{V}) - \text{trace}(\mathbf{V}^T\tilde{\mathbf{X}}\mathbf{V})| = |\text{trace}((\mathbf{X} - \tilde{\mathbf{X}})\mathbf{V}\mathbf{V}^T)| \leq \sum_{i=1}^{k} \sigma_i(\mathbf{X} - \tilde{\mathbf{X}}) \leq k\|\mathbf{X} - \tilde{\mathbf{X}}\|_2,$$

where, $\sigma_i(\mathbf{A})$ is the i-th largest singular value of $\mathbf{A}$ (we used Von-neumann's trace inequality and the fact that $\mathbf{V}\mathbf{V}^T$ is a k-dimensional projection). Now, by Lemma 10, $\text{trace}(\mathbf{V}^{*T}\mathbf{X}\mathbf{V}^*) - \text{trace}(\tilde{\mathbf{V}}^{*T}\mathbf{X}\tilde{\mathbf{V}}^*) \leq 2k\|\mathbf{X} - \tilde{\mathbf{X}}\|_2$. Lemma 4 follows by setting $\mathbf{X} = \mathbf{A}^T\mathbf{A}$ and $\tilde{\mathbf{X}} = \tilde{\mathbf{A}}^T\tilde{\mathbf{A}}$.

Appendix C. Proof of Lemma 10

In this section we provide a proof of Lemma 10. First, we need the following lemma.

Lemma 11 *Let f and g be functions on a domain $\mathcal{S}$. Then,*

$$\sup_{x \in \mathcal{S}} f(x) - \sup_{y \in \mathcal{S}} g(y) \leq \sup_{x \in \mathcal{S}} (f(x) - g(x)).$$

Proof

$$\sup_{x \in \mathcal{S}} (f(x) - g(x)) \geq f(x) - g(x) \geq f(x) - \sup_{y \in \mathcal{S}} g(y), \quad \forall x \in \mathcal{S}.$$

Since RHS holds for all x, $\sup_{x \in \mathcal{S}}(f(x) - g(x))$ is an upper bound for $f(x) - \sup_{y \in \mathcal{S}} g(\mathbf{U})$, and hence

$$\sup_{x \in \mathcal{S}} (f(x) - g(x)) \;\geq\; \sup_{x \in \mathcal{S}} \left(f(x) - \sup_{y \in \mathcal{S}} g(y) \right) = \sup_{x \in \mathcal{S}} f(x) - \sup_{y \in \mathcal{S}} g(y).$$

■

Proof (Lemma 10) Suppose that $\max_{\mathbf{V} \in \mathcal{S}} f(\mathbf{V}, \mathbf{X})$ is attained at $\mathbf{V}^*$ and $\max_{\mathbf{V} \in \mathcal{S}} f(\mathbf{V}, \tilde{\mathbf{X}})$ is attained at $\tilde{\mathbf{V}}^*$, and define $\epsilon = f(\mathbf{V}^*, \mathbf{X}) - f(\tilde{\mathbf{V}}^*, \mathbf{X})$. We have that

$$\begin{aligned} \epsilon &= f(\mathbf{V}^*, \mathbf{X}) - f(\tilde{\mathbf{V}}^*, \tilde{\mathbf{X}}) + f(\tilde{\mathbf{V}}^*, \tilde{\mathbf{X}}) - f(\tilde{\mathbf{V}}^*, \mathbf{X}) \\ &= \max_{\mathbf{V}} f(\mathbf{V}, \mathbf{X}) - \max_{\mathbf{U}} f(\mathbf{U}, \tilde{\mathbf{X}}) + f(\tilde{\mathbf{V}}^*, \tilde{\mathbf{X}}) - f(\tilde{\mathbf{V}}^*, \mathbf{X}) \\ &\leq \max_{\mathbf{V}} \left(f(\mathbf{V}, \mathbf{X}) - f(\mathbf{V}, \tilde{\mathbf{X}}) \right) + f(\tilde{\mathbf{V}}^*, \tilde{\mathbf{X}}) - f(\tilde{\mathbf{V}}^*, \mathbf{X}), \end{aligned}$$

where the last step follows from Lemma 11. Therefore,

$$\begin{aligned} |\epsilon| &\leq \max_{\mathbf{V}} \left| f(\mathbf{V}, \mathbf{X}) - f(\mathbf{V}, \tilde{\mathbf{X}}) \right| + |f(\tilde{\mathbf{V}}^*, \tilde{\mathbf{X}}) - f(\tilde{\mathbf{V}}^*, \mathbf{X})| \\ &\leq \max_{\mathbf{V}} \gamma(\mathbf{X}) \|\mathbf{X} - \tilde{\mathbf{X}}\|_2 + \gamma(\mathbf{X}) \|\mathbf{X} - \tilde{\mathbf{X}}\|_2 = 2\gamma(\mathbf{X}) \|\mathbf{X} - \tilde{\mathbf{X}}\|_2. \end{aligned}$$

(We used the Lipschitz condition in the second step.) ■

Appendix D. An alternative proof of Lemma 4

Let $\varepsilon = \text{trace}(\mathbf{V}^T\mathbf{X}\mathbf{V}) - \text{trace}(\tilde{\mathbf{V}}^T\mathbf{X}\tilde{\mathbf{V}})$.

$$\begin{aligned}
\varepsilon &= \text{trace}(\mathbf{V}^T\mathbf{X}\mathbf{V}) - \text{trace}(\mathbf{V}^T\tilde{\mathbf{X}}\mathbf{V}) + \text{trace}(\mathbf{V}^T\tilde{\mathbf{X}}\mathbf{V}) - \text{trace}(\tilde{\mathbf{V}}^T\mathbf{X}\tilde{\mathbf{V}}) \\
&\leq k\|\mathbf{X} - \tilde{\mathbf{X}}\|_2 + \text{trace}(\mathbf{V}^T\tilde{\mathbf{X}}\mathbf{V}) - \text{trace}(\tilde{\mathbf{V}}^T\mathbf{X}\tilde{\mathbf{V}}) \\
&\leq k\|\mathbf{X} - \tilde{\mathbf{X}}\|_2 + \text{trace}(\tilde{\mathbf{V}}^T\tilde{\mathbf{X}}\tilde{\mathbf{V}}) - \text{trace}(\tilde{\mathbf{V}}^T\mathbf{X}\tilde{\mathbf{V}}) \\
&\leq 2k\|\mathbf{X} - \tilde{\mathbf{X}}\|_2.
\end{aligned}$$

Setting $\mathbf{X} = \mathbf{A}^T\mathbf{A}$ and $\tilde{\mathbf{X}} = \tilde{\mathbf{A}}^T\tilde{\mathbf{A}}$ we derive the result.

Appendix E. Proof of Theorem 7

Proof Here we use the notations in Algorithm 3. Let, $p_1 = \frac{|\mathbf{A}_{ij}|}{\|\mathbf{A}\|_1}$, and $p_2 = \frac{\mathbf{A}_{ij}^2}{\|\mathbf{A}\|_F^2}$.
Note that t-th elements of S_1 and S_2 are sampled independently with ℓ_1 and ℓ_2 probabilities, respectively. We consider the following disjoint events:

$$\begin{aligned}
&\mathcal{E}_1 : S_1(t) = (i, j, \mathbf{A}_{ij}) \wedge S_2(t) \neq (i, j, \mathbf{A}_{ij}) \\
&\mathcal{E}_2 : S_1(t) \neq (i, j, \mathbf{A}_{ij}) \wedge S_2(t) = (i, j, \mathbf{A}_{ij}) \\
&\mathcal{E}_3 : S_1(t) = (i, j, \mathbf{A}_{ij}) \wedge S_2(t) = (i, j, \mathbf{A}_{ij}) \\
&\mathcal{E}_4 : S_1(t) \neq (i, j, \mathbf{A}_{ij}) \wedge S_2(t) \neq (i, j, \mathbf{A}_{ij})
\end{aligned}$$

Let us denote the events $x_1 : x \leq \alpha$ and $x_2 : x > \alpha$. Clearly, $P[x_1] = \alpha, P[x_2] = 1 - \alpha$.
The elements $S_1(t)$ and $S_2(t)$ are sampled independently, we have

$$\begin{aligned}
P[\mathcal{E}_1] &= P[S_1(t) = (i, j, \mathbf{A}_{ij})]P[S_2(t) \neq (i, j, \mathbf{A}_{ij})] = p_1(1 - p_2). \\
P[\mathcal{E}_2] &= (1 - p_1)p_2, \quad P[\mathcal{E}_3] = p_1p_2, \quad P[\mathcal{E}_4] = (1 - p_1)(1 - p_2).
\end{aligned}$$

We note that α is independent of elements of S_1 and S_2. Therefore, events x_1 and x_2 are independent of the events $\mathcal{E}_j$, $j = 1, 2, 3, 4$. Thus,

$$\begin{aligned}
P[S(t) = (i, j, \mathbf{A}_{ij})] &= P[(\mathcal{E}_1 \wedge x_1) \vee (\mathcal{E}_2 \wedge x_2) \vee \mathcal{E}_3] \\
&= P[\mathcal{E}_1 \wedge x_1] + P[\mathcal{E}_2 \wedge x_2] + P[\mathcal{E}_3] \\
&= P[\mathcal{E}_1]P[x_1] + P[\mathcal{E}_2]P[x_2] + P[\mathcal{E}_3] \\
&= p_1(1 - p_2)\alpha + (1 - p_1)p_2(1 - \alpha) + p_1p_2 \\
&= \alpha \cdot p_1 + (1 - \alpha) \cdot p_2
\end{aligned}$$

■

Algorithm 5 SELECT-s: One-pass SELECT Algorithm to Sample s Elements

Input: $\{a_1, ..., a_N\}$, $a_i \geq 0$, read in one pass sequentially over the data; number of samples s.
$I[1, ..., s] \leftarrow 0$; $V[1, ..., s] \leftarrow 0$ /* arrays to hold s indices and values */
$p_i = 0$.
/* Stream begins */
For $i = 1, ..., N$
  $p_i = p_i + a_i$.
  (in parallel) generate s independent uniform random numbers $r_j \in [0, 1]$, $j = 1, ..., s$.
  (in parallel) $I[j] = i$ and $V[j] = a_i$, if $r_j \leq a_i/p_i$.
End
Output: random indices I and corresponding values V.

Appendix F. SELECT-s Algorithm

Here we extend the SELECT algorithm appeared on p. 137 of Drineas et al. (2006) to select s elements in parallel. For one-pass ℓ_1 and ℓ_2 sampling on elements of $\mathbf{A}$ we call SELECT-s algorithm with inputs $\{|\mathbf{A}_{ij}|\}$ and $\{\mathbf{A}_{ij}^2\}$, respectively, for all i, j.

Abstract

In this paper, we describe an unsupervised measure for quantifying the 'informativeness' of correlation matrices formed from the pairwise similarities or relationships among data instances. The measure quantifies the heterogeneity of the correlations and is defined as the distance between a correlation matrix and the nearest correlation matrix with constant off-diagonal entries. This non-parametric notion generalizes existing test statistics for equality of correlation coefficients by allowing for alternative distance metrics, such as the Bures and other distances from quantum information theory. For several distance and dissimilarity metrics, we derive closed-form expressions of informativeness, which can be applied as objective functions for machine learning applications. Empirically, we demonstrate that informativeness is a useful criterion for selecting kernel parameters, choosing the dimension for kernel-based nonlinear dimensionality reduction, and identifying structured graphs. We also consider the problem of finding a maximally informative correlation matrix around a target matrix, and explore parameterizing the optimization in terms of the coordinates of the sample or through a lower-dimensional embedding. In the latter case, we find that maximizing the Bures-based informativeness measure, which is maximal for centered rank-1 correlation matrices, is equivalent to minimizing a specific matrix norm, and present an algorithm to solve the minimization problem using the norm's proximal operator. The proposed correlation denoising algorithm consistently improves spectral clustering. Overall, we find informativeness to be a novel and useful criterion for identifying non-trivial correlation structure.

1. Introduction

Shannon's entropy measures the dispersion of a sample of objects among the possible elements of a discrete space. A sample consisting solely of repeated instances of the same element has minimal entropy, and a sample wherein each object is distinct from the rest has maximum entropy. If these samples correspond to the labels assigned by a clustering algorithm, then neither the minimal entropy sample corresponding to a single cluster, nor the maximal entropy sample, where each instance is in its own cluster, is very informative about any underlying organization within the sample. In this work, we investigate and introduce univariate measures of *informativeness* that are minimized for both the maximal and minimal entropy samples. Informativeness is based on the heterogeneity of the similarity measurements for a sample and is applicable to samples from any space that has a positive semidefinite correlation measure. The positive definiteness ensures that the similarity measurements can be represented as inner-products in a Hilbert-space, or more concretely, that a given sample can be embedded in Euclidean space regardless of the original space. The restriction to correlation measurements ensures each instance is represented by a vector with equal magnitude, which distinguishes the effect of differences in similarity from differences in scale or variance, and ensures that each object is equally represented. Any positive semidefinite matrix formed from pairwise similarity measurements can be normalized to obtain a correlation matrix.

The notion of informativeness coincides with hypothesis tests for the homogeneity of correlation coefficients, that is, how uniform the off-diagonal elements of a correlation matrix are (Bartlett, 1954; Anderson, 1963; Lawley, 1963; Gleser, 1968; Aitkin et al., 1968; Steiger, 1980; Brien et al., 1984). According to this notion, a *non-informative* correlation matrix has equal off-diagonal elements, which indicates that no pair of objects is more similar than any other pair. For example, a constant matrix of all ones implies the objects are indistinguishable, and an identity matrix implies the objects are all distinct with no similarity. While observing an identity correlation matrix may be informative itself, because the objects have no dependence, no hierarchical grouping or clustering of the objects is appropriate, and any reordering of the objects yields the same correlation matrix. This last property—invariance to permutations—provides another definition of a non-informative correlation matrix.

The null hypothesis of the aforementioned tests is that the expected value of the correlation matrix has equal off-diagonal elements, where the parameter of the off-diagonal elements is left unspecified. Tests of equality of correlation coefficients are a specific case of hypothesis tests for patterns within sets of correlation coefficients (Steiger, 1980). Instead of hypothesis testing, we are interested in using informativeness as an objective function for unsupervised learning and for making relative comparisons between correlation matrices of equal size—in particular, between matrices corresponding to the same sample, e.g., kernel matrices formed with different kernel functions, or correlation matrices obtained by applying different dimensionality reduction techniques. For instance, evaluating a Gaussian kernel on a sample of distinct points yields a non-informative correlation matrix when the kernel bandwidth is chosen either too large (resulting in a nearly constant matrix) or too small (resulting in an identity matrix). These extremes correspond to the minimal and maximal cases of matrix entropy as defined by von Neumann (1955) for quantum density matrices. While many heuristics can be used to select an appropriate kernel bandwidth or

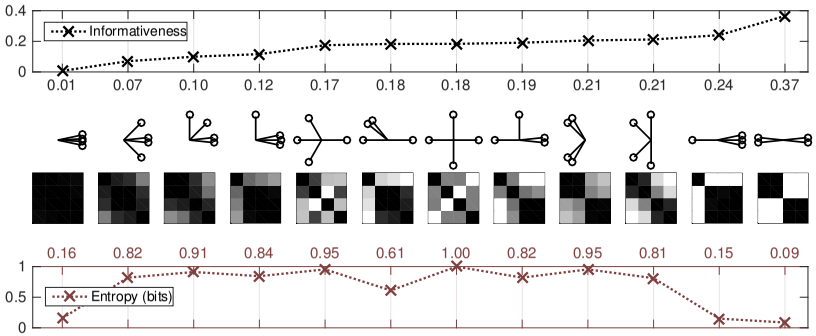

Figure 1: Informativeness versus von Neumann entropy for correlation matrices obtained from various configurations of four unit vectors. Both measures are minimal when the vectors are configured in a single cluster. Informativeness is higher for nontrivial clusterings, whereas entropy is maximized when the vectors are maximally separated.

the dimension of a lower-rank approximation of a kernel matrix, informativeness provides an unsupervised objective function for these selections.

Informativeness can be used to rank different samples and identify samples that have more structure. An example comparing informativeness to entropy for different samples of two-dimensional vectors is shown in Figure 1. Informativeness can also be applied to graphs, since the normalized graph Laplacian is a correlation matrix, and informativeness can be used to identify graphs that exhibit more structure, for example, regularity or clustering. As an objective function, informativeness can be used for enhancing the observed structure in a sample by searching for a matrix with more exaggerated differences in correlation coefficients around a target matrix.

While there are existing statistical tests to measure the heterogeneity of correlation coefficients, we define informativeness based on the distance between a given correlation matrix and the nearest non-informative matrix. In other words, informativeness is proportional to the distance between a given correlation matrix and the set of non-informative matrices. This definition is essential, since defining the distance to a particular non-informative matrix, either the identity matrix or a constant matrix, is insufficient as these distances will be proportional or inversely proportional to the von Neumann entropy. Even if two equal-sized correlation matrices are closest to distinct non-informative matrices, the distance to the set can be used to determine which matrix is more informative.

As defined, informativeness will be dependent upon the choice of the distance metric. Among other distances, we explore some from quantum information theory (Fuchs and van de Graaf, 1999; Nielsen and Chuang, 2000). These distances are applicable since any positive semidefinite matrix can be scaled to be a valid quantum density matrix. In particular, we find the Bures distance (Bures, 1969; Uhlmann, 1976), which generalizes the

Hellinger distance to matrices (Nielsen and Chuang, 2000; Koltchinskii and Xia, 2015), to have useful properties. Unlike many distance or similarity functions that are based on the Hilbert-Schmidt inner product, the similarity function for the Bures distance (known as fidelity (Jozsa, 1994)) relies on the trace norm. The Bures distance is both contractive and locally Riemannian, and can be considered the best-suited distance metric for the space of quantum density matrices (Bromley et al., 2014).

For several choices of distance metrics or dissimilarity functions, the minimum distance to the set of non-informative matrices has a closed-form expression, but this is not the case for the Bures distance. Nonetheless, using the sub-additive property of the trace norm, we derive a closed-form expression of the lower bound which is tight in most cases. Interestingly, the resulting measure leads to a convex cost function that is inversely proportional to the informativeness of a correlation matrix in terms of its Euclidean-space embedding. Besides this unique property, we find the measures of informativeness based on the Bures distance, and the other quantum distances, to perform better in machine learning applications than those based on the Hilbert-Schmidt inner product or the existing test statistics for homogeneous correlation coefficients (Bartlett, 1954; Lawley, 1963).

We organize the exposition of the paper as follows: In Section 2 we introduce some preliminaries regarding positive semidefinite, correlation, and quantum density matrices. In Section 3 we introduce the general definition of informativeness and specific measure instances based on various distance and dissimilarity functions. The derivations are included in Appendix B. We conclude the section with an illustration of the various measures on patterned correlation matrices corresponding to different partitions. In Section 4 we introduce the problem of finding a maximally informative correlation matrix nearby a target matrix, a problem we refer to as correlation matrix denoising. We also propose first-order optimizations of informativeness for a sample's correlation matrix parameterized in terms of a kernel function applied to the sample coordinates. For correlation matrix denoising, we also parameterize the optimization in terms of Euclidean-space embeddings and detail the cost functions that arise from maximizing the informativeness of the embeddings. Moreover, we show that the Bures-based informativeness is inversely proportional to a specific matrix norm. Finally, using the norm's proximal operator, we propose an algorithm to solve a relaxation of the correlation denoising problem. In Section 5 we explore different applications of informativeness for machine learning algorithms including correlation matrix denoising. A discussion of the results and general conclusions are given in Section 6.

2. Preliminaries

For a positive integer m, we use $[m]$ to denote the set $\{1, \ldots, m\}$. We denote a scalar variable as x or X, a set as $\mathcal{X}$, a real-valued column vector as $\mathbf{x}$, a matrix as $\mathbf{X}$, and its jth column as $\mathbf{x}_j$. Vectorizing the diagonal of a matrix is denoted by $\operatorname{diag}(\mathbf{X})$, and $\operatorname{diag}(\mathbf{x})$ denotes a diagonal matrix with $[\operatorname{diag}(\mathbf{x})]_{i,i} = x_i$. Inner-product notation $\langle \cdot, \cdot \rangle$ is used for both vectors and matrices, according to $\langle \mathbf{x}, \mathbf{y} \rangle = \sum_i x_i y_i$ and $\langle \mathbf{X}, \mathbf{Y} \rangle = \operatorname{tr}(\mathbf{X}^\top \mathbf{Y}) = \sum_{i,j} X_{i,j} Y_{i,j}$, respectively. The Euclidean norm of a vector is denoted by $\|\mathbf{x}\|_2$, and $\|\mathbf{X}\|_F^2 = \langle \mathbf{X}, \mathbf{X} \rangle$ denotes the square of the Frobenius norm, which is the sum of the squared entries of $\mathbf{X}$ and equals the sum of the squares of its singular values. We denote the trace norm (also called

the nuclear norm or Schatten 1-norm) by $\|\mathbf{X}\|_*$, defined as the sum of all the singular values of $\mathbf{X}$, and by $\|\mathbf{X}\|_2$ the spectral (operator) norm which is the largest singular value of $\mathbf{X}$.

2.1 Similarity, Correlation, and Embedding Matrices

We assume that we are provided with measurements of the similarity between n objects. This similarity corresponds to either a non-negative symmetric bivariate measure, for which larger positive values indicate similarity between objects and values near zero indicate weak relationships, or if the concept of negative correlation is applicable, a symmetric bivariate measure where negative values indicate inversely correlated objects. The similarity values are represented by an $n \times n$ real symmetric matrix $\mathbf{A}$, where $A_{i,j}$ denotes the similarity between objects i and j. Assuming that the similarities of all objects to themselves are greater than zero, the similarity matrix can be rescaled such that all the self-similarities are one. That is, any symmetric matrix $\tilde{\mathbf{A}}$ with $\tilde{A}_{i,i} > 0$ can be symmetrically normalized via

$$A_{i,j} = \frac{\tilde{A}_{i,j}}{\sqrt{\tilde{A}_{i,i}\tilde{A}_{j,j}}}, \tag{1}$$

such that $A_{i,i} = 1, i \in [n]$, or equivalently as $\mathbf{A} = \mathbf{D}\tilde{\mathbf{A}}\mathbf{D}$, where $\mathbf{D}$ is a diagonal matrix with entries $D_{i,i} = \frac{1}{\sqrt{\tilde{A}_{i,i}}}$. We assume that we have no further information about the objects or their original representations.

Many similarity measures, such as positive definite kernel functions, will yield a positive semidefinite similarity matrix. Positive semidefinite matrices can be represented by the embeddings of the objects in a Hilbert space for which the theory of reproducing kernel Hilbert spaces (Aronszajn, 1950) applies. That is, if a given similarity matrix is positive semidefinite, then there exists a set of n points in a Hilbert space $\mathcal{H}$, such that the inner product between any pair of points quantifies their similarity. Specifically, $A_{i,j} = \langle \mathbf{z}_i, \mathbf{z}_j \rangle$ where $\mathbf{z}_i \in \mathcal{H}$ with $i \in [n]$, denotes the point corresponding to the ith object. For finite dimensional embeddings in $\mathbb{R}^b$, we refer to the $b \times n$ matrix of concatenated vectors $\mathbf{Z} = [\mathbf{z}_1, \ldots, \mathbf{z}_n]$ as an embedding. This is not unique as any orthogonal transformation in $\mathbb{R}^b$ yields an equally valid representation.

We restrict our attention to *correlation matrices*,[1] which are matrices that are both positive semidefinite and normalized such that the diagonal elements are equal to one. Applying the symmetric normalization from Equation 1 to a positive semidefinite similarity matrix yields a correlation matrix, and in fact, the symmetric normalization yields the closest correlation matrix in terms of the Bures distance, which we show in Lemma 2 in Appendix A. A correlation matrix can be represented by a Hilbert space embedding where each object is represented by a point on a unit sphere. The convex set of all the $n \times n$ correlation matrices is known as the elliptope and it is defined as $\mathcal{E} = \left\{\mathbf{X} \in \mathbb{R}^{n \times n} : \mathbf{X} = \mathbf{X}^\top \succcurlyeq 0, X_{i,i} = 1, \forall i \in [n]\right\}$. It contains 2^{n-1} vertices that have full dimensional normal cones and correspond to rank-1 cut matrices of the form $\mathbf{v}\mathbf{v}^\top$ with $\mathbf{v} \in \{\pm 1\}^n$ (Laurent and Poljak, 1995, 1996). The convex hull of the cut matrices defines the cut polytope, and a strict subset of correlation matrices are members of this polytope. This relationship between the elliptope and the cut polytope is exploited in semidefinite programming relaxations (Saunderson et al., 2012) of combinatorial problems associated with dividing objects, such as finding the maximum cut of a graph (Goemans and Williamson, 1995). The set of embeddings of correlation matrices is the oblique manifold $\mathcal{OB} = \left\{\mathbf{Z} \in \mathbb{R}^{b \times n} : \|\mathbf{z}_i\|_2 = 1, \forall i \in [n]\right\}$ (Trendafilov and Lippert, 2002; Absil and Gallivan, 2006), where any correlation matrix can be written as $\mathbf{Z}^\top\mathbf{Z}$. When $b = 1$, the oblique manifold is simply the set of vectors with elements ± 1. The elements of a correlation matrix necessarily lie within $[-1, +1]$ since from the Cauchy-Bunyakovsky-Schwarz inequality we have $|\langle \mathbf{z}_i, \mathbf{z}_j \rangle| \leq \|\mathbf{z}_i\| \cdot \|\mathbf{z}_j\|$.

1. Their name is due to the fact they coincide with the set of Pearson correlation matrices for multivariate samples.

When the underlying objects are real-valued vectors, similarity measures that yield correlation matrices include the cosine similarity; various correlation coefficients, such as Pearson's, Spearman's, or Kendall's; and positive definite shift-invariant kernel functions, such as the Laplacian or Gaussian kernels. Efficient positive semidefinite kernels, which can generally be normalized, have also been developed for non-vectorial objects, such as strings (Lodhi et al., 2002), point sets (Kondor and Jebara, 2003), and the univariate point sets known in neuroscience as spike trains (Park et al., 2013). Nonetheless, some similarity measures yield normalized but indefinite matrices. To obtain a correlation matrix, one approach is to apply a non-negative threshold to the eigenvalues by setting any negative eigenvalues to zero (Higham, 1988) and then apply the symmetric normalization. An alternative is to find the nearest, in terms of Euclidean distance, correlation matrix (Higham, 2002; Qi and Sun, 2006). Both of these approaches, however, may distort the measures of similarity. Another approach is to treat each row of the similarity matrix as a vector-space representation of each object and compute a second-order similarity matrix using cosine similarity between these vectors. The result will be a correlation matrix. A final possibility motivated by spectral graph theory (Chung, 1997), is to treat the similarity matrix as the weighted affinity matrix of a graph, and then compute the normalized graph Laplacian, which is always a correlation matrix with non-positive off-diagonal entries.

2.2 Density Matrices

Quantum density matrices represent the probabilities associated with the outcomes of measurements on quantum states (Nielsen and Chuang, 2000; Hayashi, 2006). Ignoring their physical interpretations, density matrices are trace-normalized positive semidefinite Hermitian matrices. This means that statistical tools developed to analyze quantum density matrices can be applied to positive semidefinite matrices, including correlation matrices, after rescaling them by their trace.

Quantum information theory is based on the fact that a quantum density matrix is itself a non-commutative generalization of a probability mass function (Nielsen and Chuang, 2000). The positive semidefiniteness and unit-trace restrictions ensure that a matrix's eigenvalues are strictly positive and sum to 1; these are the same properties that a probability mass function has. This allows extensions of information theoretic quantities, such as entropy and mutual information to be defined for density matrices, and subsequently, trace-normalized positive semidefinite matrices (Sanchez Giraldo et al., 2015).

Our motivation for introducing density matrices is to leverage quantum information-based distance measures, which have unique properties compared to more familiar measures. Any correlation matrix can be converted to a density matrix by dividing by n. The set of

rescaled correlation matrices forms a subset of symmetric density matrices with constant diagonals. In the next section, we introduce our distance-based framework for measures of informativeness that can use the quantum distance measures.

3. Defining and Measuring Informativeness

In this section, we propose a univariate measure of how informative a given correlation matrix is, based on its distance from the nearest non-informative correlation matrix. This distance can be measured using various distance/dissimilarity measures and for some of these measures we show that we can obtain closed-form expressions of informativeness.

3.1 Non-informative Correlation Matrices

A set of pairwise correlation coefficients is non-informative if it indicates that no pair of objects is any more similar than any other pair, i.e., there are no groups of more (or less) related objects. Two exemplary cases of non-informativeness correspond to

1. all objects being indistinguishable, and
2. all objects being distinct and equally dissimilar.

By utilizing correlation matrices, these cases can be represented by the constant matrix $\mathbf{J} = \mathbf{1}\mathbf{1}^\top$ and the identity matrix $\mathbf{I}$, respectively. In general, any correlation matrix with constant off-diagonal elements is non-informative. Reordering the objects, i.e., simultaneously permuting the rows and columns of the correlation matrix, will not change a non-informative matrix. The set of non-informative matrices forms the null hypothesis for tests of homogeneous correlation coefficients (Bartlett, 1954; Lawley, 1963). Like these test statistics, informativeness essentially measures how heterogeneous the off-diagonal entries of the correlation matrix are.

If we let ρ be the value of the off-diagonal elements, correlation matrices with constant off-diagonal elements can be expressed as $\mathbf{A}_\rho = \rho\mathbf{J} + (1-\rho)\mathbf{I}$, where the range of ρ must be restricted to ensure $\mathbf{A}_\rho$ is a valid $n \times n$ correlation matrix. Specifically, since $\mathbf{J}\mathbf{1} = n\mathbf{1}$, the spectrum of $\mathbf{A}_\rho$ is $\{\rho n + 1 - \rho, 1 - \rho\}$. For both eigenvalues to be non-negative, we must have $\frac{-1}{n-1} \leq \rho \leq 1$.

It it more convenient, however, to substitute ρ with a variable $a \in [0, 1]$, so that it parameterizes the expression of a non-informative matrix as a convex combination of two other non-informative matrices. Linearly mapping $\rho \in \left[\frac{-1}{n-1}, 1\right]$ to a, gives $a = \frac{\rho(n-1)+1}{n}$ or equivalently $\rho = \frac{an-1}{n-1}$. Substituting the latter within the expression for $\mathbf{A}_\rho$ gives $\frac{na-1}{n-1}\mathbf{J} + \frac{n(1-a)}{n-1}\mathbf{I}$, which is also equal to the expression $a\mathbf{J} + (1-a)\frac{n}{n-1}\mathbf{H}$, where $\mathbf{H} = \mathbf{I} - \frac{1}{n}\mathbf{J}$ is the centering matrix. The parameter a is the mean of the non-informative matrix since $a = \frac{\mathbf{1}^\top \mathbf{A}_\rho \mathbf{1}}{n^2}$, whereas $\rho = \frac{\mathbf{1}^\top(\mathbf{A}_\rho - \mathbf{I})\mathbf{1}}{n(n-1)}$ is the mean of its off-diagonal elements.

In this work, we define the set of non-informative matrices to be

$$\mathcal{N} \equiv \left\{ \mathbf{N}_a = a\mathbf{J} + (1-a)\frac{n}{n-1}\mathbf{H} : 0 \leq a \leq 1 \right\}. \tag{2}$$

Under this parameterization, $\mathbf{N}_1 = \mathbf{J}$ is the rank-1 constant matrix, $\mathbf{N}_{\frac{1}{n}} = \mathbf{I}$ is the identity matrix, and $\mathbf{N}_0 = \frac{n}{n-1}\mathbf{H}$ is a scaled version of the centering matrix with rank $n-1$.

Geometrically, $\mathbf{J}$ is a vertex of the elliptope corresponding to the cut matrix $\mathbf{1}\mathbf{1}^\top$, $\mathbf{I}$ is the barycenter, $\frac{n}{n-1}\mathbf{H}$ is an extreme point with a one-dimensional normal cone, and all the non-informative matrices lie along the line connecting them.

From the characteristic polynomial of $\mathbf{N}_a$, it can be seen that it has one simple eigenvalue $\lambda_1 = an$ and one semisimple (due to the symmetry and, thus, diagonalizability of $\mathbf{N}_a$) eigenvalue $\lambda_2 = \frac{(1-a)n}{n-1}$ of multiplicity $n-1$. The corresponding eigenspaces $\mathrm{Null}(\mathbf{N}_a - \lambda_1\mathbf{I})$ and $\mathrm{Null}(\mathbf{N}_a - \lambda_2\mathbf{I})$ are orthogonal complementary subspaces and, since $(\lambda_1, \mathbf{1})$ is an eigenpair, they are common to the entire family of $\mathbf{N}_a$. Any vector within the eigenspace of λ_2 is an eigenvector. The existence of common eigenvectors is also supported by the fact that $\mathcal{N}$ is a commuting matrix family, which follows from the facts that $\mathbf{J}\mathbf{H} = \mathbf{0}$, and $\frac{1}{n}\mathbf{J}$ and $\mathbf{H}$ are symmetric and idempotent. Furthermore, for any given a, $\mathbf{N}_a$ can be expressed in terms of its eigenvalues as $\frac{\lambda_1}{n}\mathbf{J} + \lambda_2\mathbf{H}$, and since it is diagonalizable, for any function f defined at each λ_i, we have $f(\mathbf{N}_a) = \frac{f(\lambda_1)}{n}\mathbf{J} + f(\lambda_2)\mathbf{H}$. A particular instance of this, which we will use in the subsequent section, is the matrix square root given by $\sqrt{\mathbf{N}_a} = \sqrt{\frac{a}{n}}\mathbf{J} + \sqrt{\frac{(1-a)n}{n-1}}\mathbf{H}$.

3.2 Measuring the Distance Between Correlation Matrices

We propose to quantify the informativeness of a given correlation matrix $\mathbf{K}$ by its distance to the nearest non-informative correlation matrix. This measure of informativeness can be defined as

$$d_{\mathcal{N}}(\mathbf{K}) \equiv \min_{\mathbf{N}\in\mathcal{N}} d(\mathbf{K}, \mathbf{N}) = \min_{0\leq a\leq 1} d(\mathbf{K}, \mathbf{N}_a), \tag{3}$$

and can rely on various distance or dissimilarity measures applicable to matrices. To ensure informativeness is invariant to the ordering of the objects, the distance metric must be invariant to symmetric permutations of both arguments: $d(\mathbf{A}, \mathbf{B}) = d(\mathbf{\Pi}\mathbf{A}\mathbf{\Pi}^\top, \mathbf{\Pi}\mathbf{B}\mathbf{\Pi}^\top)$, where $\mathbf{\Pi}$ is a permutation matrix. For any non-informative matrix $\mathbf{N}$, we have $\mathbf{N} = \mathbf{\Pi}\mathbf{N}\mathbf{\Pi}^\top$. To ensure the informativeness measures can all be bounded between 0 and 1, we restrict our attention to bounded distance/dissimilarity measures.[2]

Table 1 contains distance metrics and dissimilarity functions—along with any underlying similarity measure—that are applicable to positive semidefinite matrices and can be used in the definition of $d_{\mathcal{N}}$. The table includes measures that have been widely applied in kernel-based machine learning, such as kernel alignment (Cristianini et al., 2002), which corresponds to the cosine similarity between the vectorized forms of matrices, the Hilbert-Schmidt independence criterion (Gretton et al., 2005), and the centered kernel alignment (Cortes et al., 2012), also known as distance correlation (Székely et al., 2007; Sejdinovic et al., 2013). The table also includes distances/dissimilarities used in quantum information theory, such as the trace distance, which is a matrix version of the Kolmogorov or total variation distance (Fuchs and van de Graaf, 1999); the quantum Jensen-Shannon divergence (Majtey et al., 2005); a distance based on the quantum Chernoff bound (Audenaert et al.,

2. This restriction excludes the family of log-determinant divergences (Lee and Lim, 2008; Cherian et al., 2011; Chebbi and Moakher, 2012; Cichocki et al., 2015) defined on the set of symmetric positive definite matrices, e.g., the affine invariant Reimannian metric (AIRM) and other symmetric log-det divergences. In preliminary experiments, we found these metrics to have unique behavior; however, they do not perform consistently as measures of informativeness, primarily because they are unbounded and the input matrix needs to be regularized to ensure it is strictly positive definite.

Table 1: Possible distance metrics/dissimilarity functions for the realization of $d_{\mathcal{N}}(\cdot)$ in Equation 3. The first five are applicable to any conformable symmetric matrices $\mathbf{A}$ and $\mathbf{B}$, whereas the second five additionally assume positive semidefiniteness and unity trace.

Distance metric/dissimilarity function $d(\mathbf{A},\mathbf{B})$:	Underlying similarity function:
Euclidean distance $\|\mathbf{A}-\mathbf{B}\|_F$	Matrix dot-product $\langle \mathbf{A},\mathbf{B}\rangle$
Cosine distance $\sqrt{2-2\frac{\langle \mathbf{A},\mathbf{B}\rangle}{\|\mathbf{A}\|_F\,\|\mathbf{B}\|_F}}$	Cosine similarity, or kernel alignment $\frac{\langle \mathbf{A},\mathbf{B}\rangle}{\|\mathbf{A}\|_F\,\|\mathbf{B}\|_F}$
Hilbert-Schmidt independence criterion (HSIC) $\|\mathbf{HAH}-\mathbf{HBH}\|_F$	$\langle \mathbf{HAH},\mathbf{HBH}\rangle$
Centered kernel alignment (CKA) $\sqrt{2-2\frac{\langle \mathbf{HAH},\mathbf{HBH}\rangle}{\|\mathbf{HAH}\|_F\,\|\mathbf{HBH}\|_F}}$	$\frac{\langle \mathbf{HAH},\mathbf{HBH}\rangle}{\|\mathbf{HAH}\|_F\,\|\mathbf{HBH}\|_F}$
Trace distance $\frac{1}{2}\mathrm{tr}\sqrt{(\mathbf{A}-\mathbf{B})^2}=\frac{1}{2}\|\mathbf{A}-\mathbf{B}\|_*$	
Quantum Jensen-Shannon (QJS) divergence $H(\frac{\mathbf{A}+\mathbf{B}}{2})-\frac{1}{2}H(\mathbf{A})-\frac{1}{2}H(\mathbf{B})$, where $H(\mathbf{A})\triangleq-\langle \mathbf{A},\ln\mathbf{A}\rangle$ is the von Neumann entropy	
Chernoff bound $\sqrt{2-2\min_{0\le s\le 1}\langle \mathbf{A}^s,\mathbf{B}^{1-s}\rangle}$	$\min_{0\le s\le 1}\langle \mathbf{A}^s,\mathbf{B}^{1-s}\rangle$
Quantum Hellinger (QH) distance $\|\sqrt{\mathbf{A}}-\sqrt{\mathbf{B}}\|_F=\sqrt{2-2\langle\sqrt{\mathbf{A}},\sqrt{\mathbf{B}}\rangle}$	Affinity $\langle\sqrt{\mathbf{A}},\sqrt{\mathbf{B}}\rangle$
Bures distance (d_B) $\sqrt{2-2\|\sqrt{\mathbf{A}}\sqrt{\mathbf{B}}\|_*}$	Fidelity $\|\sqrt{\mathbf{A}}\sqrt{\mathbf{B}}\|_*^2$
Sub-Bures dissimilarity $\sqrt{2-2\sqrt{\langle \mathbf{A},\mathbf{B}\rangle+\sqrt{(1-\|\mathbf{A}\|_F^2)(1-\|\mathbf{B}\|_F^2)}}}$	Super-fidelity $\langle \mathbf{A},\mathbf{B}\rangle+\sqrt{(1-\|\mathbf{A}\|_F^2)(1-\|\mathbf{B}\|_F^2)}$

2007); the quantum Hellinger divergence (Luo and Zhang, 2004); the Bures distance (Bures, 1969; Uhlmann, 1976; Braunstein and Caves, 1994); and the sub-Bures dissimilarity[3] measure, which is a lower bound on the Bures distance (Mendonça et al., 2008; Miszczak et al., 2009).

Of the quantum information theoretic distances, the Bures distance can be considered the natural metric between trace-normalized positive semidefinite matrices (Bromley et al., 2014). It is contractive, locally Riemannian, invariant to the choice of embedding coordinates (Uhlmann, 1976), and in its infinitesimal form it coincides with the quantum Fisher information metric for quantum densities (Braunstein and Caves, 1994). Various elements

3. The corresponding similarity measure, super-fidelity, can be used to define a metric distance, but it is not a lower bound on the Bures distance. The dissimilarity measure violates the triangle inequality for certain cases (Mendonça et al., 2008).

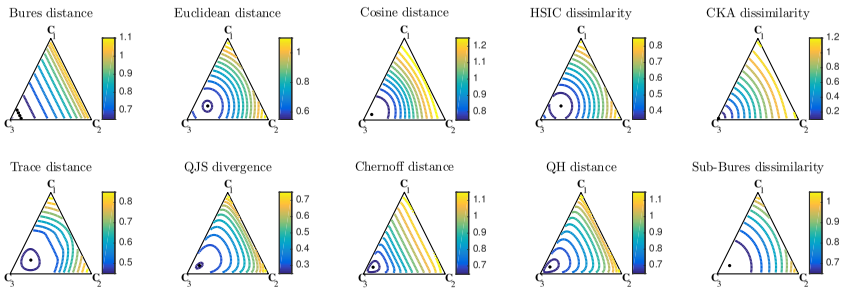

Figure 2: Equidistant contour lines for the measures in the marginal simplex of cut matrices. The Bures distance is the only distance invariant to the relative proportion of $\mathbf{C}_1$ and $\mathbf{C}_2$, which are not in the convex basis of the target matrix.

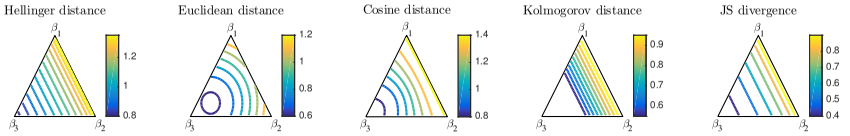

Figure 3: Equidistant contour lines for distances between points on the marginal simplex defined by $[\beta_1,\beta_2,\beta_3,0]$ to the target point $[0,0,0.5,0.5]$. The shape of the contours illustrates that most measures, besides the Euclidean and cosine distances, are invariant to the relative proportion of β_1 and β_2.

of the formulation and computation of the Bures distance and the associated fidelity similarity measure, which are relevant to the study of correlation matrices and informativeness, are presented in Appendix A.

Example 1 (Comparison of Distance/Dissimilarity Measures) *We compare the distance measures from Table 1 on correlation matrices with* $n=3$.

In particular, we consider the set of correlation matrices $\mathbf{X}_{\boldsymbol{\beta}}=\beta_1\mathbf{C}_1+\beta_2\mathbf{C}_2+\beta_3\mathbf{C}_3+\beta_4\mathbf{J}$ that can be represented as the convex combination of the elliptope vertices $\mathbf{C}_i=\mathbf{v}_i\mathbf{v}_i^\top$ and $\mathbf{J}=\mathbf{1}\mathbf{1}^\top$, with $\mathbf{v}_1=[-1,1,1]^\top$, $\mathbf{v}_2=[1,-1,1]^\top$ and $\mathbf{v}_3=[1,1,-1]^\top$. Since $\sum_i\beta_i=1$, each 3×3 matrix $\mathbf{X}_{\boldsymbol{\beta}}$ corresponds to a point of a 3-simplex. For visualization purposes, we calculate the distance between sets of correlation matrices $\mathbf{X}_{\boldsymbol{\beta}}$ and a target matrix $\mathbf{A}$. As an example, we set $\mathbf{A}$ to have as its convex basis (Brøndsted, 2012) the vertices $\mathbf{C}_3$ and $\mathbf{J}$, according to $\mathbf{A}=0.5\,\mathbf{C}_3+0.5\,\mathbf{J}$, and restrict $\mathbf{X}_{\boldsymbol{\beta}}$ to lie on one face of the tetrahedron by fixing $\beta_4=0$. Figure 2 shows the equidistant contours for various measures.

The key distinction is how convex combinations of $\mathbf{C}_1$ and $\mathbf{C}_2$ affect the calculated distances $d(\mathbf{X}_{\boldsymbol{\beta}},\mathbf{A})$. We can observe that the Bures distance is only a function of β_3, or

equivalently of $\beta_1 + \beta_2$. That is, the Bures distance is invariant to the relative proportion of β_1 and β_2, since along lines where β_3 is fixed, every correlation matrix is equidistant from the target matrix $\mathbf{A}$. This invariance is desirable since neither $\mathbf{C}_1$ nor $\mathbf{C}_2$ is in the convex basis of the $\mathbf{A}$. An equivalent invariance occurs when the corresponding vector-based distances[4] are computed between the vector of coefficients $\boldsymbol{\beta} = [\beta_1, \beta_2, \beta_3, 0]$, which defines a discrete probability distribution, and the target $[0, 0, 0.5, 0.5]$. Figure 3 shows the equidistant contours for various measures. Except for the Euclidean and cosine distances, the distance metrics are invariant to the relative proportion of β_1 and β_2, since these coefficients are not in the support of the target. In comparison, this behavior is not exhibited by any of the other matrix measures as evidenced by the nonlinear contours. For example, for fixed β_3 values, the Euclidean distance yields shorter distances to $\mathbf{A}$ when $\beta_1 = \beta_2$. The same applies to the other measures, although the effect is less obvious for the Chernoff-based measure, which behaves similar to the Bures distance for larger distances, but for shorter distances it is also susceptible to the same issue.

3.3 Derivation of Measures of Informativeness

We proceed to analytically derive closed-form expressions of informativeness for a subset of the distance/dissimilarity measures from Table 1. In the derivations we use the parametric form of the nearest non-informative matrix $\mathbf{N}_{a^\star}$, where $a^\star = \arg\min_{0\le a\le 1} d(\mathbf{K}, \mathbf{N}_a)$ and $\mathbf{K} \in \mathcal{E}$ is the input correlation matrix. Given the non-informative matrix $\mathbf{N}_{a^\star}$, we define the informativeness measures as $d_{\mathcal{N}}(\mathbf{K}) = d(\mathbf{K}, \mathbf{N}_{a^\star})$ or $\frac{1}{2}d^2_{\mathcal{N}}(\mathbf{K}) = \frac{1}{2}d^2(\mathbf{K}, \mathbf{N}_{a^\star})$ for chordal distances defined on a unit sphere whose range is intrinsically $[0, \sqrt{2}]$; this ensures the informativeness measures all range between 0 and 1. The analytic expressions for $a^\star$ and $d_{\mathcal{N}}(\mathbf{K})$ are derived in Appendix B, and the expressions of informativeness are in Table 2.

These expressions assume the input matrix is a correlation matrix $\mathbf{K} \in \mathcal{E}$. If $\mathbf{K} \notin \mathcal{E}$ then the Euclidean, cosine, HSIC, and CKA measures compute the distance/dissimilarity between $\mathbf{K}$ and the set of matrices with a diagonal of all ones and constant off-diagonal elements, i.e., the set $\{\mathbf{N}_a\}$, where a is unconstrained. In this case, the nearest matrix $\mathbf{N}_{a^\star}$ is not necessarily a correlation matrix, e.g., $a^\star < 0$ or $a^\star > 1$.

We note that for the Chernoff bound the expression for informativeness does not have a closed form, but only requires the same computational complexity as a single evaluation of the Chernoff bound. Also, the sub-Bures informativeness is not strictly closed form, requiring the maximum of two algebraic expressions. We did not find a closed-form expression of informativeness for neither the trace distance nor the quantum Jensen-Shannon divergence. Consequently, computing these measures requires a search over the family of non-informative matrices, which is costly since each search iteration requires computing either the singular values or the eigenvalues of an $n \times n$ matrix.

Each measure in Table 2 is bounded between 0 and 1, and will necessarily reach the lower bound of 0 for non-informative matrices. However, the upper limit of 1 is a loose upper bound and may not be attainable. Because of this and the fact there are no units associated with informativeness;[5] the nominal value of informativeness is not meaningful for

4. The Hellinger distance is the vector equivalent of the Bures and QH distances, and the Kolmogorov distance is the vector equivalent of the trace distance.
5. In comparison, the units of entropy (bit, nat, or hartley) are gauged to the probability of an event.

Table 2: Informativeness measures based on the distance and dissimilarity measures from Table 1. All measures, apart from the Bures-based one, are derived in Appendix B. $\mathbf{K} \in \mathcal{E}$ is a correlation matrix and $\bar{k} = \frac{1}{n^2}\mathbf{1}^\top\mathbf{K}\mathbf{1}$ is the average of its entries. All measures are bounded within the range $[0, 1]$.

Measure:	Informativeness:	Simplified expression (=), or bound (≥):	Relevant equations:
Euclidean	$d_{\mathcal{N}}(\mathbf{K}) = \min_{0\le a\le 1} \frac{1}{n}\|\mathbf{K} - \mathbf{N}_a\|_F$	$= \sqrt{\frac{1}{n^2}\|\mathbf{K}\|_F^2 - \frac{n\bar{k}^2 - 2\bar{k} + 1}{n-1}}$	(B.1),(B.2)
Cosine	$\frac{1}{2}d^2_{\mathcal{N}}(\mathbf{K}) = 1 - \max_{0\le a\le 1} \frac{\langle \mathbf{K}, \mathbf{N}_a\rangle}{\|\mathbf{K}\|_F\|\mathbf{N}_a\|_F}$	$= 1 - \frac{n}{\|\mathbf{K}\|_F}\sqrt{\frac{n\bar{k}^2 - 2\bar{k} + 1}{n-1}}$	(B.3),(B.4)
HSIC	$d_{\mathcal{N}}(\mathbf{K}) = \min_{0\le a\le 1} \frac{1}{n}\|\mathbf{H}\mathbf{K}\mathbf{H} - \mathbf{H}\mathbf{N}_a\mathbf{H}\|_F$	$= \sqrt{\frac{1}{n^2}\|\mathbf{H}\mathbf{K}\mathbf{H}\|_F^2 - \frac{(1-\bar{k})^2}{n-1}}$	(B.5),(B.6)
CKA	$\frac{1}{2}d^2_{\mathcal{N}}(\mathbf{K}) = 1 - \max_{0\le a\le 1} \frac{\langle \mathbf{H}\mathbf{K}\mathbf{H}, \mathbf{H}\mathbf{N}_a\mathbf{H}\rangle}{\|\mathbf{H}\mathbf{K}\mathbf{H}\|_F\|\mathbf{H}\mathbf{N}_a\mathbf{H}\|_F}$	$= 1 - \frac{n(1-\bar{k})}{\|\mathbf{H}\mathbf{K}\mathbf{H}\|_F\sqrt{n-1}}$	(B.7)
Chernoff	$d_{\mathcal{N}}(\mathbf{K}) = 1 - \max_{0\le a\le 1} \min_{0\le s\le 1} \frac{1}{n}\langle \mathbf{K}^s, \mathbf{N}_a^{1-s}\rangle$	$= 1 - q(\mathbf{K})$	(B.8–B.11)
QH	$\frac{1}{2}d^2_{\mathcal{N}}(\mathbf{K}) = 1 - \max_{0\le a\le 1} \frac{1}{n}\langle \sqrt{\mathbf{K}}, \sqrt{\mathbf{N}_a}\rangle$	$= 1 - \sqrt{\frac{(\mathbf{1}^\top\sqrt{\mathbf{K}}\mathbf{1})^2}{n^3} + \frac{\mathrm{tr}^2(\mathbf{H}\sqrt{\mathbf{K}})}{n(n-1)}}$	(B.12),(B.13)
Bures	$\frac{1}{2}d^2_{\mathcal{N}}(\mathbf{K}) = 1 - \max_{0\le a\le 1} \frac{1}{n}\|\sqrt{\mathbf{K}}\sqrt{\mathbf{N}_a}\|_*$	$\ge i(\mathbf{K}) = 1 - \sqrt{\bar{k} + \frac{\mathrm{tr}^2\sqrt{\mathbf{H}\mathbf{K}\mathbf{H}}}{n(n-1)}}$	(B.16),(B.17)
Sub-Bures	$\frac{1}{2}d^2_{\mathcal{N}}(\mathbf{K}) = 1 - \max_{0\le a\le 1} \sqrt{G(\frac{1}{n}\mathbf{K}, \frac{1}{n}\mathbf{N}_a)}$	$= 1 - \sqrt{g(\mathbf{K})}$	(B.21–B.24)

comparing differently-sized correlation matrices; nonetheless, informativeness can be used for relative comparisons between correlation matrices of equal size, even if they are closest to different non-informative matrices.

For comparison, the test statistics for equality of correlation coefficients proposed by Bartlett (1954) and Lawley (1963) are included in Appendix C. The null hypothesis for these tests is that the multivariate sample, corresponding to the observed correlation matrix, is drawn from a distribution whose true correlation structure is a non-informative matrix. The main benefit of using Lawley's test statistic is that, asymptotically, its distribution under the null hypothesis has a χ^2 distribution regardless of which particular non-informative matrix corresponds to the true correlation matrix. The null distribution for the other measures (including Bartlett's) depends on the underlying non-informative matrix, which is in practice unknown.

Example 2 (Informativeness for 3×3 Correlation Matrices) *To gain a perspective of informativeness measures, we evaluate them for 3×3 correlations matrices.*

Since the Bures-based informativeness is a convex function (Theorem 4 in Appendix B.7), it is necessarily maximized at the elliptope's extreme points, which are correlation matrices with rank-r where $r(r+1) \le 2n$ (Li and Tam, 1994). Figure 4 shows the Bures informativeness $i(\mathbf{K})$ across the parametric surface representing the surface of the elliptope. The measure is maximized at the three rank-1 correlation matrices besides $\mathbf{J}$. In general, the Bures-based informativeness is maximal for centered, rank-1 correlation matrices, as noted in Theorem 5 in Appendix B.7.

To compare the informativeness measures, we consider the subset of 3×3 correlation matrices $\mathbf{X}_{\boldsymbol{\beta}} = \beta_1\mathbf{C}_1 + \beta_2\mathbf{J} + \beta_3\frac{\mathbf{C}_2+\mathbf{C}_3}{2}$ with $\sum_i \beta_i = 1$, which are convex combinations

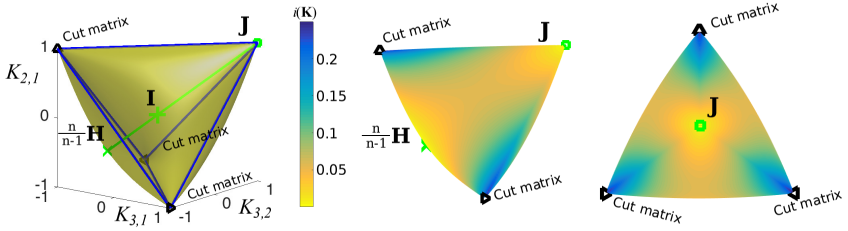

Figure 4: The Bures-based informativeness measure evaluated on the boundary of the elliptope. For $n = 3$, each correlation matrix $\mathbf{K}$ can be represented by a three-dimensional point that defines the three lower-triangular elements $K_{2,1}$, $K_{3,1}$, and $K_{3,2}$. (Left:) The family of non-informative matrices $\mathcal{N}$ is shown as a line across the elliptope passing through $\mathbf{N}_1 = \mathbf{J}$ and $\mathbf{N}_{1/n} = \mathbf{I}$ (discussed in Section 3.1). The outline of the cut polytope is shown as the wireframe connecting the four vertices. (Center, Right:) Informativeness peaks at the three extremal points corresponding to the three cut matrices.

of the elliptope vertices $\mathbf{C}_i = \mathbf{v}_i\mathbf{v}_i^\top$ and $\mathbf{J} = \mathbf{1}\mathbf{1}^\top$, with $\mathbf{v}_1 = [-1, 1, 1]^\top$, $\mathbf{v}_2 = [1, -1, 1]^\top$ and $\mathbf{v}_3 = [1, 1, -1]^\top$. Figure 5 illustrates the measures, along with Bartlett's and Lawley's test statistics, evaluated for each $\mathbf{X}_\beta$ across the 2-simplex defined by $\boldsymbol{\beta}$. All measures are maximized when $\mathbf{X}_\beta = \mathbf{C}_1$, but the shape of the level sets highlights the differences among the distance/dissimilarity measures underlying the informativeness measures.

Example 3 (Patterned Correlation Matrices) *We use* 16×16 *rank-1 and block diagonal correlation matrices to compare the measures of informativeness.*

The value of the informativeness measures for different partition sizes are shown in Figure 6. For binary partitions, the HSIC and Bures measures are uniquely maximized by balanced rank-1 matrices, and the measures—excepting the Euclidean, trace, and CKA measures—are maximized by balanced block-diagonal when there are two blocks. In general, balanced rank-1 matrices have higher informativeness than any of the block diagonal matrices (except for the CKA measure). For block-diagonal matrices, the Euclidean, HSIC, CKA, and sub-Bures measures are maximal for two equal-sized blocks, but the other measures (excepting the trace distance) are maximized when there are $\sqrt{n}$ equal-sized blocks. This latter disparity means that these two groups of measures will behave differently when evaluating correlation matrices with cluster structure.

On these patterned correlation matrices, we see that the Bures-based measure is a tight bound on the exact Bures informativeness measure. Additionally, the quantum Hellinger-based measure is a tight upper bound on the exact Bures measure except in the rank-1 case. The cosine-based measure also tracks the QH measure on these patterned matrices. The sub-Bures bound appears to be quite loose, except in the rank-1 case for which it is equal to the exact Bures measure.

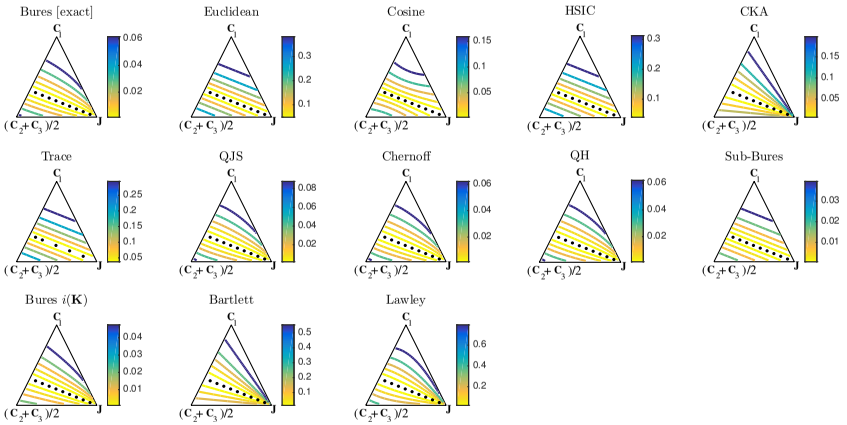

Figure 5: Equidistant contour lines for the measures on a 2-simplex of correlation matrices. The dotted line represents the non-informative matrix family $\mathcal{N}$. Informativeness is maximal at extremal points of the elliptope for convex distance metrics, but the choice of distance/dissimilarity measure affects the geometry of the level sets.

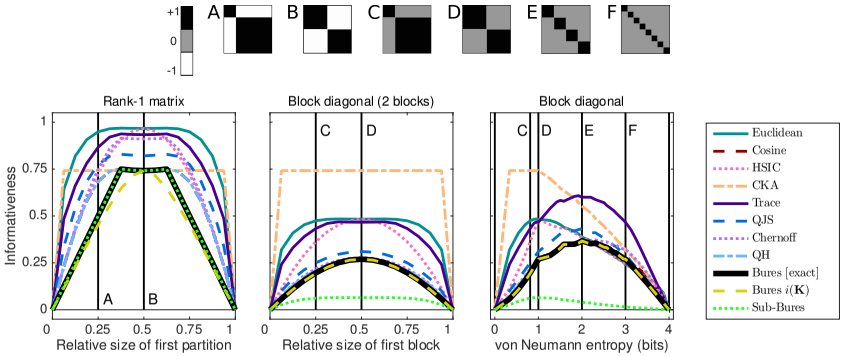

Figure 6: Comparison of informativeness measures for 16×16 correlation matrices with partition structure. Examples include rank-1 matrices (A, B); block diagonal matrices with two blocks (C, D); and block diagonal with increasing number of blocks (D, E, F) as indicated by the von Neumann entropy. (Note: The curves for the QH and cosine measures overlap on all plots, and the Bures curve covers the QH curve in the block diagonal plots.)

4. Optimization of Informativeness

In this section, we investigate constrained optimization problems based on finding a maximally informative correlation matrix close to a target matrix. We cover two types of cases; those optimizations parameterized in terms of a correlation matrix, and those in terms of a Euclidean embedding. In the latter case, we derive the analytic forms of cost functions for some measures of informativeness that can be applied directly to an embedding without requiring the explicit calculation of a correlation matrix. In particular, we show that when applied to an embedding, the Bures-based cost function is convex and corresponds to a novel matrix norm, which is a combination of trace seminorms on orthogonal subspaces. As this norm is non-differentiable, we describe its proximal operator, which requires the definition of the proximal operator for the squared trace norm. Using the Bures-based measure of informativeness as a cost function, we detail the optimization problem of finding a maximally informative correlation matrix nearby a target matrix, where nearness is assessed via the Euclidean distance between the embeddings. Although constraining the embedding to ensure it corresponds to a correlation matrix is non-convex, we relax this constraint to yield a completely convex optimization problem, the solutions of which can satisfy the original constraint. We propose an alternating direction method of multiplier (ADMM) algorithm that uses the proximal operator for the Bures-based cost function to solve this problem.

4.1 Maximally Informative Correlation Matrices

Firstly, we consider finding a maximally informative matrix that lies within an ϵ-radius ball of an arbitrary target matrix $\mathbf{A}$. This optimization can be written as

$$\begin{aligned} &\underset{\mathbf{K}\in\mathcal{E}}{\arg\max}\ d_{\mathcal{N}}(\mathbf{K}) \\ &\text{s.t. } \|\mathbf{A}-\mathbf{K}\|_F \le \epsilon, \end{aligned} \tag{4}$$

where $d_{\mathcal{N}}(\mathbf{K})$ is the distance to closest member of the family of $\mathbf{N}_a$ of non-informative matrices (or a lower bound on this distance in the case of the Bures distance). As noted in Theorem 4, the Bures-based informativeness is a convex function, as are the Euclidean and HSIC-based measures (their convexity can be verified by the properties of the Frobenius norm). Consequently, for these measures maximizing the informativeness is a convex maximization problem with multiple optima necessarily occurring at the extreme points of the elliptope, as evidenced by Figures 4. In particular, as stated in Theorem 5 in Appendix B.7, the Bures-based informativeness is maximized by the vertices of the elliptope corresponding to centered, rank-1 correlation matrices. Although there is multiple maxima, for appropriate choices of ϵ there may be a unique maximum within the local neighborhood.

For convenience, we instead define a minimization problem—replacing the ϵ-ball constraint with a penalty term scaled by ρ (where a large ρ corresponds to a small ϵ)—as

$$\underset{\mathbf{K}\in\mathcal{E}}{\arg\min}\ \rho\,\|\mathbf{A}-\mathbf{K}\|_F^2 + F\left(d_{\mathcal{N}}(\mathbf{K})\right), \tag{5}$$

where F is a monotonically decreasing function of the form $F : d \mapsto 1-\nu d^2$ with $\nu \in \{\frac{1}{2}, 1\}$ ($\nu = \frac{1}{2}$ for chordal distances in order to restrict the range of F to $[0,1]$). The

Table 3: Expressions for finding the most informative correlation matrices via cost functions of the form $J_\rho(\mathbf{K}) = \rho\,\|\mathbf{A}-\mathbf{K}\|_F^2 + F\left(d_{\mathcal{N}}(\mathbf{K})\right)$. The forms are applicable to all positive semidefinite measures, even though informativeness is only defined for correlation matrices. Because of this generality, the Euclidean and cosine measures are written in terms of $\mathbf{N}_{a^\star} = a^\star\mathbf{J} + (1-a^\star)\frac{n}{n-1}\mathbf{H}$.

Measure:	$F(d)$:	$F\left(d_{\mathcal{N}}(\mathbf{K})\right)$:	$J_\rho(\mathbf{K})$ convex?
Euclidean	$1-d^2$	$1-\frac{1}{n^2}\|\mathbf{K}-\mathbf{N}_{a^\star}\|_F^2, \quad a^\star = \frac{1}{n^2}\langle\mathbf{K},\mathbf{J}-\mathbf{I}\rangle + \frac{1}{n}$	$\rho \ge \frac{1}{n^2}$
Cosine	$1-\frac{1}{2}d^2$	$\frac{\langle\mathbf{K},\mathbf{N}_{a^\star}\rangle}{\|\mathbf{K}\|_F\|\mathbf{N}_{a^\star}\|_F}, \quad a^\star = \frac{1}{n}\frac{\langle\mathbf{K},\mathbf{J}\rangle}{\langle\mathbf{K},\mathbf{I}\rangle}$	—
HSIC	$1-d^2$	$1+\frac{1}{n^2(n-1)}\langle\mathbf{K},\mathbf{H}\rangle^2 - \frac{1}{n^2}\|\mathbf{HKH}\|_F^2$	$\rho \ge \frac{1}{n^2}$
CKA	$1-\frac{1}{2}d^2$	$\frac{\langle\mathbf{K},\mathbf{H}\rangle}{\|\mathbf{HKH}\|_F\sqrt{n-1}}$	—
QH	$1-\frac{1}{2}d^2$	$\sqrt{\frac{1}{n^3}\langle\sqrt{\mathbf{K}},\mathbf{J}\rangle^2 + \frac{1}{n(n-1)}\langle\sqrt{\mathbf{K}},\mathbf{H}\rangle^2}$	no
Bures-based	$1-\frac{1}{2}d^2$	$\sqrt{\frac{1}{n^2}\langle\mathbf{K},\mathbf{J}\rangle + \frac{1}{n(n-1)}\|\sqrt{\mathbf{K}}\mathbf{H}\|_*^2}$	no

function $F\left(d_{\mathcal{N}}(\mathbf{K})\right)$ simplifies for the measures of informativeness in Table 2 with closed-form expressions. The choice of F and the resulting expressions of $F\left(d_{\mathcal{N}}(\mathbf{K})\right)$ are listed in Table 3.

Since $1-\nu d^2$ is concave and nonincreasing with respect to d^2, when $d_{\mathcal{N}}^2(\mathbf{K})$ is convex, $\rho\,\|\mathbf{A}-\mathbf{K}\|_F^2 + F\left(d_{\mathcal{N}}(\mathbf{K})\right)$ is a difference of convex functions. By inspection we see that the cost functions for the Euclidean and HSIC-based measures of informativeness are quadratic functions of $\mathbf{K}$ and convex[6] when $\rho \ge \frac{1}{n^2}$, i.e., this choice of ρ corresponds to a sufficiently small ϵ-radius ball, such that it contains a unique maximally informative correlation matrix. In contrast, the convexity of the cost function for the cosine and CKA-based measures depends on both the target matrix $\mathbf{A}$ and the regularization ρ; in certain cases the cost function may be convex. Due to the matrix square root, neither the QH nor the Bures-based measures are convex. In particular, $\frac{1}{n^2}\langle\mathbf{K},\mathbf{J}\rangle + \frac{1}{n(n-1)}\|\sqrt{\mathbf{K}}\mathbf{H}\|_*^2$ is concave, as $\|\sqrt{\mathbf{K}}\mathbf{H}\|_*^2$ is proportional to the squared fidelity between $\frac{1}{n-1}\mathbf{H}$ and $\frac{1}{\mathrm{tr}\mathbf{K}}\mathbf{K}$ and squared fidelity is a concave function (Uhlmann, 1976) as noted in Theorem 3 in Appendix A. The function $\langle\sqrt{\mathbf{K}},\mathbf{C}\rangle$ is also concave for any positive semidefinite $\mathbf{C}$, as the function $-\langle\sqrt{\mathbf{K}},\mathbf{C}\rangle$ is convex (Borwein and Lewis, 2010, Section 3.1, Exercise 25c).

First-order gradient approaches may be applied to the expressions in Table 3 with some adjustments to ensure they are well-defined and smooth. Firstly, the cost functions corresponding to chordal distances (cosine, CKA, QH, and Bures) are squared to remove the scalar square roots from the expressions. Secondly, since the CKA measure is undefined at $\mathbf{K} = \mathbf{J}$, a log barrier of the form $-\log(1-\bar{k})$ should be added to the cost function to prevent this case. Thirdly, for the QH measure to be differentiable, $\mathbf{K}$ must be strictly

6. Letting $\mathbf{x} = \mathrm{vec}(\mathbf{K})$, these two cost functions can be written as $\mathbf{x}^\top\mathbf{M}\mathbf{x} + \mathbf{x}^\top\mathbf{u} + c$, which is a convex function if $\mathbf{M}$ is positive semidefinite. For the Euclidean measure, $\mathbf{M} = (\rho - \frac{1}{n^2})\mathbf{I} + \frac{1}{n^3(n-1)}\mathbf{v}\mathbf{v}^\top$ where $\mathbf{v} = \mathrm{vec}(\mathbf{J}-\mathbf{I})$. For the HSIC measure, $\mathbf{M} = \rho\mathbf{I} - \frac{1}{n^2}\mathbf{H}\otimes\mathbf{H}$, where $\otimes$ indicates the Kronecker product. In both cases, $\mathbf{M}$ is positive semidefinite if $\rho \ge \frac{1}{n^2}$.

Table 4: Gradients of cost functions derived from the closed-form informativeness measures with respect to $\mathbf{K}$, where $\mathbf{K} \in \mathcal{E}$ is a correlation matrix and $\bar{k} = \frac{1}{n^2}\mathbf{1}^\top\mathbf{K}\mathbf{1}$ is the average of its entries. The gradient for the QH measure is only valid if $\mathbf{K}$ is positive definite, which ensures $\sqrt{\mathbf{K}}$ and $-\sqrt{\mathbf{K}}$ have disjoint eigenvalues—guaranteeing a unique solution to the Sylvester equations (Bartels and Stewart, 1972).

Measure:	$\tilde{F}(\mathbf{K})$:	$\nabla_{\mathbf{K}}\tilde{F}(\mathbf{K})$:
Euclidean	$\frac{1}{2}\left(1 - d_{\mathcal{N}}(\mathbf{K})^2\right)$	$\frac{1}{n^2}\left(\frac{n\bar{k}-1}{n-1}\mathbf{J} - \mathbf{K}\right)$
Cosine	$\frac{1}{2}\left(1 - \frac{1}{2}d_{\mathcal{N}}(\mathbf{K})^2\right)^2$	$\frac{1}{\|\mathbf{K}\|_F^2}\left(\frac{n\bar{k}-1}{n^2}\mathbf{J} - \frac{n\bar{k}^2-2\bar{k}+1}{\|\mathbf{K}\|_F^2}\mathbf{K}\right)$
HSIC	$\frac{1}{2}\left(1 - d_{\mathcal{N}}(\mathbf{K})^2\right)$	$\frac{1}{n^2}\left(-\mathbf{HKH} - \frac{1-\bar{k}}{n-1}\mathbf{J}\right)$
CKA	$\frac{1}{2}\left(1 - \frac{1}{2}d_{\mathcal{N}}(\mathbf{K})^2\right)^2$	$\frac{\langle\mathbf{K},\mathbf{H}\rangle}{\|\mathbf{HKH}\|_F^2\sqrt{n-1}}\left(\mathbf{H} - \frac{\langle\mathbf{K},\mathbf{H}\rangle}{\|\mathbf{HKH}\|_F^2}\mathbf{HKH}\right)$
QH	$\frac{1}{2}\left(1 - \frac{1}{2}d_{\mathcal{N}}(\mathbf{K})^2\right)^2$	$\frac{\langle\sqrt{\mathbf{K}},\mathbf{J}\rangle}{n^3}\mathbf{S}_1 + \frac{\langle\sqrt{\mathbf{K}},\mathbf{H}\rangle}{n(n-1)}\mathbf{S}_2$, where $\sqrt{\mathbf{K}}\mathbf{S}_1 + \mathbf{S}_1\sqrt{\mathbf{K}} = \mathbf{J}, \quad \sqrt{\mathbf{K}}\mathbf{S}_2 + \mathbf{S}_2\sqrt{\mathbf{K}} = \mathbf{H}$
Bures-based	$\left(1 - \frac{1}{2}\tilde{d}_{\mathcal{N}}(\mathbf{K})^2\right)^2$	$\frac{1}{n^2}\mathbf{J} + \frac{S_\gamma(\mathbf{HKH})}{n(n-1)}\mathbf{S}'_\gamma(\mathbf{HKH})$
	$\frac{1}{2}\tilde{d}_{\mathcal{N}}(\mathbf{K})^2 = 1 - \sqrt{\frac{1}{n^2}\langle\mathbf{K},\mathbf{J}\rangle + \frac{1}{n(n-1)}S_\gamma^2(\mathbf{HKH})} \approx i(\mathbf{K})$	
	$S_\gamma(\mathbf{X}) = \sum_{i=1}^n s_\gamma(\lambda_i)$, where $\lambda_1, \ldots, \lambda_n$ are eigenvalues of $\mathbf{X}$	
	$s_\gamma(x) = \begin{cases} \sqrt{x} & x > \gamma \\ \frac{1}{4}\gamma^{-\frac{3}{2}}x^2 + 3\sqrt{\gamma} & x \leq \gamma \end{cases}$	
	$\mathbf{S}'_\gamma(\mathbf{X}) = \sum_{i=1}^n s'_\gamma(\lambda_i)\mathbf{u}_i\mathbf{u}_i^\top$, where $\mathbf{X} = \sum_{i=1}^n \lambda_i\mathbf{u}_i\mathbf{u}_i^\top$	

positive definite. Finally, although the Bures-based measure is not differentiable, a smooth function operating on the eigenvalues of $\mathbf{HKH}$, i.e., a spectral function (Lewis, 1996), can be used as an approximation to replace the trace of the matrix square root, which is not differentiable for any $\mathbf{K}$ since $\mathbf{HKH}$ has an eigenvalue of 0 corresponding to the constant eigenvector. For the smoothing function, we use a Huber-type approximation (Huber, 1964; Hintermüller and Wu, 2014) of the square root. Using standard identities for the differentiation of scalar-matrix functions (Lewis, 1996; Olsen et al., 2012), we derive the gradients of cost functions proportional to those in Table 3. The simplified expressions of the gradients are given in Table 4.

As informativeness is only meaningful for correlation matrices, the optimization variable must be constrained to lie within the elliptope. Restriction to correlation matrices can be enforced via a combination of a linear constraint (for the diagonal) and a semidefinite constraint. Finding the maximally informative correlation matrix is a type of semidefinite optimization (convex for the Euclidean and HSIC measures and appropriate choice of ρ). For the convex cases, the unique optimum can be sought using either a projected-gradient or a conditional gradient (Frank-Wolfe) algorithm. In the former case, the Euclidean projection to the elliptope can be used, but is non-trivial (Higham, 2002; Malick, 2004). The

latter case requires solving a semidefinite program for the approximation step at each iteration. Furthermore, both cases require an order of n^2 variables. An alternative is to factorize the correlation matrix into a lower-dimensional Euclidean embedding (Journée et al., 2010). Factorizations have been used for solving the nearest correlation matrix problem (Grubišić and Pietersz, 2007) and other semidefinite programs (Burer and Monteiro, 2003). In Section 4.2, we pursue this factorization approach and express the cost functions corresponding to the measures of informativeness in terms of a Euclidean embedding.

When the correlation matrix is a function of parameters, informativeness can be used as an objective for optimizing these parameters. For instance, the correlation matrix can be defined parametrically in terms of the squared distances among a sample of points, passed through a differentiable function κ,

$$K_{i,j} = \kappa\left((\mathbf{x}_i - \mathbf{x}_j)^\top\mathbf{U}^\top\mathbf{U}(\mathbf{x}_i - \mathbf{x}_j)\right),$$

where $\mathbf{U}^\top\mathbf{U}$ defines a Mahalanobis distance metric as $d^2_{\mathbf{U}^\top\mathbf{U}}(\mathbf{x}_i, \mathbf{x}_j) = \|\mathbf{U}\mathbf{x}_i - \mathbf{U}\mathbf{x}_j\|_2$ and $\mathbf{X} = [\mathbf{x}_1, \ldots, \mathbf{x}_n] \in \mathbb{R}^{d\times n}$ is the sample of points. If $\kappa(|x-y|^2) = k(x,y) \quad \forall x, y \in \mathbb{R}$, where k is a positive semidefinite kernel function and $\kappa(0) = k(x,x) = 1 \quad \forall x$, then $\mathbf{K}$ is always a correlation matrix. Using this form, optimization of either $\mathbf{U}$ or $\mathbf{X}$ can be performed without additional constraints to ensure $\mathbf{K}$ is a correlation matrix. Optimizing informativeness with respect to $\mathbf{X}$ will shift the points in order to increase the informativeness, and optimization in terms of $\mathbf{U}$ corresponds to an unsupervised form of metric learning: a task that is typically supervised (Lowe, 1995; Xing et al., 2003; Fukumizu et al., 2004).

The gradient in terms of the coordinates of the sample $\mathbf{X}$ is

$$\nabla_{\mathbf{X}}\tilde{F}(\mathbf{K}) = -4\mathbf{U}^\top\mathbf{U}\mathbf{X}\left(\mathbf{B} - \operatorname{diag}(\mathbf{B}\mathbf{1})\right),$$

where $\mathbf{B} = \mathbf{K}' \circ \left[\nabla_{\mathbf{K}}\tilde{F}(\mathbf{K})\right]$, $\circ$ denotes the Hadamard product, $K'_{i,j} = \kappa'_{i,j}\left(d^2_{\mathbf{U}^\top\mathbf{U}}(\mathbf{x}_i, \mathbf{x}_j)\right)$, and κ' is the derivative of the scalar kernel function, e.g., for the Gaussian kernel, $k(x,y) = \kappa\left(|x-y|^2\right) = \exp\left(-|x-y|^2\right)$ and $\kappa'\left(|x-y|^2\right) = -\kappa\left(|x-y|^2\right)$. Similarly, the gradient with respect to $\mathbf{U}$ is $\nabla_{\mathbf{U}}\tilde{F}(\mathbf{K}) = -4\mathbf{U}\mathbf{X}\left(\mathbf{B} - \operatorname{diag}(\mathbf{B}\mathbf{1})\right)\mathbf{X}^\top$.

4.2 Maximally Informative Embeddings

When the corresponding embeddings are available and in cases when the dimensionality is lower than the number of objects, the informativeness can be evaluated with lower storage and computational requirements without unnecessarily forming the full correlation matrix. This can be realized as follows. Let $\mathbf{Z} \in \mathbb{R}^{b\times n}$ be a Euclidean space embedding, such that $\mathbf{Z}^\top\mathbf{Z} = \mathbf{K} \in \mathcal{E}$. Since we assume $\mathbf{K}$ is a correlation matrix, then $\mathbf{Z}$ belongs to the oblique manifold $\mathcal{OB}$. For each expression in Table 3, an equivalent expression of the cost function $F\left(d_{\mathcal{N}}(\mathbf{Z}^\top\mathbf{Z})\right)$ is listed in Table 5. It is noteworthy that the Bures-based measure yields a convex cost function, which we investigate in the next section. Empirically, the quantum Hellinger-based cost function appears convex, but we have not been able to prove its convexity. Besides these two, the other cost functions are not convex.

Table 5: Cost functions for finding a maximally informative Euclidean embedding $\mathbf{Z} \in \mathbb{R}^{b\times n}$ of the form $F\left(d_{\mathcal{N}}(\mathbf{Z}^\top\mathbf{Z})\right)$, where F is a monotonically decreasing function of the form $F : d \mapsto 1 - \nu d^2$ with $\nu \in \{\frac{1}{2}, 1\}$, and $d_{\mathcal{N}}(\mathbf{Z}^\top\mathbf{Z})$ is the distance or dissimilarity between the matrix $\mathbf{Z}^\top\mathbf{Z}$ and the family of non-informative matrices.

Measure:	$F\left(d_{\mathcal{N}}(\mathbf{Z}^\top\mathbf{Z})\right)$:	Convexity:
Euclidean	$1 - \frac{1}{n^2}\left\|\mathbf{Z}^\top\mathbf{Z} - \mathbf{N}_a\right\|_F^2, \quad a = \frac{1}{n^2}(\|\mathbf{Z1}\|_2^2 - \|\mathbf{Z}\|_2^2 + n)$	no
Cosine	$\frac{\langle \mathbf{Z}^\top\mathbf{Z}, \mathbf{N}_a\rangle}{\|\mathbf{Z}^\top\mathbf{Z}\|_F\|\mathbf{N}_a\|_F}, \quad a = \frac{1}{n}\|\mathbf{Z1}\|_2^2/\|\mathbf{Z}\|_F^2$	no
HSIC	$1 + \frac{1}{n^2(n-1)}\|\mathbf{ZH}\|_F^4 - \frac{1}{n^2}\|\mathbf{ZHZ}^\top\|_F^2$	no
CKA	$\frac{\|\mathbf{ZH}\|_F^2}{\|\mathbf{ZHZ}^\top\|_F\sqrt{n-1}}$	no
QH	$\sqrt{\frac{1}{n^3}\langle \mathbf{J}, \sqrt{\mathbf{Z}^\top\mathbf{Z}}\rangle^2 + \frac{1}{n(n-1)}\langle \mathbf{H}, \sqrt{\mathbf{Z}^\top\mathbf{Z}}\rangle^2}$	—
Bures-based	$\sqrt{\frac{1}{n^2}\|\mathbf{Z1}\|_2^2 + \frac{1}{n(n-1)}\|\mathbf{ZH}\|_*^2}$	yes

Given these cost functions, we can now pose the problem of finding a maximally informative embedding $\mathbf{Z}$ that lies within an ϵ-radius ball of a target embedding $\mathbf{T}$, as

$$\min_{\mathbf{Z}\in\mathcal{OB}} F\left(d_{\mathcal{N}}(\mathbf{Z}^\top\mathbf{Z})\right) \quad \text{s.t. } \|\mathbf{T} - \mathbf{Z}\|_F \leq \epsilon. \tag{6}$$

The target embedding could arise from a low-rank approximation $\mathbf{T}^\top\mathbf{T} \approx \mathbf{A}$ of a target similarity matrix $\mathbf{A}$. In general, this optimization is non-convex because of the constraint that $\mathbf{Z} \in \mathcal{OB}$. In Section 4.2.2 we present a convex relaxation and optimization algorithm for the Bures-based measure of informativeness. The optimization uses properties of the Bures-based measure explored in Section 4.2.1.

4.2.1 Optimizing the Bures-based Measure of Informativeness for Embeddings

Due to its convexity, we concentrate on the Bures-based informativeness measure for embeddings and define

$$h(\mathbf{Z}) \equiv F^2\left(d_{\mathcal{N}}(\mathbf{Z}^\top\mathbf{Z})\right) = \left(1 - i(\mathbf{Z}^\top\mathbf{Z})\right)^2 = \tfrac{1}{n^2}\|\mathbf{Z1}\|_2^2 + \frac{1}{n(n-1)}\|\mathbf{ZH}\|_*^2, \tag{7}$$

where $d_{\mathcal{N}}(\mathbf{Z}^\top\mathbf{Z}) = \sqrt{2i(\mathbf{Z}^\top\mathbf{Z})}$ is the lower-bound on the Bures distance to the nearest non-informative matrix as defined in Equation B.17. The cost function $h(\cdot)$ has some interesting properties. Firstly, it is well-defined for an arbitrary matrix $\mathbf{X} \in \mathbb{R}^{b\times n}$, not necessarily on the oblique manifold. Secondly, it is convex, since it is the sum of two squared seminorms. Used as a penalty function, the two seminorms simultaneously penalize high-rank embeddings and embeddings which have a large mean, i.e., $h(\cdot)$ is minimal for rank-1,

centered embeddings. Furthermore, since $\|\mathbf{X1}\|_2^2 = \frac{1}{n}\|\mathbf{X11}^\top\|_F^2 = n\|\mathbf{X}\frac{1}{n}\mathbf{J}\|_F^2 = n\|\mathbf{X}\frac{1}{n}\mathbf{J}\|_*^2$ both seminorms correspond to trace norms on the orthogonal subspaces defined by the projections $\mathbf{H}$ and $\frac{1}{n}\mathbf{J}$. We provide a proof that $\sqrt{h(\mathbf{X})} = \sqrt{\frac{1}{n}\|\mathbf{X}\frac{1}{n}\mathbf{J}\|_*^2 + \frac{1}{n(n-1)}\|\mathbf{XH}\|_*^2}$ is itself a matrix norm in Appendix D.

Due to the underlying trace norm, $h(\cdot)$ is not differentiable everywhere. Therefore, to enable the optimization we consider its proximal operator (Moreau, 1965)

$$\mathbf{prox}_{\lambda h}(\mathbf{Z}) \equiv \arg\min_{\mathbf{X}} \frac{1}{2}\|\mathbf{Z} - \mathbf{X}\|_F^2 + \lambda h(\mathbf{X}) \tag{8}$$

with $\lambda \geq 0$. Proximal operators enable first-order optimization involving non-smooth penalty functions (Nesterov, 2007; Wright et al., 2009; Beck and Teboulle, 2009; Combettes and Pesquet, 2011; Parikh and Boyd, 2014). To derive the proximal operator of $h(\cdot)$, we use the fact that both $h(\cdot)$ and the squared Frobenius norm (and Euclidean distance) can both be decomposed into the orthogonal subspaces defined by $\mathbf{H}$ and $\frac{1}{n}\mathbf{J}$, as

$$\begin{aligned} h(\mathbf{X}) &= \tfrac{1}{n}\|\mathbf{X}\tfrac{1}{n}\mathbf{J}\|_*^2 + \tfrac{1}{n(n-1)}\|\mathbf{XH}\|_*^2 = \tfrac{1}{n}\|\bar{\mathbf{X}}\|_*^2 + \tfrac{1}{n(n-1)}\|\tilde{\mathbf{X}}\|_*^2 \\ &= \|\bar{\mathbf{x}}\|_2^2 + \tfrac{1}{n(n-1)}\|\tilde{\mathbf{X}}\|_*^2, \end{aligned} \tag{9}$$

and

$$\|\mathbf{X}\|_F^2 = \left\|\mathbf{X}(\tfrac{1}{n}\mathbf{J} + \mathbf{H})\right\|_F^2 = \left\|\bar{\mathbf{X}}\right\|_F^2 + \|\tilde{\mathbf{X}}\|_F^2 = n\|\bar{\mathbf{x}}\|_2^2 + \|\tilde{\mathbf{X}}\|_F^2,$$

where $\tilde{\mathbf{X}} = \mathbf{XH}$ is a centered version of $\mathbf{X}$, $\bar{\mathbf{X}} = \bar{\mathbf{x}}\mathbf{1}^\top$, $\bar{\mathbf{x}}$ is the average of the columns of $\mathbf{X}$, and $\|\bar{\mathbf{X}}\|_* = \|\bar{\mathbf{X}}\|_F = \sqrt{n}\|\bar{\mathbf{x}}\|_2$ since $\bar{\mathbf{X}}$ is rank-1. Thus, the proximal solution can be written as the sum of the terms $\bar{\mathbf{Y}}$ and $\tilde{\mathbf{Y}}$, each computed independently as

$$\mathbf{prox}_{\lambda h}(\mathbf{Z}) = \bar{\mathbf{Y}} + \tilde{\mathbf{Y}}, \tag{10}$$

with the two terms calculated as

$$\begin{aligned} \bar{\mathbf{Y}} &= \arg\min_{\mathbf{X}} \frac{1}{2}\left\|\bar{\mathbf{Z}} - \mathbf{X}\right\|_F^2 + \frac{\lambda}{n}\|\mathbf{X}\|_F^2 = \frac{n}{n+2\lambda}\bar{\mathbf{Z}}, \\ \tilde{\mathbf{Y}} &= \arg\min_{\mathbf{X}} \frac{1}{2}\left\|\tilde{\mathbf{Z}} - \mathbf{X}\right\|_F^2 + \frac{\lambda}{n(n-1)}\|\mathbf{X}\|_*^2 = \mathcal{Z}_\beta(\tilde{\mathbf{Z}}), \end{aligned}$$

where $\beta = \frac{2\lambda}{n(n-1)}$ and $\mathcal{Z}_\beta(\cdot)$ is the proximal operator of the squared trace norm $\frac{\beta}{2}\|\cdot\|_*^2$, which we define in Equation E.1 in Appendix E along with a proof of its optimality.

4.2.2 Correlation Matrix Denoising

Given the proximal operator for the Bures-based informativeness, we proceed to solve the maximally informative embedding problem of Equation 6. We employ the optimization problem

$$\min_{\mathbf{Z}\in\mathcal{OB}} \tfrac{1}{2}\|\mathbf{T} - \mathbf{Z}\|_F^2 + \lambda h(\mathbf{Z}), \tag{11}$$

where the ϵ-radius constraint is replaced with the penalty term $\frac{1}{2}\|\mathbf{T} - \mathbf{Z}\|_F^2$ and the informativeness is scaled by λ. The minimization's cost function is convex, but the oblique

manifold is not a convex set. We propose to relax the oblique manifold constraint, by replacing it with the constraint that each point in the embedding $\mathbf{Z}$ lies within the unit-sphere $\|\mathbf{z}_i\|_2 \leq 1, \forall i \in [n]$, rather than on it. The relaxed constraint corresponds to the convex hull of the oblique manifold, denoted by $\text{conv}(\mathcal{OB})$. We then add the penalty term $-\frac{\mu}{2}\|\mathbf{Z}\|_F^2$ to ensure the norm of each column is maximized, which pushes the solution closer to the oblique manifold. The relaxed optimization is written as

$$\min_{\mathbf{Z}\in\text{conv}(\mathcal{OB})} \tfrac{1}{2}\|\mathbf{T}-\mathbf{Z}\|_F^2 - \tfrac{\mu}{2}\|\mathbf{Z}\|_F^2 + \lambda h(\mathbf{Z}).$$

This is a convex optimization problem for $\mu \leq 1$. We choose the largest possible penalty $\mu = 1$ to satisfy convexity and approach feasibility, leading to the cost function $\langle \mathbf{Z}, -\mathbf{T}\rangle + \lambda h(\mathbf{Z})$.

To isolate the non-smooth term, we write an equivalent composite form of the optimization problem, using an auxiliary variable $\mathbf{X}$ as

$$\begin{aligned} \min_{\substack{\mathbf{X}\in\mathbb{R}^{b\times n}\\ \mathbf{Z}\in\text{conv}(\mathcal{OB})}} \quad & \langle \mathbf{Z}, -\mathbf{T}\rangle + \lambda h(\mathbf{X}) \\ \text{s.t. } & \mathbf{X} = \mathbf{Z}. \end{aligned} \tag{12}$$

An approximate solution to the composite optimization can be found by removing the equality constraint and adding the penalty term $\frac{\rho}{2}\|\mathbf{Z}-\mathbf{X}\|_F^2$ and using alternating optimization to find a solution to the relaxed problem. The optimization of $\mathbf{Z}$, for fixed $\mathbf{X}$, can be performed on each column independently, and amounts to a Euclidean projection to the unit-ball. Likewise, the optimization $\mathbf{X}$, for fixed $\mathbf{Z}$, is also convex with an analytic solution given by application of the proximal operator $\mathbf{prox}_{\frac{\lambda}{\rho}h}(\mathbf{Z})$.

Because the aforementioned alternating optimization procedure is limited by slow convergence and sensitivity to the penalty, we instead conduct an optimization through an augmented Lagrangian formulation. Specifically, we employ the alternating direction method of multipliers algorithms (ADMM) (Gabay and Mercier, 1976; Eckstein and Bertsekas, 1992; Combettes and Pesquet, 2011; Boyd et al., 2011) to find a fixed point of the augmented Lagrangian

$$\mathcal{L}_\rho(\mathbf{Z},\mathbf{X},\mathbf{M}) = I(\mathbf{Z}) + \langle \mathbf{Z}, -\mathbf{T}\rangle + \lambda h(\mathbf{X}) + \tfrac{\rho}{2}\|\mathbf{Z}-\mathbf{X}\|_F^2 + \langle \mathbf{M}, \mathbf{Z}-\mathbf{X}\rangle, \tag{13}$$

where I is the indicator function for $\text{conv}(\mathcal{OB})$: $f(\mathbf{Z}) = 0$ for $\mathbf{Z} \in \text{conv}(\mathcal{OB})$ and $f(\mathbf{Z}) = +\infty$ otherwise. This leads to a minimization that alternates between two minimization steps on each non-fixed variables $\mathbf{Z}$ and $\mathbf{X}$. Using scaled dual variables $\mathbf{U} = \frac{1}{\rho}\mathbf{M}$, the steps are

$$\begin{aligned} &\min_{\mathbf{Z}\in\text{conv}(\mathcal{OB})} \left\|\mathbf{Z}-\mathbf{X}+\mathbf{U}-\tfrac{1}{\rho}\mathbf{T}\right\|_F^2, \\ &\min_{\mathbf{X}\in\mathbb{R}^{b\times n}} \tfrac{\rho}{2}\|\mathbf{Z}-\mathbf{X}+\mathbf{U}\|_F^2 + \lambda h(\mathbf{X}), \end{aligned}$$

and are followed by an update of the dual variables $\mathbf{U}$ with the residuals $\mathbf{Z}-\mathbf{X}$. The proposed optimization procedure is summarized in Algorithm 1. The computational complexity of each iteration is $\mathcal{O}(b^2 n)$, which corresponds to the singular value decomposition of the embedding matrix required by the proximal operator of h.

Algorithm 1: Correlation Matrix Denoising

input : Initial embedding $\mathbf{T}$ of size $b \times n$, and parameters $\lambda > 0$, $\rho > 0$, and $\eta = \frac{\lambda}{\rho}$

output: A denoised embedding $\mathbf{Z}$

In practice, we use $\rho = 1$, and find that if λ is chosen appropriately, the solution at convergence lies on the oblique manifold, i.e., $\mathbf{Z} \in \mathcal{OB}$. This means that the solution to the relaxed problem (12) satisfies the constraint of the original problem (11). To understand why the convex relaxation yields solutions to the original problem, we note that for any λ, the relaxed problem can be written as a linear program over the convex set defined by the intersection of $\text{conv}(\mathcal{OB})$ and $\mathcal{I}_c = \{\mathbf{X} : \sqrt{h(\mathbf{X})} \leq c\}$, where small values of c correspond to large values of λ, and $\mathcal{I}_c$ corresponds to the set embeddings with informativeness above $1-c$. As any linear program is optimized at extremal points of a convex set, an optimizing point of the relaxed solution will either lie on the oblique manifold and within the interior of $\mathcal{I}_c$, or if λ is too large, on the boundary of $\mathcal{I}_c$ and in the interior of $\text{conv}(\mathcal{OB})$.

The convergence of the ADMM algorithm can be proven under mild conditions (Boyd et al., 2011), which are met for Algorithm 1. The conditions require the objective functions to be closed, proper, and convex; and the existence of a saddle point $(\mathbf{Z}^\star, \mathbf{X}^\star, \mathbf{M}^\star)$ of the unaugmented Lagrangian function $\mathcal{L}_0(\mathbf{Z},\mathbf{X},\mathbf{M})$, i.e., Equation 13 with $\rho = 0$, such that $\mathcal{L}_0(\mathbf{Z}^\star,\mathbf{X}^\star,\mathbf{M}) \leq \mathcal{L}_0(\mathbf{Z}^\star,\mathbf{X}^\star,\mathbf{M}^\star) \leq \mathcal{L}_0(\mathbf{Z},\mathbf{X},\mathbf{M}^\star)$ for all $\mathbf{Z},\mathbf{X},\mathbf{M}$. The saddle point $(\mathbf{Z}^\star,\mathbf{X}^\star,\mathbf{0})$ corresponds to the solution $(\mathbf{Z}^\star,\mathbf{X}^\star)$ of the relaxed optimization problem (12). This solution necessarily exists, since as mentioned, the relaxed problem is equivalent to a linear objective optimized over the convex set defined by the intersection of $\text{conv}(\mathcal{OB})$ and $\mathcal{I}_c$. Furthermore, the convergence rate of the ADMM algorithm for convex objectives is $\mathcal{O}(1/t)$, where t is the number of iterations (He and Yuan, 2015).

To obtain embeddings which are progressively more informative (low-rank and nearly centered), the algorithm can be ran with increasing values of λ and warm restarts. We start with $\lambda = 1$, increase it by 125% at each restart, and stop the sequence of warm restarts if the solution at convergence no longer lies on the boundary of the convex hull, that is, $\mathbf{Z} \notin \mathcal{OB}$. The main computational burden of the algorithm is the singular value decomposition required in computing the proximal operator of $h(\cdot)$. This burden can somewhat be alleviated by using lower dimensional embeddings (i.e., a smaller b). Rather than choosing a small initial b, which cannot preserve as much information about the target matrix, we use an adaptive truncation heuristic. Specifically, we note that $h(\cdot)$ is invariant to unitary

transformations of the embedding coordinates. Thus, we can use a singular value decomposition of the solution $\mathbf{Z} = \mathbf{\Psi}\mathbf{\Sigma}\mathbf{\Upsilon}^\top$ and transform $\mathbf{Z}$ and $\mathbf{T}$ with the left singular vectors, and then remove embedding dimensions (rows) from both $\mathbf{\Psi}^\top\mathbf{Z} = \mathbf{\Sigma}\mathbf{\Upsilon}^\top$ and $\mathbf{\Psi}^\top\mathbf{T}$, when the corresponding singular values of $\mathbf{Z}$ are less than $\frac{\sigma_1}{100}$, with $\sigma_1 = \|\mathbf{Z}\|_2$ being the maximum singular value. While truncation does distort the target matrix, this approach lowers the dimensions and decreases the processing requirements for the subsequent warm restarts.

5. Experiments

In this section we highlight example applications of the measures of informativeness[7] and compare the different measures listed in Table 2. Applications include selecting an appropriate kernel bandwidth, selecting the dimension of a low-rank kernel approximation, and detecting clustered graphs. We also demonstrate the correlation matrix denoising algorithm as a preprocessor for spectral clustering.

5.1 Kernel Bandwidth Selection

Gaussian kernel functions of the form $k_\sigma(\mathbf{x}, \mathbf{y}) = \exp\left(\frac{-1}{2\sigma^2}\|\mathbf{x} - \mathbf{y}\|_2^2\right)$ are widely used for kernel-based clustering and classification of vectors in Euclidean space, but an appropriate kernel bandwidth σ needs to be selected. For any choice of σ, evaluating the kernel function for a set of vectors yields a correlation matrix with entries $K_{i,j} = k_\sigma(\mathbf{x}_i, \mathbf{x}_j)$. If all of the vectors are distinct, the limit $\sigma \to 0$ yields the identity matrix $\mathbf{I}$, and the limit $\sigma \to \infty$ results in the constant matrix $\mathbf{J}$. Essentially, the kernel bandwidth parameterizes a curve within the elliptope that begins and finishes at non-informative correlation matrices. Since informativeness is a function of the distance to the set of non-informative correlation matrices, choosing the kernel bandwidth that maximizes the informativeness corresponds to finding an extremal point of this curve as illustrated in Figure 7. The example shows informativeness can be used to select a kernel bandwidth appropriate for the scale of the data. In comparison, measures such as the von Neumann entropy or distance from the identity matrix are maximized by the smallest and largest kernel bandwidths, respectively.

We compare the different informativeness measures on four synthetic examples in Figure 8. In these examples, the measures are maximized by kernel bandwidths dependent on the scale of the data. This holds for all measures except CKA, which is maximized by large kernel bandwidths that yield nearly constant matrices. We quantify the appropriateness of informativeness-based bandwidth selection for spectral clustering—specifically, the algorithm by Ng et al. (2002)—by using the normalized mutual information[8] between the labels corresponding to the true grouping and the clusters found when using different kernel bandwidths. For each example, 10 random instances are tested with the correct number of groups provided to the clustering algorithm. On the first example, each group is a convex shape and a large kernel bandwidth performs well. On the remaining examples, there is an intermediate kernel bandwidth that maximizes the normalized mutual information.

7. MATLAB code that implements the informativeness measures and reproduces the figures and tables is available at `http://pcwww.liv.ac.uk/~goulerma/software/brockmeier17a-code.zip`.
8. Normalized mutual information is the mutual information between two variables divided by the maximum entropy of the two (Kvålseth, 1987).

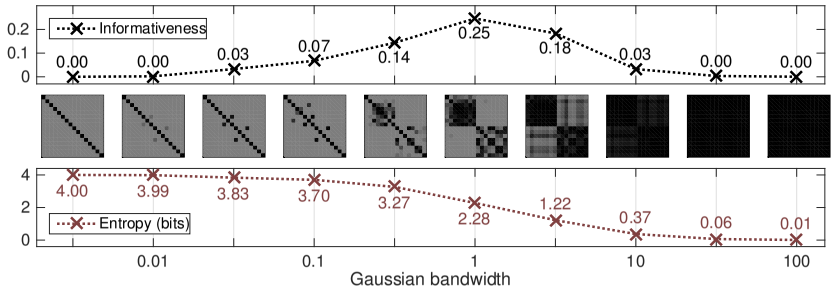

Figure 7: Informativeness versus von Neumann entropy for correlation matrices obtained from applying a Gaussian kernel with varying bandwidths to a sample drawn from a univariate mixture of two normal distributions separated by a distance of 4. (The Bures-based informativeness is used in this example.)

For each measure of informativeness and for Bartlett's and Lawley's test statistics, we collect the values of normalized mutual information corresponding to the bandwidths that maximize the measures. The results are reported as box and whisker plots in Figure 8. From the results, there appear to be four subsets of measures that select similar bandwidths: the cosine measure, which chooses the smallest kernel bandwidth, has the worst median performance on the first data set, but performs the best on the remaining; the Chernoff, QH, and Bures-based measures select a larger bandwidth, tie for the best performance on the first data set, achieve the second-best performance across the remaining; the Euclidean, HSIC, and sub-Bures measures select larger bandwidths and perform worse; and the CKA measure along with Bartlett's and Lawley's test statistics are maximized by the largest kernel bandwidth within the range, which yields a poor clustering on three of the four data sets. This example shows that the informativeness measures (except CKA) can adaptively select kernel bandwidths appropriate for the structure of the data.

5.2 Selecting an Embedding Dimension

Kernel principal component analysis (Schölkopf et al., 1998) approximates a kernel matrix using a lower-dimensional embedding obtained by truncating the eigenvalue decomposition of the centered kernel matrix. Choosing the embedding dimension (how many eigenvectors to retain) requires a criterion. We show that choosing the dimension that maximizes informativeness is an effective approach.

Specifically, kernel principal component analysis uses the top-k eigenvectors of the centered kernel matrix $\tilde{\mathbf{K}} = \mathbf{HKH}$. Let denote $\tilde{\mathbf{K}}^{(k)}$ the rank-k approximation of $\tilde{\mathbf{K}}$. In general $\tilde{\mathbf{K}}^{(k)}$ is positive definite but not a correlation matrix, and requires symmetric normalization as defined in Equation 1. However, if the original kernel matrix is far from being centered then applying normalization after centering and truncation can introduce severe distortion.

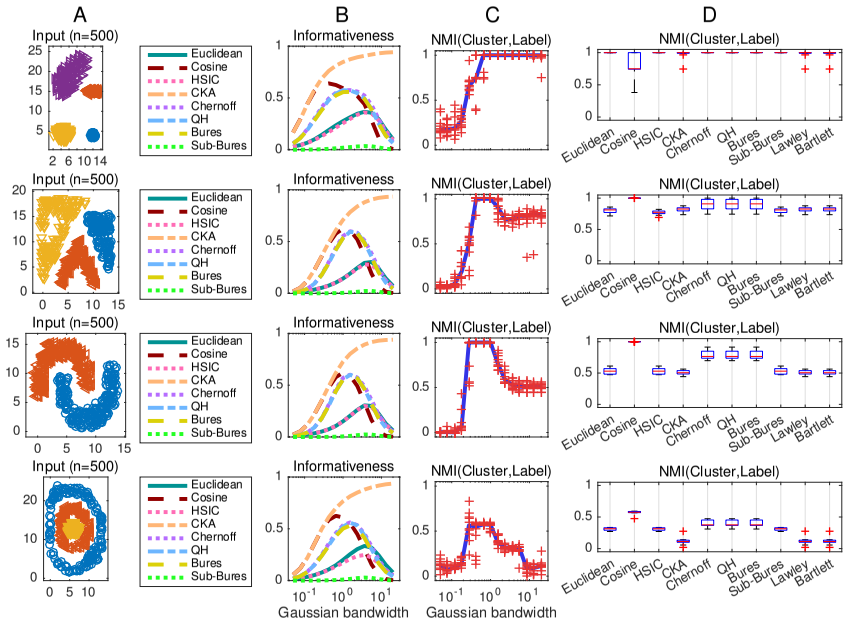

Figure 8: Selecting a Gaussian kernel bandwidth for spectral clustering by maximizing informativeness. (A) Samples are drawn from two-dimensional distributions with distinct groups. (B) Informativeness is plotted versus the kernel bandwidth. (C) For each kernel bandwidth, spectral clustering is applied with the correct number of clusters and the normalized mutual information (NMI) between the cluster label and the true label is recorded (crosses indicate values across 10 random samples; solid curve for the median). (D) Box and whisker plots of the NMI values for the clusterings obtained when the kernel bandwidth is selected by informativeness or by Lawley's and Bartlett's test statistics.

As an alternative, we truncate the original, uncentered correlation matrix and then perform renormalization.

We test the dimensionality selection method on a set of UCI data sets (Lichman, 2013). A Gaussian kernel function with a heuristic bandwidth is used for all cases. Specifically, the bandwidth is a linear combination of the minimum and maximum Euclidean distances $\sigma = 2d_{min} + \frac{2}{9}(d_{max} - 2d_{min})$, where d_{min} and d_{max} are the minimum and maximum pairwise distances (a similar heuristic was used by Shi and Malik, 2000).

Table 6: Nearest neighbor classification performance for kernel-based dimensionality reduction across 7 UCI data sets. Each entry lists the classification accuracy as a percentage, followed by the average dimensionality in parentheses. The last two rows list the average difference in performance versus using the original space and the average loss margin (absolute difference to the best method on the run) across 20 Monte Carlo runs and data sets (standard deviation across data sets).

For comparison, we use supervised selection of the dimensionality based on centered kernel alignment (Cortes et al., 2012). We test both the centered and uncentered truncations, and select the dimension that maximizes the centered kernel alignment to a target matrix obtained from the classification labels in the training set. In all cases, we use a first nearest neighbor classifier with half of the instances for training; the average classification accuracy is recorded in Table 6.

Across these data sets, the Bures, Chernoff, and QH-based informativeness measures perform the best. They select a lower dimensional embedding and improve the classification performance versus using the original distances. The cosine-based informativeness measure also outperforms using centered kernel alignment with training labels. In comparison, the Euclidean and HSIC-based informativeness measures select very low-dimensional embeddings that do not perform well, and the CKA-based informativeness and Bartlett's and

Lawley's test statistics are inappropriate for this task as they often select one-dimensional embeddings, which is an inadequate representation for a nearest neighbor classifier.

5.3 Informativeness as an Indicator of Structure in Graphs

We show that informativeness is indicative of structure in undirected graphs. We consider binary graphs whose edges are defined by a symmetric adjacency matrix $\mathbf{G} \in \{0,1\}^{n\times n}$, where $G_{i,j} = 1$ indicates an edge between vertices i and j. To enable informativeness to be applied directly, we represent a graph by its normalized graph Laplacian matrix $\mathbf{L}$, which is a correlation matrix under the following definition

$$L_{i,j} = \begin{cases} 1 & i = j, \\ \frac{-1}{\sqrt{d_i d_j}} & G_{i,j} = 1, \\ 0 & \text{otherwise}, \end{cases}$$

where d_i is the degree of the ith vertex. When the graph has unconnected vertices, the corresponding rows and columns of the normalized graph Laplacian are all zeros except at the diagonal entry. This is different than the standard convention (Chung, 1997), where the diagonal entry for an unconnected vertex would be zero.

Informativeness can be used to make relative comparisons between graphs with the same number of vertices. In particular, informativeness can be used to rank graphs and identify graphs that are more informative than a regular graph with the same number of edges. Firstly, we consider the informativeness for small graphs, $n = 5$, for which we evaluate all 34 non-isomorphic graphs. Figure 9 shows the Bures-based informativeness for each graph plotted against the number of edges; there is a clear separation of the values for the three most informative graphs, which correspond to clustered graphs. Of the remaining graphs, the path graph (a tree with maximum degree of 2) has the next highest informativeness. This ordering held for all informativeness measures. We then test the set of non-isomorphic trees for $n = 6$. The trees are shown in Figure 10 ordered by their informativeness. Once again, the path graph has the highest informativeness of all trees; the ordering is consistent for all informativeness measures.

For larger graphs, it becomes infeasible to enumerate all of the non-isomorphic graphs. As a baseline we consider regular graphs, which are defined as graphs whose vertices have the same degree. To further sample from the universe of possible graphs with $n = 100$ vertices, we consider the following random graph models:

- Erdős-Rényi model described by an edge-link probability (Erdős and Rényi, 1959),
- Barabási-Albert scale-free model with a power law degree distribution (Barabási and Albert, 1999),
- Watts and Strogatz small-world model (Watts and Strogatz, 1998), which randomly rewires each edge of a regular graphs with a certain probability (we use 5%),
- a clustered regular graph model, generated by removing all edges between vertices assigned to different clusters (the number of clusters is varied between 2 and 20).

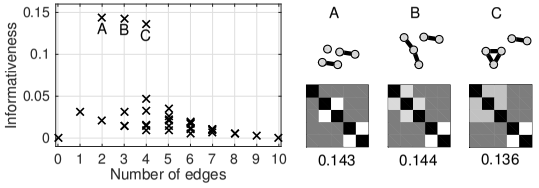

Figure 9: Bures-based informativeness of non-isomorphic graphs with $n = 5$ vertices. The three graphs (labeled A, B, C) with highest informativeness correspond to graphs with two or three clusters.

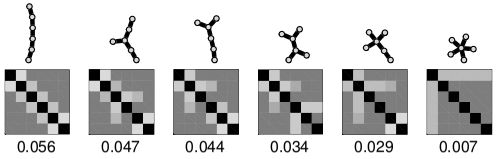

Figure 10: Non-isomorphic trees with 6 vertices sorted by Bures-based informativeness.

Erdős-Rényi graphs and Barabási-Albert scale-free graphs are both unstructured graph models that differ in their degree distributions. The degree distribution of the former is a Poisson distribution, whereas the scale-free graphs have a long-tailed degree distribution, meaning that a small number of vertices have a large number of edges.

We evaluate the informativeness of regular graphs and realizations of each random graph model, scanning any free parameters to vary the number of edges. Example graphs and the Bures-based informativeness as a function of the average degree[9] are shown in Figure 11. For any given number of edges, the informativeness is maximized by clustered graphs, and minimized by the Erdős-Rényi graphs and Barabási-Albert scale-free graphs. The random rewiring involved with the Watts and Strogatz small-world model does not drastically change the informativeness from that of regular graphs.

We compare informativeness to two existing test statistics for clustering in graphs: the modularity of two-way partitions identified using an eigenvector-based method (Newman, 2006) and the statistic defined by Bickel and Sarkar (2016) on the adjacency matrix. The latter statistic is used for testing the hypothesis that the graph is drawn from an Erdős-Rényi model; the test statistic is based on the largest eigenvalue of the difference between the adjacency matrix and the expectation over adjacency matrices under an Erdős-Rényi model, where the normalized graph Laplacian of this expectation is a non-informative correlation matrix. Bickel and Sarkar (2016) used the test statistic to identify cluster structure. Bickel and Sarkar's statistic is normalized, such that its distribution for Erdős-Rényi graphs is invariant to the number of edges. Figure 11 also shows the values obtained from these test

9. The average degree is given as $\bar{d} = \frac{2e}{n}$, where e is the number of edges.

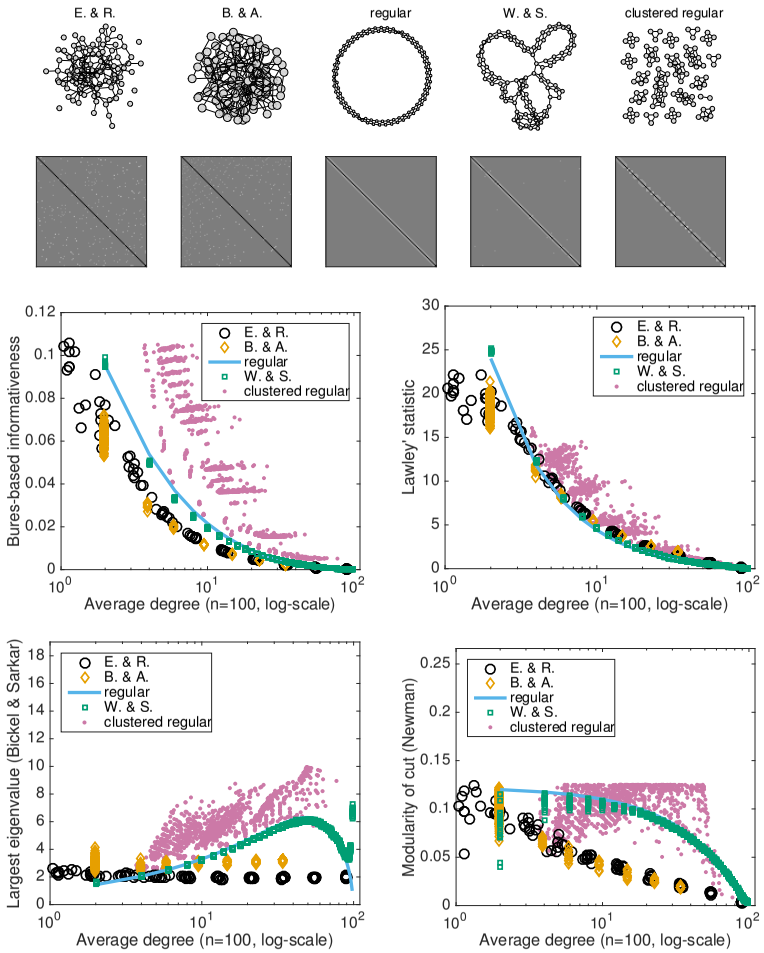

Figure 11: Comparison of informativeness and other statistics on different types of random graphs. Bures-based informativeness and Lawley's test statistic for homogeneous correlation coefficients are applied to the normalized graph Laplacians, and compared to the graph-clustering test statistics proposed by Bickel and Sarkar (2016) and Newman (2006). The random graphs were drawn from Erdős-Rényi (E. & R.), Barabási-Albert scale-free (B. & A.), Watts-Strogatz small-world (W. & S.), and clustered regular models.

Table 7: Proportion of graphs with informativeness, or other measure, greater than a threshold set as the value of a nearly-regular graph with the same number of edges. Graphs have 100 vertices. The random graphs were drawn from Erdős-Rényi (E. & R.), Barabási-Albert scale-free (B. & A.), Watts-Strogatz small-world (W. & S.), and clustered regular models.

statistics on the various graphs. The test statistics have a different range as compared to the measures of informativeness; nonetheless, for a given statistic or measure of informativeness, the values can be used to make relative comparisons between the different graphs.

The value of informativeness is dependent on the number of edges, with graphs with fewer edges being more informative. As a threshold for identifying structure, we use the informativeness of a nearly-regular graph[10] with the same number of edges. The thresholds for the other statistics are formed in the same way. Ideally, the value of a clustered graph will be above the threshold, and the value will be below the threshold for an unstructured graph. Table 7 details the proportion of random graphs above the threshold for each measure.

The QH, Chernoff, and Bures-based measures appear to be the best measures to distinguish clustered graphs from unstructured graphs. The HSIC and CKA-based measures and Bartlett's statistic perform nearly as well. The Euclidean, sub-Bures, and cosine-based measures are not as specific—a larger proportion of unstructured graphs are evaluated above the threshold. Bickel and Sarkar's and Lawley's statistics are even less specific. Newman's modularity index (designed to detect binary clustering) evaluates fewer clustered graphs above the threshold; but, it identifies the lowest proportion of Watts-Strogatz small-world model, which are not clustered. To summarize, a subset of the informativeness measures and Bartlett's statistic are specific indicators of regular structure and clustering in graphs, and Newman's modularity is useful for identifying clustered graphs specifically.

10. A graph is regular if the number of edges is divisible by the number of vertices, otherwise a nearly-regular graph is constructed by adding edges to a regular graph, where the additional edges are evenly distributed, such that the degrees of any two vertices differ by at most 1.

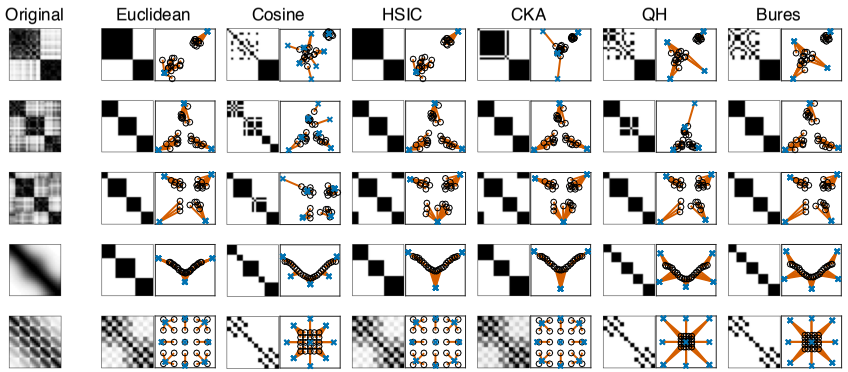

Figure 12: Sample denoising based on optimizing the informativeness of a Gaussian kernel matrix with respect to the sample's two-dimensional coordinates. Each row shows the original Gaussian kernel matrix ($n = 25$), the kernel matrices corresponding to the optimized coordinates, the location of the optimized coordinates, denoted as x's, and the original coordinates, denoted as o's.

5.4 Sample Denoising via Informativeness

To illustrate that informativeness can be used as an unsupervised objective function, we explore first-order optimization of informativeness with respect to a sample of points $\{\mathbf{x}_i\}_{i=1}^n$, defining a correlation matrix through a Gaussian function as $K_{i,j} = \kappa(\|\mathbf{x}_i - \mathbf{x}_j\|_2^2) = \exp\left(-\frac{1}{2\sigma^2}\|\mathbf{x}_i - \mathbf{x}_j\|_2^2\right)$. We first find the bandwidth σ that maximizes the informativeness using a golden search over $\theta \in [-5, 5]$, where $2\sigma^2 = 10^{-\theta}$. Then, we optimize the sample coordinates using the conjugate gradient method implemented in minFunc (Schmidt, 2012) with the gradients given in Section 4.1. For all methods, the optimization is performed in terms of $\acute{\mathbf{K}} = (1-\eta)\mathbf{K} + \eta\mathbf{I}$, where $\eta = 10^{-6}$, to ensure the correlation matrix is positive definite. A log-barrier term of $-\log(1 - \frac{1}{n^2}\mathbf{1}^\top\mathbf{K}\mathbf{1})$ is added to the cost function for the CKA measure. For the Bures-based measure, a smoothing parameter of $\gamma = 10^{-9}$ is used.

We apply the first-order optimization on five synthetic data sets consisting of $n = 25$ two-dimensional points. As shown in Figure 12, the optimization exhibits mode-seeking—i.e., groups of nearby points cluster together, which enhances the cluster structure seen in the correlation matrices.

We then apply the denoising process to a set of grayscale images of handwritten digits in the USPS data set (Hull, 1994).[11] Taking a random set of 40 images for each digit yields a sample with $n = 400$. The resulting correlation matrices and the images corresponding to the optimized point locations are shown in Figure 13. There is a clear difference in the results for the different measures: With the Euclidean measure, different digits are

11. The USPS handwritten digits data set (Hull, 1994) is available from `http://web.stanford.edu/~hastie/ElemStatLearn/data.html`, where it is labeled 'ZIP code'.

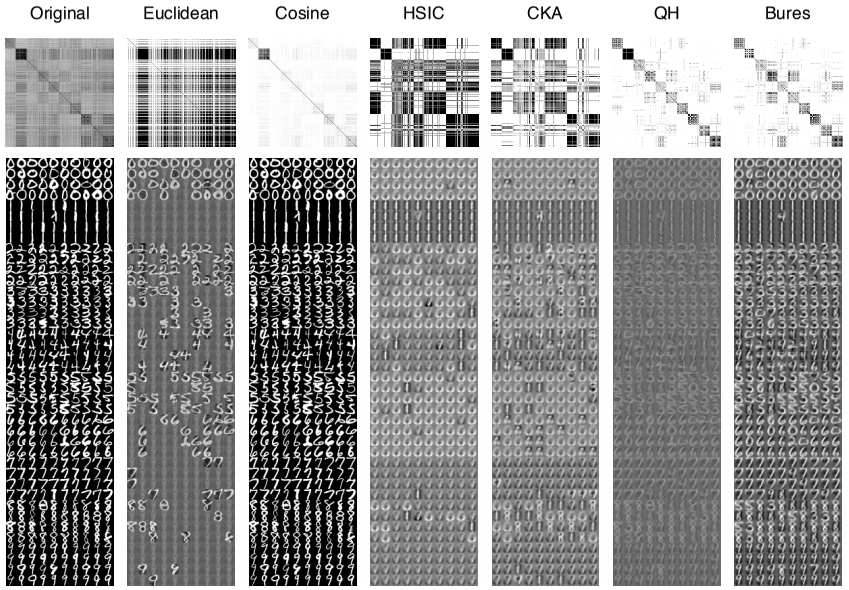

Figure 13: Sample denoising on 200 images from the USPS handwritten digits data set. The correlation matrix is formed from the Gaussian kernel applied to vectors of the pixel values. The first row shows the correlation matrices and the second row shows the corresponding images based on the optimized pixel values.

grouped together into indistinct images, while the remaining images remain unchanged. The cosine measure only slightly modifies the images. The HSIC and CKA measures seem to map most of the digits to a subset of stereotyped digits, but besides 0's, 1's, and 7's/9's the correspondence to the original digits is lost. On the other hand, the QH and Bures measures produce correlation matrices that correspond much more closely to the true class structure. Furthermore, the images appear to be denoised with the majority of the digits mapped to stereotyped versions of the original digits. To quantify the enhanced class structure, we compute the centered kernel alignment between the correlation matrix for the ground-truth labels and the optimized correlation matrix, and record the values in Table 8. As a baseline, we use the original coordinates (that is the original images) for the sample and select a kernel bandwidth that maximizes the centered kernel alignment. Only the Bures measure yields a correlation matrix with higher centered kernel alignment than this baseline.

The QH and Bures measures are also distinguished by their computation time as shown in Table 8, as the gradient calculations for these two measures have higher computational

Table 8: Performance results for sample denoising on the subset of 200 USPS digit images shown in Figure 13. The centered kernel alignment (CA) is calculated between the ground-truth label matrix (a binary correlation matrix) and the correlation matrix for the original sample and the denoised sample for each measure. Computation time logged in MATLAB R2015b on a 2.8 GHz Intel Core i7 with 16 GB RAM.

	Original	Euclidean	Cosine	HSIC	CKA	QH	Bures
CA to labels:	0.53	0.11	0.45	0.27	0.28	0.47	0.55
Time (s):	—	0.99	0.17	1.56	1.10	503.85	37.13

complexity $\mathcal{O}(n^3)$ versus $\mathcal{O}(n^2)$ for the other measures. The QH measure requires solving two Sylvester equations, and the Bures measure requires a single eigendecomposition. This makes the running time with the QH measure much longer in practice.

5.5 Correlation Matrix Denoising

We now demonstrate Algorithm 1 for correlation matrix denoising. The algorithm finds an embedding that maximizes the Bures-based informativeness within a neighborhood of a target embedding. The algorithm is completely unsupervised and can be used to obtain an arbitrary rank embedding. We use it to reduce the rank of an $n \times n$ kernel matrix to $\lfloor \sqrt{n} \rfloor$ as a preprocessing for clustering.

The initial correlation matrix is formed by using a Gaussian kernel between images for five thumbnail image data sets: ORL, MNIST, UMIST, USPS, and COIL-20.[12] The kernel bandwidth heuristic described in Section 5.2 is again used to select this parameter. The initial target embedding was given as $\mathbf{T} = \sqrt{\mathbf{\Sigma}}\mathbf{U}^\top$, where $\mathbf{U}\mathbf{\Sigma}\mathbf{U}^\top = \mathbf{K}$ is the eigendecomposition of the Gaussian kernel matrix. Figure 14 shows a visualization of the various matrices and also plots the informativeness and centered kernel alignment to the label matrix as a function of rank. As designed, the denoised matrices are more informative than the original matrix and more informative than truncated and renormalized kernel matrices (centered or uncentered) of equal rank. Additionally, except on the ORL data set, the denoised matrices have higher centered kernel alignment.

To demonstrate that the denoising preserves and enhances task-relevant structure, we perform spectral clustering with and without denoising. Starting from an embedding of the original correlation matrix, we obtain a denoised embedding $\mathbf{Z}$ with a rank of $\lfloor \sqrt{n} \rfloor$. Since spectral clustering methods assume a non-negative affinity matrix as input, we apply non-negative thresholding on the entries of the denoised correlation matrix $\mathbf{K}^\star = \mathbf{Z}^\top\mathbf{Z}$ and treat the resulting non-negative, symmetric matrix $[\mathbf{K}^\star]_+$ as the input for Ng et al.'s normalized

12. The Olivetti Research Laboratory's (ORL) face image data set was previously hosted by AT&T Cambridge and is now hosted by Cambridge University Computer Laboratory: `http://www.cl.cam.ac.uk/research/dtg/attarchive/facedatabase.html`. The MNIST handwritten digits test set is available from `http://yann.lecun.com/exdb/mnist/`. The UMIST data set (Graham and Allinson, 1998) is now the Sheffield Face Database `https://www.sheffield.ac.uk/eee/research/iel/research/face`. The COIL-20 data set consists of images of rotated objects (Nene et al., 1996), available at `http://www.cs.columbia.edu/CAVE/software/softlib/coil-20.php`.

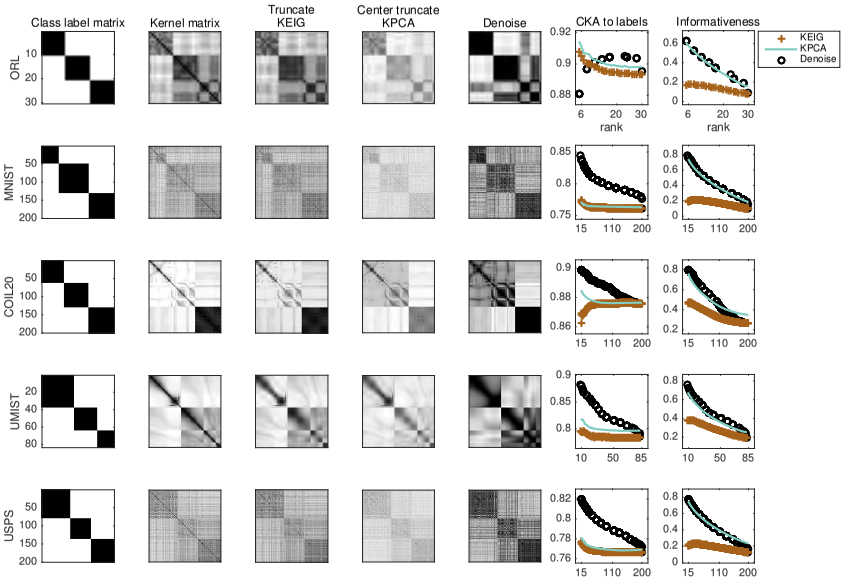

Figure 14: Examples of correlation matrix denoising on Gaussian kernel matrices obtained from samples of the ORL, MNIST, COIL-20, UMIST, and USPS data sets. Each sample contains three different classes. Each row shows the kernel matrix for the ground truth labels, the original Gaussian kernel matrix, the truncated and renormalized matrices corresponding to the uncentered kernel matrix (KEIG) and centered kernel matrix (KPCA), and the denoised correlation matrix. The latter three matrices have rank $\lfloor \sqrt{n} \rfloor$ and the symmetric normalization described in Equation 1 is applied to ensure they are correlation matrices. To the right of the matrices, the centered kernel alignment (CKA) to the ground-truth label matrix and the Bures-based informativeness is shown as a function of rank.

spectral clustering algorithm (Ng et al., 2002). For comparison we also use the spectral clustering method by Shi and Malik (2000) without denoising.

We compare clustering performance on the 20 Newsgroup text data set[13] and the five image data sets used in the previous example. Random subsets of different number of classes (2, 3, 4, and 5) are drawn with 200 samples in each Monte Carlo draw. For the text data set, each document is represented as a bag-of-words vector (a sparse vector of word counts for each document), and in each Monte Carlo division, words that are used in less than 4 documents are dropped. The remaining word counts are multiplied by the

Table 9: Clustering performance using normalized spectral clustering (NCut), the algorithm by Ng, Jordan, and Weiss (NJW), and the NJW algorithm after denoising the correlation matrix. In each case, k-means with correct number of classes is used to determine the cluster assignment from the spectral embedding. Values correspond to average accuracy (higher is better) or variation in information (lower is better) across 20 Monte Carlo runs; the average loss margin to the best performing method is shown parenthesized. Boldfaced entries indicate significantly better median performance (Wilcoxon signed-rank test with a significance threshold of 0.05).

	Accuracy (after mapping clusters to classes)				Variation in information

logarithm of the inverse of each word's document frequency (this is the standard TF-IDF weighting), and cosine similarity is used to compute the correlation matrix. For the image data sets, the Gaussian kernel (the kernel bandwidth heuristic described in Section 5.2 is used once again). We fix the number of clusters to the number of classes. The results in terms of accuracy and variation of information (Meilă, 2003) are recorded in Table 9. The clustering obtained when using the denoised and thresholded matrix better matches the ground truth (in terms of both performance metrics) than the clustering obtained using the original kernel matrix across almost every data set and number of classes.

6. Discussion

We have introduced a framework for identifying nontrivial structure in correlation matrices using informativeness, which is a distance-based framework we have proposed for measuring the equality of correlation coefficients (Bartlett, 1954; Anderson, 1963; Lawley, 1963; Gleser, 1968; Aitkin et al., 1968; Steiger, 1980; Brien et al., 1984). Correlation matrices appear in various contexts within machine learning and statistical analysis. Measures which yield correlation matrices include the normalized inner product; Pearson's, Spearman's, and Kendall's correlation coefficients between sets of vectors; kernel matrices formed from non-linear kernel functions on data of various types (since any positive semidefinite kernel function can be normalized); and the normalized graph Laplacian, which can represent any set of non-negative similarity measurements on an undirected graph.

We defined the informativeness of a correlation matrix to be proportional to the distance between it and the closest correlation matrix whose off-diagonal entries are all equal. Motivated by the fact that a scaled correlation matrix is a valid quantum density matrix, we explored quantum distance metrics, including the Bures distance. For specific distance metrics, we derived closed-form expressions of the minimal distance, and a lower-bound for the Bures distance. In particular, we proved the lower-bound, referred to as the Bures-based informativeness, is maximized by centered, rank-1 correlation matrices, which means a maximally informative matrix corresponds to a balanced cut.

The measures of informativeness are unsupervised and can be used as objective functions for machine learning applications. In particular, informativeness can be used for selecting kernel parameters or the embedding dimension for kernel-based dimensionality reduction, testing for structure in graphs, and first-order optimizations of correlation matrices. In the first case, we explored informativeness as a criterion for automatically selecting an appropriate kernel bandwidth for spectral clustering. For this task, the proposed informativeness measures (except the CKA-based measure) consistently outperform Bartlett's and Lawley's test statistics for equality of correlation coefficients, which like the CKA measure always select the largest possible kernel bandwidth. The results also indicate that there is a clear grouping of the different informativeness measures that behave similarly. The cosine measure performs best on three data sets, and the three measures applicable to quantum density matrices—Chernoff bound, QH, and Bures—have the second best performance on three data sets.

In Section 5.2, we investigated using informativeness to select the dimensionality of a kernel-based embedding in a semi-supervised case, where the kernel matrix is formed from both labeled and unlabeled samples, and the performance is assessed by the first nearest-neighbor classification error rates in the reduced dimension space. On this task, Bartlett's and Lawley's test statistics fail to select a meaningful dimensionality (selecting one or two dimensions), which yields an average classification error rate 17.3 percentage points (ppts) higher than the original, as detailed in Table 6. In comparison, the Chernoff, QH, and Bures-based measures have the best average performance with an error rate >0.9 ppts lower than using the distances in the original space. Furthermore, these measures of informativeness outperform centered kernel alignment (Cortes et al., 2012) on this task, which has an error rate of 4.9 ppts higher than the original, even though centered kernel alignment uses the training set labels.

Informativeness is also useful for quantifying the amount of structure in undirected graphs via their normalized graph Laplacian representation, as discussed in Section 5.3. Empirically, the measures of informativeness are all able to distinguish regular and clustered graphs from unstructured graphs. The quantum-based distances (Chernoff bound, QH, and Bures) perform well in distinguishing structured graphs from random graphs (identifying <15% of random graphs as structured and 100% of clustered regular graphs). These informativeness measures are better at identifying structured graphs than the test statistic for determining if the graph is a realization of an Erdős-Rényi graph (Bickel and Sarkar, 2016), which identifies 46% of random graphs and 96.2% of clustered regular graphs. For this task, Bartlett's test statistic also performs well (identifying >2% of random graphs as structured and 95.7% of clustered regular graphs), but Lawley's test statistics evaluates a larger proportion of random graphs higher than the regular graphs (36.4%).

Across these experiments, the three quantum-based distances (Chernoff bound, QH, and Bures) perform consistently well in identifying correlation matrices that are structured and more suitable for clustering or classification. One drawback of these measures is that their evaluations have a higher computation cost than the other measures of informativeness that are based on the Frobenius norm, e.g., the Euclidean distance, cosine similarity, HSIC, and CKA. Specifically, the Bures-based measure requires all of the eigenvalues of an $n \times n$ positive semidefinite matrix, the Chernoff-bound requires a full eigendecomposition, and the QH measures requires the matrix square root—a complexity of $\mathcal{O}(n^3)$ in each case. In comparison, the measures based on the Frobenius norm can be computed directly from the elements of the correlation matrix (or its centered version), with a complexity of $\mathcal{O}(n^2)$.

Closed-form measures of informativeness can also be used as optimization criteria for applications like sample denoising and metric learning through positive definite kernel functions. Using the gradients of smooth cost functions derived from the informativeness measures, we discussed first-order optimizations in Section 4.1. The experimental results for sample denoising in Section 5.4 show that when the coordinates of a sample of points are updated the points form local clusters to maximize informativeness. In this way, informativeness functions as an objective for finding local modes in a sample. This behavior is scale-invariant, since when a Gaussian or other applicable kernel is used, the scale can be automatically set by choosing the bandwidth that maximizes the informativeness. When the informativeness-based optimizations are applied to a thumbnail image data set, the optimization based on the Bures measures enhances the class structure, yielding a higher centered kernel alignment than the correlation matrix for the original sample.

Along similar lines, we investigated the optimization problem of finding maximally informative correlation matrices in terms of their lower-dimensional embeddings (Section 4.2). We proved that the Bures-based measure is especially suited for this task since it corresponds to a convex cost function on Euclidean embeddings. This cost function is a novel matrix norm, which can be used to simultaneously penalize high-rank and uncentered embeddings. Based on the proximal operator of this norm (Appendix E), we proposed a correlation matrix denoising algorithm using an ADMM scheme. In Section 5.5, we tested the proposed correlation matrix denoising algorithm on data sets with known cluster structure. On thumbnail image data sets, the denoising method is able to preserve information relevant to ground-truth classes. Furthermore, it consistently increases the clustering performance when used as a preprocessing for spectral clustering (Ng et al., 2002).

In conclusion, informativeness appears to be a well-suited criterion for a variety of unsupervised data analysis tasks that can be formulated in terms of correlation matrices, and offers a unique measure for assessing the organizational properties of a sample based on pairwise similarity measurements.

Appendix A. Bures Distance

Bures (1969) defined a distance metric between two non-commutative, positive semidefinite Hermitian matrices that generalizes the Hellinger-Kakutani probability distance to non-commuting spaces. The Bures distance is a measure of the statistical distance between two quantum states, i.e., a symmetric measure of how likely it is for one state to transition to the other (Uhlmann, 1976). In particular, as shown later, when two matrices commute the Bures distance corresponds to the Hellinger-Kakutani distance between the eigenvalues.

Let $\mathbf{A}, \mathbf{B}$ denote two positive-semidefinite matrices, which are trace-normalized so that $\mathrm{tr}\mathbf{A} = \mathrm{tr}\mathbf{B} = 1$. The squared Bures distance between them can be computed (Uhlmann, 1976) as $d_B^2(\mathbf{A}, \mathbf{B}) = 2 - 2\mathrm{tr}\sqrt{\mathbf{A}^{\frac{1}{2}}\mathbf{B}\mathbf{A}^{\frac{1}{2}}}$, where all square roots denote matrix roots. The Bures distance is a chordal distance on the space of positive semidefinite matrices with trace one. The trace term in the previous expression, denoted here as $C(\mathbf{A}, \mathbf{B})$, is equal to the trace norm of the matrix $\mathbf{A}^{\frac{1}{2}}\mathbf{B}^{\frac{1}{2}}$, that is

$$C(\mathbf{A}, \mathbf{B}) = \mathrm{tr}\sqrt{\mathbf{A}^{\frac{1}{2}}\mathbf{B}\mathbf{A}^{\frac{1}{2}}} = \left\|\mathbf{A}^{\frac{1}{2}}\mathbf{B}^{\frac{1}{2}}\right\|_*.$$

This quantity is a symmetric similarity measure between positive definite matrices. From the properties of trace-normalized positive semidefinite matrices, we have $0 \leq C(\mathbf{A}, \mathbf{B}) \leq 1$; $C(\mathbf{A}, \mathbf{B}) = 0$ iff $\langle \mathbf{A}, \mathbf{B} \rangle = 0$ (since $\mathbf{AB}$ and $\mathbf{A}^{\frac{1}{2}}\mathbf{B}\mathbf{A}^{\frac{1}{2}}$ have the same eigenvalues), and $C(\mathbf{A}, \mathbf{B}) = 1$ iff $\mathbf{A} = \mathbf{B}$. In quantum information theory, the quantity $C(\mathbf{A}, \mathbf{B})$, or the concave quantity $C^2(\mathbf{A}, \mathbf{B})$ as originally defined, is known as fidelity (Jozsa, 1994). Fidelity is a measure of how well $\mathbf{A}$ preserves the information of $\mathbf{B}$. It can also be used to directly define a geodesic distance, which is known as the statistical distance or quantum angle, and can be computed using the standard chordal to geodesic conversion, as $\arccos\left(C(\mathbf{A}, \mathbf{B})\right) = \arccos\left(1 - \frac{1}{2}d_B^2(\mathbf{A}, \mathbf{B})\right)$.

If $\mathbf{A}$ and $\mathbf{B}$ commute, then they are simultaneously diagonalizable by an orthogonal matrix $\mathbf{M}$, that is $\mathbf{M}\mathbf{\Lambda}_A\mathbf{M}^\top = \mathbf{A}$ and $\mathbf{M}\mathbf{\Lambda}_B\mathbf{M}^\top = \mathbf{B}$, with $\mathbf{\Lambda}_A$ and $\mathbf{\Lambda}_B$ being the corresponding spectral matrices. Therefore, $\mathrm{tr}\sqrt{\mathbf{A}^{\frac{1}{2}}\mathbf{B}\mathbf{A}^{\frac{1}{2}}} = \mathrm{tr}\big(\mathbf{M}\sqrt{\mathbf{\Lambda}_A\mathbf{\Lambda}_B}\mathbf{M}^\top\big) = \mathrm{tr}(\sqrt{\mathbf{\Lambda}_A}\sqrt{\mathbf{\Lambda}_B})$ and $\mathrm{tr}\big(\mathbf{M}\sqrt{\mathbf{\Lambda}_A\mathbf{\Lambda}_B}\mathbf{M}^\top\big) = \langle\sqrt{\mathbf{A}}, \sqrt{\mathbf{B}}\rangle$, which makes the fidelity $C(\mathbf{A}, \mathbf{B})$ equal to the affinity measure in Table 1, or equivalently, the Bures and the quantum Hellinger distance to coincide because $d_B^2(\mathbf{A}, \mathbf{B}) = \|\sqrt{\mathbf{A}} - \sqrt{\mathbf{B}}\|_F^2$. In this case, by using $\mathbf{p}_A = \mathrm{diag}\left(\mathbf{\Lambda}_A\right)$ and $\mathbf{p}_B = \mathrm{diag}\left(\mathbf{\Lambda}_B\right)$ to denote vectors containing the eigenvalues, $C(\mathbf{A}, \mathbf{B})$ is also equal to $\langle\sqrt{\mathbf{p}_A}, \sqrt{\mathbf{p}_B}\rangle$. This last quantity is the Bhattacharyya coefficient between the eigenspectra

of $\mathbf{A}$ and $\mathbf{B}$, and hence, $d_B^2(\mathbf{A},\mathbf{B}) = \|\sqrt{\mathbf{p}_A} - \sqrt{\mathbf{p}_B}\|_2^2$ is the squared Euclidean distance between them.

A further point to note about the Bures distance is that it serves as a lower bound for the trace distance. Specifically, as shown by Fuchs and van de Graaf (1999), we have $\frac{1}{2}d_B^2(\mathbf{A},\mathbf{B}) = 1 - C(\mathbf{A},\mathbf{B}) \leq \frac{1}{2}\|\mathbf{A}-\mathbf{B}\|_*$. It is also a lower bound on quantum Hellinger distance (Luo and Zhang, 2004). This can also be directly seen from the fact that for a given matrix $\mathbf{Q}$, we have $\mathrm{tr}(\mathbf{Q}) \leq \max_{\|\mathbf{U}\|_2\leq 1}\mathrm{tr}(\mathbf{U}^\top\mathbf{Q}) = \|\mathbf{Q}\|_*$ from the duality of the trace and spectral norms. By setting $\mathbf{Q} = \sqrt{\mathbf{A}}\sqrt{\mathbf{B}}$, we have the fidelity measure $C(\mathbf{A},\mathbf{B})$ dominating the affinity measure, $\langle\sqrt{\mathbf{A}},\sqrt{\mathbf{B}}\rangle$.

For the context of this work, we will show that a useful property of the Bures distance is that in its computation, the matrix square roots $\sqrt{\mathbf{A}}$ and $\sqrt{\mathbf{B}}$ can be substituted with any arbitrary embeddings in a Hilbert space that represent the correlation structure. Assume we have two arbitrary embeddings $\mathbf{Z}_A \in \mathbb{R}^{b_A\times n}$ and $\mathbf{Z}_B \in \mathbb{R}^{b_B\times n}$ such that $\mathbf{Z}_A^\top\mathbf{Z}_A = \mathbf{A}$ and $\mathbf{Z}_B^\top\mathbf{Z}_B = \mathbf{B}$. Since $\|\mathbf{Q}\|_* = \left\|\mathbf{Q}^\top\right\|_* = \mathrm{tr}\sqrt{\mathbf{Q}^\top\mathbf{Q}}$, we have

$$\begin{aligned}\left\|\mathbf{Z}_A\mathbf{Z}_B^\top\right\|_* &= \mathrm{tr}\sqrt{\mathbf{Z}_A\mathbf{Z}_B^\top\mathbf{Z}_B\mathbf{Z}_A^\top} = \mathrm{tr}\sqrt{\mathbf{Z}_A\mathbf{B}\mathbf{Z}_A^\top} = \left\|\mathbf{Z}_A\mathbf{B}^{\frac{1}{2}}\right\|_* \\ &= \mathrm{tr}\sqrt{\mathbf{B}^{\frac{1}{2}}\mathbf{Z}_A^\top\mathbf{Z}_A\mathbf{B}^{\frac{1}{2}}} = \mathrm{tr}\sqrt{\mathbf{B}^{\frac{1}{2}}\mathbf{A}\mathbf{B}^{\frac{1}{2}}} = \left\|\mathbf{A}^{\frac{1}{2}}\mathbf{B}^{\frac{1}{2}}\right\|_*.\end{aligned} \tag{A.1}$$

A critical conclusion from these equations, is that the fidelity $\|\mathbf{A}^{\frac{1}{2}}\mathbf{B}^{\frac{1}{2}}\|_*$ and the Bures distance d_B can potentially use any of the forms in Equation A.1 for calculating the constituent trace norm, according to computational convenience and embeddings dimensionality, even though the embeddings $\mathbf{Z}_A$ and $\mathbf{Z}_B$ are not unique representations of $\sqrt{\mathbf{A}}$ and $\sqrt{\mathbf{B}}$. For instance, the constraint $\mathbf{Z}_A^\top\mathbf{Z}_A = \mathbf{A}$ cannot imply a unique $\mathbf{Z}_A$, as a row permutation, sign change, or any orthogonal transformation of the rows of $\mathbf{Z}_A$ would not alter the underlying similarity matrix. Furthermore, one can choose a transformation matrix $\mathbf{U}_A$, which is not necessarily square, with orthonormal columns (and, by definition, orthonormal rows if $\mathbf{U}_A$ is square) that introduces the embedding into a higher dimensional space. For example, if $\mathbf{U}_A \in \mathbb{R}^{q\times b_A}$, the projection $\mathbf{U}_A\mathbf{Z}_A$ is equivalent to applying an orthogonal transformation to $\binom{\mathbf{Z}_A}{\mathbf{0}} \in \mathbb{R}^{q\times n}$. These invariances lead to an alternative formulation of fidelity via the following theorem, which is known as Uhlmann's theorem in the more general case for quantum density matrices (Uhlmann, 1976; Jozsa, 1994; Nielsen and Chuang, 2000).

Theorem 1 *For positive semidefinite matrices $\mathbf{A} \in \mathbb{R}^{n\times n}$ and $\mathbf{B} \in \mathbb{R}^{n\times n}$,*

$$C(\mathbf{A},\mathbf{B}) = \left\|\mathbf{A}^{\frac{1}{2}}\mathbf{B}^{\frac{1}{2}}\right\|_* = \max_{\substack{\mathbf{Z}_A,\mathbf{Z}_B \\ \mathbf{Z}_A^\top\mathbf{Z}_A=\mathbf{A} \\ \mathbf{Z}_B^\top\mathbf{Z}_B=\mathbf{B}}} \langle\mathbf{Z}_A,\mathbf{Z}_B\rangle.$$

Proof Let $\bar{\mathbf{Z}}_A \in \mathbb{R}^{b_A\times n}$ and $\bar{\mathbf{Z}}_B \in \mathbb{R}^{b_B\times n}$ be arbitrary embeddings such that $\bar{\mathbf{Z}}_A^\top\bar{\mathbf{Z}}_A = \mathbf{A}$ and $\bar{\mathbf{Z}}_B^\top\bar{\mathbf{Z}}_B = \mathbf{B}$ (without loss of generality, we assume $b_A \leq b_B$). The set of valid embeddings for $\mathbf{A}$ and $\mathbf{B}$ can then be expressed as transformations of $\bar{\mathbf{Z}}_A$ and $\bar{\mathbf{Z}}_B$, i.e.,

$$\left\{(\mathbf{Z}_A,\mathbf{Z}_B) : \mathbf{Z}_A^\top\mathbf{Z}_A{=}\mathbf{A},\ \mathbf{Z}_B^\top\mathbf{Z}_B{=}\mathbf{B}\right\} \ = \ \left\{(\mathbf{U}_A\bar{\mathbf{Z}}_A,\mathbf{U}_B\bar{\mathbf{Z}}_B) : \mathbf{U}_A^\top\mathbf{U}_A{=}\mathbf{I},\ \mathbf{U}_B^\top\mathbf{U}_B = \mathbf{I}\right\},$$

where $\mathbf{U}_A \in \mathbb{R}^{q\times b_A}$ and $\mathbf{U}_B \in \mathbb{R}^{q\times b_A}$ are matrices with orthonormal columns and the same number of rows. From the equivalence of these two sets, we pose the equivalent maximization problem

$$\max_{\substack{\mathbf{U}_A,\mathbf{U}_B \\ \mathbf{U}_A^\top\mathbf{U}_A=\mathbf{I} \\ \mathbf{U}_B^\top\mathbf{U}_B=\mathbf{I}}} \left\{\langle\mathbf{U}_A\bar{\mathbf{Z}}_A,\mathbf{U}_B\bar{\mathbf{Z}}_B\rangle = \mathrm{tr}\left(\bar{\mathbf{Z}}_A^\top\mathbf{U}_A^\top\mathbf{U}_B\bar{\mathbf{Z}}_B\right) = \mathrm{tr}\left(\mathbf{U}_B^\top\mathbf{U}_A\bar{\mathbf{Z}}_A\bar{\mathbf{Z}}_B^\top\right)\right\}.$$

Since $\mathbf{U}_A$ and $\mathbf{U}_B$ are semi-orthogonal, they both have all their non-zero singular values equal to one, and from the sub-multiplicative property it follows that

$$\|\mathbf{U}_B^\top\mathbf{U}_A\|_2 \leq \|\mathbf{U}_A\|_2 \cdot \|\mathbf{U}_B\|_2 = 1,$$

and furthermore, the set of pairs of semi-orthogonal matrices is a strict subset of the set of pairs with product within the spectral norm unit ball:

$$\left\{(\mathbf{U}_A,\mathbf{U}_B) : \mathbf{U}_A^\top\mathbf{U}_A = \mathbf{I},\ \mathbf{U}_B^\top\mathbf{U}_B = \mathbf{I}\right\} \ \subset \ \left\{(\mathbf{U}_A,\mathbf{U}_B) : \|\mathbf{U}_B^\top\mathbf{U}_A\|_2 \leq 1\right\}.$$

Letting $\mathbf{U}^\top = \mathbf{U}_B^\top\mathbf{U}_A$, we have

$$\max_{\substack{\mathbf{U}_A,\mathbf{U}_B \\ \mathbf{U}_A^\top\mathbf{U}_A=\mathbf{I} \\ \mathbf{U}_B^\top\mathbf{U}_B=\mathbf{I}}} \mathrm{tr}\left(\mathbf{U}_B^\top\mathbf{U}_A\bar{\mathbf{Z}}_A\bar{\mathbf{Z}}_B^\top\right) \ \leq \ \max_{\substack{\mathbf{U} \\ \|\mathbf{U}\|_2\leq 1}} \mathrm{tr}\left(\mathbf{U}^\top\bar{\mathbf{Z}}_A\bar{\mathbf{Z}}_B^\top\right) = \|\bar{\mathbf{Z}}_A\bar{\mathbf{Z}}_B^\top\|_*,$$

where the equality follows from the duality of the trace and spectral norms. Furthermore, the optimization in terms of $\mathbf{U}_A, \mathbf{U}_B$ achieves the maximum when $\mathbf{U}_A = [\mathbf{R},\ \mathbf{0}_{b_A\times(b_B-b_A)}]^\top$ and $\mathbf{U}_B = \mathbf{V}$, where $\mathbf{RSV}^\top$ is a singular value decomposition of $\bar{\mathbf{Z}}_A\bar{\mathbf{Z}}_B^\top$, since in this case[14]

$$\begin{aligned}&\mathrm{tr}\left(\mathbf{U}_B^\top\mathbf{U}_A\bar{\mathbf{Z}}_A\bar{\mathbf{Z}}_B^\top\right) = \mathrm{tr}\left(\mathbf{U}_B^\top\mathbf{U}_A\mathbf{RSV}^\top\right) = \mathrm{tr}\left(\mathbf{V}^\top\mathbf{U}_B^\top\mathbf{U}_A\mathbf{RS}\right) \\ &= \mathrm{tr}\left(\mathbf{V}^\top\mathbf{V}\left[\mathbf{R}^\top\mathbf{R},\ \mathbf{0}_{b_A\times(b_B-b_A)}\right]^\top\mathbf{S}\right) = \mathrm{tr}\left(\left[\mathbf{I}_{b_A\times b_A},\ \mathbf{0}_{b_A\times(b_B-b_A)}\right]^\top\mathbf{S}\right) = \|\bar{\mathbf{Z}}_A\bar{\mathbf{Z}}_B^\top\|_*.\end{aligned}$$

By the properties of the trace norm (A.1), $\|\bar{\mathbf{Z}}_A\bar{\mathbf{Z}}_B^\top\|_* = \|\mathbf{A}^{\frac{1}{2}}\mathbf{B}^{\frac{1}{2}}\|_*$, which completes the proof. ■

It is a significant consequence of this theorem that $d_B(\mathbf{A},\mathbf{B})$ corresponds to the minimal distance $\|\mathbf{Z}_A - \mathbf{Z}_B\|_F$ between all possible embeddings represented by $\mathbf{A}$ and $\mathbf{B}$. This is very desirable, as it makes d_B independent to the choice of their embeddings used to measure it with any of the forms in Equation A.1.

We note that Theorem 1 can also be used to show that the symmetric normalization in Equation 1, discussed in Section 2.1, which transforms a positive semidefinite matrix to a correlation matrix, corresponds to finding the closest elliptope element in the Bures distance sense.

14. Letting $\mathbf{Q} = \mathbf{V}^\top\mathbf{U}_B^\top\mathbf{U}_A\mathbf{R} = (\mathbf{U}_B\mathbf{V})^\top\mathbf{U}_A\mathbf{R}$ we have $\mathrm{tr}(\mathbf{U}_B^\top\mathbf{U}_A\bar{\mathbf{Z}}_A\bar{\mathbf{Z}}_B^\top) = \mathrm{tr}(\mathbf{QS})$. We note that no element of $\mathbf{Q}$ can exceed unity by the Cauchy-Bunyakovsky-Schwarz inequality since $\mathbf{U}_A\mathbf{R}$ and $\mathbf{U}_B\mathbf{V}$ have orthonormal columns. From this, it follows that $\mathrm{tr}(\mathbf{U}_B^\top\mathbf{U}_A\bar{\mathbf{Z}}_A\bar{\mathbf{Z}}_B^\top) = \mathrm{tr}(\mathbf{QS}) \leq \mathrm{tr}(\mathbf{S}) = \|\bar{\mathbf{Z}}_A\bar{\mathbf{Z}}_B^\top\|_*$.

Lemma 2 *For a positive semidefinite matrix* $\tilde{\mathbf{K}} \in \mathbb{R}^{n\times n}$ *with* $\mathrm{tr}(\tilde{\mathbf{K}}) = n$,

$$\operatorname*{arg\,min}_{\mathbf{K}\in\mathcal{E}} \; d_B\left(\tfrac{1}{n}\mathbf{K}, \tfrac{1}{n}\tilde{\mathbf{K}}\right) \;=\; \mathbf{D}\tilde{\mathbf{K}}\mathbf{D},$$

where $\mathbf{D}$ *is a diagonal matrix with entries* $D_{i,i} = \frac{1}{\sqrt{\tilde{K}_{i,i}}}$. *Furthermore,*

$$\min_{\mathbf{K}\in\mathcal{E}} \; d_B\left(\tfrac{1}{n}\mathbf{K}, \tfrac{1}{n}\tilde{\mathbf{K}}\right) = \sqrt{\frac{2}{n}\sum_{i\in[n]}\left(1-(\tilde{K}_{i,i})^{\frac{1}{2}}\right)},$$

i.e., the distance depends on how far the roots of the diagonal entries of $\tilde{\mathbf{K}}$ *are from unity.*

Proof Let $\tilde{\mathbf{Z}}$ be an embedding of $\tilde{\mathbf{K}}$ such that $\tilde{\mathbf{Z}}^\top\tilde{\mathbf{Z}} = \tilde{\mathbf{K}}$. Then for any choice of $\tilde{\mathbf{Z}}$,

$$\min_{\mathbf{K}\in\mathcal{E}} d_B\left(\tfrac{1}{n}\mathbf{K}, \tfrac{1}{n}\tilde{\mathbf{K}}\right) = \min_{\mathbf{Z}\in\mathcal{OB}} \left\|\tfrac{1}{\sqrt{n}}\mathbf{Z} - \tfrac{1}{\sqrt{n}}\tilde{\mathbf{Z}}\right\|_F = \sqrt{\frac{1}{n}\sum_{i\in[n]}\min_{\mathbf{x}:\|\mathbf{x}\|_2=1}\|\mathbf{x}-\tilde{\mathbf{z}}_i\|_2^2}\,,$$

where the second equality follows from the fact that both the oblique manifold constraint and the Frobenius norm are amenable to column-wise separation. The solution for the ith column is $\mathbf{z}_i = \frac{\tilde{\mathbf{z}}_i}{\|\tilde{\mathbf{z}}_i\|_2}$, which corresponds to finding the point on the unit sphere closest to the vector $\tilde{\mathbf{z}}_i$. This is equivalent to setting $\mathbf{Z} = [\mathbf{z}_1, \ldots, \mathbf{z}_n] = \tilde{\mathbf{Z}}\mathbf{D}$, where $\mathbf{D}$ is a diagonal matrix with entries $D_{i,i} = \frac{1}{\|\tilde{\mathbf{z}}_i\|_2} = \frac{1}{\sqrt{\tilde{K}_{i,i}}}$, which yields the closest matrix in the elliptope as $\mathbf{D}\tilde{\mathbf{Z}}^\top\tilde{\mathbf{Z}}\mathbf{D} = \mathbf{D}\tilde{\mathbf{K}}\mathbf{D} \in \mathcal{E}$.

The distance itself is given as

$$\begin{aligned} d_B\left(\tfrac{1}{n}\mathbf{D}\tilde{\mathbf{K}}\mathbf{D}, \tfrac{1}{n}\tilde{\mathbf{K}}\right) &= \sqrt{2 - 2\left\|\tfrac{1}{n}\tilde{\mathbf{Z}}\mathbf{D}\tilde{\mathbf{Z}}^\top\right\|_*} = \sqrt{2 - \frac{2}{n}\mathrm{tr}\left(\mathbf{D}\tilde{\mathbf{Z}}^\top\tilde{\mathbf{Z}}\right)} \\ &= \sqrt{2 - \frac{2}{n}\sum_{i\in[n]}\|\tilde{\mathbf{z}}_i\|_2} = \sqrt{\frac{2}{n}\sum_{i\in[n]}\left(1-(\tilde{K}_{i,i})^{\frac{1}{2}}\right)}\,. \end{aligned}$$

■

This simple normalization can be contrasted with the alternating projection algorithm required to find the closest correlation matrix in terms of the Euclidean distance (Higham, 2002). The latter could be considered more general, since it can be applied to any square matrix, whereas the Bures distance is only applicable to positive semidefinite matrices. Nonetheless, the symmetric normalization can be applied after first finding the nearest positive semidefinite matrix (Higham, 1988).

Another property of the Bures distance, is that its square is a convex function, which follows from the following theorem for real-valued positive-semidefinite matrices, which is a special case of the proof by Uhlmann (1976).

Theorem 3 *The squared fidelity measure* $C^2(\mathbf{A}, \mathbf{B}) = \|\mathbf{A}^{\frac{1}{2}}\mathbf{B}^{\frac{1}{2}}\|_*^2$ *is concave for positive-semidefinite matrices.*

Proof Let $\mathbf{X}, \mathbf{Y}, \mathbf{Z} \in \mathbb{R}^{n\times n}$ be three positive-semidefinite matrices. Let $\Psi_Z = \bigoplus_{i=1}^n \psi_{z_i} \in \mathcal{H}_X$ and $\Psi_X = \bigoplus_{i=1}^n \psi_{x_i} \in \mathcal{H}_X$ denote Hilbert-space embeddings defined via the direct sum $\mathcal{H}_X = \mathcal{H}_x \oplus \cdots \oplus \mathcal{H}_x = \bigoplus_{i=1}^n \mathcal{H}_x$ such that $Z_{i,j} = \langle\psi_{z_i}, \psi_{z_j}\rangle, X_{i,j} = \langle\psi_{x_i}, \psi_{x_j}\rangle$, and $\|\mathbf{Z}^{\frac{1}{2}}\mathbf{X}^{\frac{1}{2}}\|_* = \langle\Psi_Z, \Psi_X\rangle$. Likewise, let $\Phi_Z = \bigoplus_{i=1}^n \phi_{z_i} \in \mathcal{H}_Y$ and $\Psi_Y = \bigoplus_{i=1}^n \phi_{y_i} \in \mathcal{H}_Y$ denote Hilbert-space embeddings such that $Z_{i,j} = \langle\phi_{z_i}, \phi_{z_j}\rangle, Y_{i,j} = \langle\phi_{y_i}, \phi_{y_j}\rangle$, and $\|\mathbf{Z}^{\frac{1}{2}}\mathbf{Y}^{\frac{1}{2}}\|_* = \langle\Phi_Z, \Phi_Y\rangle$.

For any λ_X, λ_Y such that $\lambda_X^2 + \lambda_Y^2 = 1$, define

$$\Omega_Z = \bigoplus_{i=1}^n \omega_{z_i} = (\lambda_X\Psi_Z) \oplus (\lambda_Y\Phi_Z) \in \mathcal{H}_X \oplus \mathcal{H}_Y \equiv \mathcal{H}_W.$$

Then $Z_{i,j} = \langle\omega_{z_i}, \omega_{z_j}\rangle = \lambda_X^2\langle\psi_{z_i}, \psi_{z_j}\rangle + \lambda_Y^2\langle\phi_{z_i}, \phi_{z_j}\rangle$. Let $\mathbf{W} = \alpha\mathbf{X} + (1-\alpha)\mathbf{Y}$ denote a convex combination, where $0 \le \alpha \le 1$. Then $\Omega_W = (\sqrt{\alpha}\Psi_X) \oplus (\sqrt{1-\alpha}\Phi_Y) \in \mathcal{H}_W$ is a Hilbert-space embedding of $\mathbf{W}$. Consequently, $\langle\Omega_Z, \Omega_W\rangle = \lambda_X\sqrt{\alpha}\langle\Psi_Z, \Psi_X\rangle + \lambda_Y\sqrt{1-\alpha}\langle\Phi_Z, \Phi_Y\rangle$.

From Theorem 1 it follows that

$$\|\mathbf{Z}^{\frac{1}{2}}\mathbf{W}^{\frac{1}{2}}\|_*^2 \ge \left|\langle\Omega_Z, \Omega_W\rangle\right|^2 = \left|\lambda_X\sqrt{\alpha}\langle\Psi_Z, \Psi_X\rangle + \lambda_Y\sqrt{1-\alpha}\langle\Phi_Z, \Phi_Y\rangle\right|^2.$$

Maximizing over λ_X, λ_Y on the right hand side (which corresponds to an optimization along the positive quadrant of the circle parametrically defined by coordinates λ_X and λ_Y) we obtain

$$\|\mathbf{Z}^{\frac{1}{2}}\mathbf{W}^{\frac{1}{2}}\|_*^2 \ge \left|\sqrt{\alpha}\langle\Psi_Z, \Psi_X\rangle\right|^2 + \left|\sqrt{1-\alpha}\langle\Phi_Z, \Phi_Y\rangle\right|^2 = \alpha\|\mathbf{Z}^{\frac{1}{2}}\mathbf{X}^{\frac{1}{2}}\|_*^2 + (1-\alpha)\|\mathbf{Z}^{\frac{1}{2}}\mathbf{Y}^{\frac{1}{2}}\|_*^2.$$

■

Appendix B. Derivation of Informativeness Measures

In this appendix, we detail the derivation of the analytic expression of each measure of informativeness found in Table 2.

B.1 Euclidean Distance

We define the measure of informativeness for any correlation matrix $\mathbf{K} \in \mathcal{E}$ using the Euclidean distance as $d_{\mathcal{N}}(\mathbf{K}) = \frac{1}{n}\min_{\mathbf{N}_a\in\mathcal{N}}\|\mathbf{K} - \mathbf{N}_a\|_F$. Expanding the Frobenius norm term yields

$$\begin{aligned} &\|\mathbf{K} - \mathbf{N}_a\|_F^2 = \|\mathbf{K}\|_F^2 + \|\mathbf{N}_a\|_F^2 - 2\langle\mathbf{K}, \mathbf{N}_a\rangle, \\ &\|\mathbf{N}_a\|_F^2 = (an)^2 + (1-a)^2\frac{n^2}{n-1}, \\ &\langle\mathbf{K}, \mathbf{N}_a\rangle = a\mathbf{1}^\top\mathbf{K}\mathbf{1} + (1-a)\frac{n}{n-1}\mathrm{tr}(\mathbf{H}\mathbf{K}) = a\bar{k}n^2 + (1-a)(1-\bar{k})\frac{n^2}{n-1}, \end{aligned}$$

since $\mathrm{tr}(\mathbf{H}\mathbf{K}) = n - \frac{1}{n}\mathrm{tr}(\mathbf{J}\mathbf{K}) = n(1-\bar{k})$, where $\bar{k} = \frac{1}{n^2}\mathbf{1}^\top\mathbf{K}\mathbf{1}$. Taking the derivative with respect to a yields a linear function of a whose root is $\bar{k}$. That is, the value of the parameter

a that defines the closest non-informative matrix $\mathbf{N}_{a^\star}$ is

$$a^\star = \underset{0\le a\le 1}{\arg\min}\ \|\mathbf{K}-\mathbf{N}_a\|_F^2 = \bar{k}, \tag{B.1}$$

and

$$\|\mathbf{K}-\mathbf{N}_{\bar{k}}\|_F^2 = \|\mathbf{K}\|_F^2 - (n\bar{k})^2 - (1-\bar{k})^2\frac{n^2}{n-1} = \|\mathbf{K}\|_F^2 - \frac{n^2}{n-1}(n\bar{k}^2 - 2\bar{k} + 1).$$

The informativeness measure is

$$d_{\mathcal{N}}(\mathbf{K}) = \sqrt{\frac{1}{n^2}\|\mathbf{K}\|_F^2 - \frac{1}{n-1}(n\bar{k}^2 - 2\bar{k} + 1)}. \tag{B.2}$$

This expression is a specific case of the formula for the Euclidean distance of an arbitrary matrix to the closest correlation matrix with uniform off-diagonal elements (Borsdorf et al., 2010).

B.2 Cosine Distance

Using the cosine similarity, one can define a chordal distance, which amounts to Euclidean distance after normalizing the matrices by their Frobenius norm. By squaring the chordal distance and dividing by two, we obtain a measure of informativeness as $1-\max_{0\le a\le 1}\frac{\langle \mathbf{K},\mathbf{N}_a\rangle}{\|\mathbf{K}\|_F\|\mathbf{N}_a\|_F}$. For a specific value of a and $\mathbf{K}\in\mathcal{E}$ we have

$$\frac{\langle \mathbf{K},\mathbf{N}_a\rangle}{\|\mathbf{K}\|_F\|\mathbf{N}_a\|_F} = \frac{a\mathbf{1}^\top\mathbf{K}\mathbf{1} + (1-a)\frac{n}{n-1}\mathrm{tr}(\mathbf{H}\mathbf{K})}{\|\mathbf{K}\|_F\sqrt{(an)^2 + (1-a)^2\frac{n^2}{n-1}}} = \frac{a\bar{k}n + (1-a)(1-\bar{k})\frac{n}{n-1}}{\|\mathbf{K}\|_F\sqrt{(a^2n - 2a + 1)\frac{1}{n-1}}}.$$

Taking the derivative of this expression and solving for its root, yields

$$a^\star = \underset{0\le a\le 1}{\arg\max}\ \frac{\langle \mathbf{K},\mathbf{N}_a\rangle}{\|\mathbf{K}\|_F\|\mathbf{N}_a\|_F} = \bar{k}. \tag{B.3}$$

Substituting $a^\star$ back into the cosine similarity, leads to

$$\max_{0\le a\le 1}\frac{\langle \mathbf{K},\mathbf{N}_a\rangle}{\|\mathbf{K}\|_F\|\mathbf{N}_a\|_F} = \frac{\langle \mathbf{K},\mathbf{N}_{a^\star}\rangle}{\|\mathbf{K}\|_F\|\mathbf{N}_{a^\star}\|_F} = \frac{n\bar{k}^2 + (1-\bar{k})^2\frac{n}{n-1}}{\|\mathbf{K}\|_F\sqrt{(\bar{k}^2n - 2\bar{k} + 1)\frac{1}{n-1}}} = \frac{n}{\|\mathbf{K}\|_F}\sqrt{\frac{n\bar{k}^2 - 2\bar{k} + 1}{n-1}}.$$

The measure of informativeness based on the chordal distance is

$$\frac{1}{2}d_{\mathcal{N}}^2(\mathbf{K}) = 1 - \frac{n}{\|\mathbf{K}\|_F}\sqrt{\frac{n\bar{k}^2 - 2\bar{k} + 1}{n-1}}. \tag{B.4}$$

B.3 Hilbert-Schmidt Independence Criterion (HSIC)

The use of HSIC as a measure of similarity between a correlation matrix and the closest non-informative one leads to a trivial function. Specifically, for any a we have

$$\mathrm{HSIC}(\mathbf{K},\mathbf{N}_a) = \langle \mathbf{H}\mathbf{K}\mathbf{H},\mathbf{N}_a\rangle = \mathrm{tr}(\mathbf{H}\mathbf{K}\mathbf{H}\mathbf{N}_a) = \frac{(1-a)n}{n-1}\mathrm{tr}(\mathbf{H}\mathbf{K}).$$

This similarity is maximized for $a=0$ and the informativeness would be inversely proportional to $\mathrm{tr}(\mathbf{H}\mathbf{K}) = n(1-\bar{k})$ for $\mathbf{K}\in\mathcal{E}$, where $\bar{k}$ is as defined previously to be the average of the entries of $\mathbf{K}$.

A more meaningful measure of informativeness, however, is based on the Euclidean distance after centering (see Table 1). This is defined as

$$d_{\mathcal{N}}(\mathbf{K}) = \frac{1}{n}\min_{\mathbf{N}_a\in\mathcal{N}}\|\mathbf{H}\mathbf{K}\mathbf{H} - \mathbf{H}\mathbf{N}_a\mathbf{H}\|_F = \frac{1}{n}\min_{\mathbf{N}_a\in\mathcal{N}}\left\|\mathbf{H}\mathbf{K}\mathbf{H} - \frac{(1-a)n}{n-1}\mathbf{H}\right\|_F.$$

Expanding the norm we have

$$\left\|\mathbf{H}\mathbf{K}\mathbf{H} - \frac{(1-a)n}{n-1}\mathbf{H}\right\|_F^2 = \|\mathbf{H}\mathbf{K}\mathbf{H}\|_F^2 + \frac{(1-a)^2n^2}{n-1} - 2\frac{(1-a)n}{n-1}\mathrm{tr}(\mathbf{H}\mathbf{K}).$$

Taking the derivative of this expression and solving for its root yields

$$a^\star = \underset{0\le a\le 1}{\arg\min}\ \|\mathbf{H}\mathbf{K}\mathbf{H} - \mathbf{H}\mathbf{N}_a\mathbf{H}\|_F^2 = \bar{k}, \tag{B.5}$$

and the measure of informativeness is

$$d_{\mathcal{N}}(\mathbf{K}) = \sqrt{\frac{1}{n^2}\|\mathbf{H}\mathbf{K}\mathbf{H}\|_F^2 - \frac{1}{n-1}(1-\bar{k})^2}. \tag{B.6}$$

B.4 Centered Kernel Alignment (CKA)

The CKA similarity measurement between kernel matrices can be used to define a chordal distance between centered kernel matrices. By squaring the chordal distance and dividing by two, we define the measure of informativeness as

$$\begin{aligned}\frac{1}{2}d_{\mathcal{N}}^2(\mathbf{K}) &= 1 - \max_{0\le a\le 1}\frac{\langle \mathbf{H}\mathbf{K}\mathbf{H},\mathbf{N}_a\rangle}{\|\mathbf{H}\mathbf{K}\mathbf{H}\|_F\|\mathbf{H}\mathbf{N}_a\mathbf{H}\|_F} = 1 - \max_{0\le a\le 1}\frac{\frac{(1-a)n}{n-1}\mathrm{tr}(\mathbf{H}\mathbf{K})}{\|\mathbf{H}\mathbf{K}\mathbf{H}\|_F\frac{(1-a)n}{n-1}\|\mathbf{H}\|_F}\\ &= 1 - \frac{\mathrm{tr}(\mathbf{H}\mathbf{K})}{\|\mathbf{H}\mathbf{K}\mathbf{H}\|_F\sqrt{n-1}} = 1 - \frac{n(1-\bar{k})}{\|\mathbf{H}\mathbf{K}\mathbf{H}\|_F\sqrt{n-1}},\end{aligned} \tag{B.7}$$

where $\bar{k}$ is as defined before, and $\mathrm{tr}(\mathbf{H}\mathbf{K}) = n(1-\bar{k})$ for $\mathbf{K}\in\mathcal{E}$. The measure is undefined for the constant matrix $\mathbf{K}=\mathbf{N}_1=\mathbf{J}$, because $\|\mathbf{H}\mathbf{K}\mathbf{H}\|_F = 0$, but since $\mathbf{J}$ is non-informative, the informativeness measure in this case should be defined to be zero. Furthermore, for a rank-1 matrix $\mathbf{K}=\mathbf{v}\mathbf{v}^\top$, this measure is constant with value of $1-\frac{1}{\sqrt{n-1}}$, since $\mathrm{tr}(\mathbf{H}\mathbf{K}) = \mathbf{v}^\top\mathbf{H}\mathbf{v} = \sqrt{\mathrm{tr}(\mathbf{v}^\top\mathbf{H}\mathbf{v}\mathbf{v}^\top\mathbf{H}\mathbf{v})} = \|\mathbf{H}\mathbf{v}\mathbf{v}^\top\mathbf{H}\|_F = \|\mathbf{H}\mathbf{K}\mathbf{H}\|_F$.

B.5 Chernoff Bound

The quantum Chernoff bound is a lower bound on both the affinity and fidelity, and it can thus be used to define an upper bound on a function of the quantum Hellinger and Bures distances (Audenaert et al., 2007). We define a measure of informativeness based on the Chernoff bound $Q(\frac{1}{n}\mathbf{K},\frac{1}{n}\mathbf{N}_a) = \min_{0\le s\le 1}\frac{1}{n}\langle \mathbf{K}^s,\mathbf{N}_a^{1-s}\rangle$, for $\mathbf{K}\in\mathcal{E}$ as

$$d_{\mathcal{N}}(\mathbf{K}) = 1 - \max_{0\le a\le 1}Q(\tfrac{1}{n}\mathbf{K},\tfrac{1}{n}\mathbf{N}_a) = 1 - \max_{0\le a\le 1}\min_{0\le s\le 1}f(\mathbf{K},a,s),$$

where

$$f(\mathbf{K}, a, s) \equiv \frac{(an)^{1-s}}{n}\text{tr}(\mathbf{K}^s\mathbf{J}) + \left(\frac{(1-a)n}{n-1}\right)^{1-s}\text{tr}(\mathbf{K}^s\mathbf{H}). \tag{B.8}$$

For a fixed s, the value of a that maximizes $f(\mathbf{K}, a, s)$ can be found analytically. When $\text{tr}(\mathbf{KJ}) = 0$, letting $a = 0$ maximizes the quantity $f(\mathbf{K}, a, s)$. Otherwise, taking the derivative with respect to a, yields

$$\frac{\partial f(\mathbf{K}, s, a)}{\partial a} = \frac{1-s}{n^{s+1}}a^{-s}\text{tr}(\mathbf{K}^s\mathbf{J}) - \frac{1-s}{n-1}\left(\frac{(1-a)n}{n-1}\right)^{-s}\text{tr}(\mathbf{K}^s\mathbf{H}).$$

Equating this quantity to zero, rearranging, and taking the sth root of both sides, gives the maximizing value defined as

$$a_s^* \equiv \left(1 + \sqrt[s]{\frac{\text{tr}(\mathbf{K}^s\mathbf{H})}{\text{tr}(\mathbf{K}^s\mathbf{J})}\frac{n}{(n-1)^{1-s}}}\right)^{-1}, \tag{B.9}$$

for $\text{tr}(\mathbf{K}^s\mathbf{J}) > 0$. Now defining

$$q(\mathbf{K}) \equiv \min_{0\le s\le 1} f(\mathbf{K}, s, a_s^*) = \min_{0\le s\le 1}\max_{0\le a\le 1}\langle \mathbf{K}^s, \mathbf{N}_a^{1-s}\rangle, \tag{B.10}$$

the measure of informativeness using the Chernoff bound is

$$d_{\mathcal{N}}(\mathbf{K}) = 1 - q(\mathbf{K}). \tag{B.11}$$

By precomputing the eigenvalue decomposition of $\mathbf{K} = \mathbf{U}\Lambda\mathbf{U}^\top$, each evaluation of $f(\mathbf{K}, s, a_s^*)$ requires computations on the order of $\mathcal{O}(n)$ (Mendonça et al., 2008). Specifically, $\text{tr}(\mathbf{K}^s\mathbf{J}) = \text{tr}(\Lambda^s\mathbf{U}^\top\mathbf{1}\mathbf{1}^\top\mathbf{U}) = \sum_i \lambda_i^s\langle\mathbf{u}_i, \mathbf{1}\rangle^2$, and $\text{tr}(\mathbf{K}^s\mathbf{H}) = \sum_i \lambda_i^s(1 - \frac{1}{n}\langle\mathbf{u}_i, \mathbf{1}\rangle^2)$. By consequence, the complexity of computing $q(\mathbf{K})$ via a line search on s, is the same as computing the Chernoff bound.

B.6 Quantum Hellinger (QH)

The quantum version of Hellinger distance shares some of the same properties as the Bures distance (Luo and Zhang, 2004). Squaring the quantum Hellinger distance (a chordal distance on the space of trace-normalized positive semidefinite matrices) and dividing by two yields a measure of informativeness for correlation matrices $\mathbf{K} \in \mathcal{E}$ as

$$\frac{1}{2}d_{\mathcal{N}}^2(\mathbf{K}) = \min_{0\le a\le 1} 1 - \frac{1}{n}\langle\sqrt{\mathbf{K}}, \sqrt{\mathbf{N}_a}\rangle.$$

Firstly, we expand the affinity term as

$$\frac{1}{\sqrt{n}}\langle\sqrt{\mathbf{K}}, \sqrt{\mathbf{N}_a}\rangle = \langle\sqrt{\mathbf{K}}, \tfrac{\sqrt{a}}{n}\mathbf{J}\rangle + \langle\sqrt{\mathbf{K}}, \sqrt{\tfrac{1-a}{n-1}}\mathbf{H}\rangle = \frac{\sqrt{a}}{n}\mathbf{1}^\top\sqrt{\mathbf{K}}\mathbf{1} + \frac{\sqrt{1-a}}{\sqrt{n-1}}\text{tr}(\mathbf{H}\sqrt{\mathbf{K}}).$$

Maximizing the latter, corresponds to an optimization along the positive quadrant of the circle parametrically defined by coordinates $\sqrt{a}$ and $\sqrt{1-a}$. The maximizing value is

$$a^\star = \arg\max_{0\le a\le 1}\langle\sqrt{\mathbf{K}}, \sqrt{\mathbf{N}_a}\rangle = \frac{\left(\frac{1}{n}\mathbf{1}^\top\sqrt{\mathbf{K}}\mathbf{1}\right)^2}{\left(\frac{1}{n}\mathbf{1}^\top\sqrt{\mathbf{K}}\mathbf{1}\right)^2 + \frac{1}{n-1}\text{tr}^2(\mathbf{H}\sqrt{\mathbf{K}})}. \tag{B.12}$$

Substituting $a^\star$ back into the expression of affinity leads to

$$\max_{0\le a\le 1}\langle\sqrt{\mathbf{K}}, \sqrt{\mathbf{N}_a}\rangle = \langle\sqrt{\mathbf{K}}, \sqrt{\mathbf{N}_{a^\star}}\rangle = \sqrt{\left(\tfrac{1}{n}\mathbf{1}^\top\sqrt{\mathbf{K}}\mathbf{1}\right)^2 + \tfrac{1}{n-1}\text{tr}^2(\mathbf{H}\sqrt{\mathbf{K}})},$$

and the measure of informativeness is

$$\frac{1}{2}d_{\mathcal{N}}^2(\mathbf{K}) = 1 - \sqrt{\tfrac{1}{n^3}(\mathbf{1}^\top\sqrt{\mathbf{K}}\mathbf{1})^2 + \tfrac{1}{n(n-1)}\text{tr}^2(\mathbf{H}\sqrt{\mathbf{K}})}. \tag{B.13}$$

B.7 Bures

By employing the Bures distance d_B for trace-normalized matrices in Equation 3, we can define a measure of informativeness of an arbitrary correlation matrix $\mathbf{K} \in \mathcal{E}$ as

$$\frac{1}{2}d_{\mathcal{N}}^2(\mathbf{K}) = \frac{1}{2}\min_{\mathbf{N}\in\mathcal{N}} d_B^2\left(\tfrac{1}{n}\mathbf{K}, \tfrac{1}{n}\mathbf{N}\right) = 1 - 1\max_{0\le a\le 1}\tfrac{1}{n}\left\|\sqrt{\mathbf{K}}\sqrt{\mathbf{N}_a}\right\|_*. \tag{B.14}$$

Since $0 \le \frac{1}{n}\left\|\sqrt{\mathbf{K}}\sqrt{\mathbf{N}_a}\right\|_* \le 1$ (discussed in Appendix A), this distance is bounded as $0 \le d_{\mathcal{N}}^2(\mathbf{K}) \le 2$, with $d_{\mathcal{N}}(\mathbf{K}) = 0$ when $\mathbf{K} \in \mathcal{N}$.

We now define for convenience the function

$$f(\mathbf{K}, a) \equiv \frac{1}{\sqrt{n}}\left\|\sqrt{\mathbf{K}}\sqrt{\mathbf{N}_a}\right\|_* = \left\|\tfrac{\sqrt{a}}{n}\sqrt{\mathbf{K}}\mathbf{J} + \sqrt{\tfrac{1-a}{n-1}}\sqrt{\mathbf{K}}\mathbf{H}\right\|_*,$$

where the right hand side is obtained by using the equation $\sqrt{\mathbf{N}_a} = \sqrt{\frac{a}{n}}\mathbf{J} + \sqrt{\frac{(1-a)n}{n-1}}\mathbf{H}$ introduced in Section 3.1. We note that $\frac{1}{n}f^2(\mathbf{K}, a) = C^2(\frac{1}{n}\mathbf{K}, \frac{1}{n}\mathbf{N}_a)$, where $C^2(\cdot,\cdot)$ is the concave fidelity measure (Jozsa, 1994) discussed in Appendix A. The function simplifies for $a = 0$ and $a = 1$, yielding the following two quantities that will be useful for subsequent calculations

$$f^2(\mathbf{K}, 1) = \frac{1}{n^2}\left\|\sqrt{\mathbf{K}}\mathbf{J}\right\|_*^2 = \frac{1}{n^2}\text{tr}^2\sqrt{\mathbf{JKJ}} = \frac{1}{n}\mathbf{1}^\top\mathbf{K}\mathbf{1}\,,$$
$$f^2(\mathbf{K}, 0) = \frac{1}{n-1}\left\|\sqrt{\mathbf{K}}\mathbf{H}\right\|_*^2 = \frac{1}{n-1}\text{tr}^2\sqrt{\mathbf{HKH}}\,.$$

For general correlation matrices $\mathbf{K}$, exact computation of the informativeness $d_{\mathcal{N}}(\mathbf{K})$ requires finding the value of a that maximizes $f(\mathbf{K}, a)$, or equivalently $f^2(\mathbf{K}, a)$. Since the latter expression is concave, this concave maximization is tractable and can be done using line search. However, each evaluation of $f(\mathbf{K}, a)$ requires the calculation of a trace norm, and therefore the singular values of an $n \times n$ matrix; for large matrices, this would be a costly search. Consequently, as a surrogate, we seek a lower bound on $d_{\mathcal{N}}(\mathbf{K})$, or equivalently an upper bound on $\max_a\|\sqrt{\mathbf{K}}\sqrt{\mathbf{N}_a}\|_*$. One such useful bound can be found by simply employing the sub-additive property $\|\mathbf{A} + \mathbf{B}\|_* \le \|\mathbf{A}\|_* + \|\mathbf{B}\|_*$ for matrices $\mathbf{A}$ and $\mathbf{B}$ of equal size. Thus, for any $a \in [0, 1]$, we have

$$\begin{aligned} f(\mathbf{K}, a) &\le \frac{\sqrt{a}}{n}\left\|\sqrt{\mathbf{K}}\mathbf{J}\right\|_* + \sqrt{\frac{1-a}{n-1}}\left\|\sqrt{\mathbf{K}}\mathbf{H}\right\|_* = \sqrt{\frac{a}{n}\mathbf{1}^\top\mathbf{K}\mathbf{1}} + \sqrt{\frac{1-a}{n-1}}\left\|\sqrt{\mathbf{K}}\mathbf{H}\right\|_* \\ &= \sqrt{a}\, f(\mathbf{K}, 1) + \sqrt{1-a}\, f(\mathbf{K}, 0) \;\equiv\; \overline{f}(\mathbf{K}, a). \end{aligned} \tag{B.15}$$

Additionally, we have $\max_a f(\mathbf{K},a) \le \max_a \overline{f}(\mathbf{K},a)$. As the maximization of $\overline{f}(\mathbf{K},a)$ corresponds to a linear program constrained to a circle parameterized by coordinates $\sqrt{a}$ and $\sqrt{1-a}$, the unique optimizing value of a is given as

$$a^* = \operatorname*{arg\,max}_{0\le a\le 1} \overline{f}(\mathbf{K},a) = \frac{f^2(\mathbf{K},1)}{f^2(\mathbf{K},1)+f^2(\mathbf{K},0)} = \frac{\mathbf{1}^\top\mathbf{K}\mathbf{1}}{\mathbf{1}^\top\mathbf{K}\mathbf{1}+\frac{n}{n-1}\mathrm{tr}^2\sqrt{\mathbf{H}\mathbf{K}\mathbf{H}}}. \tag{B.16}$$

Substituting a^* into Equation B.15 yields $\overline{f}(\mathbf{K},a^*) = \sqrt{f^2(\mathbf{K},1)+f^2(\mathbf{K},0)}$. This finally provides a lower bound for $d^2_{\mathcal{N}}(\mathbf{K})$ as

$$\begin{aligned}\frac{1}{2}d^2_{\mathcal{N}}(\mathbf{K}) &\ge 1-\frac{1}{\sqrt{n}}\sqrt{f^2(\mathbf{K},1)+f^2(\mathbf{K},0)}\\ &= 1-\sqrt{\tfrac{1}{n^2}\mathbf{1}^\top\mathbf{K}\mathbf{1}+\tfrac{1}{n(n-1)}\mathrm{tr}^2\sqrt{\mathbf{H}\mathbf{K}\mathbf{H}}} \;\equiv\; i(\mathbf{K}).\end{aligned} \tag{B.17}$$

We refer to $i(\mathbf{K})$ as the *Bures-based informativeness*, since $\sqrt{2i(\mathbf{K})}$ is a lower bound on the Bures distance between $\mathbf{K}$ and the closest member in the set of non-informative correlation matrices $\mathcal{N}$.

Theorem 4 *The Bures-based informativeness $i(\mathbf{K})$ is convex. For $\mathbf{K}_1,\mathbf{K}_0 \in \mathcal{E}$ and $0 \le \alpha \le 1$, $i(\alpha\mathbf{K}_1+(1-\alpha)\mathbf{K}_0) \le \alpha i(\mathbf{K}_1)+(1-\alpha)i(\mathbf{K}_0)$.*

Proof We write the Bures-based informativeness as the composition $i(\mathbf{K}) = g(f(\mathbf{K}))$ where $f(\mathbf{K}) = \frac{1}{n^2}\mathbf{1}^\top\mathbf{K}\mathbf{1}+\frac{1}{n(n-1)}\mathrm{tr}^2\sqrt{\mathbf{H}\mathbf{K}\mathbf{H}}$ and $g(u) = 1-\sqrt{u}, \quad 0 \le u$. The function $f(\mathbf{K}) = \langle \mathbf{K}, \frac{1}{n^2}\mathbf{J}\rangle + \frac{1}{n(n-1)}\|\sqrt{\mathbf{K}}\sqrt{\mathbf{H}}\|^2_*$ is concave as it is the sum of a linear function and the concave function $\frac{1}{n(n-1)}\|\sqrt{\mathbf{K}}\sqrt{\mathbf{H}}\|^2_*$, which is itself proportional to the concave fidelity function (Uhlmann, 1976; Jozsa, 1994) (see Theorem 3 in Appendix A). Furthermore, the function g is convex and nonincreasing. From these properties, it follows that

$$\begin{aligned} i(\alpha\mathbf{K}_1+(1-\alpha)\mathbf{K}_0) = g(f(\alpha\mathbf{K}_1+(1-\alpha)\mathbf{K}_0)) &\le g(\alpha f(\mathbf{K}_1)+(1-\alpha)f(\mathbf{K}_0))\\ &\le \alpha g(f(\mathbf{K}_1))+(1-\alpha)g(f(\mathbf{K}_0))\\ &= \alpha i(\mathbf{K}_1)+(1-\alpha)i(\mathbf{K}_0),\end{aligned}$$

where the first inequality follows from the concavity of f and the monotonicity of g, and the second inequality follows from the convexity of g. ■

Special case 1: If $\mathbf{K}$ is centered, that is $\mathbf{K}\mathbf{1} = \mathbf{0}$, we have $\sqrt{\mathbf{K}}\mathbf{1} = \mathbf{0}$ and $f(\mathbf{K},a) = \sqrt{\frac{1-a}{n-1}}\mathrm{tr}\sqrt{\mathbf{K}}$. Therefore, in this case we obtain a closed-form for Equation B.14, given as

$$\frac{1}{2}d^2_{\mathcal{N}}(\mathbf{K}) = 1-\frac{1}{\sqrt{n(n-1)}}\mathrm{tr}\sqrt{\mathbf{K}}. \tag{B.18}$$

Thus, Equation B.17 yields an equality with $\frac{1}{2}d^2_{\mathcal{N}}(\mathbf{K}) = i(\mathbf{K})$. Centered correlation matrices have zero-mean embeddings, that is, $\mathbf{Z}\mathbf{1} = \mathbf{0}$, for any $\mathbf{Z}$ such that $\mathbf{Z}^\top\mathbf{Z} = \mathbf{K}$.

Special case 2: If $\mathbf{K}$ is a rank-1, then $\left\|\sqrt{\mathbf{K}}\sqrt{\mathbf{N}_a}\right\|_* = \left\|\sqrt{\mathbf{K}}\sqrt{\mathbf{N}_a}\right\|_F = \sqrt{\mathrm{tr}(\mathbf{N}_a\mathbf{K})}$. In this case, we have

$$f^2(\mathbf{K},a) = \frac{a}{n}\mathbf{1}^\top\mathbf{K}\mathbf{1}+\frac{1-a}{n-1}\mathrm{tr}(\mathbf{H}\mathbf{K}) = \frac{an^2(\bar{k}-\frac{1}{n})}{n-1}+\frac{n(1-\bar{k})}{n-1},$$

where $\bar{k} = \frac{1}{n^2}\mathbf{1}^\top\mathbf{K}\mathbf{1}$ is the average of all the entries of $\mathbf{K}$, and $\mathrm{tr}(\mathbf{H}\mathbf{K}) = n(1-\bar{k})$. This shows that $f^2(\mathbf{K},a)$ is linear with respect to a, and will be maximized by the extreme values 1 or 0 of a (depending on whether or not, $\bar{k}$ is greater than $\frac{1}{n}$). Substituting the expression of $f(\mathbf{K},a)$ into Equation B.14 and simplifying yields

$$\frac{1}{2}d^2_{\mathcal{N}}(\mathbf{K}) = 1-\sqrt{\max\left(\bar{k},\frac{1-\bar{k}}{n-1}\right)}. \tag{B.19}$$

Similarly, when $\mathbf{K}$ is rank-1, then $\mathrm{tr}^2\sqrt{\mathbf{H}\mathbf{K}\mathbf{H}} = \mathrm{tr}(\mathbf{H}\mathbf{K}\mathbf{H}) = n(1-\bar{k})$, and Equation B.17 becomes

$$i(\mathbf{K}) = 1-\sqrt{\bar{k}+\frac{1-\bar{k}}{n-1}} = 1-\sqrt{\frac{\bar{k}(n-2)+1}{n-1}}. \tag{B.20}$$

Rank-1 correlation matrices $\mathbf{K} = \mathbf{v}\mathbf{v}^\top$ with $\mathbf{v} \in \{\pm 1\}^n$ correspond to vertices of the elliptope (discussed in Section 2.1). Using the cut vector $\mathbf{v}$, it is easy to see that $\mathbf{1}^\top\mathbf{K}\mathbf{1} = (\mathbf{v}^\top\mathbf{1})^2 = (2c-n)^2 = 4(c-\frac{n}{2})^2$, where c is the number of positive entries of $\mathbf{v}$. Thus, Equation B.19 can be directly expressed in terms of c as

$$\frac{1}{2}d^2_{\mathcal{N}}(\mathbf{K}) = \begin{cases} 1-\frac{2}{n}\sqrt{\frac{c(n-c)}{n-1}}, & \text{if } c \in \left[\frac{n-\sqrt{n}}{2},\frac{n+\sqrt{n}}{2}\right],\\ 1-\frac{2}{n}\left|c-\frac{n}{2}\right|, & \text{otherwise,}\end{cases}$$

and likewise Equation B.20 can be expressed as

$$i(\mathbf{K}) = 1-\frac{2}{n}\sqrt{\left(c-\frac{n}{2}\right)^2\frac{n-2}{n-1}+\frac{n^2}{4(n-1)}}.$$

Figure 15 compares $\sqrt{2i(\mathbf{K})}$ and $d_{\mathcal{N}}(\mathbf{K})$ for rank-1 matrices. For this case, $i(\mathbf{K})$ provides a tight lower bound except near the balanced cut.

Finally, we note the following result for the Bures-based informativeness.

Theorem 5 *For $n > 2$ and even, the Bures-based informativeness is maximized by rank-1 correlation matrices that are centered. That is, if $\mathbf{K}^\star \in \mathbb{R}^{n\times n}$ is a rank-1 correlation matrix with $\bar{k}^\star = \frac{1}{n^2}\mathbf{1}^\top\mathbf{K}^\star\mathbf{1} = 0$, then $i(\mathbf{K}^\star) = \max_{\mathbf{K}\in\mathcal{E}} i(\mathbf{K})$.*

Proof From Equation B.20, it follows that $i(\mathbf{K}^\star) = 1-\sqrt{\frac{1}{n-1}}$. Maximizing $i(\mathbf{K})$ over $\mathbf{K} \in \mathcal{E}$ corresponds to minimizing the expression $\bar{k}+\frac{1}{n(n-1)}\|\mathbf{H}\sqrt{\mathbf{K}}\|^2_*$. Using the matrix norm inequality $\|\mathbf{A}\|_* \ge \|\mathbf{A}\|_F$, it follows that

$$\frac{1}{n(n-1)}\left\|\mathbf{H}\sqrt{\mathbf{K}}\right\|^2_* \ge \frac{1}{n(n-1)}\left\|\mathbf{H}\sqrt{\mathbf{K}}\right\|^2_F = \frac{1}{n(n-1)}\mathrm{tr}\left(\mathbf{H}\mathbf{K}\right) = \frac{1-\bar{k}}{n-1}.$$

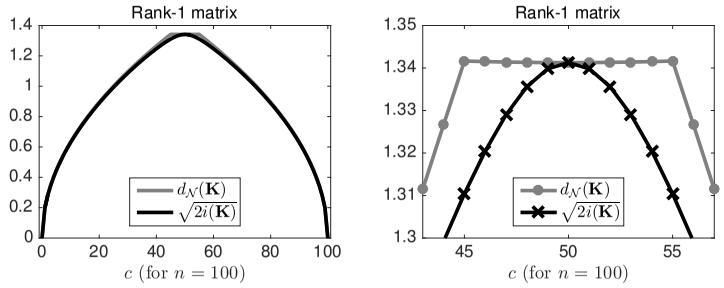

Figure 15: Comparison of the distance to the non-informative matrix family $d_{\mathcal{N}}(\mathbf{K})$ using the exact Bures distance d_B versus the lower bound $\sqrt{2i(\mathbf{K})}$ for rank-1 matrices $\mathbf{K} = \mathbf{v}\mathbf{v}^\top$, where c is the number of positive elements in the cut vector $\mathbf{v}$. The plot on the right magnifies the area around a balanced cut.

Substituting this expression back into the informativeness measure and maximizing over the possible values of $\bar{k}$, it follows that

$$i(\mathbf{K}) \leq 1 - \sqrt{\bar{k} + \frac{1-\bar{k}}{n-1}} \leq 1 - \sqrt{\frac{1}{n-1}} = i(\mathbf{K}^\star).$$

■

B.8 Sub-Bures Dissimilarity via Super-Fidelity

The modified fidelity or super-fidelity provides an upper bound of fidelity used in the Bures distance, and its computation has a lower complexity (Mendonça et al., 2008; Miszczak et al., 2009). Using super-fidelity, a lower bound on the Bures distance can be formed, which we refer to as the sub-Bures dissimilarity. (We use the term dissimilarity since it is not a metric, although a distance metric version can be obtained by removing the square root in the corresponding expression.) Using the sub-Bures dissimilarity, the informativeness is

$$\frac{1}{2} d^2_{\mathcal{N}}(\mathbf{K}) = 1 - \max_{0 \leq a \leq 1} \sqrt{G(\tfrac{1}{n}\mathbf{K}, \tfrac{1}{n}\mathbf{N}_a)}.$$

The super-fidelity between $\mathbf{K}$ and a non-informative matrix $\mathbf{N}_a$ is given by

$$\begin{aligned} G(\tfrac{1}{n}\mathbf{K}, \tfrac{1}{n}\mathbf{N}_a) &= \frac{1}{n^2}\langle \mathbf{K}, \mathbf{N}_a \rangle + \sqrt{\left(1 - \left\|\tfrac{1}{n}\mathbf{K}\right\|_F^2\right)\left(1 - \left\|\tfrac{1}{n}\mathbf{N}_a\right\|_F^2\right)} \\ &= \frac{a(n\bar{k}-1) + 1 - \bar{k}}{n-1} + \sqrt{\tfrac{n(1-a^2)+2(1-a)}{n-1}\left(1 - \left\|\tfrac{1}{n}\mathbf{K}\right\|_F^2\right)}, \end{aligned} \tag{B.21}$$

where $\bar{k}$ is as defined before, and $\left\|\frac{1}{n}\mathbf{N}_a\right\|_F^2 = a^2 + \frac{(1-a)^2}{n-1}$ was used to simplify the right hand side.

If $\mathbf{K}$ is rank-1, then $\|\frac{1}{n}\mathbf{K}\|_F = 1$ and the super-fidelity is proportional to $\langle \mathbf{K}, \mathbf{N}_a \rangle$. The inner product is maximized for $a = 1$ if $\bar{k} > \frac{1}{n}$, and $a = 0$ otherwise. In these two cases, super-fidelity obtains the values of $\bar{k}$ and $\frac{1-\bar{k}}{n-1}$, respectively. For more general cases, the maximizing value of a can be found using the derivative of super-fidelity given by

$$\frac{\partial G(\frac{1}{n}\mathbf{K}, \frac{1}{n}\mathbf{N}_a)}{\partial a} = \frac{\bar{k}n - 1}{n-1} + \frac{1 - an}{\sqrt{n(1-a^2) + 2(1-a)}} \sqrt{\frac{1 - \|\frac{1}{n}\mathbf{K}\|_F^2}{n-1}},$$

which vanishes when

$$\frac{\bar{k}n - 1}{n-1} = \frac{an - 1}{\sqrt{n(1-a^2) + 2(1-a)}} \sqrt{\frac{1 - \|\frac{1}{n}\mathbf{K}\|_F^2}{n-1}}.$$

Squaring both sides yields a quadratic expression whose roots are given by

$$a^{\pm} = \frac{b + cn \pm \sqrt{(cn+b)^2 - (cn^2 + bn)(c + b(2-n))}}{cn^2 + bn},$$

where $b = \frac{(\bar{k}n-1)^2}{(n-1)^2}$ and $c = \frac{1 - \|\frac{1}{n}\mathbf{K}\|_F^2}{n-1}$.

The super-fidelity is maximized when a is at one of its limits or by the root that satisfies $\operatorname{sign}(\bar{k} - \frac{1}{n}) = \operatorname{sign}(a - \frac{1}{n})$. Now, if we define $a_1 \equiv \min(1, a^+)$ and $a_0 \equiv \max(0, a^-)$, we have

$$a^\star = \operatorname*{arg\,max}_{0 \leq a \leq 1} G(\tfrac{1}{n}\mathbf{K}, \tfrac{1}{n}\mathbf{N}_a) = \begin{cases} a_1 & \text{if } G(\frac{1}{n}\mathbf{K}, \frac{1}{n}\mathbf{N}_{a_1}) \geq G(\frac{1}{n}\mathbf{K}, \frac{1}{n}\mathbf{N}_{a_0}) \\ a_0 & \text{otherwise.} \end{cases} \tag{B.22}$$

The maximal super-fidelity is

$$\max_{0 \leq a \leq 1} G(\tfrac{1}{n}\mathbf{K}, \tfrac{1}{n}\mathbf{N}_a) = \max\left(G(\tfrac{1}{n}\mathbf{K}, \tfrac{1}{n}\mathbf{N}_{a_1}),\ G(\tfrac{1}{n}\mathbf{K}, \tfrac{1}{n}\mathbf{N}_{a_0}) \right) \equiv g(\mathbf{K}), \tag{B.23}$$

and, hence, the sub-Bures measure of informativeness is

$$\frac{1}{2} d^2_{\mathcal{N}}(\mathbf{K}) = 1 - \sqrt{g(\mathbf{K})}. \tag{B.24}$$

Although this closed-form expression seems algebraically complex, it only depends on $\bar{k}$ and the norm of $\mathbf{K}$.

Appendix C. Statistics for Equality of Correlation Coefficients

In this appendix, we present Bartlett's and Lawley's test statistics for equality of correlation coefficients (Lawley, 1963) using notation consistent with the proposed measures of informativeness.

C.1 Lawley's Test Statistic

Lawley proposed a test statistic for equality of correlation coefficients (Lawley, 1963), which is a function of the Frobenius norm, element-wise mean, and variance of the row sums of a correlation matrix $\mathbf{K}$. The test assumes the correlation matrix is estimated from m observations of n-dimensional vectors. Under the null hypothesis the true correlation matrix is $\mathbf{N}_{a^*}$ for some value $0 \leq a^* \leq 1$. Letting $\lambda = \frac{n(1-a^*)}{n-1}$ and $\bar{k} = \frac{1}{n^2}\mathbf{1}^\top\mathbf{K}\mathbf{1}$, the test statistic can be written as

$$\begin{aligned} T_1(\mathbf{K}) &= \frac{m}{\lambda^2}\left(\frac{1}{2}\left\|\mathbf{K}-\mathbf{N}_{\bar{k}}\right\|_F^2 - \frac{1-\lambda^2}{n-\lambda^2(n-2)}\left\|\mathbf{K}\mathbf{1}-\mathbf{N}_{\bar{k}}\mathbf{1}\right\|_2^2\right) \\ &= \frac{m}{\lambda^2}\left(\frac{1}{2}\left(\|\mathbf{K}\|_F^2 - \frac{n^2}{n-1}(\bar{k}^2 n - 2\bar{k}+1)\right) - \frac{1-\lambda^2}{n-\lambda^2(n-2)}\left\|\mathbf{K}\mathbf{1}-n\bar{k}\mathbf{1}\right\|_2^2\right), \end{aligned} \tag{C.1}$$

where the simplification comes from $\|\mathbf{K}-\mathbf{N}_{\bar{k}}\|_F^2 = \|\mathbf{K}\|_F^2 - (n\bar{k})^2 - (1-\bar{k})^2\frac{n^2}{n-1} = \|\mathbf{K}\|_F^2 - \frac{n^2}{n-1}(n\bar{k}^2 - 2\bar{k}+1)$.

Asymptotically (as $m \to \infty$), the test statistic under the null hypothesis has a χ^2 distribution with $\frac{1}{2}(n+1)(n-2)$ degrees of freedom. In practice, a^* is unknown, but $\bar{k}$ can be used with $\lambda = \frac{n(1-\bar{k})}{n-1}$. This substitution does not affect the χ^2 limiting distribution (Lawley, 1963). Given only $\mathbf{K}$, m is unknown, and while it must be equal or greater than the rank of $\mathbf{K}$, we use the quantity $\frac{1}{m}T_1(\mathbf{K})$ for comparisons.

C.2 Bartlett's Asymptotic Test Statistic

Similarly, Bartlett's asymptotic test statistic (Lawley, 1963) is also a function of the Frobenius norm, element-wise mean, and variance of the rows sum of the given correlation matrix. Letting $\bar{k}$ and λ be defined as before, this test statistic is

$$\begin{aligned} T_2(\mathbf{K}) &= \frac{m}{\lambda^2}\left(\frac{1}{2}\left\|\mathbf{K}-\mathbf{N}_{\bar{k}}\right\|_F^2 - \frac{1}{n}\left\|\mathbf{K}\mathbf{1}-\mathbf{N}_{\bar{k}}\mathbf{1}\right\|_2^2\right) \\ &= \frac{m}{\lambda^2}\left(\frac{1}{2}\left(\|\mathbf{K}\|_F^2 - \frac{n^2}{n-1}(\bar{k}^2 n - 2\bar{k}+1)\right) - \frac{1}{n}\left\|\mathbf{K}\mathbf{1}-\bar{k}n\mathbf{1}\right\|_2^2\right). \end{aligned} \tag{C.2}$$

For $n = 3$ the asymptotic distribution of the test statistic under the null hypothesis is a scaled χ^2 distribution with two degrees of freedom (Anderson, 1963). For $n > 3$ the test statistic under the null hypothesis has a distribution described by the conic combination of two χ^2 distributions; however, this combination depends on the unknown value of a^* in terms of λ (Lawley, 1963). Again, we use the quantity $\frac{1}{m}T_2(\mathbf{K})$ since we assume m is unknown.

Appendix D. Matrix Norm Properties of $\sqrt{h(\cdot)}$

Theorem 6 *The cost function* $\sqrt{h(\mathbf{X})} = \sqrt{\frac{1}{n}\|\mathbf{X}\frac{1}{n}\mathbf{J}\|_*^2 + \frac{1}{n(n-1)}\|\mathbf{X}\mathbf{H}\|_*^2}$*, derived from the Bures-based informativeness measure, is a matrix norm for* $\mathbf{X} \in \mathbb{R}^{b\times n}$ *that satisfies the*

following properties:

$$\sqrt{h(\mathbf{X})} \geq 0, \tag{D.1}$$

$$\sqrt{h(c\mathbf{X})} = |c|\sqrt{h(\mathbf{X})} \quad \forall c, \tag{D.2}$$

$$\sqrt{h(\mathbf{X}+\mathbf{Y})} \leq \sqrt{h(\mathbf{X})} + \sqrt{h(\mathbf{Y})}, \tag{D.3}$$

$$\sqrt{h(\mathbf{X})} = 0 \text{ iff } \mathbf{X} = \mathbf{0}. \tag{D.4}$$

Furthermore, $\sqrt{h(\cdot)}$ *is convex.*

Proof The first two properties of non-negativity and scalability are readily apparent. We proceed to show that $\sqrt{h(\cdot)}$ satisfies the triangle inequality (D.3). For compactness, we set $\alpha_1 = \frac{1}{n}$, $\alpha_2 = \frac{1}{n(n-1)}$, and $\acute{\mathbf{J}} = \frac{1}{n}\mathbf{J}$. For all conformable matrices $\mathbf{X}$ and $\mathbf{Y}$, we have

$$\begin{aligned} h(\mathbf{X}+\mathbf{Y}) &= \alpha_1\|(\mathbf{X}+\mathbf{Y})\acute{\mathbf{J}}\|_*^2 + \alpha_2\|(\mathbf{X}+\mathbf{Y})\mathbf{H}\|_*^2 \\ &\leq \alpha_1(\|\mathbf{X}\acute{\mathbf{J}}\|_* + \|\mathbf{Y}\acute{\mathbf{J}}\|_*)^2 + \alpha_2(\|\mathbf{X}\mathbf{H}\|_* + \|\mathbf{Y}\mathbf{H}\|_*)^2 \\ &= h(\mathbf{X}) + h(\mathbf{Y}) + 2\sqrt{\left(\alpha_1\|\mathbf{X}\acute{\mathbf{J}}\|_*\|\mathbf{Y}\acute{\mathbf{J}}\|_* + \alpha_2\|\mathbf{X}\mathbf{H}\|_*\|\mathbf{Y}\mathbf{H}\|_*\right)^2} \\ &= h(\mathbf{X}) + h(\mathbf{Y}) \\ &\quad + 2\sqrt{\alpha_1^2\|\mathbf{X}\acute{\mathbf{J}}\|_*^2\|\mathbf{Y}\acute{\mathbf{J}}\|_*^2 + \alpha_2^2\|\mathbf{X}\mathbf{H}\|_*^2\|\mathbf{Y}\mathbf{H}\|_*^2 + 2\alpha_1\alpha_2\|\mathbf{X}\acute{\mathbf{J}}\|_*\|\mathbf{Y}\acute{\mathbf{J}}\|_*\|\mathbf{X}\mathbf{H}\|_*\|\mathbf{Y}\mathbf{H}\|_*} \\ &\leq h(\mathbf{X}) + h(\mathbf{Y}) \\ &\quad + 2\sqrt{\alpha_1^2\|\mathbf{X}\acute{\mathbf{J}}\|_*^2\|\mathbf{Y}\acute{\mathbf{J}}\|_*^2 + \alpha_2^2\|\mathbf{X}\mathbf{H}\|_*^2\|\mathbf{Y}\mathbf{H}\|_*^2 + \alpha_1\alpha_2\left(\|\mathbf{X}\acute{\mathbf{J}}\|_*^2\|\mathbf{Y}\mathbf{H}\|_*^2 + \|\mathbf{Y}\acute{\mathbf{J}}\|_*^2\|\mathbf{X}\mathbf{H}\|_*^2\right)} \\ &= h(\mathbf{X}) + h(\mathbf{Y}) + 2\sqrt{h(\mathbf{X})h(\mathbf{Y})} = \left(\sqrt{h(\mathbf{X})} + \sqrt{h(\mathbf{Y})}\right)^2, \end{aligned}$$

where the first inequality follows from the sub-additivity and non-negativity of the trace norm, and the second one from the arithmetic and geometric means inequality. Therefore, taking the square root yields $\sqrt{h(\mathbf{X}+\mathbf{Y})} \leq \sqrt{h(\mathbf{X})} + \sqrt{h(\mathbf{Y})}$.

To ensure that $\sqrt{h(\mathbf{X})}$ is a norm, rather than a seminorm, we now show that property (D.4) holds. Firstly, if $\mathbf{X} = \mathbf{0}$, then $h(\mathbf{X}) = \alpha_1\|\mathbf{0}\acute{\mathbf{J}}\|_*^2 + \alpha_2\|\mathbf{0}\mathbf{H}\|_*^2 = 0$. We prove the converse by contradiction for any $\alpha_1, \alpha_2 > 0$. Suppose that $h(\mathbf{X}) = 0$ and $\mathbf{X} \neq \mathbf{0}$. For the trace norm, $\|\mathbf{X}\acute{\mathbf{J}}\|_*^2 = 0$ iff $\mathbf{X}\acute{\mathbf{J}} = \mathbf{0}$, and $\|\mathbf{X}\mathbf{H}\|_*^2 = 0$ iff $\mathbf{X}\mathbf{H} = \mathbf{0}$. Since the trace-norm is non-negative and $\alpha_1, \alpha_2 > 0$, $h(\mathbf{X}) = 0$ implies that $\mathbf{X}\acute{\mathbf{J}} = \mathbf{0}$ and $\mathbf{X}\mathbf{H} = \mathbf{0}$. Summing these yields $\mathbf{X}\acute{\mathbf{J}} + \mathbf{X}\mathbf{H} = \mathbf{0}$, which, since $\acute{\mathbf{J}} + \mathbf{H} = \mathbf{I}$, yields $\mathbf{X} = \mathbf{0}$, but this contradicts the assumption that $\mathbf{X} \neq \mathbf{0}$.

The convexity of $\sqrt{h(\cdot)}$ follows from the norm properties. For $\mathbf{X}_1, \mathbf{X}_0$ and $0 \leq \alpha \leq 1$, $\sqrt{h(\alpha\mathbf{X}_1 + (1-\alpha)\mathbf{X}_0)} \leq \sqrt{h(\alpha\mathbf{X}_1)} + \sqrt{h((1-\alpha)\mathbf{X}_0)} = \alpha\sqrt{h(\mathbf{X}_1)} + (1-\alpha)\sqrt{h(\mathbf{X}_0)}$. ■

Appendix E. Second-Order Spectral Soft-Thresholding Operator

The trace norm is well known as the tightest convex surrogate for the rank of a matrix (Fazel et al., 2001; Recht et al., 2010) and its proximal operator, the spectral soft-thresholding

operator, has been used in the context of matrix completion (Cai et al., 2010; Mazumder et al., 2010; Ma et al., 2011). The generalization of proximal operators on vectors to matrices holds for any vector functional that is absolutely symmetric (invariant to permutation and change of sign), or equivalently any matrix functional that is unitarily invariant, since in these cases Lewis (1995) proved that the subdifferential of the matrix functional can be written as a composition of the subdifferential of the vector functional and the singular value functional (Lewis's result generalizes the classical theorem by von Neumann (1937) relating symmetric gauge functions to unitary invariant norms). For example, the trace norm can be written as the ℓ_1-norm of the singular values of a matrix, and thus, the spectral soft-thresholding operator is the matrix analog of the soft-thresholding operator Donoho et al. (1995), which is the proximal operator of the ℓ_1-norm (Wright et al., 2009).

By the same reasoning, the squared trace-norm is the matrix analog to the squared ℓ_1-norm. The squared ℓ_1-norm has been used in the context of multiple kernel learning (Lanckriet et al., 2004; Bach, 2008; Kowalski and Torrésani, 2009; Martins et al., 2011), and its proximal operator uses the soft-thresholding operator (Donoho et al., 1995) with a data-dependent penalty (Bach, 2008; Kowalski and Torrésani, 2009; Martins et al., 2011). Since the squared ℓ_1-norm is absolutely symmetric, the subdifferential of the squared trace norm is found by composition of the subdifferential of the squared ℓ_1-norm and the singular value functional (Lewis, 1995). The proximal operator for the squared trace norm applies the proximal operator of the squared ℓ_1-norm to the singular values of the target matrix.

Let $\mathbf{X} \in \mathbb{R}^{m\times n}$ denote an arbitrary matrix (without loss of generality we assume $m \leq n$), and let $\mathbf{U}\mathbf{\Sigma}\mathbf{V}^\top$ denote the singular value decomposition of $\mathbf{X}$, such that $\mathbf{U}, \mathbf{V}$ are unitary and $\mathbf{\Sigma}$ is a diagonal matrix with its first m entries $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_m \geq 0$ and any remaining entries being 0. The spectral soft-thresholding operator is defined as

$$\mathcal{S}_\tau(\mathbf{X}) = \arg\min_{\mathbf{Y}} \frac{1}{2}\|\mathbf{X}-\mathbf{Y}\|_F^2 + \tau\|\mathbf{Y}\|_* = \mathbf{U}[\mathbf{\Sigma}-\tau\mathbf{I}]_+\mathbf{V}^\top,$$

where $[\cdot]_+$ denotes the element-wise non-negative thresholding operation that sets any negative values to zero. Using the proximal operator for the squared ℓ_1-norm (Kowalski and Torrésani, 2009; Martins et al., 2011), we define the second-order spectral soft-thresholding operator $\mathcal{Z}_\beta(\cdot)$ as

$$\begin{aligned}\mathcal{Z}_\beta(\mathbf{X}) &= \mathcal{S}_{\tau^\star}(\mathbf{X}), \qquad\qquad (E.1)\\ \tau^\star &= \tfrac{\beta}{1+k^\star\beta}\|\mathbf{X}\|_{k^\star},\\ k^\star &= \max\{k\in[m] \;:\; \sigma_k - \tfrac{\beta}{1+k\beta}\|\mathbf{X}\|_k > 0\},\\ \|\mathbf{X}\|_k &= \sigma_1+\cdots+\sigma_k \quad \text{(Ky-Fan } k\text{-norm)}.\end{aligned}$$

Theorem 7 *$\mathcal{Z}_\beta(\cdot)$ is the proximal operator of the function $\frac{\beta}{2}\|\cdot\|_*^2$ such that*

$$\mathcal{Z}_\beta(\mathbf{X}) = \arg\min_{\mathbf{Y}} \tfrac{1}{2}\|\mathbf{X}-\mathbf{Y}\|_F^2 + \tfrac{\beta}{2}\|\mathbf{Y}\|_*^2.$$

Proof

Since $\frac{1}{2}\|\mathbf{X}-\mathbf{Y}\|_F^2 + \frac{\beta}{2}\|\mathbf{Y}\|_*^2$ is convex, to prove the optimality of the second-order spectral thresholding operator it is sufficient to show that

$$\mathbf{0} \in \partial\tfrac{1}{2}\|\mathbf{X}-\mathcal{Z}_\beta(\mathbf{X})\|_F^2 + \partial\tfrac{\beta}{2}\|\mathcal{Z}_\beta(\mathbf{X})\|_*^2,$$

where $\partial f(\mathbf{X})$ denotes the subdifferential of the function f at $\mathbf{X}$, defined as

$$\partial f(\mathbf{X}) = \{\mathbf{G} : \forall \mathbf{Y}\in\mathbb{R}^{m\times n}, f(\mathbf{Y}) \geq f(\mathbf{X}) + \langle \mathbf{Y}-\mathbf{X}, \mathbf{G}\rangle\}.$$

To do this we use the optimality of the spectral thresholding operator (Cai et al., 2010; Mazumder et al., 2010; Ma et al., 2011), which implies that for any $\tau \geq 0$

$$\mathbf{0} \in \partial\tfrac{1}{2}\|\mathbf{X}-\mathcal{S}_\tau(\mathbf{X})\|_F^2 + \partial\tau\|\mathcal{S}_\tau(\mathbf{X})\|_*,$$

where the subdifferential of the trace norm (Watson, 1992) is

$$\partial\|\mathbf{X}\|_* = \{\mathbf{U}_1\mathbf{V}_1^\top + \mathbf{M} : \mathbf{U}_1^\top\mathbf{M} = \mathbf{0}, \mathbf{M}\mathbf{V}_1 = \mathbf{0}, \|\mathbf{M}\|_2 \leq 1\},$$

where the columns of $\mathbf{U}_1$ and $\mathbf{V}_1$ are the left and right singular vectors associated to non-zero singular values.

We note that any subgradient of squared trace-norm is a scaled version of the subgradient of the trace-norm with location-dependent scaling, i.e., $(2\|\mathbf{X}\|_*)\mathbf{G} \in \partial\|\mathbf{X}\|_*^2$ iff $\mathbf{G} \in \partial\|\mathbf{X}\|_*$.

Given $\mathcal{Z}_\beta(\mathbf{X}) = \mathcal{S}_{\tau^\star}(\mathbf{X})$, $\tau^\star = \frac{\beta}{1+k^\star\beta}\|\mathbf{X}\|_{k^\star}$, and $\|\mathcal{Z}_\beta(\mathbf{X})\|_* = \|\mathbf{X}\|_{k^\star} - k^\star\tau^\star = \frac{\tau^\star}{\beta}$, it follows that

$$\partial\tfrac{\beta}{2}\|\mathcal{Z}_\beta(\mathbf{X})\|_*^2 = \tfrac{\beta}{2}(2\|\mathcal{Z}_\beta(\mathbf{X})\|_*)\partial\|\mathcal{Z}_\beta(\mathbf{X})\|_* = \tau^\star\partial\|\mathcal{S}_{\tau^\star}(\mathbf{X})\|_*.$$

Thus, $\partial\frac{1}{2}\|\mathbf{X}-\mathcal{Z}_\beta(\mathbf{X})\|_F^2 + \partial\frac{\beta}{2}\|\mathcal{Z}_\beta(\mathbf{X})\|_*^2 = \partial\frac{1}{2}\|\mathbf{X}-\mathcal{S}_{\tau^\star}(\mathbf{X})\|_F^2 + \partial\tau^\star\|\mathcal{S}_{\tau^\star}(\mathbf{X})\|_*$. ■

Editor: David Barber

Abstract

The machine learning community adopted the use of null hypothesis significance testing (NHST) in order to ensure the statistical validity of results. Many scientific fields however realized the shortcomings of frequentist reasoning and in the most radical cases even banned its use in publications. We should do the same: just as we have embraced the Bayesian paradigm in the development of new machine learning methods, so we should also use it in the analysis of our own results. We argue for abandonment of NHST by exposing its fallacies and, more importantly, offer better—more sound and useful—alternatives for it.

Keywords: comparing classifiers, null hypothesis significance testing, pitfalls of p-values, Bayesian hypothesis tests, Bayesian correlated t-test, Bayesian hierarchical correlated t-test, Bayesian signed-rank test

1. Introduction

Progression of Science and of the scientific method go hand in hand. Development of new theories requires—and at the same time facilitates—development of new methods for their validation.

Pioneers of machine learning were playing with ideas: new approaches, such as induction of classification trees, were worthy of publication for the sake of their interestingness. As the field progressed and found more practical uses, variations of similar ideas began emerging, and with that the interest in determining which of them work better in practice. A typical example are the different measures for assessing the quality of attributes; deciding which work better than others required tests on actual, real-world data. Papers thus kept introducing new methods and measured, for instance, classification accuracies to prove their advantages over the existing methods. To ensure the validity of such claims, we adopted—starting with the work of Dietterich (1998) and Salzberg (1997), and later followed by Demšar (2006)—the common statistical methodology used in all scientific areas relying on empirical observations: the null hypothesis significance testing (NHST).

This spread the understanding that the observed results require statistical validation. On the other hand, NHST soon proved inadequate for many reasons (Demšar, 2008). Noteworthy, the American Statistical Association has recently made a statement against p-values (Wasserstein and Lazar, 2016). NHST nowadays it is also falling out of favour in other fields of science (Trafimow and Marks, 2015). We believe that the field of machine learning is ripe for a change as well.

We will spend a whole section demonstrating the many problems of NHST. In a nutshell: it does not answer the question we ask. In a typical scenario, a researcher proposes a new method and desires to prove that it is more accurate than another method on a *single* data set or on a *collection* of data sets. She thus runs the competing methods and records their results (classification accuracy or another appropriate score) on one or more data sets, which is followed by NHST. The difference between what the researcher has in mind and what the NHST provides for is evident from the following quote from a recently published paper: "*Therefore, at the 90% confidence level, we can conclude that (...) method is able to significantly outperform the other approaches.*" This is wrong. The stated *90% confidence level* is not the probability of one classifier outperforming another. The NHST computes the probability of getting the observed (or a larger) difference between classifiers if the null hypothesis of equivalence was true, which is not the probability of one classifier being more accurate than another, given the observed empirical results. Another common problem is that the claimed statistical significance might have no practical impact. Indeed, the common usage of NHST relies on the wrong assumptions that the p-value is a reasonable proxy for the probability of the null hypothesis and that statistical significance implies practical significance.

As we wrote at the beginning, development of Science not only requires but also facilitates the improvement of scientific methods. Advancement of computational techniques and power reinvigorated the interest for Bayesian statistics. Bayesian modelling is now widely adopted for designing principled algorithms for learning from data (Bishop, 2007; Murphy, 2012). It is time to also switch to Bayesian statistics when it comes to analysis of our own results.

The questions we are actually interested in—e.g., is method A better than B? Based on the experiments, how probably is A better? How high is the probability that A is better by more than 1%?—are questions about posterior probabilities. These are naturally provided by the Bayesian methods (Edwards et al., 1963; Dickey, 1973; Berger and Sellke, 1987). The core of this paper is thus a section that establishes the Bayesian alternatives to frequentist NHST and discusses their inference and results. We eventually describe also the software libraries with the necessary algorithms and give short instructions for their use.

2. Frequentist analysis of experimental results

Why do we need to go beyond the frequentist analysis of experimental results? To answer this question, we will focus on a practical case: the comparison of the accuracy of classifiers on different datasets. We initially consider two classifiers: naive Bayes (nbc) and averaged one-dependence estimator (aode). A description of these algorithms with exhaustive references is given in the book by Witten et al. (2011). Assume that our aim is to compare *nbc* versus *aode*. These are the steps we must follow:

1. choose a comparison metric;

2. select a group of datasets to evaluate the algorithms;

3. perform m runs of k-fold cross-validation for each classifier on each dataset.

We have performed these steps in WEKA, choosing *accuracy* as metric, on a collection of 54 data sets downloaded from the the WEKA website[1] and with 10 runs of 10-fold cross-validation. Table 1 reports the accuracies obtained on each dataset by each classifier.

First of all, we aim at knowing which is the best classifier for each dataset. The answer to this question is probabilistic, since on each data set we have only estimates of the performance of each classifier.

Table 1: Accuracies for 10 runs of 10-fold cross-validation on 54 UCI datasets for *nbc* (blue row) versus *aode* (white rows).

.

Since during cross-validation we have provided both classifiers with the same training and test sets, we can compare the classifiers by considering the difference in accuracies on each test set. This yields the vector of *differences of accuracies* $\boldsymbol{x} = \{x_1, x_2, \ldots, x_n\}$, where $n = 100$ (10 runs of 10-fold cross-validation). We can compute the mean of the vector of differences $\boldsymbol{x}$, i.e., the mean difference of accuracy between the two classifiers, and statistically evaluate whether the mean difference is significantly different from zero. In frequentist analysis, we would perform a NHST using the t-test. The problem is that the t-test assumes the observations to be independent. However, the differences of accuracies

1. See `http://www.cs.waikato.ac.nz/ml/weka/`.

are not independent of each other because of the overlapping training sets used in cross-validation. Thus the usual t-test is *not* calibrated when applied to the analysis of cross-validation results: when sampling the data under the null hypothesis its rate of Type I errors is much larger than α (Dietterich, 1998). Moreover, the correlation cannot be estimated from data; Nadeau and Bengio (2003) have proven that there is no unbiased estimator of the correlation of the results obtained on the different folds. Introducing some approximations, they have proposed a heuristic to choose the correlation parameter: $\rho = \frac{n_{te}}{n_{tot}}$, where n_{te}, n_{tr} and $n_{tot} = n_{te} + n_{tr}$ respectively denote the size of the training set, of the test set and of the whole available data set.[2]

Frequentist correlated t-test

The correlated t-test is based on the modified Student's t-statistic:

$$t(\boldsymbol{x}, \mu) = \frac{\overline{x} - \mu}{\sqrt{\hat{\sigma}^2(\frac{1}{n} + \frac{\rho}{1-\rho})}} = \frac{\overline{x} - \mu}{\sqrt{\hat{\sigma}^2(\frac{1}{n} + \frac{n_{te}}{n_{tr}})}}, \tag{1}$$

where $\overline{x} = \frac{1}{n}\sum_{i=1}^{n} x_i$ and $\hat{\sigma} = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(x_i - \overline{x})^2}$ are the sample mean and sample standard deviation of the data $\boldsymbol{x}$, ρ is the correlation between the observations and μ is the value of the mean we aim at testing. The statistic follows a Student distribution with $n-1$ degrees of freedom:

$$St\left(\bar{x}; n-1, \mu, \left(\frac{1}{n} + \frac{\rho}{1-\rho}\right)\hat{\sigma}^2\right). \tag{2}$$

For $\rho = 0$, we obtain the traditional t-test. For $\rho = \frac{n_{te}}{n_{tot}}$, we obtain the correlated t-test proposed by Nadeau and Bengio (2003) to account for the correlation due to the overlapping training sets. Usually the test is run in a two-sided fashion. Its hypotheses are: $H_0 : \mu = 0$; $H_1 : \mu \neq 0$. The p-value of the statistic under the null hypotheses is:

$$p = 2 \cdot (1 - \mathcal{T}_{n-1}(|t(\boldsymbol{x}, 0)|)), \tag{3}$$

where $\mathcal{T}_{n-1}(|t(\boldsymbol{x}, 0)|)$ denotes the cumulative distribution of the standardized Student distribution with $n-1$ degrees of freedom in $|t(\boldsymbol{x}, \mu)|$ for $\mu = 0$. For instance, for the first data set in Table 1 we have that $\bar{x} = -0.0194$, $\hat{\sigma} = 0.01583$, $\rho = 1/10$, $n = 100$ and so $t(\bar{x}, 0) = -3.52$. Hence, the two-sided p-value is $p = 2 \cdot (1 - \mathcal{T}_{n-1}(|t(\boldsymbol{x}, 0)|)) = 0.00065 \approx 0.001$. Sometimes the directional one-sided test is performed. If the alternative hypothesis is the positive one, the hypotheses of the one-sided test are: $H_0 : \mu \leq 0$; $H_1 : \mu > 0$. The p-value is $p = 1 - \mathcal{T}_{n-1}(t(\boldsymbol{x}, 0))$.

Table 2 reports the two-sided p-values for each comparison on each dataset obtained via the correlated t-test. The common practice in NHST is to declare all the comparisons such that $p \leq 0.05$ as significant, i.e., the accuracy of the two classifiers is significantly different on that dataset. Conversely, all the comparisons with $p > 0.05$ are declared not significant.

2. Nadeau and Bengio (2003) considered the case in which random training and test sets are drawn from the original data set. This is slightly different from k-fold cross-validation, in which the folds are designed not to overlap. However the correlation heuristic by Nadeau and Bengio (2003) has since become commonly used to analyse the cross-validation results (Bouckaert, 2003).

Note that these significance tests can, under the NHST paradigm, only be considered in isolation, while combined they require either an omnibus test like ANOVA or corrections for multiple comparisons.

Table 2: Two sided p-values for each dataset. The difference is significant ($p < 0.05$) in 19 out of 54 comparisons.

2.1 NHST: the pitfalls of black and white thinking

Despite being criticized from its inception, NHST is still considered necessary for publication, as $p \leq 0.05$ is trusted as an objective proof of the method's quality. One of the key problems of decisions based on $p \leq 0.05$ is that it leads to "black and white thinking", which ignores the fact that (i) a *statistically significant difference* is completely different from a *practically significant difference* (Berger and Sellke, 1987); (ii) two methods that *are not statistically significantly different are not necessarily equivalent*. The NHST and this p-value-related "black and white thinking" do not allow for making informed decisions. Hereafter, we list the limits of NHST in order of severity using, as a working example, the assessment of the performance of classifiers.

NHST does not estimate probabilities of hypotheses. *What is the probability that the performance of two classifiers is different (or equal)?* This is *the question* we are asking when we compare two classifiers; and NHST cannot answer it.

In fact, the p-value represents the probability of getting the observed (or larger) differences assuming that the performance of the classifiers is equal (H_0). Formally, $p = p(t(\boldsymbol{x}) > \tau|H_0)$, where $t(\boldsymbol{x})$ is the statistic computed from the data $\boldsymbol{x}$, and τ is the critical value corresponding to the test and the selected α. This is not the probability of the hypothesis, $p(H_0|\boldsymbol{x})$, in which we are interested.

Yet, researchers want to know the probability of the null and the alternative hypotheses on the basis of the observed data, rather than the probability of the data assuming the null hypothesis to be true. Sentences like "*at the 95% confidence level, we can conclude that* (...)", are formally correct, but they seem to imply that $1 - p$ is the probability of the alternative hypothesis, while in fact $1 - p = 1 - p(t(\boldsymbol{x}) > \tau|H_0) = p(t(\boldsymbol{x}) < \tau|H_0)$, which is not the same as $p(H_1|\boldsymbol{x})$. This is summed up in Table 3.

what we compute	**what we would like to know**
$p(t(\boldsymbol{x}) > \tau\|H_0)$	$p(H_0\|\boldsymbol{x})$
$1 - p(t(\boldsymbol{x}) > \tau\|H_0) = p(t(\boldsymbol{x}) < \tau\|H_0)$	$1 - p(H_0\|\boldsymbol{x}) = p(H_1\|\boldsymbol{x})$

Table 3: Difference between the probabilities of interest for the analyst and the probabilities computed by the frequentist test.

Point-wise null hypotheses are practically always false. *The difference between two classifiers can be very small; however there are no two classifiers whose accuracies are perfectly equivalent.*

By using a NHST, the null hypothesis is that the classifiers are equal. However, the null hypothesis is practically always false! By rejecting the null hypothesis NHST indicates that the null hypothesis is unlikely; but this is known even before running the experiment. This problem of the NHST has been pointed out in many different scientific domains (Lecoutre and Poitevineau, 2014, Sec 4.1.2.2). A consequence is that, since the null hypothesis is always false, **by adding enough data points it is possible to claim significance even when the effect size is trivial**. This is because the p-value is affected both by the sample size and the effect size, as discussed in the next section. Quoting Kruschke and Liddell (2015): *"null hypotheses are straw men that can virtually always be rejected with enough data."*

The p-value does not separate between the effect size and the sample size. The usual explanation for this phenomenon is that if the effect size H_0 is small, more data is needed to demonstrate the difference. Enough data can confirm arbitrarily small effects. Since the sample size is manipulated by the researcher and the null hypothesis is always wrong, *the researcher can reject it by testing the classifiers on enough data.* On the contrary, conceivable differences may fail to yield small p-values if there are not enough suitable data for testing the method (e.g., not enough datasets). Even if we pay attention not to confuse the p-value with the probability of the null hypothesis, the p-value is intuitively understood as the indicator of the effect size. In practice, it is the function of effect size and sample size: same p-values do not imply same effect sizes.

Figure 1 reports the *density plots* of the differences of accuracy between nbc and aode on the dataset *hepatitis* in two cases: (1) considering only 15 of the 100 accuracies in Table 1 (left); (2) considering all the 100 accuracies (right). The *two orange vertical lines*

define the region in which the differences of accuracy is less than 1%—the meaning of these lines will be clarified in the next sections.

The p-value is 0.077 in the first case and so the null hypothesis cannot be rejected. The p-value becomes 0.048 in the second case and so the null hypothesis can be rejected. This demonstrates how adding data leads to rejection of the null hypothesis although the difference between the two classifiers is very small in this dataset (all the mass is inside the two orange vertical lines). Practical significance can be equated with the effect size, which is what the researcher is interested in. Statistical significance—the p-value—is not a measure of practical significance, as shown in the example.

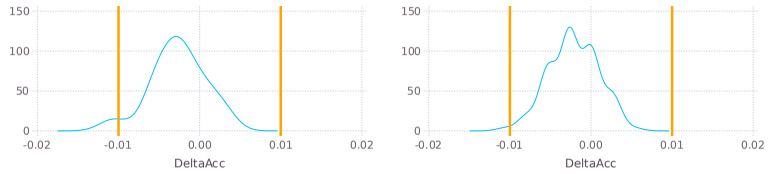

Figure 1: Density plot for the differences of accuracy between *nbc* and *aode* for the dataset *hepatitis* considering only 15 of the 100 data (left) or all the data (right). Left: the null hypothesis cannot be rejected ($p = 0.077 > 0.05$) using half the data. Right: the null hypothesis is rejected when all the data are considered ($p = 0.048 < 0.05$), despite the very small effect size.

NHST ignores magnitude and uncertainty. *A very important problem with NHST is that the result of the test does not provide information about the magnitude of the effect or the uncertainty of its estimate, which are the key information we should aim at knowing.*

A consequence of this limit is that: (i) a null hypothesis can be rejected despite a very small effect; (ii) a null hypothesis can be rejected even though there is a large uncertainty in the effect's magnitude and the region of uncertainty includes (or is extremely close to) zero, that is, no effect. Figure 1 (right) shows a case for which $p = 0.048 < 0.05$ and the result is therefore declared to be statistically significant. However, from the density plot, it is clear that the magnitude of the effect is very small (all inside the orange vertical lines bounding the less than 1% difference of accuracy region). Thus rejecting a null hypothesis does not provide any information about the magnitude of the effect and whether or not the effect is trivial. Figure 2 shows two cases for which $p \approx 0.001 < 0.05$ and the result is therefore declared to be statistically significant. Such p-values are similarly low, but the two cases are extremely different. For the dataset *ecoli* (left), the differences of accuracy are spread from 0.1 to -0.25 (the magnitude of the uncertainty is very large, about 35%), while in the second case the data are spread from 0 to -0.07, a much smaller uncertainty. Thus, rejecting a null hypothesis does not provide us with any information about the uncertainty of the estimate.

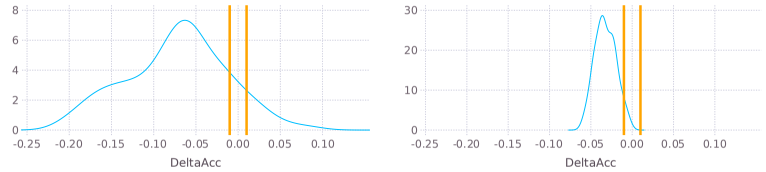

Figure 2: Density plot for the differences of accuracy (DeltaAcc) between *nbc* and *aode* for the datasets *ecoli* (left) and *iris* (right). The null hypothesis is rejected ($p < 0.05$) with similar p-values, even though the two cases have very different uncertainty. For *ecoli*, the uncertainty is very large and includes zero.

NHST yields no information about the null hypothesis. *What can we say when NHST does not reject the null hypothesis?*

The scientific literature contains examples of non-significant tests interpreted as evidence of no difference between the two methods/groups being compared. This is wrong since NHST cannot provide evidence in favour of the null hypothesis (see also Lecoutre and Poitevineau (2014, Sec 4.1.2.2) for further examples on this point). When NHST does not reject the null hypothesis, no conclusion can be made.

Researchers may be interested in the probability that two classifiers are equivalent. For instance, a recent paper contains the following conclusion: "*there is no significant difference between (...) under the significance level of* 0.05. *This is quite a remarkable conclusion.*" This is not correct, we cannot conclude anything in this case! Consider for example Figure 3 (left), which shows the density plot of the differences of accuracy between nbc and aode for the dataset *audiology*. The correlated t-test gives a p-value $p = 0.622$ and so it fails to reject the null hypothesis. However, NHST does not allow us to reach any conclusion about the possibility that the two classifiers may actually be equivalent in this dataset, although the majority of data (density plot) seems to support this hypothesis. We tend to interpret these cases as acceptance of the null hypothesis or to even (mis)understand the p value as a "62.2% probability that the performance of the classifiers is the same". This is also evident from Figure 3 (right), where a very similar p-value, $p = 0.598$, corresponds to a different density plot—with more uncertainty and so less evidence in favour of the null.

There is no principled way to decide the α level. In the above examples, we rejected the null hypothesis at $\alpha = 0.05$. We understand this difference as significant, but not as significant as if we could reject it at $\alpha = 0.01$. What is the actual meaning of this? Can we reject it at $\alpha = 0.03$? The α level represents the crucial threshold to declare the experiment successful. With its importance, it needs to be set with care. However, since it is used to compare the meaningless p-values, α is equally meaningless. By using the NHST, the researcher is forced to select an important threshold with no practical meaning. Using the customary thresholds of 0.05 and 0.01 merely allows her/him to shift the responsibility to the unsubstantiated traditional habit.

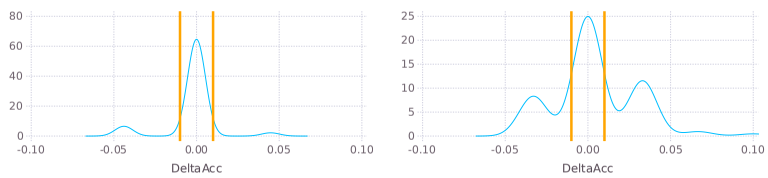

Figure 3: Density plot for the differences of accuracy between *nbc* and *aode* for the datasets *audiology* (left) and *breast-cancer* (right). In *audiology*, we can only say that the null hypothesis cannot be rejected $p = 0.622$ (> 0.05). NHST does not allow the conclusion that the null hypothesis is true although practically all the data lies in the interval $[-0.01, 0.01]$ (the differences of accuracy are less than 1%). A similar p-value corresponds to a very different situation for *breast-cancer*.

We pretend that α is the proportion of cases in which H_0 would be falsely rejected if the same experiment was repeated. This would be true if the p-value represented the probability of the null hypothesis. In reality, α is the proportion of cases in which experiments yield the data that is more extreme than expected under H_0; the actual probability of falsely rejecting H_0 is also related to the probability of H_0 and the data.

For α to be meaningful, it would need to set the required effect size or at least the probability of the hypothesis, not the likelihood of the data.

The inference depends on the sampling intention. Consider analysing a data set of n observations with a NHST test. The sampling distribution used to determine the critical value of the test assumes that our intention was to collect exactly n observations. If the intention was different—for instance in machine learning you typically compare two algorithms on all the datasets that are available—, the sampling distribution changes to reflect the actual sampling intentions (Kruschke, 2010). This is never done, given the difficulty of formalizing one's intention and of devising an appropriate sampling distribution. This problem is thus important but generally ignored. Thus for the data set the hypothesis test (and thus the p-value) should be computed differently, depending on the intention of the person who collected the data (Kruschke, 2010).

3. Bayesian analysis of experimental results

There are two main Bayesian approaches for the analysis of experimental results. The first Bayesian approach, as NHST, is also based on a null value. The analyst has to set up two competing models of what values are possible. One model assumes that only the null value is possible. The alternative model assumes a broad range of other values is also possible. Bayesian inference is used to compute which model is more credible, given the data. This method is called *Bayesian model comparison* and uses so-called "Bayes factors" (Berger, 1985; Aitkin, 1991; Kass and Raftery, 1995; Berger and Pericchi, 1996).

The second Bayesian approach does not set any null value. The analyst simply has to set up a range of candidate values (prior model), including the zero effect, and use Bayesian inference to compute the relative credibilities of all the candidate values (the posterior distribution). This method is called *Bayesian estimation* (Gelman et al., 2014; Kruschke, 2015).

The choice of the method depends on the situation – is a point-wise null hypothesis plausible ? (Bayarri and Berger, 2013, Sec.18.2.3.1)

In machine learning the estimation approach is preferable because there is not plausible reason to believe that two *different* classifiers have exactly the same accuracy. For this reason, we will focus on the Bayesian estimation approach that hereafter we will simply call *Bayesian analysis*.

The first step in Bayesian analysis is establishing a descriptive mathematical model of the data. In a parametric model, this mathematical model is the the *likelihood function* that provides the probability of the observed data for each candidate value of the parameter(s) $p(Data|\theta)$. The second step is to establish the credibility for each value of the parameter(s) before observing data, the *prior distribution* $p(\theta)$. The third step is to use Bayes' rule to combine likelihood and prior to obtain the *posterior distribution* of the parameter(s) given the data $p(\theta|Data)$. The questions we pose in statistical analysis can be answered by querying this posterior distribution in different ways.

As a concrete example of Bayesian analysis we will compare the accuracies of two competing classifiers via cross-validation on multiple data sets (Table 1). For this purpose, we will adopt the *correlated Bayesian t-test* proposed by Corani and Benavoli (2015).

Bayesian correlated t-test

The Bayesian correlated t-test is used for the analysis of cross-validation results on a single dataset and it accounts for the correlation due to the overlapping training sets. The test is based on the following (generative) model of the data:

$$\mathbf{x}_{n\times 1} = \mathbf{1}_{n\times 1}\mu + \mathbf{v}_{n\times 1}, \tag{4}$$

where $\boldsymbol{x} = (x_1, x_2, \ldots, x_n)$ is the vector of differences of accuracy, $\mathbf{1}_{n\times 1}$ is a vector of ones, μ is the parameter of interest (the mean difference of accuracy) and $\mathbf{v} \sim \text{MVN}(0, \boldsymbol{\Sigma}_{n\times n})$ is a multivariate Normal noise with zero mean and covariance matrix $\boldsymbol{\Sigma}_{n\times n}$. The covariance matrix $\boldsymbol{\Sigma}$ is characterized as follows: $\boldsymbol{\Sigma}_{ii} = \sigma^2$ and $\boldsymbol{\Sigma}_{ij} = \sigma^2\rho$ for all $i \neq j \in 1, \ldots, n$, where ρ is the correlation and σ^2 is the variance and, therefore, the covariance matrix takes into account the correlation due to cross-validation. Hence, the likelihood model of data is

$$p(\mathbf{x}|\mu, \boldsymbol{\Sigma}) = \frac{\exp(-\frac{1}{2}(\mathbf{x} - \mathbf{1}\mu)^T\boldsymbol{\Sigma}^{-1}(\mathbf{x} - \mathbf{1}\mu))}{(2\pi)^{n/2}\sqrt{|\boldsymbol{\Sigma}|}}. \tag{5}$$

The likelihood (5) does not allow to estimate ρ from data, since the maximum likelihood estimate of ρ is $\hat{\rho} = 0$ regardless the observations (Corani and Benavoli, 2015). This confirms that ρ is not identifiable: thus the Bayesian correlated t-test adopts the same heuristic $\rho = \frac{n_{te}}{n_{tot}}$ suggested by Nadeau and Bengio (2003).

In Bayesian estimation, we aim at estimating the unknown parameters $\mu, \nu = 1/\sigma^2$ and in particular μ, which is the parameter of interest in the Bayesian correlated t-test. To this

end, we consider the following prior:

$$p(\mu, \nu|\mu_0, k_0, a, b) = N\left(\mu; \mu_0, \frac{k_0}{\nu}\right) G(\nu; a, b) = NG(\mu, \nu; \mu_0, k_0, a, b),$$

which is a Normal-Gamma distribution (Bernardo and Smith, 2009, Chap. 5) with parameters (μ_0, k_0, a, b). The Normal-Gamma prior is conjugate to the likelihood (5). If we choose the prior parameters $\{\mu_0 = 0,\ k_0 \to \infty,\ a = -1/2,\ b = 0\}$ (matching prior), the resulting posterior distribution of μ is the following Student distribution:

$$p(\mu|\boldsymbol{x}, \mu_0, k_0, a, b) = St\left(\mu; n-1, \bar{x}, \left(\frac{1}{n} + \frac{\rho}{1-\rho}\right)\hat{\sigma}^2\right), \tag{6}$$

where $\bar{x} = \frac{\sum_{i=1}^{n} x_i}{n}$ and $\hat{\sigma}^2 = \frac{\sum_{i=1}^{n}(x_i - \bar{x})^2}{n-1}$. For these values of the prior parameters, the posterior distribution of μ (6) coincides with the Student distribution used in the frequentist correlated t-test in (2). For instance, consider the first data set in Table 1, we have that $\bar{x} = -0.0194$, $\hat{\sigma} = 0.01583$, $\rho = 1/10$, $n = 100$ and so $p(\mu|\boldsymbol{x}, \mu_0, k_0, a, b) = St(\mu; 99, -0.0194, 0.000030)$. The output of the Bayesian analysis is the posterior of μ, $p(\mu|\boldsymbol{x}, \mu_0, k_0, a, b)$, which we can plot and query.

In (6), we have reported the posterior distribution obtained under the matching prior—for which the probability of the Bayesian correlated t-test and the p-value of the frequentist correlated t-test are numerically equivalent. Our aim is to show that although they are numerically equivalent the inferences drawn by the two approaches are very different. In particular we will show that a different interpretation of the same numerical value can completely change our prospective and allow us to make informative decisions. In other words, in this case **the cassock does make the priest**!

3.1 Comparing nbc and aode through Bayesian analysis: a colour thinking

Consider the dataset *squash-unsorted*, with the posterior computed by the Bayesian correlated t-test for the difference between *nbc* and *aode*, as shown in Figure 4. The vertical orange lines mark again the region corresponding to a difference of accuracy of less than 1% (we will clarify the meaning of this region later in the section). In Bayesian analysis, the experiment is summarized by the posterior distribution (in this case a Student distribution). The posterior describes the distribution of the mean difference of accuracies between the two classifiers.

By querying the posterior distribution, we can evaluate the probability of the hypothesis. We can for instance infer the probability that *nbc* is better/worse than *aode*. Formally $P(nbc > aode) = 0.165$ is the integral of the posterior distribution from zero to infinity or, equivalently, the posterior probability that the mean of the differences of accuracy between *nbc* and *aode* is greater than zero. $P(aode > nbc) = 1 - P(nbc > aode) = 0.835$ is the integral of the posterior between minus infinity and zero or, equivalently, the posterior probability that the mean of the differences of accuracy is less than zero.

Can we say anything about the probability that *nbc* is practically equivalent to *aode*? Bayesian analysis can answer this question. First, we need to define the meaning of "practically equivalent". In classification, it is sensible to define that two classifiers whose mean difference of accuracies is less that 1% are practically equivalent. The interval $[-0.01, 0.01]$ thus defines a *region of practical equivalence* (rope) (Kruschke and Liddell, 2015) for classifiers.[3] Once we have defined a rope, from the posterior we can compute the probabilities:

- $P(nbc \ll aode)$: the posterior probability of the mean difference of accuracies being *practically* negative, namely the integral of the posterior on the interval $(-\infty, -0.01)$.
- $P(nbc = aode)$: the posterior probability of the two classifiers being practically equivalent, namely the integral of the posterior over the rope interval.
- $P(nbc \gg aode)$: the posterior probability of the mean difference of accuracies being *practically* positive, namely the integral of the posterior on the interval $(0.01, \infty)$.

$P(nbc = aode) = 0.086$ is the integral of the posterior distribution between the vertical lines (the rope) shown in Figure 4 and it represents the probability that the two classifiers are practically equivalent. Similarly, we can compute the probabilities that the two classifiers are practically different, which are $P(nbc \ll aode) = 0.788$ and $P(nbc \gg aode) = 0.126$.

The posterior also shows the uncertainty in the estimate, because the distribution shows the relative credibility of values across the continuum. One way to summarize the uncertainty is by marking the span of values that are the most credible and cover $q\%$ of the distribution (e.g., $q = 90\%$). These are called the *High Density Intervals* (HDIs) and they are shown in Figure 5 (center) for $q = 50, 60, 70, 80, 90, 95, 99$.

Thus the posterior distribution equipped with rope:

1. estimates the posterior probability of a sensible null hypothesis (the area within the rope);
2. claims significant differences that also have a practical meaning (the area outside the rope);

3. In classification 1% seems to be a reasonable choice. However, in other domains a different value could be more suitable.

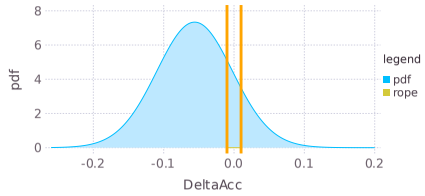

Figure 4: Posterior of the Bayesian correlated t-test for the difference between *nbc* and *aode* in the dataset *squash-unsorted*.

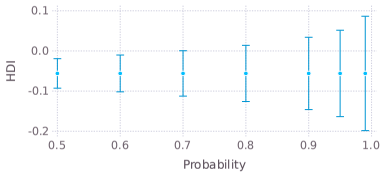

Figure 5: Posterior HDIs of the Bayesian correlated t-test for the difference between *nbc* and *aode* in the dataset *squash-unsorted*.

3. represents magnitude (effect size) and uncertainty (HDIs);

4. does not depend on the sampling intentions.

To see that, we apply Bayesian analysis to the critical cases for NHST presented in the previous section. Figure 6 shows the posterior for *hepatitis* (top), *ecoli* (left) and *iris* (right). For *hepatitis*, all the probability mass is inside the *rope* and so we can conclude that *nbc* and *aode* are practically equivalent: $P(nbc = aode) = 1$. For *ecoli* and *iris*, the probability mass is all in $(-\infty, 0]$ and so $nbc < aode$. However, the posterior gives us more information: there is much more uncertainty in the *iris* dataset. The posteriors thus provide us the same information as the density plots shown in Figures 1–3.

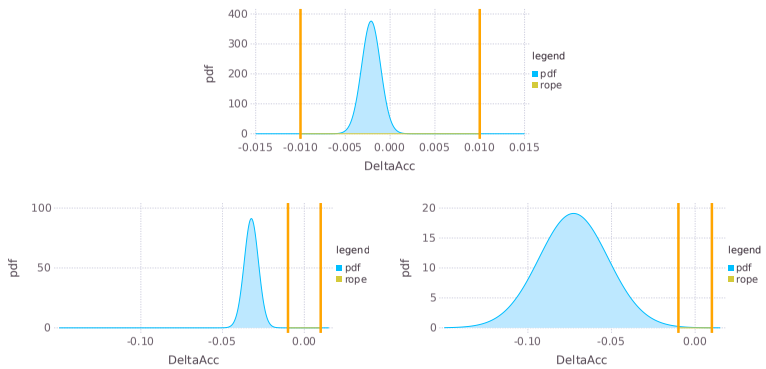

Figure 6: Posterior for *nbc* vs. *aode* in *hepatitis* (top), *ecoli* (left) and *iris* (right).

Consider now Figure 7; those are two examples for which we cannot clearly say whether *nbc* and *aode* are practically equivalent or practically different. We cannot decide in an

obvious way and this is evident from the posterior. Compare these figures with Figure 4, which is similar.

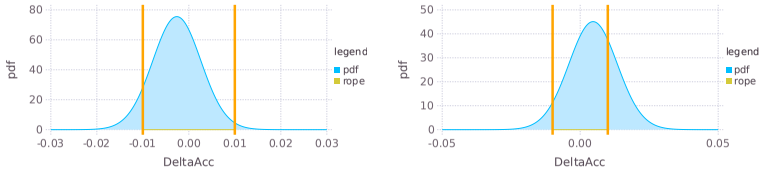

Figure 7: Posterior for *nbc* vs. *aode* in *audiology* (left) and *breast-cancer* (right).

Let us repeat the previous analysis for all 54 datasets: Figure 8 reports the posteriors for *nbc* versus *aode* in all those cases. Looking at the posteriors, we see that there are 12 cases where *aode* is practically better than *nbc*, since all the posterior is outside (to the left of) the rope (in the datasets *ecoli, iris, monks1, monks, mushroom, nursey, optdigits, pasture, segment, spambase, credit, owel*). There are 6 datasets where *nbc* and *aode* are practically equivalent (*hayes-roth*, *hungarian14*, *hepatitis*, *labor*, *wine*, *yeast*), since the entire posterior is inside the rope. We see also that there are no cases where *nbc* is practically better than *aode* (posterior to the right of the rope). The posteriors give us information about the magnitude of effect size, practical difference and equivalence, as well as the related uncertainty.

3.2 Sensible automatic decisions

In machine learning, we often need to perform many analyses. So it may be convenient to devise a tool for automatic decision from the posterior. This means that we have to summarize the posterior in some way, with a few numbers. However, we must be aware that every time we do that we go back to that sort of black and white analysis whose limitations have been discussed before. In fact, by summarizing the posterior, we lose information, but we can do so in a conscious way. We have already explained the advantages of introducing a *rope*, so we can make automatic decisions based on the three probabilities $P(nbc \ll aode)$, $P(nbc = aode)$ and $P(nbc \gg aode)$. In this way, we lose information but we introduce shades in the black and white thinking. $P(nbc \ll aode)$, $P(nbc = aode)$ and $P(nbc \gg aode)$ are probabilities and their interpretation is clear. $P(nbc = aode)$ is the area of the posterior within the rope and represents the probability that *nbc* and *aode* are practically equivalent. $P(nbc \ll aode)$ is the area of the posterior to the left of the rope and corresponds to the probability that *nbc* is practically better than *aode*. Finally, $P(nbc \gg aode)$ is the area to the right of the rope and represents the probability that *aode* is practically better than *nbc*. Since these are the actual probabilities of the decisions we are interested in, in classification, we need not think in terms of Type-I errors to make decisions. We can simply make decisions using these probabilities, which have a direct interpretation—contrarily to *p*-values. For instance we can decide

1. $nbc \ll aode$ if $P(nbc \ll aode) > 0.95$;

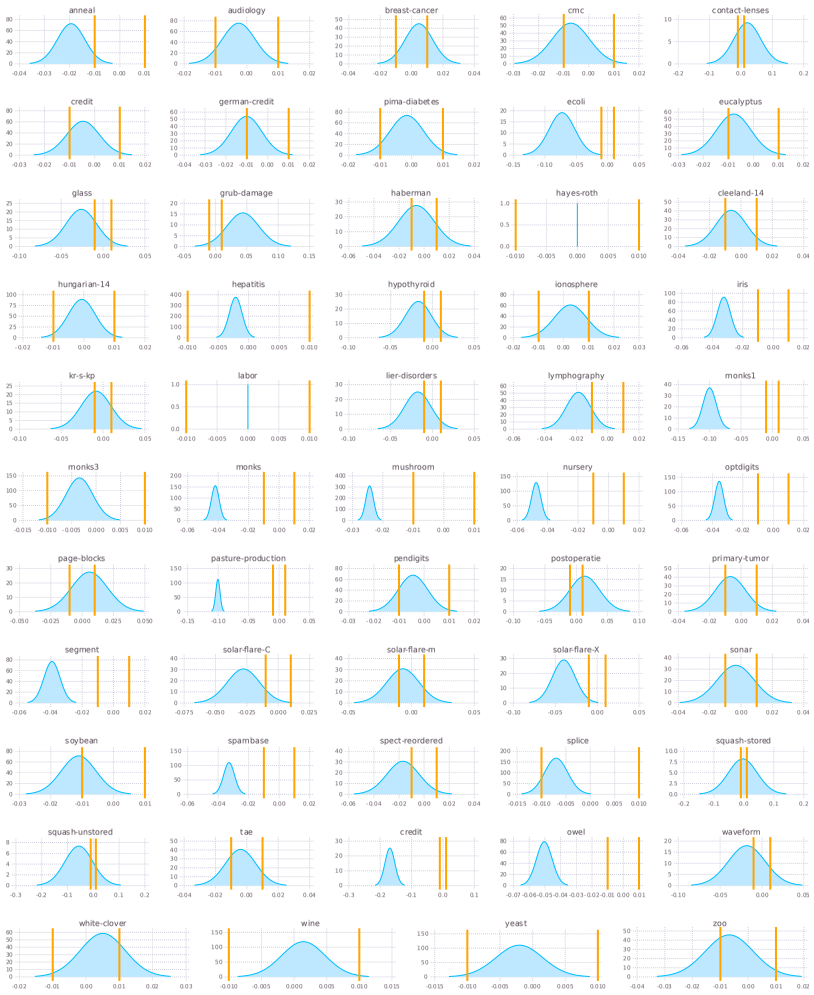

Figure 8: Posteriors of *nbc* versus *aode* for all 54 datasets.

2. $nbc \gg aode$ if $P(nbc \gg aode) > 0.95$;

3. $nbc = aode$ if $P(nbc = aode) > 0.95$.

We can also decide with a probability of, for instance, 0.90 or 0.80 (if this is appropriate in the given context). Table 4 compares the Bayesian decisions based on the above rule with the NHST decisions. The NHST fails to reject the null in 35/54 datasets; Bayesian analysis declares the two classifiers equivalent in 6 of such datasets. Conversely, when NHST rejects the null (in 19/54 datasets), the Bayesian analysis declares nbc$\ll$aode or nbc$\gg$aode in 14 cases, nbc=aode in 1 case and no decision in 4 cases. Overall, Bayesian analysis allows us to make a decision in $6 + 1 + 14 = 21$ datasets, while NHST makes a decision only in 19 cases.

When NHST does not reject the null

pair	Data sets (out of 54)	Bayesian decision	
		nbc=aode	No decision
nbc-aode	35	6	29

When NHST rejects the null

pair	Data sets (out of 54)	Bayesian decision		
pair		nbc=aode	nbc$\ll$aode or nbc$\gg$aode	No decision
nbc-aode	19	1	14	4

Table 4: Results referring to comparisons in which the NHST *rejects* the null.

Sometimes also in Bayesian analysis it may be convenient to think in terms of errors. We can easily do that by defining a loss function. A loss function defines the loss we incur in making the wrong decision. The decisions we can take are nbc$\ll$aode (denoted as a_l), nbc$\gg$aode (a_r), nbc=aode (a_c) or none of them (a_n). Consider for instance the following loss matrix.

$$\begin{array}{c} \\ a_l \\ a_c \\ a_r \\ a_n \end{array} \begin{array}{c} \begin{array}{ccc} a_l & a_c & a_r \end{array} \\ \begin{bmatrix} 0 & 20 & 20 \\ 20 & 0 & 20 \\ 20 & 20 & 0 \\ 1 & 1 & 1 \end{bmatrix} \end{array} \tag{7}$$

The first row gives us the loss we incur in deciding a_l when a_l is true (zero loss), a_c is true (loss is 20) and a_r is true (loss is 20). Similarly for the second and third rows. The last row is the loss we incur in making no decision. The expected loss can be simply obtained by multiplying the above matrix L for the vector of posterior probabilities of nbc$\ll$aode, nbc=aode and nbc$\gg$aode ($p = [p_l, p_c, p_r]^T$), i.e., Lp. The row of Lp corresponding to the lowest loss determines the final decision. Since $0.05 \cdot 20 = 1$, this leads to the same decision rule discussed previously ($P(\cdot) > 0.95$).

3.3 Comparing NHST and Bayesian analysis for other classifiers

In this section we extend the previous analysis to other classifiers besides nbc and aode: hidden naive Bayes (hnb), j48 decision tree (j48) and j48 grafted (j48-gr).

The aim of this section is to show that the pattern described above is general and it also holds for other classifiers. The results are presented in two tables. First we report on the cases in which NHST does not reject the null (Tab. 5). Then we report on the comparisons in which the NHST rejects the null (Tab. 6).

The NHST test does not reject the null hypothesis (Tab. 5) in 341/540 comparisons. In these cases the NHST does not make any conclusion: it cannot tell whether the null hypothesis is true[4] or whether is false but the evidence is too weak to reject it.

By applying the Bayesian correlated t-test with rope and taking decisions as discussed in the previous section, we can draw more informative conclusions. In 74/341=22% of the rejections failed by NHST, the posterior probability of the rope is larger than 0.95, allowing to declare that the two analyzed classifiers are practically equivalent. In the remaining cases, no conclusion can be drawn with probability 0.95.

The rope thus provides a sensible null hypothesis which can be accepted on the basis of the data. When this happens we conclude that the two classifiers are practically equivalent. This is impossible with the NHST.

When NHST does not reject the null

pair	Data sets (out of 54)	Bayesian decision P(rope) >.95	Bayesian decision No decision
nbc–aode	35	6	29

hnb–j48gr	32	3	29
j48–j48gr	50	40	10
total	341	74	267
rates		74/341= 0.22	267/341=0.78

Table 5: Results referring to comparisons in which the NHST correlated t-test does not reject the null.

Let us consider now the comparisons in which NHST claims significance (Tab. 6). There are 199 such cases. The Bayesian estimation procedure confirms the significance of 142/199 (71%) of them: in these cases it estimates either $P(left) > 0.95$ or $P(right) > 0.95$.[5] In these cases the accuracy of the two compared classifiers are *practically* different. In 51/199 cases (26%) the Bayesian test does not make any conclusion. This means that a sizeable amount of probability lies within the rope, despite the statistical significance claimed by the

4. A point null is however always false, as already discussed.
5. In the comparison nbc-aode, left means $nbc \ll aode$ and right $nbc \gg aode$.

When NHST rejects the null

pair	Data sets (out of 54)	Bayesian decision rope	Bayesian decision difference	Bayesian decision no decision
nbc–aode	19	1	14	4
nbc–hnb	24	0	19	5
nbc–j48	27	0	20	7

j48–j48gr	4	2	1	1
total	199	6	142	51
rates		6/199= 0.03	142/199=0.71	51/199=0.26

Table 6: Results referring to comparisons in which the NHST *rejects* the null.

frequentist test. In the remaining cases (6/199=3%) the Bayesian test concludes that the two classifiers are practically equivalent ($P(rope) > 0.95$) despite the significance claimed by the NHST. In this case it draws the opposite conclusion from the NHST.

Summing up, the Bayesian test with rope is more conservative, reducing the claimed significances by 30% as compared with the NHST. The Bayesian test is thus more conservative due to the rope, which constitutes a sensible null hypothesis, while the null hypothesis of the NHST is surely wrong. However counting the detection of practically equivalent classifiers as decisions, the Bayesian test with rope takes more decisions than the NHST (222 vs. 199).

4. Comparing two classifiers on multiple data sets

So far we have discussed how to compare two classifiers on the same data set. In machine learning, another important problem is how to compare two classifiers on a collection of q different data sets, after having performed cross-validation on each data set.

4.1 The frequentist approach

There is no direct NHST able to perform such statistical comparison, i.e., one that takes as inputs the m runs of the k-fold cross-validation differences of accuracy for each dataset and returns as output a statistical decision about which classifier is better in all the datasets. The usual NHST procedure that is employed for performing such an analysis has two steps:

1. compute the mean *difference* of accuracy for each dataset (averaging the differences of accuracies obtained in the m runs of the k-fold cross-validation);

2. perform a NHST to establish if the two classifiers have different performance or not based on these mean differences of accuracy.

For our case study, *nbc* vs. *aode*, the mean *differences* of accuracy in each dataset computed from Table 1 are shown in Table 7. We denote these measures generically with $\boldsymbol{z} = \{z_1, \ldots, z_q\}$ (in our case $q = 54$). The recommended NHST for this task is the signed-rank test (Demšar, 2006).

Frequentist signed-rank test
The Wilcoxon signed-rank test is a non-parametric statistical hypothesis test used when comparing two paired samples. The signed-rank test assumes the observations $z_1, \ldots, z_q$ to be i.i.d. and generated from a symmetric distribution. The test is miscalibrated if the distribution is not symmetric. A strict usage of the test should thus include first a test for symmetry. One should run the signed-rank only if "the symmetry test fails to reject the null" (note that, as we discussed before, this does not actually prove that the distribution is symmetric!). However this would make the whole testing procedure cumbersome, requiring also corrections for the test of multiple hypotheses. In the common practice thus the test for symmetry is not performed, and we follow this practice in this paper.

The test is typically used as follows. The null hypothesis is that the median of the distribution from which the z_i's are sampled is 0; when the test rejects the null hypothesis, it claims that it is significantly different from 0. The test ranks the z_i's according to their absolute value and then compares the ranks of the positive differences and negative

differences. The test statistic is:

$$t = \sum_{\{i:\ z_i \geq 0\}} r_i(|z_i|) \quad = \sum_{1 \leq i \leq j \leq q} t^+_{ij},$$

where $r_i(|z_i|)$ is the rank of $|z_i|$ and

$$t^+_{ij} = \begin{cases} 1 & \textit{if } z_i \geq -z_j, \\ 0 & \textit{otherwise.} \end{cases}$$

For instance, let us consider the following two cases $\boldsymbol{z} = \{-2, -1, 4, 5\}$ or $\boldsymbol{z} = \{-1, 4, 5\}$, then the statistic is $t = 7$ and, respectively, $t = 5$. For a large enough number of samples (e.g., $q > 10$), the statistic under the null hypothesis is approximately normally distributed and in this case the two-sided test is performed as follows:

$$w = \frac{t - \frac{q(q+1)}{4}}{\sqrt{\frac{q(q+1)(2q+1) - \text{tie}}{24}}}, \qquad p = 2(1 - \Phi(|w|)), \tag{8}$$

where p denotes the p-value computed w.r.t. Φ, which is the cumulative distribution function of the standard Normal distribution; *tie* is an adjustment for ties in the data $|\boldsymbol{z}|$, i.e., $z_i = -z_j$ for some i, j, required by the nonparametric test (Sidak et al., 1999; Hollander et al., 2013), while it is zero in case of no ties.

Being non-parametric, the signed-rank is robust to outliers. It assumes commensurability of differences, but only qualitatively: greater differences count more as they top the rank; yet their absolute magnitudes are ignored (Demšar, 2006).

4.1.1 Experimental results

If we apply this method to compare *nbc* vs. *aode*, we obtain p-value=10^{-6} (the rank $t = 162$ with no ties and w is -4.8). Since the p-value is less than 0.05, the NHST concludes that the null hypothesis can be rejected and that *nbc* and *aode* are significantly different. Table 8 reports the p-values of all comparisons of the five classifiers. The pairs *nbc-aode*, *nbc-hnb*, *j48-j48gr* are statistically significantly different. Again by applying this black and white mechanism, we encounter the same problems as before, i.e., we do not have any idea of the magnitude of the effect size, the uncertainty, the probability of the null hypothesis, et cetera. The density plot of the data (the mean differences of accuracy in each dataset) for *nbc* versus *aode* shows for instance that there are many datasets where the mean difference is small (close to zero), see Figure 9. Instead for *j48* versus *j48gr*, it is clear that the difference of accuracy is very small.

4.2 The Bayesian analysis approach

We will present two ways of approaching the comparison between two classifiers in multiple datasets. The first will be based on a nonparametric approach that directly extends the Wilcoxon signed-rank test. The second is a hierarchical model.

Figure 9: Density plot for *nbc* versus *aode* (left) and *j48* versus *j48gr* (right)

hnb	j48gr	0.084
j48	j48r	0.000

Table 8: p-values for the comparison of the five classifiers.

4.2.1 Nonparametric test

Benavoli et al. (2014) have proposed a Bayesian counterpart of the frequentist sign and signed-rank test, which is based on the Dirichlet process.

Bayesian sign and signed-tank test
Let z denote the scalar variable of interest and $\boldsymbol{z} = \{z_1, \dots, z_q\}$ denotes a vector of i.i.d. observations of z. To derive the Bayesian sign and signed-rank test, we assume a Dirichlet Process (DP) prior on the probability distribution of z. A DP is a distribution over probability distributions such that marginals on finite partitions are Dirichlet distributed. Like the Dirichlet distribution, the DP is therefore completely defined by two parameters: the prior strength $s > 0$ and the prior mean that, for the DP, is a probability measure G_0 on z. If we choose $G_0 = \delta_{z_0}$, i.e., a Dirac's delta centred on the pseudo-observation z_0, the posterior probability density function of Z has this simple expression:

$$p(z) = w_0\delta_{z_0}(z) + \sum_{j=1}^{n} w_j\delta_{z_j}(z), \quad (w_0, w_1, \dots, w_n) \sim Dir(s, 1, \dots, 1), \tag{9}$$

i.e., it is a mixture of Dirac's deltas centred on the observations z_j for $j = 1, \dots, q$ and on the prior pseudo-observation z_0, whose weights are Dirichlet distributed with parameters $(s, 1, \dots, 1)$. We can think about (9) as a hierarchical model: $p(z)$ depends on the weights

w that are Dirichlet distributed. The model (9) is therefore a posterior distribution of the probability distribution of z and encloses all the information we need for the experimental analysis. We can summarize it in different way. If we compute:

$$\theta_l = P(z < -r) = \sum_{i=0}^{q} w_i I_{(-\infty,-r)}(z_i),$$
$$\theta_e = P(|z| \le r) = \sum_{i=0}^{q} w_i I_{[-r,r]}(z_i),$$
$$\theta_r = P(z > r) = \sum_{i=0}^{q} w_i I_{(r,\infty)}(z_i),$$

where the indicator $I_A(z) = 1$ if $z_0 \in A$ and zero otherwise, then we obtain a Bayesian version of the **sign test** that also accounts for the rope $[-r, r]$. In fact, $\theta_l, \theta_e, \theta_r$ are respectively the probabilities that the mean difference of accuracy is in the interval $(-\infty, -r)$, $[-r, r]$, or (r, ∞). Since $(w_0, w_1, \dots, w_n) \sim Dir(s, 1, \dots, 1)$, it can easily be shown that

$$\theta_l, \theta_e, \theta_r \sim Dirichlet(n_l + sI_{(-\infty,-r]}(z_0), n_e + sI_{[-r,r]}(z_0), n_r + sI_{[r,\infty)}(z_0)), \tag{10}$$

where n_l is the number of observations z_i that fall in $(-\infty, -r]$, n_e is the number of observations z_i that fall in $[-r, r]$ and n_r is the number of observations z_i that fall in $[r, \infty)$, obviously $n_l + n_e + n_r = q$. If we neglect $sI_{(-\infty,-r]}(z_0), sI_{[-r,r]}(z_0), sI_{[r,\infty)}(z_0)$, then (10) says that the posterior probability of $\theta_l, \theta_e, \theta_r$ is Dirichlet distributed with parameters (n_l, n_e, n_r). The terms $sI_{(-\infty,-r]}(z_0), sI_{[-r,r]}(z_0), sI_{[r,\infty)}(z_0)$ are due to the prior. Therefore, to fully specify the Bayesian sign test, we must choose the value of the prior strength s and where to place the pseudo-observation z_0 in $(-\infty, -r]$ or $[-r, r]$ or $[r, \infty)$. We will return to this choice in Section 4.3. Instead, if we compute

$$\theta_l = \sum_{i=0}^{q}\sum_{j=0}^{q} w_i w_j I_{(-\infty,-2r)}(z_j + z_i),$$
$$\theta_e = \sum_{i=0}^{q}\sum_{j=0}^{q} w_i w_j I_{[-2r,2r]}(z_j + z_i),$$
$$\theta_r = \sum_{i=0}^{q}\sum_{j=0}^{q} w_i w_j I_{(2r,\infty)}(z_j + z_i), \tag{11}$$

then we derive a Bayesian version of the **signed rank test** (Benavoli et al., 2014) that also accounts for the rope $[-r, r]$. This time the distribution of $\theta_l, \theta_e, \theta_r$ has not a simple closed form but we can easily compute it by Monte Carlo sampling the weights $(w_0, w_1, \dots, w_n) \sim Dir(s, 1, \dots, 1)$. Also in this case we must choose s, z_0, see Section 4.3.

It should be observed that the Bayesian signed-rank test does not require the symmetry assumption about the distribution of the observations z_i. This test works also in case the distribution is asymmetric thanks to the Bayesian estimation approach (i.e., it estimates

the distribution from data). This is another advantage of the Bayesian estimation approach w.r.t. the frequentist null hypothesis tests (Benavoli et al., 2014).

4.2.2 Experiments

Let us start by comparing *nbc* vs. *aode* by means of the Bayesian sign-rank tests *without* rope ($r = 0$). Hereafter we will choose the prior parameter of the Dirichlet as $s = 0.5$ and $z_0 = 0$; we will return to this choice in Section 4.3. Since without rope $\theta_r = 1 - \theta_l$, we have only reported the posterior of θ_l (denoted as "Pleft") that represents the probability that *aode* is better than *nbc*. The samples of the posteriors are shown in Figure 10: this is simply the histogram of 150′000 samples of θ_l generated according to (11). For all samples, it results in θ_l greater than 0.5 and so $\theta_r = 1 - \theta_l$. So we can conclude with probability ≈ 1 that *aode* is better than *nbc*. We can in fact think about the comparison of two classifiers as the inference on the bias (θ_l) of a coin. In this case, all the 150′000 sampled coins from the posterior have a bias that is greater than 0.5 and, therefore, all the coins are always biased towards *aode* (which is then preferable to *nbc*).

This conclusion is in agreement with that derived by the frequentist sign-rank test (very small p-value, see Table 8).

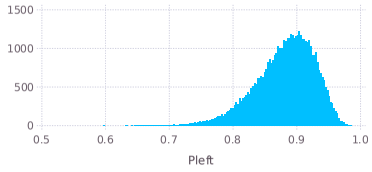

Figure 10: Posterior for *nbc* vs. *aode* for the Bayesian sign-rank test.

The introduction of the *rope* partially changes the previous conclusion. A way to visualize the posterior of $\theta_l, \theta_e, \theta_r$ in this case, is by plotting the 150′000 Monte Carlo samples of these probabilities in barycentric coordinates: each trinomial vector of probabilities is a point in the simplex having vertices $\{(1,0,0),(0,1,0),(0,0,1)\}$. The three vertices are respectively denoted as "aode", "rope" and "nbc" and represent decisions with certainty in favour of "aode", "rope" and, respectively, "nbc". Figure 11 reports the simplex as well as the two-dimensional projections of the posterior for the Bayesian sign-rank test. In particular Figure 11 reports the marginal of the posterior distribution of "aode" vs. "rope" (left); the marginal of the posterior distribution "nbc" vs. "rope" (right). From these two figures we can deduce the other marginal since $\theta_l + \theta_e + \theta_r = 1$. Finally, Figure 11 (bottom) reports the joint of the three variables in barycentric coordinates (we are again exploiting the fact that $\theta_l + \theta_e + \theta_r = 1$). In particular, Figure 11 (bottom) reports the samples from the posteriors (cloud of points), the simplex (the large orange triangle) and three regions (in orange) that are limited by the level curves: $\theta_i \geq \max(\theta_j, \theta_k)$ with $i \neq j \neq k$ (hypothesis i is more probable than both hypotheses j, k together). For instance, the region at the bottom-right of the triangle is relative to the case where "aode" is more probable than "rope" and "nbc" together; the region at the top of the triangle represents the case where "rope" is more

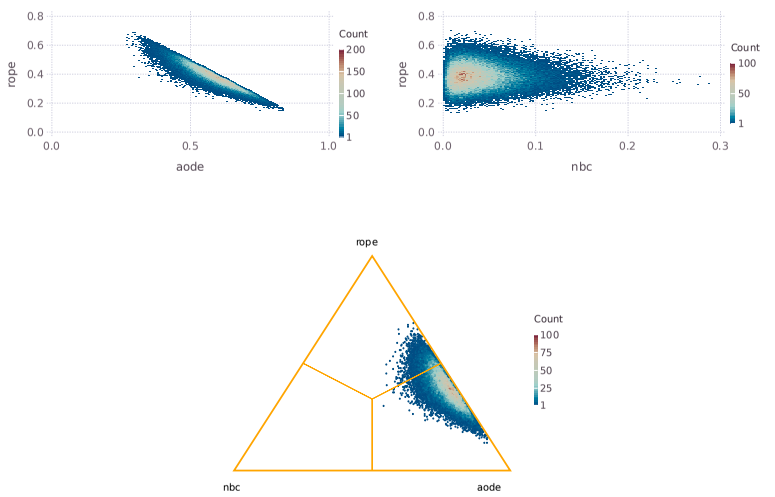

Figure 11: Posterior for *nbc* vs. *aode* for the Bayesian sign-rank test.

probable than "aode" and "nbc" together; the region at the left of the triangle corresponds to the case where "nbc" is more probable than "aode" and "rope" together. Hence, if all the points fall inside one of these three regions, we conclude that such hypothesis is true with probability ≈ 1. Looking at Figure 11 (bottom), it is evident that the majority of cases support *aode* more than *rope* and definitively more than *nbc*. We can quantify this numerically by counting the number of points that fall in the three regions, see first row in Table 9. *aode* is better in 90% of cases, while *rope* is selected in the remaining 10%. We can therefore conclude with probability 90% that *aode* is practically better than *nbc*. Table 9 reports also these probabilities for the other comparisons of classifiers computed using 150′000 Monte Carlo samples. We conclude that *hnb* is practically better than *nbc* with probability 0.999; *aode* and *hnb* are equivalent with probability 0.95; *aode* is better than *j48* and *j48gr* with probability 0.9; *hnb* is better than *j48* and *j48gr* with probability greater than 0.95 and finally *j48* and *j48gr* are practically equivalent. These conclusions are in agreement with the data.

The computational complexity of the Bayesian sign-rank test is low. The comparison of two classifiers (based on 150′000 samples) takes less than one second on a standard computer.

4.3 Choice of the prior

In the previous section, we have selected the prior parameters of the Dirichlet process as $s = 0.5$ and $z_0 = 0$. In terms of rank, this basically means that the prior strength is

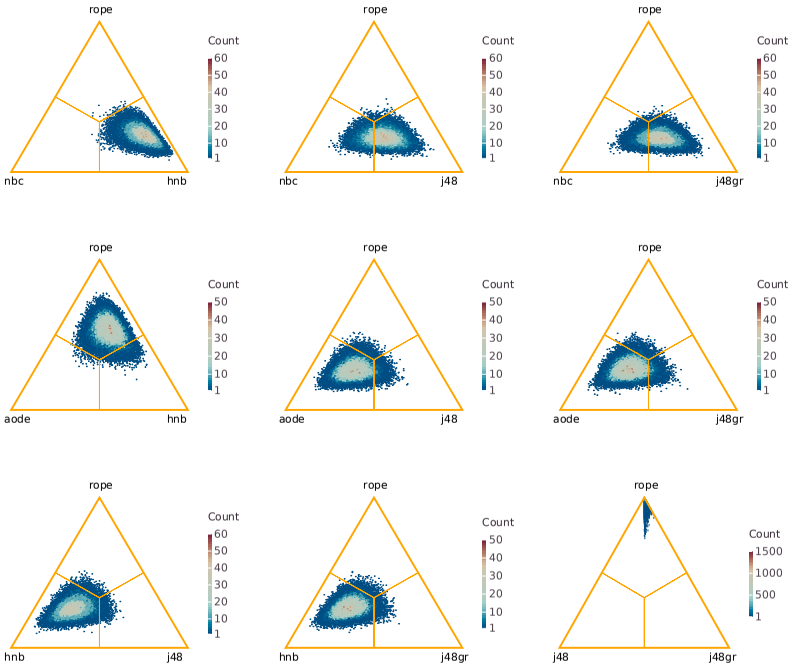

Figure 12: Posterior for *nbc* vs. *aode* for Bayesian sign-rank test.

equivalent to that of one pseudo-observation that is located inside the rope (Benavoli et al., 2014). How are the inferences sensitive to this choice? For instance, we can see how the probabilities on Table 9 would change based on z_0. We have considered two extreme cases $z_0 = -\infty$ and $z_0 = \infty$ and reported these probabilities in Table 10 and 11 (this is an example of robust Bayesian analysis (Berger et al., 1994)). It is evident that the position of z_0 has only a minor effect on the probabilities. We could have performed this analysis jointly by considering all the possible Dirichlet process priors obtained by varying $z_0 \in \mathbb{R}$. This set of Dirichlet priors is called "Imprecise Dirichlet Process" (IDP). IDP allows us to start the inference with very weak prior assumptions, much in the direction of letting data speak for themselves. More details about the properties of IDP and the choice of the prior can be found in Benavoli et al. (2014, 2015b); Walley (1996).

4.3.1 Hierarchical models

In Section 3 we have presented the Bayesian correlated t-test that is used for the analysis of cross-validation results on a single dataset. In particular, it makes inference about the mean difference of accuracy between two classifiers in the i-th dataset (μ_i) by exploiting three pieces of information: the sample mean ($\bar{x}_i$), the variability of the data (sample standard deviation $\hat{\sigma}_i$) and the correlation due to the overlapping training set (ρ). This test can only be applied to a single dataset. We have already discussed the fact that there is no direct NHST able to extend the above statistical comparison to multiple datasets, i.e., that takes as inputs the m runs of the k-fold cross-validation results for each dataset and returns as output a statistical decision about which classifier is better in all the datasets. The usual NHST procedure that is employed for performing such analysis has two steps: (1) compute

the mean *difference* of accuracy for each dataset $\bar{x}_i$; (2) perform a NHST to establish if the two classifiers have different performance or not based on these mean differences of accuracy. This discards two pieces of information: the correlation ρ and sample standard deviation $\hat{\sigma}_i$ in each dataset. The standard deviation is informative about the accuracy of $\bar{x}_i$ as an estimator of μ_i. The standard deviation can largely vary across data sets, as a result of each data set having its own size and complexity. The aim of this section is to present an extension of the Bayesian correlated t-test that is able to make inference on multiple datasets and at the same time to account for all the available information (mean, standard deviation and correlation). In Bayesian estimation, this can be obtained by defining a hierarchical model (Corani et al., 2017). Hierarchical models are among the most powerful and flexible tools in Bayesian analysis.

Bayesian hierarchical correlated t-test

The hierarchical correlated t-test is based on following hierarchical probabilistic model:

$$\mathbf{x}_i \sim MVN(\mathbf{1}\mu_i, \mathbf{\Sigma_i}), \tag{12}$$

$$\mu_1 ... \mu_q \sim t(\mu_0, \sigma_0, \nu), \tag{13}$$

$$\sigma_1 ... \sigma_q \sim \text{unif}(0, \bar{\sigma}). \tag{14}$$

Equation (12) models the fact that the cross-validation measures $\boldsymbol{x_i} = \{x_{i1}, x_{i2}, \ldots, x_{in}\}$ of the i-th data set are jointly multivariate-normal distributed with the same mean (μ_i), same variance (σ_i) and correlation (ρ). In fact, it states that, for each dataset i, $\mathbf{x}_i$ is multivariate normal with mean $\mathbf{1}\mu_i$ (where $\mathbf{1}$ is a vector of ones) and covariance matrix $\mathbf{\Sigma}_i$ defined as follows: the diagonal elements are σ_i^2 and the out-of-diagonal elements are $\rho\sigma_i^2$, where $\rho = \frac{n_{te}}{n_{tr}}$. This model is the same we discussed in Section 3. Equation (13) models the fact that the mean difference of accuracies in the single datasets, μ_i, depends on μ_0 that is the average difference of accuracy between the two classifiers on the population of data sets. This is the quantity we aim at estimating. Equation (13) assumes the μ_i's to

be drawn from a high-level Student distribution with mean μ_0, variance σ_0^2 and degrees of freedom ν. The choice of a Student distribution at this level of the hierarchical model enables the model to robustly deal with data sets whose μ_i's are far away from the others (Gelman et al., 2014; Kruschke, 2013). Moreover the heavy tails of the Student make more cautious the conclusions drawn by the model.

The hierarchical model assigns to the i-th data set its own standard deviation σ_i, assuming the σ_i's to be drawn from a common distribution, see Equation (14). In this way it realistically represents the fact the estimates referring to different data sets data sets have different uncertainty. The high-level distribution of the σ_i's is unif$(0, \bar{\sigma})$, as recommended by Gelman (2006), as it yields inferences which are insensitive to $\bar{\sigma}$, if $\bar{\sigma}$ is large enough. To this end we set $\bar{\sigma} = 1000 \cdot \bar{s}$ (Kruschke, 2013), where $\bar{s} = \sum_i^q \hat{\sigma}_i / q$.

We complete the model with the prior on the parameters δ_0, σ_0 and ν of the high-level distribution. We assume δ_0 to be uniformly distributed within 1 and -1. This choice works for all the measures bounded within ± 1, such as accuracy, AUC, precision and recall. Other type of indicators might require different bounds.

For the standard deviation σ_0 we adopt the prior $unif(0, \bar{s_0})$, with $\bar{s_0} = 1000 s_{\bar{x}}$, where $s_{\bar{x}}$ is the standard deviation of the $\bar{x}_i$'s.

As for the prior $p(\nu)$ on the degrees of freedom, there are two proposals in the literature. Kruschke (2013) proposes an exponentially shaped distribution which balances the prior probability of nearly normal distributions (ν >30) and heavy tailed distributions (ν <30). We re-parameterize this distribution as a Gamma(α,β) with α=1, β= 0.0345. Juárez and Steel (2010) proposes instead $p(\nu) = \text{Gamma}(2, 0.1)$, assigning larger prior probability to normal distributions.

We have no reason for preferring a prior over another, but the hierarchical model shows some sensitivity on the choice of $p(\nu)$. We model this uncertainty by representing the coefficients α and β of the Gamma distribution as two random variables (hierarchical prior). In particular we assume $p(\nu) = \text{Gamma}(\alpha, \beta)$, with $\alpha \sim \text{unif}(\underline{\alpha}, \bar{\alpha})$ and $\beta \sim \text{unif}(\underline{\beta}, \bar{\beta})$, setting $\underline{\alpha}$=0.5, $\bar{\alpha}$=5, $\underline{\beta}$=0.05, $\bar{\beta}$=0.15. The simulations in (Corani et al., 2017) show that the inferences of the model are stable with respect to perturbations of $\underline{\alpha}$, $\bar{\alpha}$, $\underline{\beta}$, and $\bar{\beta}$, and that the resulting hierarchical generally fits well the experimental data.

These considerations are reflected by the following probabilistic model:

$$\nu \sim Ga(\alpha, \beta), \tag{15}$$

$$\alpha \sim \text{unif}(\underline{\alpha}, \overline{\alpha}), \tag{16}$$

$$\beta \sim \text{unif}(\underline{\beta}, \overline{\beta}), \tag{17}$$

$$\mu_0 \sim \text{unif}(-1, 1), \tag{18}$$

$$\sigma_0 \sim \text{unif}(0, \bar{\sigma_0}). \tag{19}$$

We want to make inference about the μ_i's and μ_0. Such inferences are computed by marginalizing out the σ_i's, and thus accounting for the different uncertainty which characterizes each data set. This characteristic is unique among the methods discussed so far. Computations in hierarchical models are obtained by Markov-Chain Monte Carlo sampling.

A further merit of the hierarchical model is that it jointly estimates the μ_i's while the existing methods estimate independently the difference of accuracy on each data set using the $\bar{x}_i$'s. The consequence of the joint estimation performed by the hierarchical model is that *shrinkage* is applied to the $\bar{x}_i$'s. The hierarchical model thus estimates the μ_i's more accurately than the $\bar{x}_i$'s adopted by the other tests. This result is valid under general assumptions, such as a severe misspecification between the high-level distributions of the true generative model and of the fitted model (Corani et al., 2017). By applying the rope on the posterior distribution of the μ_i's and the μ_0 in a similar way to what discussed for the Bayesian correlated t-test, the model is able to detect equivalent classifiers and to claim significances that have a practical impact.

4.3.2 Experiments

In the experiments, we have computed the posterior of μ_0, σ_0, ν for the ten pairwise comparisons between the classifiers *nbc*, *aode*, *hnb*, *j48* and *j48gr*. As inference we have computed the prediction on the next (unseen) dataset, which is formally equivalent to the inference computed by the Bayesian signed-rank test. For instance, for *nbc* vs. *aode*, we have computed the probabilities that in the next dataset *nbc* is better than *aode* (θ_r), *nbc* is equivalent to *aode* (θ_e), *aode* is better than *nbc* (θ_l). This is the procedure we have followed:

1. we have sampled μ_0, σ_0, ν from the posteriors of these parameters;

2. for each sample of μ_0, σ_0, ν we have defined the posterior of the mean difference of accuracy on the next dataset, i.e., $t(\mu_{next}; \mu_0, \sigma_0, \nu)$;

3. from $t(\mu_{next}; \mu_0, \sigma_0, \nu)$ we have computed the probabilities θ_l (integral on $(-\infty, r]$), θ_e (integral on $[-r, r]$) and θ_r (integral on $[r, \infty)$).

We have repeated this procedure $4'000$ times, obtaining $4'000$ samples of $(\theta_l, \theta_e, \theta_r)$ and the results are shown in Figure 13. The results are quite in agreement with those of the Bayesian signed-rank test. For instance, it is evident that *aode* is clearly better than *nbc*. We can quantify this numerically by counting the number of points that fall in the three regions (see the first row in Table 12). *aode* is better in almost 100% of cases. Table 12 reports also these probabilities for the other comparisons of classifiers computed using $4'000$ Monte Carlo samples. By comparing Tables 12 and 9, we can see that the two tests are substantially in agreement apart from differences in *aode* vs. *j48* and *j48gr*. The hierarchical test is taking into account of all available infromation: the sample mean ($\bar{x}_i$), the variability of the data (sample standard deviation $\hat{\sigma}_i$) and the correlation due to the overlapping training set (ρ), while the Bayesian signed rank only considers $\bar{x}_i$. Therefore, when the two tests differ substantially, it means that there is substantial variability of the cross-validation estimate.

We have implemented the hierarchical model in Stan (`http://mc-stan.org`) (Carpenter et al., 2016), a language for Bayesian inference. The analysis of the results of 10 runs of 10-fold cross-validation on 54 data sets (that means a total of 5400 observations) takes about three minutes on a standard computer.

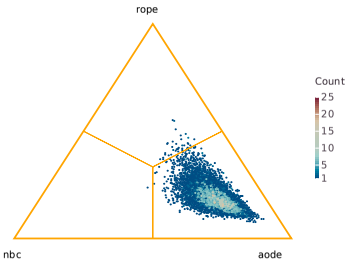

Figure 13: Posterior of *nbc* versus *aode* for all 54 datasets.

4.4 Choice of the hyper-priors parameters

The choice of of the hyper-priors parameters can be critical in Bayesian hierarchical models. We have conducted a sensitivity analysis by using different constants in the top-level gamma and uniform distributions, to check whether they have any notable influence on the resulting posterior distribution. Whether all gamma/uniform distributions are assumed, the results are essentially identical. More details about this sensitivity analysis are reported in Corani et al. (2017). This means that for the hierarchical model inferences and decisions are stable w.r.t. the choice of the hyper-parameters.

4.5 Bayesian signed rank or hierarchical model?

So far we have presented two methods for comparing two classifiers on multiple datasets: Bayesian signed-rank and hierarchical model. Which one should we use for comparing

classifiers? In our opinion, the hierarchical model is preferable because it takes as inputs the m runs of the k-fold cross-validation results for each dataset and so it makes inference about the mean difference of accuracy between two classifiers in the i-th dataset (μ_i) by exploiting all available information: the sample mean ($\bar{x}_i$), the variability of the data (sample standard deviation $\hat{\sigma}_i$) and the correlation due to the overlapping training set (ρ). Conversely, the Bayesian signed rank only considers $\bar{x}_i$. On the other hand, the hierarchical model is slower than the Bayesian signed rank. In machine learning, we often need to run statistical tests hundreds of times for instance for features selection or algorithms racing and, in this case, it is more convenient to use a light test as the Bayesian signed rank.

5. Comparisons of multiple classifiers

Another important problem with NHST is the issue of multiple hypothesis testing. Considering the results in Table 8, which reports the p-values for the comparison of the five classifiers obtained by the Wilcoxon signed-rank test. From the p-values, we concluded that "*nbc* was found significantly better than *aode* and *hnb*, and algorithms *j48* and *j48gr* were significantly different, while there were no significant differences between other pairs". When many tests are made, the probability of making at least one Type 1 error in any of the comparisons increases. One of the most popular fixes to this problem is the Bonferroni correction. The Bonferroni correction adjusts the p-value at which a test is evaluated for significance according to the number of tests being performed. More specifically, the adjusted p-value is calculated as the original p-value divided by the number of tests being performed. Implicitly, Bonferroni's correction assumes that these test statistics are independent. So in our current example an overall desired significance level of 0.05 would translate into individual tests each using a p-value threshold of $0.05/10 = 0.005$ (we are performing 10 comparisons). In this case, this would not change our previous sections, since all significant p-values were less than 0.005. The Bonferroni correction reduces false rejections but it also increases the number of instances in which the null is not rejected when actually it should have been. Thus, the Bonferroni adjustment can reduce the power to detect an important effect. Motivated by this issue of the Bonferroni correction, researchers have proposed alternative procedures. The goal of these methods typically is to reduce the family-wise error rate (that is, the probability of having at least one false positive) without sacrificing power too much. A natural way to achieve this is by considering the dependence across tests (Westfall et al., 1993).

We have already discussed in Section 2 the pitfalls of NHST Type I error thinking. Type I error underlies these corrections and, therefore, corrections inherit all its problems. The most critical one is that the correction factor depends on the way the analyst intends to conduct the comparison. For instance, the analyst may want to compare *nbc* with the other four classifiers (in this case the Bonferroni correction would be $0.05/4 = 0.0125$—he/she is conducting only four comparisons) or to perform all the ten comparisons (0.05/10) and so on. This creates a problem because two analysts can c draw different conclusions from the same data because of the variety of comparisons that they made. Another important issue with the multiple-comparison procedure based on mean-ranks test is described in Benavoli et al. (2016).

How do we manage the problem of multiple hypothesis testing in Bayesian analysis? Paraphrasing Gelman et al. (2012): "in Bayesian analysis we usually do not have to worry about multiple comparisons. The reason is that we do not worry about Type I error, because the null hypothesis is hardly believable to be true." How does Bayesian Analysis mitigate false alarms? Gelman et al. (2012) suggest using multilevel analysis (in our case a hierarchical Bayesian model on multiple classifiers). Multilevel models perform partial pooling; they shift estimates toward each other. This means that the comparisons of the classifiers are more conservative, in the sense that intervals for comparisons are more likely to include zero. This may be a direction to pursue in future research. In this paper, we instead mitigate false alarms through the rope. The rope mitigates false alarms because it decreases the asymptotic false alarm rate (Kruschke, 2013).

6. Software and available Bayesian tests

All the tests that we have presented in this paper are available in *R* and *Python* code at

`https://github.com/BayesianTestsML/tutorial/`.

Moreover, the code that is necessary to replicate all the analyses we performed in this paper is also available at the above URL in form of *Ipython* notebooks (implemented in *Python* and *Julia*). The software is open source and that can be freely used, changed, and shared (in modified or unmodified form).

Machine learning researchers may be interested in using other Bayesian tests besides the ones we have discussed in this paper. General Bayesian parametric tests can be found in Kruschke (2015) (together with R code) and also in Gelman et al. (2013). We have specialized some of these tests to the case of correlated data, such as the Bayesian correlated t-test (Corani and Benavoli, 2015) discussed in Section 3. We have also implemented several Bayesian nonparametric tests for comparing algorithms: Bayesian rank test (Benavoli et al., 2015b), Friedman test (Benavoli et al., 2015a) and tests that account for censored data (Mangili et al., 2015). Finally, we have developed an extension of the Bayesian sign test to compare algorithms taking into account multiple measures at the same time (accuracy and computational time for instance) (Benavoli and Campos, 2015). For the analysis of multiple data sets, another approach has been proposed by Lacoste et al. (2012) that models each data set as an independent Bernoulli trial. The two possible outcomes of the Bernoulli trial are the first classifier being more accurate than the second or vice versa. This approach yields the posterior probability of the first classifier being more accurate than the second classifier on more than half of the q data sets. A shortcoming is that its conclusions apply only to the q available data sets without generalizing to the whole population of data sets

7. Conclusions

We discourage the use of frequentist null hypothesis significance tests (NHST) in machine learning and, in particular, for comparison of the performance of classifiers. In this, we follow the current trends in other scientific areas. For instance, the journal of Basic and Applied Social Psychology, has banned the use of NHSTs and related statistical procedures (Trafimow and Marks, 2015). We believe that also in machine learning is time to move on from NHST and p-values.

In this paper, we have discussed how Bayesian analysis can be employed instead of NHST. In particular, we have presented three Bayesian tests: Bayesian correlated t-test, Bayesian signed rank test and a Bayesian hierarchical model that can be used for comparing the performance of classifiers and that solve the drawbacks of the frequentist tests. All the code of these tests is freely available and so researchers can already use these tests for their analysis. In this paper, we have mainly discussed the use of Bayesian tests for comparing the performance of algorithms. However, in machine learning, NHST statistical tests are also employed inside the algorithms. For instance, nonparametric tests are used in racing algorithms, independence tests are used to learn the structure of Bayesian networks, etcetera. Bayesian tests can be used to replace all NHST tests because of their advantages (for instance, Bayesian tests can assess whether two algorithms are similar through the use of the rope (Benavoli et al., 2015a)).

Abstract

Probabilistic planners have improved recently to the point that they can solve difficult tasks with complex and expressive models. In contrast, learners cannot tackle yet the expressive models that planners do, which forces complex models to be mostly handcrafted. We propose a new learning approach that can learn relational probabilistic models with both action effects and exogenous effects. The proposed learning approach combines a multi-valued variant of inductive logic programming for the generation of candidate models, with an optimization method to select the best set of planning operators to model a problem. We also show how to combine this learner with reinforcement learning algorithms to solve complete problems. Finally, experimental validation is provided that shows improvements over previous work in both simulation and a robotic task. The robotic task involves a dynamic scenario with several agents where a manipulator robot has to clear the tableware on a table. We show that the exogenous effects learned by our approach allowed the robot to clear the table in a more efficient way.

Keywords: Learning Models for Planning, Model-Based RL, Probabilistic Planning, Active Learning, Robot Learning

1. Introduction

Task planning has been a useful tool to solve complex problems where an agent has to reach a goal by executing actions, including robotic tasks (Kulick et al., 2013; Martínez et al., 2015a) and scheduling (Zhu et al., 2014). Task planners can find solutions that optimize a reward function for any state, even if this state was unexpected. The reward function encodes the priorities when solving the task, and new actions can be added easily to extend tasks.

Traditionally, applications have mostly used deterministic planners (Hoffmann and Nebel, 2001; Helmert, 2006) as they are easier to set-up and can solve complex problems with many variables. Recently the planning community has improved successfully the existing planners to solve more expressive and complex tasks. In the latest International Probabilistic Planning Competition (IPPC 2014) (Vallati et al., 2015), the best planners were able to solve probabilistically interesting tasks (Little and Thiebaux, 2007) that included both action effects and exogenous effects (Kolobov et al., 2012; Keller and Eyerich, 2012) and many relational variables. We consider that action effects are those that occur when the agent executes an action (e.g. a robot moves to a new position, the robot grasps an object), while exogenous effects are those that do not depend on an action (e.g. people moving in the street, a traffic light turns red, a plant grows).

However, these planners rely on a model, that has to be either handcrafted or learned. In contrast to planners, learners cannot tackle yet the expressive models as planners do, which forces complex models to be mostly handcrafted. Relational action models with uncertain effects from a log of completely observable state-action-state transitions can be learned using the approach by Pasula et al. (2007), but in this paper we propose a new method that, in addition to relational probabilistic action models, it can also learn exogenous effects.

Relational model learners can be integrated in Reinforcement Learning (RL) approaches such as REX (Lang et al., 2012), allowing an agent to learn a task autonomously. However, heuristic model learners may have trouble learning certain domains if exploration is scarce when using REX. Thus we show that our approach can be integrated in V-MIN (Martínez, Alenyà, and Torras, 2015b), an extension of REX that can successfully learn such domains by actively requesting a few teacher demonstrations.

Finally, we will present how this learner can be integrated in a robot to improve its performance in tasks where exogenous effects are important. Specifically, we show a robot that has to help clearing the tableware on a table. Exogenous effects allow us to model the frequency at which different types of tableware arrive, and to coordinate with the waiter robots that take piles of tableware back to the kitchen. When a model with such exogenous effects can be learned, the performance of the task is increased significantly.

To summarize, we propose a novel method that takes as input a set of state-action-state transitions, and learns a relational model with probabilistic and exogenous effects to be used for planning. We also show that the learner can be integrated in a RL framework to learn and solve new tasks. This RL approach can be integrated in a robot decision-maker to improve the performance in the task of clearing the tableware of a table.

This work is an extension of Martínez et al. (2016), where the model learner was presented. The most significant additions are the integration with RL, the experiments with a robot, and showing the way input transitions must be normalized.

2. Background

In this section we present the formulation that we will use throughout this paper, as well as the background on reinforcement learning required to understand Section 4.

2.1 Formulation

Two types of representations are combined in this work, a relational one for the planning operators, and a propositional one that will be used internally by some parts of the learner. We assume complete observability and uncertain effects.

2.1.1 Relational Formulation

Literals l are expressions of the form $(\neg)var(t_1, ..., t_m)$ where var is a predicate symbol that represents a variable, $(\neg)$ means that the atom may be optionally negated, and t_i are the terms. Terms can be variables, which have a preceding "?" symbol (e.g. ?X), and can also be objects, which are represented without an "?" symbol (e.g. box1). We use a relational representation where expressions take objects as arguments to define their grounded counterparts. A state s is defined as a conjunction of grounded literals l^g that follow the closed world assumption $s = l^g_1, ..., l^g_N$.

A planning operator $o \in \mathcal{O}$ defines the probability of a literal taking a value based on a set of preconditions. Operators take the form

$$o(t_1, ..., t_n) = l_h : p_o \leftarrow l_1 \wedge \cdots \wedge l_m, (a) \tag{1}$$

where l_h is the head of the operator, p_o is the probability of l_h being true in the next state given that the body and the action are satisfied, $l_1 \wedge \cdots \wedge l_m$ are the literals in the body, (a) is an optional action, and t_i are the terms that may appear in the head, body and action. The action is optional so that operators can capture both action effects when there is an action, and exogenous effects when there is no action. Operators are not Horn clauses as negation can appear in both the body and the head. Also note that this representation does not model correlated effects, as each operator can only have one effect. There can be two operators with the same body and different heads, but they would be independent.

Example 1 *An example operator for an action is:*
$o1(?X, ?Y, ?Z) = \textit{robot-at}(?X, ?Y) : 0.82 \leftarrow \textit{robot-at}(?X, ?Z) \wedge \textit{adj}(?Z, ?Y) \wedge \textit{move}(?X, ?Y)$.
If the "move" action is applied, the robot would move to $(?X, ?Y)$ *with a probability of* 0.82 *if it is on an adjacent position.*

A grounded operator only has objects as terms. If an operator o has n variables, its groundings $Gr(o)$ are a set of operators, each taking one of the possible combinations of n objects.

Example 2 *Having the objects* $\{x1, y1, y2\}$ *and the operator* $o1(?X, ?Y)$*, the possible groundings can be obtained by substituting* $?X$ *and* $?Y$ *for every permutation of 2 objects. One possible grounding is:*
$o1(x1, y2, y1) = \textit{robot-at}(x1, y2) : 0.82 \leftarrow \textit{robot-at}(x1, y1) \wedge \textit{adj}(y1, y2) \wedge \textit{move}(x1, y2)$.

The transition dynamics are defined by a set of planning operators $\mathcal{O}$. A grounded operator o_g is said to cover a state-action pair (s, a) when the literals of the body are in s, and the optional action of the operator is either a, or the operator has no action:

$$cov(o_g, s, a) = (body(o_g) \subset s) \wedge ((action(o_g) = a) \vee (action(o_g) = \varnothing)).$$

Likewise, a non-grounded operator o covers (s, a) if one of its groundings does:

$$cov(o, s, a) = \exists\, o_g \in Gr(o) \mid cov(o_g, s, a).$$

Transitions T are defined as triples $t = (s, a, s')$ where s' is the successor state of s after executing a. A successor state s' is obtained by applying all groundings of all operators to (s, a). When a grounded operator o_g is applied to (s, a), its head is added to the state s' with a probability p_{o_g} if $cov(o_g, s, a)$.

Example 3 *An example transition is:*
s*:* $\textit{adj}(y1, y2) \wedge \textit{adj}(x1, x2) \wedge \textit{robot-at}(x1, y1) \wedge \textit{moving-obstacle}(x1, y2)$
a*:* $\textit{move}(x2, y1)$
s'*:* $\textit{adj}(y1, y2) \wedge \textit{adj}(x1, x2) \wedge \textit{robot-at}(x2, y1) \wedge \textit{moving-obstacle}(x2, y2)$
Where the action "move" modifies the literal "robot-at", and an exogenous effect modifies "moving-obstacle".

We require operators to be mutually exclusive, there cannot be two operators with the same head atom that cover the same (s, a) as their heads may conflict. One example of such conflict would be $[o_{g,1}(r1) = at(r1) : 0.8 \leftarrow ...]$ and $[o_{g,2}(r1) = \neg at(r1) : 0.6 \leftarrow ...]$ where both heads cannot hold at the same time as one contradicts the other. The objective of this work is to learn models that can be used by planners, and planners require conflict-free operators. A planner has to know precisely the expected effects of applying a planning operator. If two different operators were to make conflicting changes, the effects would be undefined. This constraint is similar to the one in Pasula et al. (2007)'s learner, but in this case a different operator can be applied to each head.

If s' is a successor state of s, we define $changes(s, s')$ as the set of literals $\{c \in s', c \notin s\}$. Given a transition $t = (s, a, s')$ and a grounded operator o_g, a transition change $c \in changes(s, s')$ has a likelihood

$$P(c \mid o_g) = \begin{cases} p_{o_g}, & cov(o_g, s, a) \wedge (c = head(o_g)) \\ 0, & \text{otherwise.} \end{cases} \tag{2}$$

And a set of non-grounded operators $\mathcal{O}$ gives the following likelihood to a change c:

$$P(c|\mathcal{O}) = \begin{cases} P(c|o_g), & \exists!\, o_g \in Gr(\mathcal{O}) \mid P(c|o_g) > 0 \\ 0, & \text{otherwise,} \end{cases} \tag{3}$$

where $\exists!$ is the operator for uniqueness quantification. If more than one operator covers the same change given the same state-action pair, there is a conflict and the behavior is undefined, so a likelihood of 0 is given.

2.1.2 Propositional Formulation

On the propositional level, atoms are multi-valued variables that take the form p^x, where p is a predicate symbol, x is the value, and atoms have no parameters. A *state* is a conjunction of propositional atoms $s = var_1^{val_1} \wedge \cdots \wedge var_n^{val_n}$ such that $var^{val'}, var^{val''} \in s$ implies $val' = val''$.

We consider a *probabilistic multi-valued logic program* as a set of *propositional rules* r of the form

$$r = var_0^{val_0} : p_r \leftarrow var_1^{val_1} \wedge \cdots \wedge var_n^{val_n} \tag{4}$$

where $var_i^{val_i}$ for all $i \geq 0$ are atoms and p_r is a probability. A propositional rule r is interpreted as follows: with probability p_r the variable var_0 takes the value val_0 in the next state if all variables var_i have the value val_i in the current state. For any rule r, $var_0^{val_0}$ is called the *head* and $var_1^{val_1} \wedge \cdots \wedge var_n^{val_n}$ are the literals in the *body*.

Example 4 *Let's consider the following rules,*
$r_1 = a^1 : 0.7 \leftarrow b^1$,
$r_2 = b^2 : 1.0 \leftarrow a^1 \wedge b^0$,
$r_3 = a^0 : 0.3 \leftarrow b^2$,
then the logic program $P = \{r_1, r_2, r_3\}$ *is a probabilistic multi-valued logic program.*

Finally, propositional transitions E are defined as pairs of states $e = (s, s')$ where s' is the successor state of s.

2.2 Reinforcement Learning

Reinforcement learning (RL) is a framework for sequential decision-making problems where the dynamics of the environment are not known in advance. At each time step, the agent takes an observation, decides which action to execute, and is given a reward. The agent's goal is to maximize the total sum of discounted rewards over time. In model-based RL the agent maintains a model that is updated with every transition, and a planner uses this model to select the action to be executed.

Formally, fully-observable problems with uncertainty are represented with Markov Decision Processes (MDP). A finite MDP is a five-tuple $\langle S, A, M, R, \gamma \rangle$ where S is a set of states, A is the set of actions that an agent can perform, $M : S \times A \times S \rightarrow [0, 1]$ is the transition model, $R : S \times A \rightarrow \mathbb{R}$ is the reward function and $\gamma \in [0, 1)$ is the discount factor.

The goal of RL algorithms is to find a policy $\pi : S \rightarrow A$ that chooses the actions to maximize the value function. The sum of expected rewards is the value function $V^\pi(s) = E[\sum_t \gamma^t R(s_t, a_t) | s_0 = s, \pi]$ which is to be maximized.

As the model is not known in advance, RL approaches have to balance exploration (visiting state-action pairs to learn the dynamics related to unknown parts of the model, thereby allowing better policies to be obtained in the future) and exploitation (executing actions to maximize rewards based on the current model).

3. Model Learner

In this section we show how to learn a relational probabilistic model with exogenous effects from a log of input state-action transitions. The learned model will consist of a set of planning operators that define both action effects and exogenous effects.

There exist previous works that tackle the problem of learning models. Some of them estimate the parameters of a model (Moldovan et al., 2012; Thon et al., 2011), but the structure of the model has to be provided and only its parameters are learned. The work by Jiménez et al. (2008) can capture the preconditions and uncertainty in the models given that the possible effects are known in advance. A more complete approach by Sykes et al. (2013) learns probabilistic logic programs, but the restrictions for the initial set of candidate rules need to be manually coded. In contrast, we learn the complete model and no restrictions are required.

Most approaches that learn complete models handle deterministic tasks, and although they can tackle partial observability (Molineaux and Aha, 2014; Mourão et al., 2012; Zhuo and Kambhampati, 2013) or apply transfer learning (Zhuo and Yang, 2014), they do not consider uncertain effects. In this work we focus on models with uncertain effects.

The most similar approaches to ours are those that learn relational action models with uncertain effects (Pasula et al., 2007; Deshpande et al., 2007; Mourão, 2014). They learn the effects that each action may have for each set of preconditions, which are then represented with probabilistic STRIPS-like models. However, they do not learn exogenous effects that are not related to any action.

These methods cannot be easily extended to learn exogenous effects. Pasula et al. (2007) and Deshpande et al. (2007)'s approach use a local search algorithm that works well when transitions are explained by one rule, but faces many local minima when tackling domains with exogenous effects, as two or more new rules may have to be added to properly explain a transition. Mourão (2014)'s approach exhibits a similar problem since it learns one rule per transition. To favor a better understanding of this problem, let's assume that we have a transition that is optimally modeled by 2 rules, one of which relates to an exogenous effect. These 2 rules are likely to have a very low score individually as they only cover part of the transition. The local search in Pasula's learner would choose a rule that covered the complete transition to maximize the score, even if the rule had a lot of noise and low probability to guess the effect. As a local search is used, the learner can only make one change at a time, and selecting only one of the 2 optimal rules would decrease the score, so they would never be chosen.

Note that although those methods cannot learn exogenous effects, they have other advantages. Pasula et al. (2007)'s approach can learn correlated effects while Mourão (2014)'s learner can also tackle partial observability. Therefore the best method will depend on the type of domain being learned.

The problem of learning minimal effects from a log of input data transitions is known to be NP-Hard (Walsh, 2010). The approaches shown before, as well as our approach, apply heuristics to find solutions with any number of input experiences. Optimal approaches that learn complete probabilistic models have also been proposed (Walsh et al., 2009), but they require too many input experiences or assumptions not made in the current work.

The learned model will consist of a set of planning operators that define the different effects. The proposed method can be divided into two parts:

- *Candidate planning operator generation.* Candidates are generated with the LFIT (Learning From Interpretation Transitions) framework (Inoue et al., 2014). LFIT induces a set of propositional rules that realize the given input transitions. Specifically, an algorithm that guarantees to learn the set of minimal rules is used (Ribeiro and Inoue, 2014).

- *Planning operator selection.* To select the best subset of candidates, we define a score function that is maximized by candidates that explain input transitions while being general enough. Based on this score function, a search optimization method guided by an heuristic function is proposed. Moreover, suboptimal solutions to make complex tasks tractable are provided.

Our approach combines (a) LFIT on the propositional level to ensure that candidates are minimal, (b) an optimization method that works on the relational level to apply relational generalizations when selecting subsets, and (c) grounded input data. Since, as mentioned, the approach requires three different types of data (grounded, relational and propositional), data transformation methods are needed.

3.1 LFIT

The LFIT framework (Inoue et al., 2014) is used to obtain the set of probabilistic candidate rules that model the dynamics. Given a batch of propositional transitions (s, s'), LFIT induces a *normal logic program* that realizes the given transitions. This framework has been extended (Ribeiro and Inoue, 2014) with a new algorithm that guarantees that the learned rules are minimal: the body of each rule constitutes a prime implicant to infer the head. It is based on a top-down method that generates hypotheses by *specialization* from the most general rules. Moreover, the framework has been adapted to capture also probabilistic dynamics (Martínez et al., 2015c).

In this section we explain briefly how to obtain probabilistic logic programs with minimal rules. For more details please refer to the work by Ribeiro and Inoue (2014) and Martínez et al. (2015c).

3.1.1 Rule Specialization

To learn multi-valued logic programs with minimal rules we need to define the ground resolution and the least specialization for multi-valued propositional variables.

Definition 1 (Subsumption) *Let r_1 and r_2 be two rules. If $head(r_1) = head(r_2)$ and $body(r_1) \subseteq body(r_2)$ then r_1* subsumes *r_2. Let P be a logic program and r be a rule. P* subsumes *r if there exists a rule $r' \in P$ that subsumes r.*

We say that a rule r_1 is *more general* than another rule r_2 if r_1 subsumes r_2 and $body(r_1) \subset body(r_2)$. In particular, a rule r is *most general* if there is no rule $r'(\neq r)$ that subsumes r ($body(r) = \emptyset$).

Example 5 *Let r_1 and r_2 be the two following rules: $r_1 = (a^1 \leftarrow b^1)$, $r_2 = (a^1 \leftarrow a^0 \wedge b^1)$, r_1 subsumes r_2 because $(body(r_1) = \{b^1\}) \subset (body(r_2) = \{a^0, b^1\})$. When r_1 appears in a logic program P, r_2 is useless for P, because whenever r_2 can be applied, r_1 can be applied.*

Definition 2 (Complement) *Let r_1 and r_2 be two rules, r_2 is a* complement *of r_1 on var^{val} if $var^{val} \in body(r_1)$, $var^{val'} \in body(r_2), val \neq val'$ and $(body(r_2) \setminus \{var^{val'}\}) \subseteq (body(r_1) \setminus \{var^{val}\})$.*

Definition 3 (Ground resolution) *Let r be a rule, P be a logic program and $\mathcal{B}$ be a set of atoms, r can be* generalized *on var^{val} if $\forall var^{val'} \in \mathcal{B}, val \neq val'$, $\exists r' \in P$ such that r' is a complement of r on var^{val}:*

$$generalise(r, P) = head(r) \leftarrow body(r) \setminus \{var^{val}\}$$

Definition 4 (Least specialization) *Let r_1 and r_2 be two rules such that $head(r_1) = head(r_2)$ and r_1 subsumes r_2. Let $\mathcal{B}$ be a set of atoms. The least specialization $ls(r_1, r_2, \mathcal{B})$ of r_1 over r_2 w.r.t $\mathcal{B}$ is*

$$ls(r_1, r_2, \mathcal{B}) = \{head(r_1) \leftarrow body(r_1) \wedge var^{val'}\} \text{ such that}$$
$$var^{val} \in body(r_2) \setminus body(r_1),\ var^{val'} \in \mathcal{B},\ val' \neq val$$

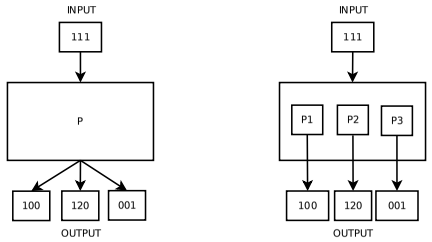

Figure 1: **Left:** A black-box probabilistic system where one program has multiple possible next states. **Right:** The LFIT algorithm uses a set of deterministic programs that form an equivalent probabilistic system. Each deterministic program outputs one of the possible next states.

Least specialization can be used on a rule r to avoid the subsumption of another rule with a minimal reduction of the generality of r. By extension, least specialization can be used on the rules of a logic program P to avoid the subsumption of a rule with a minimal reduction of the generality of P. Let P be a logic program, $\mathcal{B}$ be a set of atoms, r be a rule and S be the set of all rules of P that subsume r. The least specialization $ls(P, r, \mathcal{B})$ of P by r w.r.t $\mathcal{B}$ is as follows:

$$ls(P, r, \mathcal{B}) = (P \setminus S) \cup (\bigcup_{r_P \in S} ls(r_P, r, \mathcal{B}))$$

3.1.2 Probabilistic LFIT

To learn probabilistic systems, LFIT represent them as a set of deterministic programs. Given a state s, we compute the set of possible next states by querying each program. Figure 1 (left) shows a probabilistic system P where the possible successors of the state 111 can be 100, 120 or 001. This behavior can be captured by a set of three deterministic programs $\{P1, P2, P3\}$ (right), such that $P1$ obtains a transition $e_1 = (\{a^1, b^1, c^1\}, \{a^1, b^1, c^1\})$, $P2$ obtains $e_2 = (\{a^1, b^1, c^1\}, \{a^1, b^2, c^0\})$, and $P3$ obtains $e_3 = (\{a^1, b^1, c^1\}, \{a^0, b^0, c^0\})$. Each program will also encode the behavior of the system for all possible other states. This representation allows us to capture any probabilistic system dynamics. It provides a model than can reproduce the possible behavior but no information about which transition is more likely to occur. To output such information, probabilities have to be extracted from observed transitions and reflected in the model. There are many ways of encoding likelihood and probabilities in logic programs, hence here we choose to simply consider rules likelihood independently for each rule. For each rule, we simply check how many times it could be applied in the input transitions and how many times the next state could effectively be the result of the use of this rule. This provides us with a simple likelihood for each rule, a ratio matches/realizes that can be used to give the likelihood of the possible next states. Other methods and normalization of the probabilities could be performed with the same sets of programs.

In this work we use an extension of *LFIT* (Martínez et al., 2015c) to learn a set of deterministic logic programs that can model probabilistic domains. The main idea is that when two transitions are not consistent, we need two different programs to realize them. The first program will realize the first transition and the second one will realize the second transition. The algorithm will output a set of logic programs such that every transition given as input is realized by at least one of those programs.

Probabilistic LFIT

- **Input**: a set of propositional transitions E and a set of atoms $\mathcal{B}$.
- Step 1: Initialize a set of logic programs P with one program P_1 with fact rules for each atom of $\mathcal{B}$.
- Step 2: Pick $e = (s, s')$ in E, check consistency of e with all programs of P:
- If there is no logic program in P that realizes e then
  - Copy one of the logic programs P_i into a P'_i and add rules in P'_i to realize e.
  - Use ground resolution to generalize P'_i.
- Step 3: Revise all logic programs that realize e by using least specialization.
- Step 4: If there is a remaining transition in E, go to step 2.
- Step 5: Compute the probability of each rule of all programs P_i according to E.
- **Output**: P a set of multi-valued logic programs that realize E.

The detailed pseudo-code of the *Probabilistic LFIT* is given in Algorithm 1. The algorithm starts with one logic program that contains all fact rules (lines 1-7). Each input transition e is analyzed one by one. If no program can realize the observed transition (lines 10-20), one is copied and rules are added into this copy so that it realizes the transition (lines 21-28). The programs that realize e are then revised using least specialization like in LFIT (Ribeiro and Inoue, 2014) (lines 29-36). The programs that do not realize the transition realize another one previously observed that is not consistent with the new one because of the non-determinism of the system. Those programs cannot be specialized by this transition because we would lose the information of the previous transition they realize. Finally, the likelihood of each rule is computed by just counting the number of observations covered/realized (lines 39-53). The algorithm outputs a set of logic programs, each one of them realizes some transitions of E, and all transitions of E are realized by at least one program. The complexity belongs to $O(d \cdot |E| \cdot nv^n)$ for run time and $O(d \cdot 2^n)$ for memory, with d the maximal out-degree of an observed state (degree of non-determinism), E the set of input transitions, n the number of variables and v the maximal domain of a variable (the maximal number of values a variable may have).

Finally, all the learned programs P are combined in one set that will become the set of planning operator candidates.

Algorithm 1 Probabilistic LFIT($E, \mathcal{B}$)

Input: a set of pair of states E and a set of atoms $\mathcal{B}$
Output: P a set of logic programs

```
1: E' := ∅
2: P := ∅
   // Initialize P: one program with the most general rules
3: P_1 := ∅
4: for each var^val ∈ B do

46:                if head(r) ∈ s' then
47:                    i := i + 1
48:                end if
49:            end if
50:        end for
           // Update the probability p_r of the rule r
51:        p_r = i/j
52:    end for
53: end for
54: return P
```

3.2 Candidate Planning Operator Generation

The input of the method is a set T of training transitions which are triples $t = (s, a, s')$ where s' is a successor state of s when the action a was executed. The state s' would have the effects of the action and all the applicable exogenous effects. The output is a set of planning operators $\mathcal{O}$ that define the model. Figure 2 shows the data transformations and processing done in the algorithm, which are described below:

- Transform grounded transitions to relational (non-grounded) ones. The objective is to learn relational operators that can take objects as arguments to generalize. Note that grounded literals are different from propositional ones because the objects and the variables in their terms can be identified. The transformation to relational transitions requires to substitute objects with variables.
- Obtain candidate operators. LFIT is used to obtain all possible candidate operators for a given set of transitions. The main advantage of using LFIT is that it obtains the set of minimal rules that model both action effects and exogenous effects. To use LFIT, first the relational transitions have to be transformed to propositional ones, and later, the output propositional rules to planning operators.
- Select the subset of candidate planning operators that best models the training transitions. This is detailed in Section 3.3.

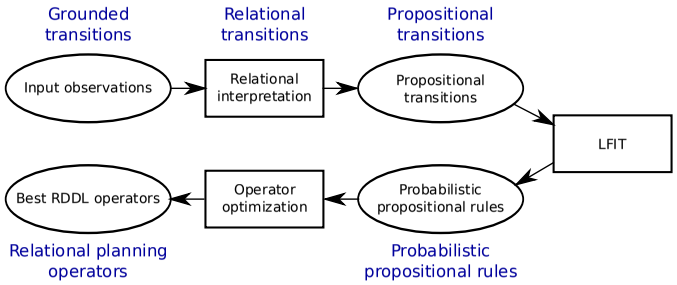

Figure 2: Data representation used for each module. The input and output data are shown in ellipses, and the processing modules are shown in boxes. The data representation used is indicated at each step.

The aim of these transformations is to generalize better, a relational representation is more compact and general as an infinite number of objects can be represented by each variable. By replacing objects with variables, LFIT learns rules that model relational data. The trade-off of learning relational generalizations is that the number of generated relational transitions is larger than the number of input grounded transitions, which increases the learning time.

3.2.1 Input Normalization

The first step is to normalize the input so that all state-action pairs (s, a) in the training data get the same number of transitions. Given a transition $t = (s_t, a_t, s'_t)$, the coverage of a pair (s, a) by t is defined as $cov(t, s, a) = (s_t = s) \wedge (a_t = a)$.

This step is specially important if the learner is integrated in a RL method, as state-action pairs with high expected values will be visited much often than those with low expected values. Without normalizing the input, when using heuristic learners, the selection of the best operators (Section 3.3) would be biased to perfectly model repeated state-action pairs and ignore rare ones.

The normalization is done by repeating transitions so that every (s, a) gets a similar number of covering transitions:

- *Input*: grounded transitions T.
- Get maximum coverage $n_{max} = \max_{(s,a)} |\{t \mid cov(t, s, a), t \in T\}|$.
- For each (s, a) covered by $T' \subset T$ (with $|T'| > 1$):
  - Number of times each transitions should be repeated: $n_{rep} = n_{max}/|T'|$.
  - Add n_{rep} times each $t' \in T'$ to T_{out}.
- *Output*: normalized transitions T_{out}.

Note that this input normalization is used exclusively to calculate the likelihood of the sets of operators (Sec. 3.3), and it is not used for the RL exploration nor the confidence in the operators. Moreover, it does not have an impact on performance if implemented correctly. Every transition should have a counter representing the number of times it is repeated to avoid extra computation.

3.2.2 Grounded to Relational Transitions

The goal is to obtain a relational representation that can generalize to different objects. If the dynamics of an object are learned, the same dynamics can be applied to other objects, not requiring examples of every possible grounding.

Since generating all possible relational combinations of every transition would be highly inefficient, we limit the number of relational variables to a fixed number ω, which imposes a limit on the maximum number of variables that learned operators will have. This type of constraint has been frequent in previous works to tackle complex domains (Mourão et al., 2012; Walsh et al., 2009; Amir and Chang, 2008).

Selecting the right value of ω is important. To learn effects that involve n objects, a value $\omega \geq n$ is required. However, the number of relational transitions scales exponentially with ω, thus a large value of ω is intractable.

This module generates all possible relational transitions with at most ω variables. For every transition $t \in T$, the following method is applied:

- *Input*: grounded transition $t = (s, a, s')$, max variables ω. We define the objects in s as $b_{s,i}$ and the objects in a as $b_{a,i}$. The action a has m objects.
- Initialize an empty set V_{obj} of object combinations.
- Obtain combinations of ω objects. For each combination of $\omega - m$ objects $(b_{s,1}, \ldots b_{s,\omega-m})$ that are not in the action $(b_{s,i} \neq b_{a,j}, \forall i, j)$ do:
  - Create $v_{obj} = (b_{a,1}, \ldots b_{a,m}, b_{s,1}, \ldots b_{s,\omega-m})$ where $(b_{a,1}, \ldots b_{a,m})$ are the objects in the action a.
  - Add v_{obj} to V_{obj}.
- For each $v_{obj} \in V_{obj}$:
  - A new transition $t' = t$ is created.
  - Replace in t' all objects in v_{obj} for variables.
  - Remove from t' any remaining literal with objects.
  - Add the new transition t' to T'.
- *Output*: a set of relational transitions T'.

Example 6 *Given a grounded transition* $(s, a \rightarrow s')$ *:*

$$at(r1) \wedge road(r2, r3) \wedge road(r1, r3), move(r3) \rightarrow$$
$$road(r1, r3) \wedge road(r2, r3) \wedge at(r3),$$

the following relational transitions are generated (ω=2):

$$v_{obj} = (r3, r1): \; at(?Y) \wedge road(?Y, ?X), move(?X) \rightarrow road(?Y, ?X) \wedge at(?X);$$
$$v_{obj} = (r3, r2): \; road(?Y, ?X), move(?X) \rightarrow road(?Y, ?X) \wedge at(?X).$$

3.2.3 Relational to Propositional Transitions

To create the input that LFIT requires, which are pairs (s, s') of propositional states, a library L_{conv} that converts between relational and propositional atoms is created. For each relational atom d_r, a new propositional atom d_p is created and the pair (d_r, d_p) is added to L_{conv}. Using L_{conv}, everything is substituted by its propositional counterpart:

- Relational literals are represented with propositional atoms that take the values 1 (true) or 0 (false).
- Relational transitions are triples (s, a, s'), while propositional transitions are pairs (s, s'). Therefore, an additional multi-valued atom is added to propositional transitions to represent the action (if the agent executed an action during that transition). This atom takes as value the corresponding action name in L_{conv}, or "*noaction*" if there is no action. In the input, the "*noaction*" value will only be used in those transitions where the robot did not execute any action. In the output, it identifies exogenous effects. Note that literals are binary, so the multi-valued representation is only required to model the action, as there may be more than 2 different actions, and only one action can be executed per transition.

Example 7 *Using the relational transitions in example 6, the following library is created* $L_{conv} = \{(at(?Y), b1), (at(?X), b2), (road(?Y, ?X), b3), (move(?X), b4)\}$. *The propositional transitions obtained by using* L_{conv} *are:*

$$(b1{=}1) \wedge (b3{=}1) \wedge (action{=}b4) \rightarrow (b3{=}1) \wedge (b2{=}1);$$
$$(b3{=}1) \wedge (action{=}b4) \rightarrow (b3{=}1) \wedge (b2{=}1).$$

3.2.4 Generation of Rules

The LFIT framework is used to obtain the set of probabilistic candidate rules from a set of proposition transitions (s, s'). LFIT induces a set of *normal logic programs* that realize the given transitions. Our approach uses the specialization and probabilistic algorithm of LFIT, so it learns the sets of minimal probabilistic rules that model all effects appearing in the input transitions. The learned sets are combined into a single set before converting them to planning operators. LFIT learns both action effects and exogenous effects because the action is just another atom that may or may not appear in the body of a rule.

Example 8 *Using a larger set of propositional transitions such as the ones obtained previously, LFIT could obtain a set of rules such as:*

$$(b2{=}1) : 0.8 \leftarrow (b1{=}1) \wedge (b3{=}1) \wedge (action{=}b4);$$
$$(b2{=}1) : 0.1 \leftarrow (b1{=}1) \wedge (b3{=}0) \wedge (action{=}b4);$$
$$(b1{=}1) : 0.6 \leftarrow (b2{=}1);$$
$$\ldots$$

3.2.5 Propositional Rules to Planning Operators

Planning operators (eq. 1) can be reconstructed from probabilistic rules (eq. 4) by using the library L_{conv} created before. For each propositional rule:

- The atoms in the body and head of the rule are transformed to relational ones (using L_{conv}), and added to the body and head of a planning operator.
- The action is extracted from the multi-valued action atom in the rule body. If the atom is present, the corresponding action in L_{conv} is added to the operator.

Example 9 *Given that LFIT had learned the following rule*

$$(b2{=}1) : 0.8 \leftarrow (b1{=}1) \wedge (b3{=}1) \wedge (action{=}b4),$$

using the library L_{conv} *generated in example 7, the resulting operator* $o(?X, ?Y)$ *is*

$$at(?X) : 0.8 \leftarrow at(?Y) \wedge road(?Y, ?X), move(?X).$$

Traditionally, PPDDL (Younes and Littman, 2004) has been the standard language to model probabilistic domains, but it cannot model exogenous effects directly (PPDDL1.0 rules model actions, not exogenous effects). Therefore, our approach uses the RDDL language (Sanner, 2010), which has been the standard for the latest probabilistic planning competitions (IPPC 2011 and 2014). Writing our planning operators with RDDL is straightforward, and this language can be used directly by state-of-the art planners. RDDL objects and variables have types, and a variable can only be substituted by an object of the same type. However, for clarity and simplicity, we assume through the paper that there are no types, as adding them is trivial.

3.3 Planning Operator Selection

LFIT provides the set of minimal rules (that have been transformed to planning operators) that describe all the transitions. Note that LFIT learns the set of minimal rules, and not the minimal set of rules, so many operators may model the same changes and underfit or overfit. The subset of operators to model the transition dynamics is selected as follows:

- A score function is defined to evaluate the planning operators.
- A heuristic search algorithm selects the set of operators that maximizes the score. Note that this set may differ from the actual model, as it depends on the coverage of the input transitions and the quality of the score function.
- The subsumption tree is used to improve efficiency by partitioning the set of candidates into smaller subsets.

3.3.1 Score Function

The score function values the quality of a set of operators. The following functions are used by the score function:

- The likelihood is the probability that a transition $t = (s, a, s')$ is covered by a set of planning operators $\mathcal{O}$:

$$P(t \mid \mathcal{O}) = \prod_{c \in \text{changes}(t)} P(c \mid \mathcal{O}, s, a). \tag{5}$$

- The penalty term $Pen(o) = |body(o)|$ is the number of atoms in the operator bodies.
- The confidence $Conf(T, \widehat{o}, \epsilon)$ is obtained from (Hoeffding, 1963)'s inequality. The probability that an estimate $\widehat{o_{prob}}$ is accurate enough, i.e. $|\widehat{o_{prob}} - o_{prob}| \leq \epsilon$, is bounded by $Conf(T, \widehat{o}, \epsilon) \leq 1 - e^{-2\epsilon^2 |T_{\widehat{o}}|}$, where $|T_{\widehat{o}}|$ is the number transitions covered by $\widehat{o}$.

Finally, the proposed score function is defined as

$$s(\mathcal{O}, T) = \underset{t \in T}{E}[\log(P(t|\mathcal{O}))] - \alpha \sum_{o \in \mathcal{O}} \frac{Pen(o)}{Conf(T, o, \epsilon)}, \tag{6}$$

where $\alpha > 0$ is a scaling parameter for the penalty term. This score function is based on Pasula et al. (2007)'s one, where the likelihood is maximized to obtain operators that explain the transitions well, and the penalty term is minimized to prefer general operators when specific ones have very limited contributions. In contrast to Pasula et al.'s approach, the confidence term is added so that the penalty is increased when few transitions are available, as the estimates are less reliable.

3.3.2 Heuristic Search

Given a set of operators $\mathcal{O}$ with the same head, a heuristic search method is used to find the best subset of operators that maximizes the score function. To that end, we define the heuristic version of the change likelihood (eq. 3) as:

$$P_h(c|\mathcal{O}) = \begin{cases} P(c|o_g), & \exists! o_g \in Gr(\mathcal{O}) \,|P(c|o_g) > 0 \\ 1 - \delta, & \nexists\, o_g \in Gr(\mathcal{O}) \,|cov(o_g, s, a) \\ 0, & \text{otherwise } (|Gr(\mathcal{O})| > 1), \end{cases} \tag{7}$$

where δ is a parameter that can trade quality for efficiency. This heuristic modifies the change likelihood (eq. 3) when no operator covers the change, giving a likelihood of $1 - \delta$ instead of 0. The heuristic score function $s_h(\mathcal{O}, T)$ is defined as the score function (eq. 6) but replacing the standard change likelihood (eq. 3) with this heuristic likelihood.

This heuristic gets the expected likelihood that can be obtained by adding new operators to $\mathcal{O}$. When $\delta = 0$, it works as an admissible heuristic (prop. 1) as it gives the maximum likelihood = 1 to uncovered changes. When $\delta > 0$ but close to 0, then the heuristic penalizes very specific operators when more general operators with a high likelihood are also

available. The practical result is that the algorithm usually runs faster, but the heuristic is not admissible anymore.

Algorithm 2 selects the best subset of operators to explain the input transitions. In line 1, the candidate list Γ is initialized by creating one separate subset for each operator in the input set of candidates $\mathcal{O}_{input}$. Note that Γ is a set of sets of planning operators, which is initialized to $\Gamma = \{\{o_1\}, \ldots, \{o_n\}\}$ assuming that $\mathcal{O}_{input} = \{o_1, \ldots, o_n\}$. Afterwards, lines 2-3 find the best subset in Γ (which is the best set with only one operator). From that point, the candidate sets in Γ are iteratively joined together to find the best set with any number of operators, until none has $s_h(\mathcal{O}, T) > max_{score}$ (lines 4-17). In lines 5-6, the candidate $\mathcal{O}$ with the largest heuristic score is selected and removed from Γ. Then, in lines 7-9, new candidates are generated by combining the selected subset $\mathcal{O}$ with every subset in Γ. The *IsNew* method checks that the new candidate has not been already analyzed. If any of the new candidates has a new best score, it is saved as the best candidate (lines 10-13). Finally, the new candidates are added to Γ.

This method works as a search algorithm guided by an heuristic. The nodes to be analyzed are the subsets of operators stored in Γ, where they are ordered by the heuristic score value. The search tree is expanded by joining one subset with every other subset. Finally, the algorithm continues until no subset has a heuristic score larger than the best score so that the solution has been found.

The search can be used as an *anytime* algorithm, it can be stopped at any point to get the best solution found so far. Moreover, there are two options to limit in advance the processing time of the algorithm in complex problems: set a time limit, or set a limit in the size of Γ (only maintain the κ sets with the highest score in Γ). Experimental tests showed that in some domains the heuristic leads quickly to the best set, and subsequent processing is done only to confirm that no other set is better.

Property 1 *If $\delta = 0$, then the heuristic s_h is admissible: $\forall \mathcal{O}, s_h(\mathcal{O}) \geq s(\mathcal{O}^*) \mid \mathcal{O}^* = \underset{\mathcal{O}' \supset \mathcal{O}}{\text{argmax}}\, s(\mathcal{O}')$. Therefore the optimal set will be found.*

Proof The two parts of the score function in eq. 6 (likelihood and regularization) can be analyzed separately. Note that subsets of operators may only increase in size, as they start with one operator and can only be combined with other subsets.

- When adding operators to a set, the likelihood only increases when transition changes that were not covered before are covered by the added operators. In the heuristic score (eq. 7) all non-covered transition changes are already set to the maximum value of 1, so adding new operators cannot improve the result over the heuristic.
- The regularization part of the score function ($Reg(\mathcal{O}) = -\alpha \sum_{o \in \mathcal{O}} \frac{Pen(o)}{Conf(T,o,\epsilon)}$) is monotonically decreasing with respect to adding operators. If new operators are added, the new penalty $\frac{Pen(o)}{Conf(T,o,\epsilon)}$ will be positive as $Conf \in (0, 1]$, $Pen \geq 0$ and $\alpha > 0$.

■

Algorithm 2 OperatorSelection($\mathcal{O}_{input}$, T)

Current candidates $\Gamma \leftarrow \{o\}, \forall o \in \mathcal{O}_{input}$
$max_{score} = \max_{\mathcal{O}\in\Gamma} s(\mathcal{O}, T)$
$\mathcal{O}_{best} = \operatorname{argmax}_{\mathcal{O}\in\Gamma} s(\mathcal{O}, T)$
while $\max_{\mathcal{O}\in\Gamma} s_h(\mathcal{O}, T) > max_{score}$ **do**
  $\mathcal{O} = \operatorname{argmax}_{\mathcal{O}\in\Gamma} s_h(\mathcal{O}, T)$
  Remove $\mathcal{O}$ from Γ
  for $\mathcal{O}' \in \Gamma$ **do**
    if IsNew($\mathcal{O} \cup \mathcal{O}'$) **then**
      $\mathcal{O}_{new} = \mathcal{O} \cup \mathcal{O}'$
      if $s(\mathcal{O}_{new}, T) > max_{score}$ **then**
        $max_{score} = s(\mathcal{O}_{new}, T)$
        $\mathcal{O}_{best} = \mathcal{O}_{new}$
      end if
      Add $\mathcal{O}_{new}$ to Γ
    end if
  end for
end while
Output $\mathcal{O}_{best}$

Property 2 *When relaxing the admissibility criterion with $\delta > 0$, the solution found by Algorithm 2 is bounded to be no worse than $\mathcal{C} \cdot \log(1-\delta)$ plus the optimal score, where $\mathcal{C}$ is the average number of literals with the same predicate that change in a transition.*

Proof Operators with different head predicates are analyzed separately as their effects are independent, so $\mathcal{C}$ only depends on the average changes to one predicate literals. Also note that $\delta \in [0, 1)$, and thus, $\log(1-\delta) \leq 0$. Let $\mathcal{O}_n$ be the optimal solution with n operators and $s(\mathcal{O}_n) = opt$, then $\forall i < n$, at least one predecessor of i operators $\mathcal{O}_i$ and $s_h(\mathcal{O}_i) \geq opt + \mathcal{C} \cdot \log(1-\delta)$ will exist.

- The regularization term is monotonically decreasing (see explanation of property 1), so $Reg(\mathcal{O}_n) \leq Reg(\mathcal{O}_i)$.
- The maximum difference between $P(\mathcal{O}_n)$ and $P_h(\mathcal{O}_i)$ is $P(t|\mathcal{O}_n) = 1$ and $P_h(t|\mathcal{O}_i) = (1-\delta)^x$, which is the case where $\mathcal{O}_n$ has perfect coverage, $\mathcal{O}_i$ has no coverage (all the coverage is obtained from $\mathcal{O}_n \setminus \mathcal{O}_i$) and the transition has x changes. Then, if we take the worst case for all transitions, and an average of $\mathcal{C}$ changes per transition, $P(\mathcal{O}_n) - P_h(\mathcal{O}_i) = E[\log(P(T|\mathcal{O}_n))] - E[\log(P_h(T|\mathcal{O}_i))] = \log(1) - \log(1-\delta)^{\mathcal{C}} = \mathcal{C} \cdot \log(1-\delta)$.

Therefore, the predecessors of the optimal solution are checked (and thus the optimal solution found) unless a solution with $s(\mathcal{O}) \geq opt + \mathcal{C} \cdot log(1-\delta)$ is found before. ■

Algorithm 3 OperatorSelectionSubsumption($Tree_{\mathcal{O}}, T$)

1: **do**
2: $\quad\mathcal{O}_L = leaves(Tree_{\mathcal{O}})$
3: $\quad\mathcal{O}_{L,best} =$ OperatorSelection$(\mathcal{O}_L, T)$
4: $\quad$Remove $(\mathcal{O}_L \setminus \mathcal{O}_{L,best})$ from $Tree_{\mathcal{O}}$
5: $\quad\mathcal{O}_P = \mathcal{O}_{L,best} \cup parents(Tree_{\mathcal{O}}, \mathcal{O}_{L,best})$
6: $\quad\mathcal{O}_{P,best} =$ OperatorSelection$(\mathcal{O}_P, T)$
7: $\quad$Remove $(\mathcal{O}_L \setminus \mathcal{O}_{P,best})$ from $Tree_{\mathcal{O}}$
8: **while** $Tree_{\mathcal{O}}$ changed
9: **Output** $= leaves(Tree_{\mathcal{O}})$

A value of $\delta > 0$ can speed up the algorithm considerably at the expense of optimality. When two operators have similar likelihoods, $\delta > 0$ penalizes the most specific one. This results in general operator sets being analyzed first, and thus models with better likelihoods are obtained earlier.

3.3.3 Subsumption Tree

In this section we present a method to speed up the approach by partitioning the set of candidates into smaller groups. The idea is to organize the operators in a tree using the OI-subsumption (Esposito et al., 2004), then start with the specialized operators, and iteratively check if more general operators yield better scores.

Definition 5 (OI-subsumption relation) *First, we define the extended body of an operator as $body_{ext}(o) = body(o)(\wedge a)$ where $(\wedge a)$ only appears if o has an action. Let o_1 and o_2 be two planning operators with $head(o_1) = head(o_2)$, o_1 is OI-subsumed by o_2 if $(body_{ext}(o_1) \supseteq body_{ext}(o_2))$, given that different terms t_i cannot take the same object.*

Definition 6 (OI-subsumption tree) *The OI-subsumption tree $Tree_{\mathcal{O}}$ of a set of planning operators $\mathcal{O} = \{o_1, ..., o_n\}$ is a directed graph with arcs (o_i, o_j) when o_i OI-subsumes o_j and $|body_{ext}(o_j)| - |body_{ext}(o_i)| = 1$. We call the set of leaves $L(Tree_{\mathcal{O}})$. Figure 3 shows an example of a OI-subsumption tree.*

The OI-subsumption tree orders the operators in levels that represent the generality of the operators: the less literals the more general the operator. Based on this tree, Algorithm 3 selects the operators. The idea is to start by identifying the best specific operators, and then check if their generalizations improve the results. In lines 2-4, the best subset of leaves $\mathcal{O}_{L,best}$ is identified, and all leaves not in $\mathcal{O}_{L,best}$ are removed from the tree. Then, in lines 5-7, a new set of operators $\mathcal{O}_P$ is created that includes $\mathcal{O}_{L,best}$ and the operators that OI-subsume them (their parents in the tree). The best subset $\mathcal{O}_{P,best}$ in $\mathcal{O}_P$ is selected, and $\mathcal{O}_L \setminus \mathcal{O}_{P,best}$ are removed. This is repeated until nothing is changed in the tree.

The performance is improved by using the OI-subsumption tree: it divides the candidates into subsets, and the planning operator selection is much faster with smaller sets of candidates. Although it sacrifices optimality, experimental tests showed that the results obtained were in many cases optimal or near optimal. This happens due to the fact that

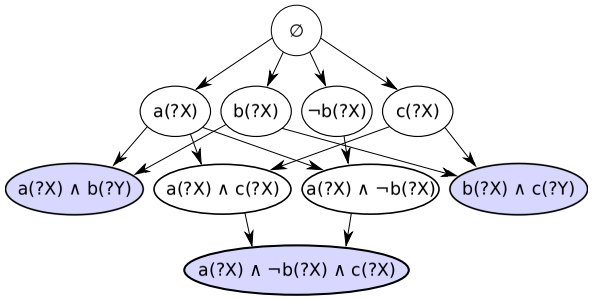

Figure 3: Example of a OI-subsumption tree. Each letter (a, b, c) represents a literal in the extended body of a planning operator. The leaves are the nodes painted in blue.

in most cases $P(\mathcal{O}) >> Reg(\mathcal{O})$. The operators in the leaves maximize $P(\mathcal{O})$ as they are more specialized, while the operators near the root maximize $Reg(\mathcal{O})$ as they are more general. Thus, the subset of leaves selected in the first iteration usually is near optimal, and afterwards the method only has to find the right level of generalization.

Note that if the OI-subsumption tree is used, the best operators may be close to the root of the tree (and thus they will be analyzed at the end), so the learner shouldn't be used as an anytime algorithm. However, the processing time can still be bounded with satisfactory results by limiting the size of Γ to κ sets in Algorithm 2.

4. Integration with RL

In this section we present how to integrate the model learner with a RL approach. The objective is to allow an agent to learn and solve a task from scratch by using a task planner and the learner presented before.

Model-based RL has proven to be an excellent tool to learn and solve a task that is unknown initially (Littman, 2015). There are several RL approaches that can learn complete relational models for planning (Džeroski et al., 2001; Diuk et al., 2008; Walsh et al., 2009), but they require a large amount of samples to make sure that they can solve the problem (Walsh, 2010). Other approaches use heuristics to reduce the number of samples needed to make the problem tractable, such as TEXPLORE (Hester and Stone, 2013) and REX (Lang et al., 2012). Specifically, REX uses Pasula et al. (2007)'s model learner internally, and proposes an exploration method based on R-MAX (Brafman and Tennenholtz, 2003) and E^3 (Kearns and Singh, 2002) that takes advantage of the relational representation to generalize and reduce the exploration required to learn relational tasks. However, REX can obtain models that are a local minimum as they cut exploration.

Our objective is to learn models without requiring too many input transitions. Therefore we choose to use the V-MIN algorithm (Martínez, Alenyà, and Torras, 2015b) as the RL framework. V-MIN extends the REX (Lang et al., 2012) with active learning: it explores

to learn the basic dynamics of the actions, but when it cannot find a plan with value larger than a certain threshold V_{min}, it requests help from a teacher. In contrast to REX, V-MIN can ensure that it will solve the task with a value larger than V_{min} (given that the internal learner can obtain the model for the task). Moreover, it also performs well with scarce exploration, because even if it misses the exploration of an important state-action pair, V-MIN will visit it later (if it is needed to get V_{min}) by requesting demonstrations.

Many RL approaches focus on learning specific tasks, but have trouble when parts of the problem change. Model-based approaches have been proposed to learn models that generalize between different states and number of objects (Diuk et al., 2008), while others have applied transfer learning in combination with RL to reuse knowledge in similar tasks (Konidaris et al., 2012). The REX and V-MIN algorithms learn relational operators that can be used by standard planners, which provides a great flexibility in the changes that can be made to the task without having to relearn or adapt the model. Using Taylor and Stone (2009)'s transfer learning categorization, the following changes can be done:

- The initial state, the goal state, and the number of objects can be changed without requiring further learning.
- The reward function can change without having to modify the rest of the model.

V-MIN in addition can incorporate new actions easily to the model through demonstrations if they are needed to get a value $> V_{min}$. This results in an approach with good adaptation capabilities when compared to other works (Taylor and Stone, 2009), and it also has the advantage of learning models with less exploratory actions. The drawback is that a teacher is required.

The inclusion of a teacher in the learning loop has been also tackled by other approaches. In some methods the teacher issues corrective demonstrations when the robot doesn't perform as desired (Meriçli et al., 2012; Walsh et al., 2010), which implies that the teacher has to actively monitor the agent. The teacher has also been used to provide approval or disapproval of the agent performance (Knox and Stone, 2012). When using V-MIN, the agent is the one that actively requests help whenever it is needed, and thus the teacher is free from monitoring the agent. Other approaches also require help directly from the agent (Grollman and Jenkins, 2007; Chernova and Veloso, 2009), but they only learn from demonstrations, so they have to request a larger number of demonstrations to learn. Agostini et al. (2017)'s approach requests demonstrations from the teacher when the planner cannot find a solution with its current set of planning operators. However, this approach only works in goal-driven deterministic problems, and the interaction with the teacher lacks flexibility as it does not consider rewards. Finally, Walsh et al. (2011) proposed a similar approach to V-MIN where the agent communicates the expected value to the teacher, and if it is lower than the optimal value then the teacher demonstrates an action. This approach can learn STRIPS rules efficiently, but it would require many input experiences to learn exogenous effects in the same way because the number of possible rules would be much larger.

4.1 The V-MIN Algorithm

The REX algorithm (Lang et al., 2012) is devised to apply relational generalizations to R-MAX, reducing the exploration needed. State-action pairs are grouped in contexts that have the same dynamics (i.e. that are covered by the same relational planning operator). Based on these contexts, exploration is reduced by defining a context-based density function that considers all possible state-action pairs in a context to be equivalent when deciding if a state is known. Although exploration generalizations improve the learning performance, they also have drawbacks. Using a context-based count function implies that not all states are explored before considering them as known, as we assume that all states within a context behave likewise. Thus, state-action pairs needed to attain the best policy may not be visited and their contexts (i.e. planning operators) not learned.

The V-MIN algorithm requests teacher demonstrations to learn new actions and contexts, and improve performance. It uses the concept of V_{min}, which is the minimum expected value. If the planner cannot obtain a value $V^{\pi}(s) \geq V_{min}$, it actively requests help from a teacher, who will demonstrate the best action $a = \pi^*(s_i)$ for the current state s_i. Therefore, when exploration and exploitation can no longer yield the desired results, demonstrations are requested to learn yet unknown actions, or to obtain demonstrations of actions whose effects were unexpected (i.e. new unknown contexts). The result is that good models can be learned even if exploration is scarce. The V_{min} parameter provides flexibility to the system:

- A high V_{min} forces the system to learn good policies at the cost of a higher number of demonstrations, whereas a lower V_{min} leads to a faster and easier learning process, but worse policies are learned.
- The teacher can change V_{min} online until the system performs as desired, forcing it to find either better or easier policies.
- Demonstrations can be used to learn new actions that weren't required before.

4.1.1 Algorithm Details

The V-MIN algorithm uses a model M that consists of a set of planning operators $\mathcal{O}$, which define the contexts. The algorithm creates an extension M_{vmin} of the model M to implicitly plan exploration and demonstration requests. As in the R-MAX version of the REX algorithm, every unknown context (those that have been explored less than a threshold ζ) gets the maximum reward R_{max}, implicitly following the principle of "optimism under uncertainty". Moreover, a special action "TeacherRequest()" is added which leads to an absorbing state with a V_{min} value. "TeacherRequest()" is also limited to be the only action in a plan when selected, as otherwise a value of $V(s')+V_{min}$ could be obtained by combining it in a plan.

Algorithm 4 shows a pseudocode for V-MIN. This algorithm maintains a model M that represents the robot actions with a set of relational planning operators. The model is updated in every iteration (line 3) to adapt to newer experiences using the learner presented in Section 3. The M_{vmin} model is then created to plan the action to execute, implicitly selecting exploratory actions until all the relevant contexts become known, and requesting teacher demonstrations whenever a value $V^{\pi}(s) > V_{min}$ cannot be obtained. Finally a new state is observed, and a transition is added to the log of experiences.

Algorithm 4 V-MIN

Input: Reward function R, confidence threshold ζ
Updates: Set of input transitions T

```
1:  Observe state s_0
2:  loop
3:      Update transition model M according to T
4:      Create M_vmin(M, R, ζ)
5:      Plan an action a_t using M_vmin
6:      if a_t == "TeacherRequest()" then
7:          Request demonstration
8:          a_t = demonstrated action
9:      else
10:         Execute a_t
11:     end if
12:     Observe new state s_{t+1}
13:     Add {(s_t, a_t, s_{t+1})} to E
14: end loop
```

The V-MIN algorithm provides the framework that selects which actions to explore and when a demonstration should be requested, but the most important piece is the learner used to obtain the model. Using the learner presented in Section 3 implies that a probabilistic relational model with exogenous effects will be learned.

Another important piece is the planner used, as it has to support planning with the learned model. PROST (Keller and Eyerich, 2012) is the planner used as it can obtain good results with probabilistic models containing exogenous effects.

Note that in this work we consider the reward function to be known. A KWIK algorithm can learn a reward function with a polynomial number of samples (Li et al., 2011), but it remains as future work to show how to effectively combine that reward learner with the V-MIN algorithm.

5. Experiments

This section describes the experimental evaluation of our approach. Three domains of the 2014 International Probabilistic Planning Competition (IPPC) (Vallati et al., 2015) were used in the experiments. The standalone learner introduced in Section 3 was used to learn from a batch of given input transitions, while the RL approach presented in Section 4 was used to solve tasks.

5.1 Domains

Three IPPC 2014 domains were used in the experiments. Note that they were slightly modified to remove redundancy (e.g. a *north(?X,?Y)* literal is equivalent to *south(?Y,?X)*, so one can be replaced by the other).

- *Triangle Tireworld.* This domain is the easiest one, it has uncertain effects, but no exogenous effects. It is modeled with 5 different predicates, 3 actions, 7 operators, and operators require at most 2 terms ($\omega = 2$). This domain serves as a good baseline to compare with the state of the art as there are not exogenous effects.

- *Crossing Traffic.* This domain has an intermediate difficulty. It has uncertain effects and exogenous effects, which makes it more challenging, but the complexity of the model is still moderate: 8 predicates, 4 actions, 6 operators, and operators take at most 3 terms.

- *Elevators.* This is the most challenging domain. It has uncertain effects and exogenous effects. It is modeled with 10 predicates, 4 actions, 17 operators, and operators take at most 3 terms.

5.2 Evaluation of the Model Learner

To evaluate the learner presented in Section 3 the scheme used by Pasula et al. (2007) was followed. The learners had to obtain models from sets of input transitions $(s, a, s') \in T$ that were generated randomly. To create a transition, first the state s is constructed by randomly assigning a value (positive or negative) to every literal, but ensuring that the resulting state is valid (e.g. in the elevators domain, an elevator cannot be in two different floors at the same time). Then, the action a arguments are picked randomly, and the state s' is obtained by applying all operators to (s, a). The distribution used to construct s is biased to guarantee that, in at least half of the examples, the operators that contain a have a chance of changing the state.

The evaluation of the learned models is carried out by calculating the *average variational distance* between the true model $\mathcal{O}$ and the estimate $\hat{\mathcal{O}}$. This evaluation uses a new set of similarly generated random transitions T':

$$D(\mathcal{O}, \hat{\mathcal{O}}) = \frac{1}{|T'|} \sum_{t \in T'} \left| P(t|\mathcal{O}) - P(t|\hat{\mathcal{O}}) \right|. \tag{8}$$

As the *average variational distance* may be difficult to interpret, here we give an intuition about the utility of the learned models. A planner usually ($p > 0.9$) yields a plan that can solve the task (optimally or suboptimally) when the *average variational distance* is below:

- 0.09 in the *Triangle Tireworld* domain.

- 0.15 in the *Crossing Traffic* domain.

- 0.1 in the *Elevators* domain.

As the *average variational distance* becomes lower, the planner will obtain better solutions.

We analyze experimentally the proposed algorithm, its parameters, and how it compares with the state of the art. The learner uses the following parameters: α, ϵ, and δ, which are the score function parameters; κ, which is the size limit of Γ (Algorithm 2); and "*tree*" to denote that the subsumption tree is being used.

The difficulty to learn a domain is mostly given by:

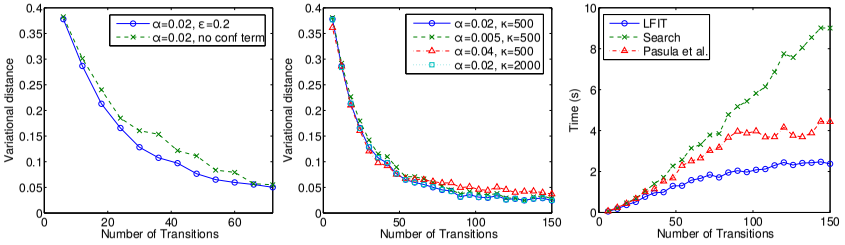

Figure 4: Evaluation of different configurations in the Triangle Tireworld domain, MDP-2. Unless stated otherwise, the following parameters were used: ($\alpha = 0.02$, $\epsilon = 0.2$, $\omega = 2$, $\delta = 0$, $\kappa = 500$, no-tree). The results shown are the means obtained from 50 runs. The evaluation was done with 3000 transitions. **Left:** Influence of the confidence term. **Center:** Comparing different values of α and κ. **Right:** Execution time of the search (optimization) and the LFIT modules. The total learning time would be the sum of LFIT plus one of the search configurations.

- The maximum number of terms ω that operators may have. The number of terms increases exponentially the number of relational transitions generated from the input grounded transitions (Section 3.2.2), and therefore the number of candidate rules. If the value of ω is larger than the number of terms that operators actually require, the learning time increases while the quality of the models remains the same.

- The number of predicates, both constant and variable, used to represent the states. The candidates that LFIT generates consider all combinations of predicates that are consistent with the transitions.

- The number of uncertain and exogenous effects. LFIT generates all candidates that may explain an effect, including operators that overfit and underfit, and all combinations of action effects and exogenous effects.

5.2.1 Configuration Parameters

Here we discuss the impact of the different configuration parameters on the quality of the models learned.

Triangle Tireworld domain:

- As seen in Fig. 4-left, the confidence term in the score function improves the quality of the models learned when few input transitions are available. This confidence term penalizes very specialized operators in cases where there is a large uncertainty in the predictions. Once many transitions are available, the impact of this term disappears. Note that only probabilistic operators are improved as deterministic ones are completely specialized anyway. The impact of this term is relatively small in the experiments because it only affects 1 probabilistic operator.

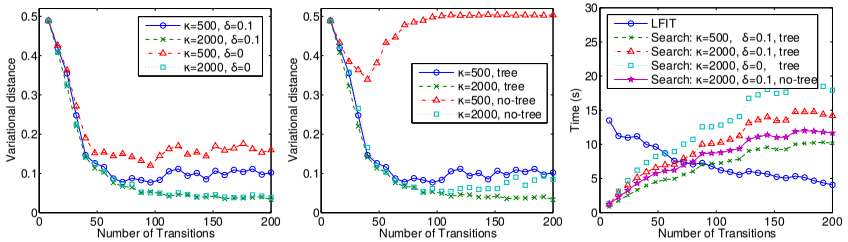

Figure 5: Evaluation of different configurations in the Crossing Traffic domain, MDP-1. Unless stated otherwise, the following parameters were used: ($\alpha = 0.02$, $\epsilon = 0.2$, $\omega = 3$, $\delta = 0.1$, $\kappa = 500$, tree). The results shown are the means obtained from 50 runs. The evaluation was done with 4000 transitions. **Left:** Influence of the κ and the δ terms. **Center:** Influence of κ and the subsumption tree. **Right:** Execution time of the search (optimization) and the LFIT modules. The total learning time would be the sum of LFIT plus one of the search configurations.

- Figure 4-middle compares different values of α. Small changes of the α term produce almost the same results, and any value ~ 0.02 yielded good results in all the domains analyzed in this paper. Moreover, as the Triangle Tireworld domain is simple, a value of $\kappa = 500$ already produces good models, and increasing it does not improve the results.
- The execution time is shown in Fig. 4-right. Even with 150 input transitions only a few seconds are required to learn a model. Most of the execution time is spent in obtaining the likelihood of the operators as there are a lot of possible candidates in this domain.

Crossing Traffic domain:

- As can be seen in all the experiments, the number of operator candidates that the algorithm analyzes (κ) has a great influence on both the quality of the learned domain and the learning time. The best value of κ will depend on the quality required for the domains and the time available for learning.
- Figure 5-left shows the advantages of a non-admissible heuristic ($\delta > 0$). A small value of δ prioritizes operators that explain many transitions with a high likelihood, and very specific operators that may not be interesting are given a smaller heuristic score. Although the same results could be obtained with a larger value of κ, the non-admissible heuristic speeds up the search (Fig. 5-right).
- Figure 5-center shows the advantages of the subsumption tree. This tree divides the search problem in smaller ones, and thus a much lower κ is enough to learn good models, specially when the number of input transitions is large. Since to get the same model quality a much larger κ would be required, the learning time is reduced.

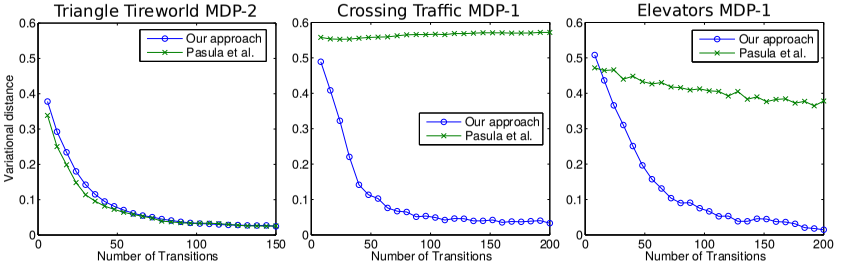

Figure 6: Comparison with Pasula et al. The results shown are the means obtained from 50 runs. The evaluation was done with 5000 random transitions. The parameters used were $\alpha = 0.02$, $\epsilon = 0.2$, $\delta = 0.1$, tree. **Left:** Triangle Tireworld ($\kappa = 500$). **Center:** Crossing Traffic ($\kappa = 2000$). **Right:** Elevators ($\kappa = 2000$).

5.2.2 Comparison with Pasula et al.

Comparison is performed only with Pasula et al. (2007)'s learner, as Deshpande et al. (2007)'s learner is an extension to include transfer learning, and Mourão (2014)'s learner yields similar results to Pasula et al.'s approach in completely observable problems. The experiments were carried out with the implementation by Lang and Toussaint (2010) and the fix by Mourão (2014).

Figure 6-left shows the results of learning the *Triangle Tireworld* domain. It can be easily learned by both, ours, and Pasula et al.'s approach, as there are no exogenous effects. With this experiment we want to show that our method can learn domains without exogenous effects as well as state-of-the-art learners. Pasula et al.'s learner gets slightly better results with few transitions as one of the actions is easier to learn with correlated effects.

Figures 6-center and 6-right refer to two domains with exogenous effects. As Pasula et al.'s learner cannot learn exogenous effects, it tries to build overcomplicated operators. These operators try to explain every possible combination of action effects and exogenous effects at the same time instead of learning each effect separately, and thus it is not able to yield a good general model. In contrast, our approach is able to distinguish action effects from exogenous effects once enough transitions are given as input.

5.2.3 Limitations of the Learner

The main limitation of the algorithm is the scalability. If the number of generated propositional predicates is large (either because the domain is represented with a large number of predicates, or because ω takes a high value), the problem may become intractable. The *Elevators* domain has the highest complexity that our approach can learn within a reasonable time. With 100 input transitions, the planning operator selection took an average of 2 minutes, and LFIT took up to 2 hours.

Moreover, in comparison with previous approaches, our learner cannot model correlated effects so it is not able to learn domains such as slippery gripper (Pasula et al., 2007). Our learner considers all effects as candidates, and thus, it would have to consider all possible

combinations of effects to learn correlated effects, which would be intractable. In contrast, approaches that do not learn exogenous effects can afford to find correlated effects because they search for a single effect per transition.

Finally, many IPPC 2014 domains cannot be directly learned. The following features would be needed to support all domains:

- The universal quantifier (*forall*) and the negative existential quantifier ($\sim$ *exists*) are not supported. When doing the translation from propositional rules to relational planning operators, new candidates could be generated that considered a positive atom in the preconditions as a (*forall*), or a negative atom as a ($\sim$ *exists*). It remains as future work to analyze the effectiveness of such candidates, and to check if the operator selection process would still be efficient with the addition of new candidates.

- Some IPPC domains have operators whose probabilities are encoded as a function. Unfortunately, our approach can only consider real numbers as probabilities.

5.3 Evaluation of the RL Integration

Here we evaluate how the learner can be integrated in a RL approach to learn models from scratch as explained in Section 4. The learner proposed by (Pasula et al., 2007) was also integrated in the V-MIN approach to compare against our approach.

5.3.1 Triangle Tireworld

In this domain, a car has to move to its destination, but it has a probability of getting a flat tire while it moves. The car starts with no spare tires but it can pick them up in some locations. The actions available in this domain are: a "Move" action to go to an adjacent position, a "Change Tire" action to replace a flat tire with a spare tire, and a "Load Tire" action to load a spare tire into the car if there are any in the current location. The main difficulty in the *Triangle Tireworld* domain is the dead end when the agent gets a flat tire and no spare tires are available. Safe and long paths exist with spare tires, but the shortest paths do not have any spare tires.

It should be noted that in the IPPC 2014 representation of the *Triangle Tireworld* domain there is one exogenous effect: when the goal reward is received, the "goal-reward-received" literal becomes true. As this is modeled as an exogenous effect and Pasula et al.'s approach cannot learn it, that planning operator is given to it at the beginning. Our approach can learn this effect easily because it appears isolated after the goal is reached, so it doesn't have a significant impact on the performance.

Figure 7 shows the results of learning the *Triangle Tireworld* domain. Initially the robot chooses the shortest path and thus 50% of the times gets an irrecoverable flat tire. The learners have to learn that the robot cannot move with a flat tire, and that a spare tire is required to recover from a flat tire before the planner opts to go through the safe but longer path. MDP-4 is learned in less episodes because more actions are executed per episode. As expected, the performance of our learner is similar to Pasula et al.'s one, both learners can obtain the model of the task with few transitions so they also work well when integrated in V-MIN. Pasula et al.'s learner performs slightly better in the MDP-2 and our learner got slightly better results in the MDP-4, but the differences are not significant.

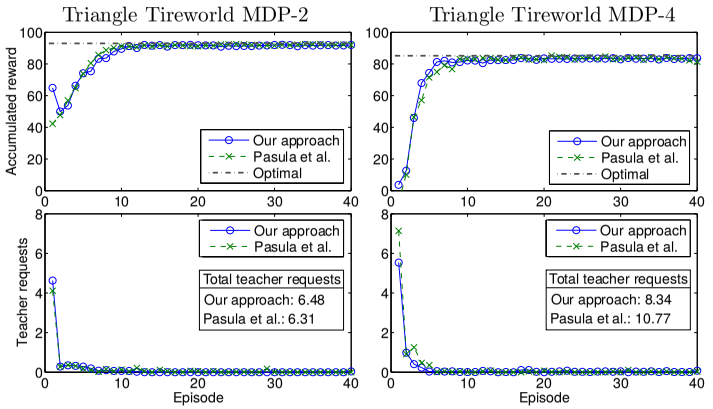

Figure 7: Learning the Triangle Tireworld domain with V-MIN. Comparison of using V-MIN with our learner and Pasula et al.'s learner. The difference between MDP-2 and MDP-4 is that in the latter the state space is larger, and more actions are required to reach the goal. The results shown are the means obtained from 100 runs. The exploration threshold is $\zeta = 3$ and V_{min} is 85 in MDP-2, and 65 in MDP-4.

5.3.2 Crossing Traffic

The Crossing Traffic domain is a grid where a robot must get to a goal and avoid cars arriving randomly and moving left. The goal is located on the top right of the grid, and the robot starts on the bottom right position. If a car overlaps with the robot, the robot disappears and can no longer move around. The robot can "duck" underneath a car by deliberately moving right when a car is to the right of it. The robot receives -1 for every time step it has not reached the goal. The best strategy is to move first to the left to be able to see if a car is coming, and crossing whenever there are no cars in the way.

The difficulty in this domain is learning that if the robot ends in the same position as a car, it will disappear independently of the action executed. Our model learner has to see one transition of the disappear effect for every action until it can learn the disappear effect completely. Figure 8 shows the results of V-MIN and REX with our model learner. Pasula et al.'s learner was not compared here because, as mentioned previously, it cannot learn the exogenous effects in this task.

The main problem for REX in this domain is that some action effects can only be learned if the robot has moved previously and has not collided with a car. For example, the "move-right" action can only be learned if the robot moved first to the left (because it starts in the bottom-right corner) and if it did not collide before with any car. Thus, if the exploration threshold is low, REX may start to exploit with an incomplete model that provides suboptimal results.

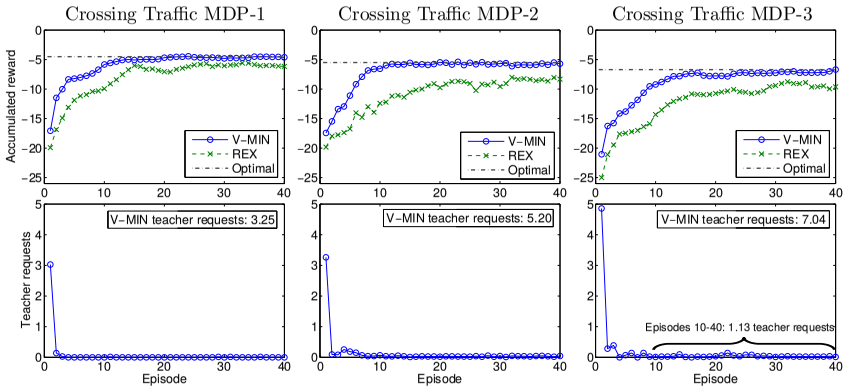

Figure 8: Learning the Crossing Traffic domain with V-MIN and REX. The results shown are the means obtained from 300 runs. MDP-1 is the easiest set up: its state space is small and the probability that a car arrives to each middle lane is 0.3. MDP-2 has also a small state space but cars arrive with a probability of 0.6. MDP-3 has a larger state space and a 0.3 probability of car arrivals. The exploration threshold is $\zeta = 3$ and V_{min} is -8 in MDP-1, -12 in MDP-2, and -15 in MDP-3.

In contrast, V-MIN requests demonstrations when the models do not provide good enough policies, and the demonstrations quickly teach the missing action effects. Below we analyze each MDP separately:

- In MDP-1, the naive strategy of going directly to the goal has a high success ratio (70%), and thus it may take some episodes until the robot collides with a car. The robot always takes the shortest route until it learns that it disappears after a collision with a car independently of the action taken. This in an easy problem so V-MIN only requires a few teacher demonstrations during the first episodes to get good results. REX takes longer to get a high reward because it has to explore more to obtain a good model.

- In MDP-2, the success ratio of reaching the goal with the shortest route is only 40%. In this problem V-MIN requires a few extra demonstrations in episodes 2-6 if it could not learn the "move-right" action before. In contrast, REX failed to obtain good models in a few iterations because it had already collided or was in an edge every time it tried to explore an important action.

- MDP-3 works similarly to MDP-1, but as it has a larger state space, the probability of reaching the goal without dodging cars is around 50%. The larger state space also implies that new problematic situations may appear. For example, the robot may start to go up, and if too many cars appear so that the robot cannot dodge them, it has to go back down by executing a "move-south" action. The "move-south" action is not needed in MDPs 1 and 2, but it is needed in some cases in MDP-3. After the 10th episode, most of the teacher demonstrations requested by V-MIN are to learn how to solve these unexpected problems that didn't appear in the simpler problems. As REX cannot request teacher demonstrations, it has a harder time dealing with these unexpected situations, and this is reflected in a lower accumulated reward mean when compared to MDP-1.

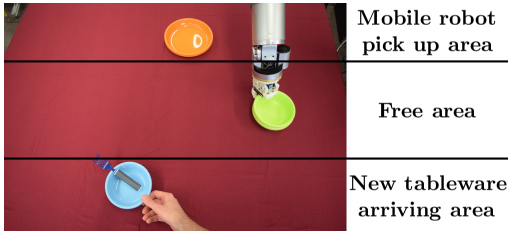

Figure 9: Table clearing task. On the bottom area, people leave the used tableware. On the top area, the robot has to prepare piles for the mobile robots that take tableware to the kitchen. The middle space is free for the robot to store objects while piling them up and waiting for mobile robots.

6. Robot Table Clearing

This section describes a task where a robot has to clear the tableware laying on a table. To that end, V-MIN with the learner presented previously was used as the decision-maker of the robot to solve the task.

This task represents a robotized restaurant. The manipulator robot that we control has to clear the tableware on a table. It has to cooperate with mobile robots that can take a pile of tableware from the table to the kitchen to be cleaned. The number of mobile robots is limited, so our robot should pile tableware together to minimize the number of piles to be taken. The difficulty of the task comes from the fact that people will continuously bring new used tableware to the table. The robot has to organize continuously the tableware on the table so that there is always enough space for people to leave new tableware, and also to ensure that the mobile robots always have a prepared pile of tableware when they come to the table.

This task is illustrated in Fig. 9. People leave used tableware on the bottom area, the robot has the central area to organize tableware and create piles, and the top area is where the mobile robots pick a pile up when they come to the table. The tableware being used includes plates, cups and cutlery.

The robot system has three modules, the decision-maker module that includes the planner and the learner, the perception module that obtains a representation of the scene that can be used by the decision-maker, and the manipulation module that executes actions.

The perception module uses a camera that is located on top of the table (hanging from the ceiling) to update continuously a symbolic state that represents the table. This state consists of a set of literals that describe the different locations on the table. These literals are:

- "ArrivingLocation(?loc)" indicates that ?loc is a location where people will leave new tableware. This literal is constant as people always leave objects on the bottom side of the table.
- "PickUpLocation(?loc)" indicates that ?loc is a location where mobile robots will pick up piles to take them to the kitchen. This literal is constant as mobile robots always pick up piles from the top side of the table.
- "mobileRobotPickingUp(?loc)" indicates that a mobile robot will pick up a pile during the next iteration.
- "plate(?loc)" indicates that there is at least one plate at ?loc.
- "cup(?loc)" indicates that there is at least one cup at ?loc.
- "cutlery(?loc)" indicates that there is at least one fork, knife or spoon at ?loc.
- "stable(?loc)" indicates that the pile at ?loc is stable. An unstable pile cannot be picked up by a mobile robot.

The objects in this domain are the locations. The perception module generates the location objects dynamically by assigning one location to each pile of tableware, and then generates extra locations for (large enough) empty areas.

The manipulator module executes the actions planned. It takes the 3D perceptions obtained by the camera and generates the arm trajectories and gripper movements required to move the objects as desired. The symbolic actions that can be planned are:

- The "put(?loc1, ?loc2)" action to put the top object from a pile in location ?loc1 into location ?loc2.
- The "movePile(?loc1, ?loc2)" action that drags a whole pile from ?loc1 to ?loc2 if ?loc2 is empty. This action has high failure rates with unstable piles.

Piles may become unstable if objects are not piled properly. For example, if a plate is placed on top of a pile containing a cup and a fork, there is a high probability that it will become unstable. To obtain stable piles, in general, plates should be placed at the bottom, cups on top of them, and cutlery at the top. Unstable piles are harder to move, and mobile robots cannot pick them successfully.

Finally the decision-maker module uses the V-MIN algorithm (Section 4) in combination with the learner presented in Section 3 to learn, and the PROST planner (Keller and Eyerich, 2012) to plan.

Figures 10 and 11 show examples of the Table Clearing task. The robot plans the optimal action to execute based on the state of the table.

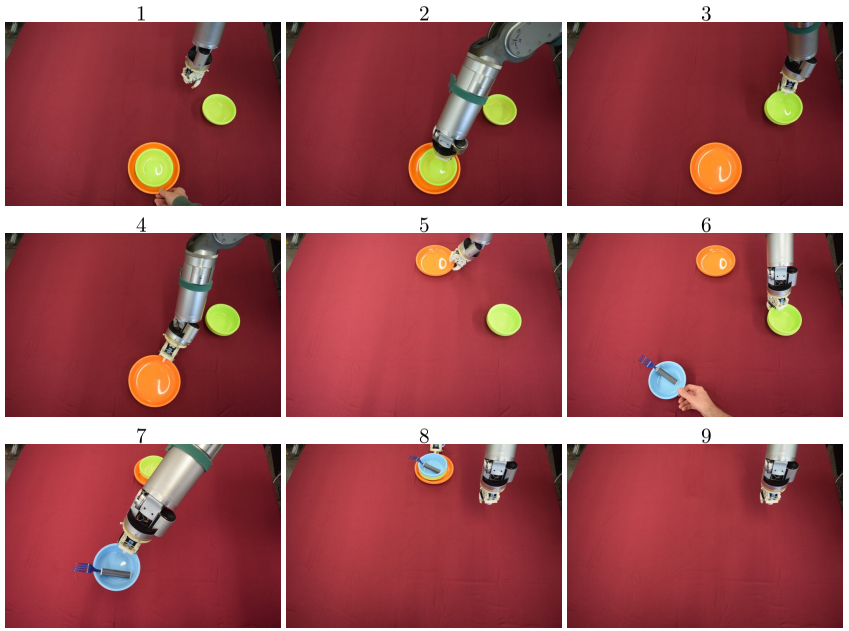

Figure 10: Table clearing with a learned model. As the robot does not know if new tableware will arrive shortly, it decides first to place the two cups together (images $1-3$), and then moves the plate to the *pick up* area (images $4-5$). Afterwards, a new pile arrives that contains no plates (image 6), so the robot decides to move the cups to the picking up area (image 7), and finally, as a mobile robot is arriving, the robot places the last pieces of tableware on the *pick up* area (image 8). Image 9 shows the final state after a mobile robot picked up the pile.

6.1 Learning a Model with RL

Using the setup described above, we executed the learner to obtain a model of the task from scratch while solving it. To make the experimentation easier, instead of having mobile robots picking up piles from the *pick up* area, a person did it. The robot had to solve experiments of increasing difficulty, and it transferred the learned knowledge from one experiment to the next. All experiments lasted 30 iterations during which piles were picked up 5 times from the *pick up* area.

1. The easiest experiment was executed once. People left 10 objects on the table during the experiment, including only plates and cups.

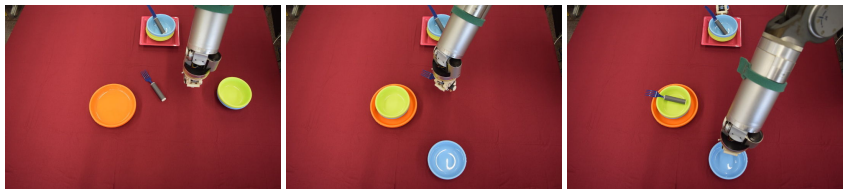

Figure 11: Table clearing with a learned model. **Initially**, the robot has already one pile prepared for the mobile robots. The planner opts to prepare a new pile with the tableware on the table as it expects that at some point a mobile robot will pick up the pile on top. **In the second image**, the new pile is halfway done, and a new cup arrives. The planner knows that in the next iteration a mobile robot is coming, so it decides to finish the new pile. **In the third image**, a mobile robot picks the top pile, and the manipulator robot plans that the best action is to move the new cup to the center free area to make more space in the arriving area. Once the mobile robot takes the top pile, the manipulator robot will plan the action of taking the center pile to the *pick up* area.

2. The medium experiment was executed twice. People left 13 objects on the table that included plates, cups and cutlery.

3. The difficult experiment was executed twice. People left 18 objects on the table that included plates, cups and cutlery.

The goals of the robot were to minimize the number of objects on the table, and to have empty space in the *arriving* area so that people always had space to place new tableware. Therefore big enough piles had to be given to the mobile robot at the same time that the arriving area had to be cleared quickly.

The learner parameters used were $\alpha = 0.01$, $\epsilon = 0.1$, $\omega = 2$, $\delta = 0.05$, $\kappa = 1000$, and the subsumption was enabled. The V-MIN exploration threshold was $\zeta = 3$ and V_{min} was selected and updated by the teacher depending on the robot performance.

6.1.1 Learning Results

Table 1 summarizes the performance of the manipulator robot. During the easy experiment, 7 teacher demonstration requests were required to complete the task. The robot had to learn the "put" action to pick and place objects, and also the operators defining how mobile robots took piles from the *pick up* area.

In the second experiment, as cutlery appeared for the first time, and piles that have cutlery in the middle are usually unstable, the robot needed 6 extra demonstrations to learn how to manipulate cutlery and how unstable piles could be unpiled to make them stable again. The third experiment needed only 3 more demonstrations as the robot already knew most of the dynamics.

	Easy 1	Medium 1	Medium 2	Difficult 1	Difficult 2
Number of objects	10*	13	13	18	18
Sum of reward	−48	−90	−82	−148	−130
Optimal rewards	−41	−64	−65	−97	−101
Teacher requests	7	6	3	4	1

*In the easy setup no cutlery was used (only plates and cups).

Table 1: Learning results in the robot table clearing task. The columns show the different learning experiments, which were executed in order of increasing difficulty. The rows show the number of objects that arrived in each experiment, the sum of rewards, and the number of teacher demonstration requests.

Finally, in the last difficult experiments, 5 teacher demonstrations were needed once many objects accumulated on the table. The robot had to learn that it could assemble a pile in the middle area, and then move it directly to the *pick up* area by using the action "movePile(?loc1, ?loc2)". In previous experiments this action was not needed as less tableware arrived and the robot could just make piles directly on the *pick up* area with the "put" action.

Appendix A explains in more detail the execution of the learning process as well as the behavior of the manipulator robot during the easy experiment and the first medium experiment.

It should be noted that during the learning experiments we observed that the effectiveness of the robot actions was very important. If actions failed often, many more action executions were needed to obtain a proper model. Therefore, before running the experiments presented here, the robot actions were improved so that they succeeded in most cases to make the task simpler.

6.2 Evaluation of the Learned Model

Finally, an experiment was carried out to evaluate the usefulness of learning exogenous effects. Here we compare the performance when using the model learned in the previous section, with another model learned with no exogenous effects (Pasula et al., 2007). The exogenous effects allow the planner to know the probabilities with which each type of tableware arrives, and the probability with which mobile robots come to pick piles up. There was a reward of −1 for every object on the table at each step, and a reward of −2 if new tableware was arriving but the arriving area was full. The results are shown in Table 2.

- An optimal action sequence obtained a reward of −99. Note that this optimal action sequence was not obtained in a fair way: it was created knowing in advance when and which type of tableware was arriving at each step, and when a mobile robot approached. In contrast the manipulator robot did not have this information, it could only know the probabilities of these effects.

- The model containing exogenous effects obtained a reward of −119. In this experiment the manipulator robot performed well in general, but it created some inefficient piles

	Optimal	Model with exogenous	Model with no exogenous
Sum of rewards	−99	−119	−136
Operators (actions)	-	8	20
Operators (exogenous)	-	11	0

Table 2: Execution results with the learned models. The columns show the results with an optimal sequence of actions, a learned model considering exogenous effects, and a learned model not considering exogenous effects. The rows show the sum of rewards and the number of planning operators that represent actions and exogenous effects.

as a mobile robot would take shorter or longer than expected to arrive. Moreover, the manipulator robot took a conservative strategy and it didn't complete fast enough some piles, as it did not know if new tableware would be arriving shortly. The model consisted of 8 planning operators for action effects, and 11 planning operators for exogenous effects.

- The model without exogenous effects obtained a reward of −136. This model had more trouble to complete the task. The manipulator robot did not know that new tableware would arrive because it did not have the exogenous effect for it. Thus, it tried to make the best piles with the given objects, which resulted in the robot redoing the piles whenever new tableware arrived (e.g. if a new cup arrived, the robot would put it on top of the other cups in an existing pile, and below the cutlery). The model had 20 operators that represented action effects. As exogenous effects were not learned separately, each operator actually represented combinations of an action effect with exogenous effects. However, these operators were less effective to represent the model than separate action and exogenous operators, so the planner selected worse policies.

Analyzing the results we can see that the proposed learner allows a robot to learn tasks including exogenous effects. Given that only 5 episodes of 30 action executions were used for training, the results were good. The experiment also shows that a model considering exogenous effects improves the performance when external agents interact. Here the planner was able to find much better plans when it anticipated that new tableware or a mobile robot were arriving. However, extending this task with a richer representation and more external agents would be costly. For every literal and exogenous effect that gets added, the number of input transitions and computational time required to learn a model increases significantly.

7. Conclusions

We have introduced a new method that, given a set of input transitions, learns a general model explaining them. In contrast to previous approaches, it can learn exogenous effects (effects not related to any action), while still being similarly good at obtaining a relational representation of the problem and at learning uncertain effects. Moreover optimal and suboptimal search methods are provided, so the best approach can be chosen depending on

the quality requirements, the difficulty of the problem, and the learning time available. The main limitation of the algorithm is scalability when the number of generated propositional predicates becomes large.

This learner can be combined with a RL algorithm to learn models from scratch. We validated experimentally that the integration in the V-MIN algorithm allowed an agent to learn models with a relatively small number of actions and teacher demonstration requests.

The learner was also integrated in a robot to perform the task of clearing the tableware on a table. In this task external agents interacted, people brought new tableware continuously and the manipulator robot had to cooperate with mobile robots to take the tableware to the kitchen. The learner was able to learn a usable model in just 5 episodes of 30 action executions. Finally, the model was used to complete the task, and learning models with such exogenous effects proved to increase the obtained reward significantly.

Many robotic problems cannot be learned yet. As future work, the learner could be extended to tackle correlated effects and partial observations.

- The challenge with correlated effects is to identify the candidates. A possible path to explore is to replace LFIT by Ribeiro et al. (2015)'s approach, in which preconditions can be literals in both the previous state (s_t) and the resulting state (s_{t+1}). In this case, an effect (a literal in s_{t+1}) can be a precondition for another effect, so they would be correlated effects.

- Partial observations would require to change the heuristic search and the cost function to consider that the given state transitions may be wrong or incomplete.

Appendix A. Learning the Table Clearing Task

In Sec. 6.1 we explained how the manipulator robot learned the table clearing task. This appendix shows the detailed execution of the easy experiment and the first medium experiment to provide a deeper understanding of the learning process.

A.1 Easy Experiment

The states at each iteration of the easy experiment are shown in Fig. 12. The robot starts with no prior knowledge and has to learn the complete model. Below is an explanation of the actions taking place at each iteration:

1. Initially the robot does not have prior knowledge and its model is empty, so no action is taken. A person brings a plate (exogenous effect).

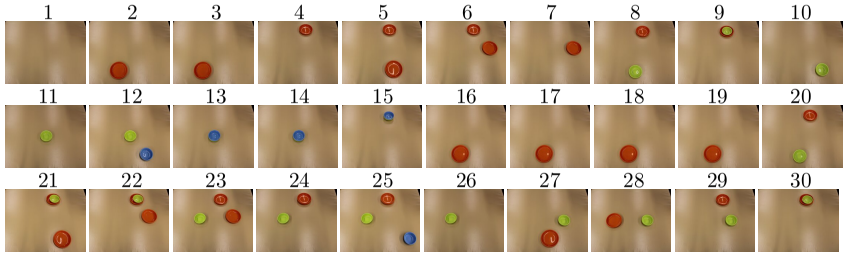

Figure 12: The state at the beginning of each iteration during the easy experiment.

2. No action is taken.
3. The manipulator robot learns that plates remain in the same location if no action is taken. A demonstration is requested to learn how to deal with plates, and the teacher demonstrates the "put" action to move the plate to the *pick up* area.
4. The manipulator robot executes the "put" action with an empty location as parameter, so it does not move anything. A new plate arrives.
5. The new plate is moved to the middle of the table.
6. The manipulator robot executes "put" with an empty location. Meanwhile, a mobile robot comes and picks the plate on the *pick up* area (another type of exogenous effect).
7. After learning that mobile robots pick up plates on the *pick up* area, the manipulator robot moves the plate on the middle to the *pick up* area. A cup arrives to the table.
8. A demonstration is requested, and the teacher moves it to the *pick up* area with a "put" action.
9. It is not known yet that mobile robots also pick cups up, so a demonstration is requested. The teacher does not execute any action because a mobile robot is already arriving to take the pile. A new cup appears.
10. The learned model is not good enough yet, so a demonstration is requested. The teacher puts the cup in the center of the table.
11. An exploratory "put" action with an empty location is taken. A new cup arrives.
12. A demonstration is requested. The teacher shows that both cups can be piled together.
13. No action is taken.
14. As a mobile robot is arriving, the cups are moved to the *pick up* area.
15. The mobile robot takes the cups and a new plate appears.

16. The robot executes a "put" action that fails.
17. An exploratory "put" action is executed with an empty location (a new planning operator with the action "put" and the precondition "cup(?X)" was generated and it is explored).
18. An exploratory "put" action is executed with an empty location.
19. The plate is moved to the *pick up* area. A cup appears.
20. The new cup is moved to the *pick up* area. A new plate appears.
21. A demonstration is requested (the robot does not know yet that it can pile plates together). The teacher decides to put the new plate on an empty location because piling it on the *pick up* area could be unstable.
22. As an exploratory action, the cup is moved to an empty location.
23. A demonstration is requested, and the teacher piles the two plates together.
24. No action was taken (exploration is not needed, so it decides to wait until new objects arrive or a mobile robot approaches). A new cup arrives.
25. The new cup is moved to the pile in the *pick up* area because a mobile robot is arriving.
26. As an exploration action, the cup is moved to a different location on the center of the table. A plate arrives.
27. The plate is moved to the center.
28. The plate is moved to the *pick up* area.
29. The cup is put on top of the plate.
30. A mobile robot comes and takes the last pile.

A.2 First Medium Experiment

Here the robot reuses the knowledge that it obtained during the easy experiment. The states at each iteration of the first medium experiment are shown in Fig. 13. Below is an explanation of the actions taking place at each iteration:

1. Initially there is no tableware, so no action is taken. A plate arrives.
2. The plate is "put" on the *pick up* area. A cup arrives.
3. An exploratory "put" action that does nothing is executed (the first parameter is an empty location and the second one is the cup, so it does not move anything).
4. The operators learned are not complete enough, so a demonstration is requested. The teacher places the cup in the middle of the table. A plate arrives

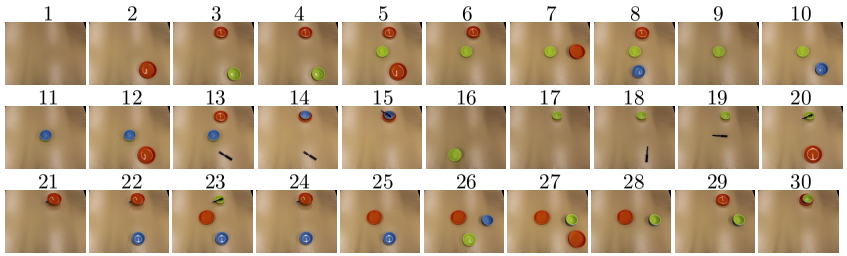

Figure 13: The state at the beginning of each iteration during the first medium experiment.

5. The new plate is moved to the *pick up* area.
6. As an exploratory action, the plates are moved to the center of the table.
7. The plates are moved back to the *pick up* area. A cup arrives.
8. As a mobile robot is arriving, it is piled up directly in the *pick up* area. The pile on the *pick up* area is taken.
9. No action is taken (exploration is not needed, so it decides to wait until new objects arrive or a mobile robot approaches). A new cup arrives
10. The new cup is piled with the other one.
11. No action is taken and a plate arrives.
12. The new plate is moved to the *pick up* area.
13. Cutlery appears for the first time. A demonstration is requested and the teacher decides to move the cups to the *pick up* area. Note that the teacher shows the best action, and not the action that would make the robot learn the most. In this case it is better to first put the cup on the plate, and later put the cutlery on the cup.
14. As the actions to manipulate cutlery have not been learned yet, another demonstration is requested. This time the teacher executes a "put" action to pile up the fork.
15. The manipulator robot has still to learn that mobile robots also take cutlery, so another demonstration is requested. As a mobile robot is arriving to take the pile, the teacher does not execute any action. A cup arrives.
16. The new cup is moved to the *pick up* area.
17. No action is taken. A fork arrives.
18. The new fork is moved to the center of the table.
19. The fork is put on top of the cup at the *pick up* area. A plate arrives.

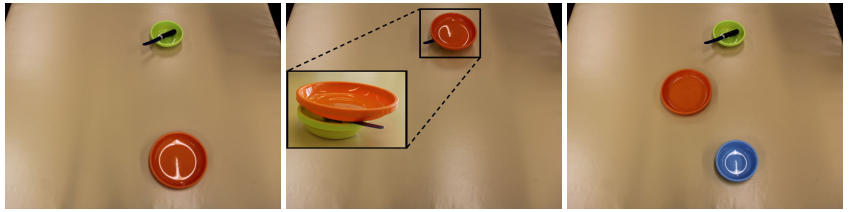

Figure 14: Unstable pile during the first medium experiment. **Left:** the state before the manipulator robot placed the plate on the top pile. **Center:** the pile became unstable, and thus it was not taken by mobile robots. **Right:** to make the pile stable again, the plate was positioned back in the table.

20. The new plate is moved to the pile at the *pick up* area. However, the pile becomes unstable as a plate is on top of a cup with a knife (see Fig. 14).
21. A mobile robot comes, but it does not take the pile because it is unstable. A cup arrives.
22. The manipulator robot has learned that mobile robots do not take unstable piles, so a demonstration is requested. The teacher shows that putting the plate back to the table makes the pile stable again.
23. As an exploratory action, the plate is put again on the pile, making it unstable.
24. The manipulator robot makes the pile stable again by removing the plate. A mobile robot comes and takes the pile on the *pick up* area as it is stable.
25. The cup on the *arriving* area is moved to the center of the table. A new cup arrives.
26. The model has updated its probabilities with which new objects and mobile robots arrive, and the resulting plan has a value $V(s) < V_{min}$ even though it is a good plan. The problem is that V_{min} was too high, and the teacher updates it after piling the two cups together. A plate arrives.
27. The plate is piled on top of the other plate.
28. The plates are moved to the *pick up* area.
29. The cups are piled on top of the plates.
30. A mobile robot comes and takes the last pile.

Abstract

We propose a Bayesian approach to regression with a scalar response on vector and tensor covariates. Vectorization of the tensor prior to analysis fails to exploit the structure, often leading to poor estimation and predictive performance. We introduce a novel class of multiway shrinkage priors for tensor coefficients in the regression setting and present posterior consistency results under mild conditions. A computationally efficient Markov chain Monte Carlo algorithm is developed for posterior computation. Simulation studies illustrate substantial gains over existing tensor regression methods in terms of estimation and parameter inference. Our approach is further illustrated in a neuroimaging application.

Keywords: Multiway Shrinkage Prior, Magnetic Resonance Imaging (MRI), Parafac Decomposition, Posterior Consistency, Tensor Regression

1. Introduction

In many application areas, it is common to collect predictors that are structured as a multiway array or tensor. For example, the elements of this tensor may correspond to voxels in a brain image (Lindquist, 2008; Lazar, 2008; Hinrichs et al., 2009; Ryali et al., 2010). Existing approaches for quantifying associations between an outcome and such tensor predictors mostly fall within two groups. The first approach assesses the association between each cell (for brain images referred to as voxel) and the response independently, providing a p-value 'map' (Lazar, 2008). The p-values can be adjusted for multiple comparisons to identify 'significant' sub-regions of the tensor. Although this approach is widely used and appealing in its simplicity, clearly such independent screening approaches have key disadvantages relative to methods that take into account the joint impact of the overall tensor simultaneously. Unfortunately, the literature on simultaneous analysis approaches is sparse.

One naive approach is to simply vectorize the tensor and then use existing methods for high-dimensional regression. Such vectorization fails to preserve spatial structure, making it more difficult to learn low-dimensional relationships with the response. Efficient learning is of critical importance, as the sample size is typically massively smaller than the total number of cells. Alternative approaches within the regression framework include functional regression and two stage approaches. The former views the tensor as a discretization of a continuous functional predictor. Most of the literature on functional predictors focuses on 1D functions; Reiss and Ogden (2010) consider the 2D case, but substantial challenges arise in extensions to 3D due to dimensionality and collinearity among cells. Recently Wang et al. (2014) considered 3D regularized functional regression with Haar wavelet basis. The article is essentially frequentist in nature with simulation studies showing only the mean squared error and the percentage of correctly identified zero and nonzero elements. Additionally, the article reveals that functional regression is largely affected by the choice of proper basis functions. The second set of approaches, i.e. Two stage approaches first conduct a dimension reduction step, commonly using PCA, and then fit a model using lower dimensional predictors (Caffo et al., 2010). A clear disadvantage of such approaches is that the main principal components driving variability in the random tensor may have relatively limited impact on the response variable. Potentially, supervised PCA could be used, but it is not clear how to implement such an approach in 3D or higher dimensions.

Zhou et al. (2013) propose extending generalized linear regression to include a tensor structured parameter corresponding to the measured tensor predictor. To circumvent difficulties with extensions to higher order tensor predictors, they impose additional structure on the tensor parameter, supposing it decomposes as a rank-R parafac sum (see Section 2.1). This massively reduces the effective number of parameters to be estimated. They develop a penalized likelihood approach where adaptive lasso penalties are be imposed on individual margins of the parafac decomposition, focusing on good point estimation for the tensor parameter. However, their method relies heavily on cross-validation for selecting tuning parameters which are sensitive to the tensor dimension, the signal-to-noise ratio (degree of sparsity) and the parafac rank. Given that there is no automatic selection procedure for the tuning parameters provided in Zhou et al. (2013), they have to be fed manually by the end user which is problematic for an unknown tensor regression problem.

Of practical interest is a "self calibrating" procedure which adapts the complexity of the model to the data. We propose a principled method to effectively shrink unimportant cell coefficients to zero while maintaining accuracy in estimating important cell coefficients. Our framework gives rise to the automatic selection of tuning parameters, with carefully constructed shrinkage priors that naturally induce sparsity within and across components in the tensor factorization of the tensor coefficient for optimal region selection. In addition, the need for valid measures of uncertainty on parameter (predictive) estimates is crucial, especially in settings with low or moderate sample sizes, which naturally motivates our Bayesian approach. Recently Suzuki (2015) proposed a Bayesian tensor regression approach with naive Gaussian prior on the components of the tensor factorization of the tensor coefficients. In contrast, our proposed prior on the tensor coefficient is more sophisticated in the sense that it imparts shrinkage in three ways: at a global level, at a local level of

individual parameters, and also provides shrinkage towards low rank decomposition of the tensor coefficient. Similarly, Bayesian tensor regression framework proposed in Goldsmith et al. (2014) uses binary indicators to determine whether a cell in the tensor predictor is predictive of the response. For a tensor predictor with $30 \times 30 \times 30$ cells, such an approach requires to update 27000 binary indicators in each MCMC iteration and is deemed unsatisfactory due to mixing issues and poor inference.

Our approach differs from image reconstruction literature as we do not model the distribution of the tensor $\boldsymbol{X}$ (Qiu, 2007). There is a considerable recent literature on frequentist tensor modeling in which one typically encounters time series (generally to study social networks or images evolving over time) with response at every time point is an array/tensor (Gerard and Hoff, 2015; Hoff et al., 2015). There is also a Bayesian literature that facilitates joint modeling of a large number of unordered categorical variables (Zhou et al., 2015). Our framework is fundamentally different from these approaches in the sense that *these are all unsupervised tensor modeling approach while we propose a framework for supervised tensor regression.* To the best of our knowledge, we are the first to propose a novel multiway shrinkage prior in Bayesian tensor regression framework (with scalar response on a tensor predictor) that accommodates shrinkage of the tensor coefficient for the appropriate identification of important cells in the tensor predictor. Besides, we offer strong posterior consistency results on Bayesian tensor regression framework with multiway shrinkage prior.

Remainder of the manuscript evolves as follows. In Section 2, we propose the basic framework of the tensor regression model with a scalar response, vector predictors and a tensor predictor. Section 3 characterizes desirable criteria for a multiway shrinkage prior and proposes a novel multiway shrinkage prior on the tensor coefficient. Sections 4 and 5 provide theoretical results on the convergence of posterior distribution under the mutiway shrinkage prior and details on posterior computation respectively. Various simulation studies with 2D and 3D tensor predictors are presented in Sections 6 and 7 respectively to study effectiveness of the Bayesian tensor regression under various degrees of sparsity and signal strength. Section 8 is devoted to a real brain connectome data analysis using the proposed Bayesian tensor regression model along with its competitors. The manuscripts ends with a discussion.

2. Tensor Regression

This section provides details on the tensor regression model.

2.1 Basic Notation

Let $\boldsymbol{\beta}_1 = (\beta_{11}, \ldots, \beta_{1p_1})'$ and $\boldsymbol{\beta}_2 = (\beta_{21}, \ldots, \beta_{2p_2})'$ be vectors of length p_1 and p_2, respectively. The vector outer product $\boldsymbol{\beta}_1 \circ \boldsymbol{\beta}_2$ is a $p_1 \times p_2$ matrix with (i,j)-th entry $\beta_{1i}\beta_{2j}$. A D-way outer product between vectors $\boldsymbol{\beta}_j = (\beta_{j1}, \ldots, \beta_{jp_j})$, $1 \leq j \leq D$, is a $p_1 \times \cdots \times p_D$ multi-dimensional array denoted $\boldsymbol{B} = \boldsymbol{\beta}_1 \circ \boldsymbol{\beta}_2 \circ \cdots \circ \boldsymbol{\beta}_D$ with entries $(\boldsymbol{B})_{i_1,\ldots,i_D} = \prod_{j=1}^{D} \beta_{ji_j}$. Define a vec$(\boldsymbol{B})$ operator as stacking elements of this D-way tensor into a column vector of length $\prod_{j=1}^{D} p_j$. From the definition of outer products, it is easy to see that $\text{vec}(\boldsymbol{\beta}_1 \circ \boldsymbol{\beta}_2 \circ \cdots \circ \boldsymbol{\beta}_D) = \boldsymbol{\beta}_D \otimes \cdots \otimes \boldsymbol{\beta}_1$. As a higher order generalization of matrix singular value decomposition, Tucker decomposition of a D-way tensor $\boldsymbol{B} \in \otimes_{j=1}^{D} \Re^{p_j}$ is

often considered. The Tucker decomposition (Kolda and Bader, 2009) can be expressed as

$$\boldsymbol{B} = \sum_{r_1=1}^{R_1} \sum_{r_2=1}^{R_2} \cdots \sum_{r_D=1}^{R_D} \lambda_{r_1,\ldots,r_D} \boldsymbol{\beta}_1^{(r_1)} \circ \boldsymbol{\beta}_2^{(r_2)} \circ \cdots \circ \boldsymbol{\beta}_D^{(r_D)} \tag{1}$$

where $\boldsymbol{\beta}_j^{(r_j)}$ is a p_j dimensional vector, $1 \leq j \leq D$, and $\boldsymbol{\Lambda} = (\lambda_{r_1,\ldots,r_D})_{r_1,\ldots,r_D=1}^{R_1,\ldots,R_D}$ is referred to as the *core tensor*. If one considers $\{\boldsymbol{\beta}_j^{(r_j)}; 1 \leq r_j \leq R_j, 1 \leq j \leq D\}$ as "factor loadings" and $\lambda_{r_1,\ldots,r_D}$ to be the corresponding coefficients, then the Tucker decomposition may be thought of as a multiway analogue to factor modeling.

A rank-R parafac decomposition emerges as a special case of Tucker decomposition 1 when $R_1 = R_2 = \cdots = R_D = R$ and $\lambda_{r_1,\ldots,r_D} = I(r_1 = r_2 = \cdots = r_D)$. In particular, $\boldsymbol{B} \in \otimes_{j=1}^{D} \Re^{p_j}$ assumes a rank-R parafac decomposition if

$$\boldsymbol{B} = \sum_{r=1}^{R} \boldsymbol{\beta}_1^{(r)} \circ \cdots \circ \boldsymbol{\beta}_D^{(r)} \tag{2}$$

where $\boldsymbol{\beta}_j^{(r)}$, $1 \leq j \leq D$ and $1 \leq r \leq R$ are the p_j dimensional 'margins'. The parafac decomposition is more widely used due to its relative simplicity.

2.2 Model Framework

Let $y \in \mathcal{Y}$ denotes a response variable, with $\boldsymbol{z} \in \mathcal{X} \subset \Re^p$ and $\boldsymbol{X} \in \otimes_{j=1}^{D} \Re^{p_j}$ scalar and tensor predictors, respectively. We consider a tensor regression model having a general form

$$y \sim f\left(\alpha + \boldsymbol{z}'\boldsymbol{\gamma} + \langle \boldsymbol{X}, \boldsymbol{B} \rangle, \sigma\right), \quad \langle \boldsymbol{X}, \boldsymbol{B} \rangle = \text{vec}(\boldsymbol{X})'\text{vec}(\boldsymbol{B}), \tag{3}$$

where $f(\mu, \sigma)$ is a family of distributions having location μ and scale σ, $\boldsymbol{\gamma}$ is a $p \times 1$ coefficient for scalar preditors and $\boldsymbol{B} \in \otimes_{j=1}^{D} \Re^{p_j}$ is the tensor parameter corresponding to measured tensor predictor $\boldsymbol{X}$. We focus more specifically on the Gaussian linear model case with

$$y = \alpha + \boldsymbol{z}'\boldsymbol{\gamma} + \langle \boldsymbol{X}, \boldsymbol{B} \rangle + \epsilon, \; \epsilon \sim N(0, \sigma^2). \tag{4}$$

The coefficient tensor $\boldsymbol{B}$ has $\prod_{j=1}^{D} p_j$ elements, necessitating substantial dimensionality reduction. A rank-1 parafac decomposition assumes $\boldsymbol{B} = \boldsymbol{\beta}_1 \circ \cdots \circ \boldsymbol{\beta}_D$ and $\text{vec}(\boldsymbol{B}) = \boldsymbol{\beta}_D \otimes \cdots \otimes \boldsymbol{\beta}_1$. This reduces to modeling $y = \alpha + \boldsymbol{z}'\boldsymbol{\gamma} + \boldsymbol{\beta}_1'\boldsymbol{X}\boldsymbol{\beta}_2$ when $D = 2$, corresponding to the bilinear model considered in Hung and Wang (2013). Since only the single parameter vector $\boldsymbol{\beta}_j$ captures signal along the jth dimension, a rank-1 assumption severely limits flexibility, ruling out interactions among dimensions. Following Zhou et al. (2013), we use a more flexible rank-R parafac decomposition for $\boldsymbol{B} = \sum_{r=1}^{R} \boldsymbol{\beta}_1^{(r)} \circ \cdots \circ \boldsymbol{\beta}_D^{(r)}$ introduced in (2) with $\boldsymbol{\beta}_j^{(r)} \in \Re^{p_j}$, $1 \leq j \leq D$, and $1 \leq r \leq R$. Expression (4) then becomes

$$\begin{aligned} y &= \alpha + \boldsymbol{z}'\boldsymbol{\gamma} + \left\langle \boldsymbol{X}, \sum_{r=1}^{R} \boldsymbol{\beta}_1^{(r)} \circ \cdots \circ \boldsymbol{\beta}_D^{(r)} \right\rangle + \epsilon \\ &= \alpha + \boldsymbol{z}'\boldsymbol{\gamma} + \sum_{(i_1,\ldots,i_D)} (\boldsymbol{X})_{i_1,\ldots,i_D} (\boldsymbol{B})_{i_1,\ldots,i_D} + \epsilon \end{aligned} \tag{5}$$

where voxel $(\boldsymbol{X})_{i_1,\ldots,i_D}$ of the tensor predictor has corresponding parameter

$$(\boldsymbol{B})_{i_1,\ldots,i_D} = \sum_{r=1}^{R}\prod_{j=1}^{D}\beta_{j,i_j}^{(r)}, \quad (i_1,\ldots,i_D) \in \mathcal{V}_{\boldsymbol{B}} = \otimes_{j=1}^{D}\{1,\ldots,p_j\}. \tag{6}$$

The model is therefore nonlinear in the parameters defining $\boldsymbol{B}$. A hierarchical specification is completed by placing priors over unknown model parameters. While placing priors over α and $\boldsymbol{\gamma}$ is straightforward, Section 3.2 focuses on specification of the prior over tensor parameters which is nontrivial and one of the main contributions of this work.

Under the assumed rank-R parafac decomposition for $\boldsymbol{B}$, model (5) requires estimating $p+2+R\sum_{j=1}^{D}p_j$ as opposed to $p+2+\prod_{j=1}^{D}p_j$ parameters for the unstructured vectorized (saturated) model. As we are interested in identifying geometric sub-regions of the tensor across which coefficients are not close to zero, with the remaining elements being very close to zero, one wonders whether such dramatic dimension reduction retains sufficient flexibility. Finally, we would like to accurately estimate coefficient values in these sub-regions. Consistent with our theoretical analysis in Section 4, extensive simulation studies in Section 6 confirm our ability to accomplish these goals.

2.3 Model Identifiability

From model (5) it is clear that only voxel-level coefficients are identified and not the individual tensor margins defining their product-sum given in (6). In the tensor setting, identifiability restrictions are understood in light of the following indeterminacies:

1. *Scale indeterminacy*: for each $r = 1,\ldots,R$, define $\boldsymbol{\lambda}_r = (\lambda_{1r},\ldots,\lambda_{Dr})$ such that $\prod_{j=1}^{D}\lambda_{jr} = 1$. Then replacing $\boldsymbol{\beta}_j^{(r)}$ by $\lambda_{jr}\boldsymbol{\beta}_j^{(r)}$ leaves the tensor parameter $\boldsymbol{B}$ unaltered.

2. *Permutation indeterminacy*: $\sum_{r=1}^{R}\circ_{j=1}^{D}\boldsymbol{\beta}_j^{(r)} = \sum_{r=1}^{R}\circ_{j=1}^{D}\boldsymbol{\beta}_j^{(P(r))}$ for any permutation $P(\cdot)$ of $\{1,2,\ldots,R\}$. In particular, this implies that $\circ_{j=1}^{D}\boldsymbol{\beta}_j^{(r)}$ are not identifiable for $r = 1,\ldots,R$.

3. *Orthogonal transformation indeterminacy* ($D = 2$ only): for any orthonormal matrix $\boldsymbol{O}$, one has $(\boldsymbol{\beta}_1^{(r)}\boldsymbol{O}) \circ (\boldsymbol{\beta}_2^{(r)}\boldsymbol{O}) = \boldsymbol{\beta}_1^{(r)} \otimes \boldsymbol{\beta}_2^{(r)}$.

For $D > 2$, imposing the following $(D-1)R$ constraints ensures identifiability of the margin parameters comprising the rank-R parafac decomposition:

$$\beta_{j,1}^{(r)} = 1,\ 1 \le j < D,\ 1 \le r \le R, \qquad \text{and} \qquad \beta_{D,1}^{(1)} > \cdots > \beta_{D,1}^{(R)}. \tag{7}$$

In the context of Bayesian tensor regression, our emphasis is on accurate estimation and inference on tensor parameter $\boldsymbol{B}$, and on state-of-the-art predictive performance. Importantly, $\boldsymbol{B}$ is always identifiable even if the tensor margins $\boldsymbol{\beta}_j^{(r)}$'s are not, hence we avoid imposing identifiability restrictions on the latter. As is evident from our simulation studies, non-identifiability of $\boldsymbol{\beta}_j^{(r)}$ does not appear to cause convergence issues and in-fact, simplifies the design of efficient computational algorithms.

3. Multiway Shrinkage Priors

This Section outlines the novel multiway shrinkage prior on the tensor coefficient.

3.1 Vector Shrinkage Priors

There has been recent interest in high-dimensional regression with vector predictors, choosing priors which shrink small coefficients towards zero while minimizing shrinkage of large coefficients. Many of these priors can be expressed as a global-local (GL) scale mixtures (Polson and Scott, 2012) with

$$\theta_j \sim \mathrm{N}(0,\psi_j\tau), \quad \psi_j \sim g, \quad \tau \sim h, \tag{8}$$

where $(\theta_1,\ldots,\theta_p)$ is a coefficient vector, τ is a global scale and ψ_j is a local-scale. When g is a mixture of two components, with one concentrated near zero and the other away from zero, a spike and slab prior is obtained. Many other choices of g and h have been considered. Although the GL family is widely used and versatile, Bhattacharya et al. (2015) note advantages in drawing the local scales jointly. In particular, they propose to let

$$\theta_j \sim \mathrm{DE}(\cdot|\phi_j\tau), \quad (\phi_1,...,\phi_p) \sim \mathrm{Dirichlet}(a,\ldots,a), \quad \tau \sim h.$$

where $\mathrm{DE}(\cdot)$ denote the double-exponential distribution. For small a and large p, the $\mathrm{Dirichlet}(a,\ldots,a)$ prior has the property of favoring many values close to zero with a few much larger values, but with $\sum_j \phi_j = 1$. Though we draw motivation from literature on vector shrinkage priors, our goal of proposing a shrinkage prior on tensor parameter $\boldsymbol{B}$ is fundamentally more challenging as discussed in forthcoming sections.

3.2 Multiway Priors

We propose a new class of multiway shrinkage priors in the generalized linear model setting with tensor valued predictors. Assuming tensor parameter $\boldsymbol{B}$ admits a rank-R parafac decomposition, model (5) results in cell-level coefficients that are a nonlinear function of the corresponding tensor margin parameters (see (6)). Moreover, this implies simultaneous shrinkage on each of the $\prod_{j=1}^{D}p_j$ cell coefficients as imposed by the prior over $R\sum_{j=1}^{D}p_j$ parameters. This necessitates careful prior specification on the tensor margins $\{\boldsymbol{\beta}_j^{(r)}; 1 \le j \le D, 1 \le r \le R\}$ such that the induced cell-level prior has adequate tails so as to prevent over shrinkage.

There are a number of desirable characteristics for a multiway prior on the tensor margins. The proposed multiway shrinkage prior must have a structure that facilitates efficient and reliable model fitting. In addition, it is important to ensure that

1. For each $r = 1,\ldots,R$, $(\beta_{1,i_1}^{(r)},\ldots,\beta_{D,i_D}^{(r)})$ and $(\beta_{1,k_1}^{(r)},\ldots,\beta_{D,k_D}^{(r)})$ are equal in distribution, for any $(i_1,\ldots,i_D),(k_1,\ldots,k_D) \in \mathcal{V}_{\boldsymbol{B}} \times \mathcal{V}_{\boldsymbol{B}}$ and $(i_1,\ldots,i_D) \neq (k_1,\ldots,k_D)$. This is to ensure that $(B)_{i_1,\ldots,i_D}$ and $(B)_{k_1,\ldots,k_D}$ have the same distribution apriori.

2. Shrinkage towards a low rank decomposition, with the model adapting to the complexity and signal in the data, effectively deleting unnecessary dimensions.

3. The prior should favor recovery of contiguous geometric subregions of the tensor across which the cell observations are predictive of the response.

3.3 The Multiway Dirichlet GDP Prior

There are many ways of specifying priors over tensor margins $\boldsymbol{\beta}_j^{(r)}$ to satisfy the criteria listed. We propose a particular choice called the *multiway Dirichlet generalized double Pareto* (M-DGDP) prior. This prior induces shrinkage across components in an exchangeable way, with global scale $\tau \sim \text{Ga}(a_\tau, b_\tau)$ adjusted in each component as $\tau_r = \phi_r \tau$ for $r = 1, \ldots, R$, where $\Phi = (\phi_1, \ldots, \phi_R) \sim \text{Dirichlet}(\alpha_1, \ldots, \alpha_R)$ encourages shrinkage towards lower ranks in the assumed parafac decomposition. In addition, $\boldsymbol{W}_{jr} = \text{diag}(w_{jr,1}, \ldots, w_{jr,p_j})$, $j = 1, \ldots, D$ and $r = 1, \ldots, R$ are margin-specific scale parameters for each component. The hierarchical margin-level prior is given by

$$\boldsymbol{\beta}_j^{(r)} \sim \text{N}\big(0, (\phi_r \tau)\boldsymbol{W}_{jr}\big), \quad w_{jr,k} \sim \text{Exp}(\lambda_{jr}^2/2), \quad \lambda_{jr} \sim \text{Ga}(a_\lambda, b_\lambda). \tag{9}$$

Collapsing over element-specific scales, notice that $\beta_{j,k}^{(r)} | \lambda_{jr}, \phi_r, \tau \overset{\text{iid}}{\sim} \text{DE}(\lambda_{jr}/\sqrt{\phi_r \tau})$, $1 \le k \le p_j$. Prior (9) induces a GDP prior on the individual margin coefficients which in turn has the form of an adaptive Lasso penalty (Armagan et al., 2013a). Flexibility in estimating $\boldsymbol{B}_r = \{\boldsymbol{\beta}_j^{(r)}; 1 \le j \le D\}$ is accommodated by modeling within-margin heterogeneity via element-specific scaling $w_{jr,k}$. Common rate parameter λ_{jr} shares information between margin elements, encouraging shrinkage at the local scale.

The framework adpoted by Zhou et al. (2013) for Frequentist tensor regression starts by assuming the true parafac rank and relying on shrinkage through a global parameter for estimating the tensor coefficient. In contrast, M-DGDP prior proposes joint shrinkage on the global and local component parameters to achieve improved inference and estimation. Though rank-selection is not our purview, our prior also accomodates dimension reduction by favoring low-rank factorizations as discussed below.

4. Posterior Consistency for Tensor Regression

This Section details out theoretical properties of the tensor regression framework.

4.1 Notation and Framework

We establish convergence results for tensor regression model (5) under the simplifying assumptions that the intercept is omitted by centering the response and the error variance is $\sigma^2 = 1$. Since our main focus is on the tensor coefficient, we assume coefficients for ordinary scalar covariates to be known. Without loss of generality, we assume $\boldsymbol{\gamma} = (0, \ldots, 0)$. We consider an asymptotic setting in which the dimensions of the tensor grow with n. This paradigm attempts to capture the fact that tensor dimension $\prod_j p_{j,n}$ is typically substantially larger than sample size. This creates theoretical challenges, related to (but distinct from) those faced in showing posterior consistency for high dimensional regression (Armagan et al., 2013b) and multiway contingency tables (Zhou et al., 2015).

Suppose the data generating model comes from the same class of models where the fitted model belongs to, i.e., having true tensor parameter $\boldsymbol{B}_n^0 \in \otimes_{j=1}^D \Re^{p_j, n}$, error variance $\sigma_0^2 = 1$. We also assume that the true tensor coefficient $\boldsymbol{B}_n^0$ generating the data admits a

rank-R PARAFAC decomposition as below

$$\boldsymbol{B}_n^0 = \sum_{r=1}^R \boldsymbol{\beta}_{1,n}^{0(r)} \circ \cdots \circ \boldsymbol{\beta}_{D,n}^{0(r)}, \qquad \boldsymbol{\beta}_{j,n}^{0(r)} = (\beta_{j,n,1}^{0(r)}, \ldots, \beta_{j,n,p_{j,n}}^{0(r)})' \in \Re^{p_{j,n}}.$$

In addition, define $\boldsymbol{F}_n, \boldsymbol{F}_n^0 \in \Re^{R \sum_{j=1}^D p_{j,n}}$ as the vectorized parameters:

$$\boldsymbol{F}_n = \text{vec}\big(\boldsymbol{\beta}_{1,n}^{(1)}, \cdots, \boldsymbol{\beta}_{1,n}^{(R)}, \cdots, \boldsymbol{\beta}_{D,n}^{(1)}, \cdots, \boldsymbol{\beta}_{D,n}^{(R)}\big)$$
$$\boldsymbol{F}_n^0 = \text{vec}\big(\boldsymbol{\beta}_{1,n}^{0(1)}, \cdots, \boldsymbol{\beta}_{1,n}^{0(R)}, \cdots, \boldsymbol{\beta}_{D,n}^{0(1)}, \cdots, \boldsymbol{\beta}_{D,n}^{0(R)}\big).$$

Define a Kulback-Leibler (KL) neighborhood around the true tensor $\boldsymbol{B}_n^0$ as

$$\mathcal{B}_n = \left\{ \boldsymbol{B}_n : \frac{1}{n} \sum_{i=1}^n \text{KL}(f(y_i|\boldsymbol{B}_n^0), f(y_i|\boldsymbol{B}_n)) < \epsilon \right\}.$$

Denote $\text{KL}(f(y_i|\boldsymbol{B}_n^0), f(y_i|\boldsymbol{B}_n))$ as KL_i. The KL-distance between $\text{N}(\mu_1, \sigma_1^2)$ and $\text{N}(\mu_2, \sigma_2^2)$ is $\log(\sigma_2/\sigma_1) + \big(\sigma_1^2 + (\mu_1 - \mu_2)^2\big)/2\sigma_2^2 - \frac{1}{2}$, so it follows $\text{KL}_i = \text{KL}\left(\text{N}\big(\langle \boldsymbol{X}_i, \boldsymbol{B}_n \rangle, 1\big), \text{N}\big(\langle \boldsymbol{X}_i, \boldsymbol{B}_n^0 \rangle, 1\big)\right)$ $= \frac{1}{2}\left(\langle \boldsymbol{X}_i, \boldsymbol{B}_n^0 \rangle - \langle \boldsymbol{X}_i, \boldsymbol{B}_n \rangle\right)^2$. Hence, a KL neighborhood of radius ϵ around $\boldsymbol{B}_n^0$ can be re-expressed as $\mathcal{B}_n = \left\{ \boldsymbol{B}_n : \frac{1}{2n} \sum_{i=1}^n \left(\langle \boldsymbol{X}_i, \boldsymbol{B}_n^0 \rangle - \langle \boldsymbol{X}_i, \boldsymbol{B}_n \rangle\right)^2 < \epsilon \right\}$. Further, let π_n and Π_n denote prior and posterior densities with n observations, respectively, and

$$\Pi_n(\mathcal{B}_n^c) = \frac{\int_{\mathcal{B}_n^c} f(\boldsymbol{y}_n|\boldsymbol{B}_n)\pi_n(\boldsymbol{F}_n)}{\int f(\boldsymbol{y}_n|\boldsymbol{B}_n)\pi_n(\boldsymbol{F}_n)},$$

with $\boldsymbol{y}_n = (y_1, \ldots, y_n)'$ and $f(\boldsymbol{y}_n|\boldsymbol{B}_n)$ is the density of $\boldsymbol{y}_n$ under model (5). Posterior consistency is established by showing that

$$\Pi_n\left(\mathcal{B}_n^c\right) \to 0 \quad \text{under } \boldsymbol{B}_n^0 \quad \text{a.s. as } n \to \infty. \tag{10}$$

4.2 Main Result

Our main theorem is that (10) holds under a simple sufficient condition on the prior and the tensor predictors.

Theorem 1 *Let* $\zeta_n = n^{\frac{1+\rho_3}{2}}$ $(\rho_3 > 0)$, $M_n = \frac{1}{n}\sqrt{\sum_{i=1}^n ||\boldsymbol{X}_i||_2^2}$. *Given Lemma 6 in Appendix A, for any* $\epsilon > 0$, $\Pi_n(\boldsymbol{B}_n : \frac{1}{n}\sum_{i=1}^n KL_i > \epsilon) \to 0$ *a.s. under* $\boldsymbol{B}_n^0$, *for the prior* $\pi_n(\boldsymbol{B}_n)$ *that satisfies*

$$\pi_n\left(\boldsymbol{B}_n : ||\boldsymbol{B}_n - \boldsymbol{B}_n^0||_2 < \frac{2\eta}{3M_n\zeta_n}\right) > \exp(-dn), \ \textit{for all large } n \tag{11}$$

for any $d > 0$ *and* $\eta < \frac{\epsilon}{32} - d$. *That is, the model is posterior consistent when* (11) *holds.*

Lemma 6 in Appendix A verifies the existence of exponentially-consistent tests. The proof of the Lemma and Theorem are provided in the Appendix A. The proposed multiway shrinkage prior satisfies (11) and hence leads to posterior consistency under the following Theorem.

Theorem 2 *For fixed constants H_1, H_2, M_1, ρ_1 and $\rho_2 > 0$, the M-DGDP prior (9) on $\boldsymbol{B}_n$ satisfies (11), i.e. yields posterior consistency under conditions:*

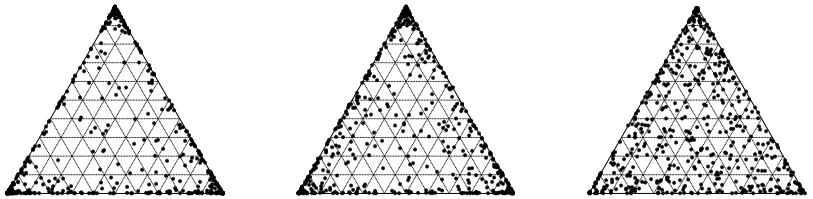
(a) $H_1 n^{\rho_1} < M_n < H_2 n^{\rho_2}$

(b) $\sup_{l=1,\ldots,p_{j,n}} |\boldsymbol{\beta}^{0(r)}_{j,n,l}| < M_1 < \infty$, *for all* $j = 1, \ldots, D$, $r = 1, \ldots, R$

(c) $\sum_{j=1}^{D} p_{j,n} \log(p_{j,n}) = o(n)$.

Remark 3 *Condition (a) in Theorem 2 gives an upper and lower bound on the sum of the Frobenius norms of tensor predictors. In tensor predictors with $\{0,1\}$ entries (often observed for white/grey matter fMRI data), this condition simply imposes a restriction on the minimum and maximum number of 1s in a tensor predictor as a function of the sample size n. Condition (b) is mild, assuming the supremum of all entries in the tensor margins are bounded. Finally, condition (c) in Theorem 2 requires that $\sum_{j=D} p_{j,n}$ grows sub-linearly with sample size n. However, note that the number of cells $\prod_{j=1}^{D} p_{j,n}$ in the tensor can grow at a rate much faster than the sample size n; hence, the modeling framework allows large tensor covariates even for moderate sample sizes. Of course, condition (c) trivially holds when the dimension of the tensor is kept fixed as n grows.*

Remark 4 *Our Section on posterior consistency is based on the assumption that $\boldsymbol{\gamma} = (0, \ldots, 0)'$ and error variance 1, however the results are trivially extendable to cases with unknown $\boldsymbol{\gamma}$ and σ^2. In such a generalization, it is important to note that one would need to assume the dim($\boldsymbol{\gamma}$) is fixed and not growing with n.*



4.3 Prior Hyper-parameter Elicitation

The marginal distribution of cell coefficients (6) under the proposed M-DGDP prior (9) is not available in closed-form. To assess how a shrinkage prior on the margins induces prior on cell coefficients of the tensor, we turn to an expression for the cell-level variance:

$$\begin{aligned}
\text{var}(\boldsymbol{B}_{i_1,\ldots,i_D}) &= \mathbb{E}\Big(\text{var}\Big\{ \sum_{r=1}^{R} \prod_{j=1}^{D} \boldsymbol{\beta}^{(r)}_{j,i_d} \,|\, \boldsymbol{W}, \Lambda, \Phi, \tau \Big\} \Big) \\
&= \mathbb{E}_{\Phi}\Big(\sum_{r=1}^{R} \phi_r^D \, \mathbb{E}_{\tau}\{\tau^D\} \, \mathbb{E}_{\Lambda_{\cdot,r}}\Big\{ \mathbb{E}_{\boldsymbol{W}_r|\boldsymbol{\Lambda}_r}\Big(\prod_{j=1}^{D} w_{jr,i_j} \Big) \Big\} \Big) \\
&= \frac{\Gamma(\alpha_0 + D)}{\Gamma(\alpha_0)\, b_\tau^D} (2C_\lambda)^D \, \mathbb{E}_{\Phi}\Big(\sum_{r=1}^{R} \phi_r^D \Big).
\end{aligned}$$

The following Lemma provides lower and upper bounds on the variance that can be useful for elicitation of default hyperparameter values.

Lemma 5 *Under M-DGDP shrinkage prior (9) and for $D > 1$, if $\alpha_1 = \cdots = \alpha_R = c/R$, $c \in \mathbb{N}_+$, with constants $C_\lambda = b_\lambda^2/\big((a_\lambda - 1)(a_\lambda - 2)\big)$, $a_\lambda > 2$, $A_\tau = \exp((D^2 - 3D)/2)$, then the cell-level variance is bounded below by $R\alpha_1^D (2C_\lambda/b_\tau)^D$ and above by $A_\tau (2C_\lambda/b_\tau)^D \exp(\alpha_1 RD)$.*

(a) $\boldsymbol{\alpha} = (0.2, 0.2, 0.2)$ (b) $\boldsymbol{\alpha} = (0.3, 0.3, 0.3)$ (c) $\boldsymbol{\alpha} = (0.5, 0.5, 0.5)$

Figure 1: Visualization of points in the $\mathcal{S}^2$ probability simplex for 500 independent realizations of Dirichlet($\boldsymbol{\alpha}$). As $\alpha \downarrow 0$, points increasingly tend to concentrate around vertices of the $\mathcal{S}^{R-1}$ simplex. This notion of sparsity is made precise in Yang and Dunson (2014).

Hyperparameters of the Dirichlet component in multiway prior (9) play a key role in controlling dimensionality of the model, with smaller values favoring more component-specific scales $\tau_r \approx 0$, thus effectively collapsing on a low-rank tensor factorization. Figure 1 plots realizations from the Dirichlet distribution when $R = 3$ for different concentration parameters[2] α.

A discrete uniform prior is placed on α over a grid, $\mathcal{A}$. By default, grid values are chosen to be 10 equally spaced values in $[R^{-D}, R^{-0.10}]$, letting the data tune this parameter according to the degree of sparisty present. Armagan et al. (2013a) study various choices of $(a_\lambda, \zeta = b_\lambda/a_\lambda)$ that lead to desirable shrinkage properties, such as Cauchy-like tails for $\beta^{(r)}_{j,k}$ while retaining Laplace-like shrinkage near zero. Empirical results from simulation studies across a variety of settings in Section 6 reveal no strong sensitivity to choices for hyper-parameters a_λ, b_λ. From Lemma 5, setting $a_\lambda = 3$ and $b_\lambda = \sqrt[2D]{a_\lambda}$ avoids overly narrow variance of the induced prior on tensor elements, $\boldsymbol{B}_{i_1,\ldots,i_D}$. Table 1 provides various quantiles of the induced prior on these elements under these default hyperparameter settings as a function of the parafac rank-R and tensor dimension D.

5. Posterior Computation and Model Fitting

Letting $y \in \Re$ denote a response, and $\boldsymbol{z} \in \Re^p, \boldsymbol{X} \in \otimes_{j=1}^{D} \Re^{p_j}$ predictors, we let

$$\begin{aligned}
& y|\boldsymbol{\gamma}, \boldsymbol{B}, \sigma \sim \text{N}\big(\boldsymbol{z}'\boldsymbol{\gamma} + \langle \boldsymbol{X}, \boldsymbol{B} \rangle, \sigma^2\big) \\
& \boldsymbol{B} = \sum_{r=1}^{R} \boldsymbol{B}_r, \;\; \boldsymbol{B}_r = \boldsymbol{\beta}_1^{(r)} \circ \cdots \circ \boldsymbol{\beta}_D^{(r)} \\
& \sigma^2 \sim \pi_\sigma, \;\; \boldsymbol{\gamma} \sim \pi_\gamma, \;\; \boldsymbol{\beta}_j^{(r)} \sim \pi_{\boldsymbol{\beta}}.
\end{aligned} \tag{12}$$

2. For simplicity we assume $\alpha_1 = \cdots = \alpha_R = \alpha$.

	R	5%	25%	50%	75%	95%

	10	0.001	0.017	0.111	0.608	5.996

Table 1: Percentiles for $|\boldsymbol{B}_{i_1,\ldots,i_D}|$ under the M-DGDP prior with default $a_\lambda = 3$, $b_\lambda = \sqrt[2D]{a_\lambda}$, $b_\tau = \alpha R^{1/D}\,(v=1)$ and $\alpha = 1/R$. Statistics are displayed as the parafac rank-R vary and dimension D of the tensor vary.

The noise variance is modeled using a conjugate inverse-gamma prior, $\sigma^2 \sim \text{IG}(v/2, vs_0^2/2)$, with $v=2$ and s_0^2 chosen by default so $\Pr(\sigma^2 \leq 1) = 0.95$ assuming a centered and scaled response. Regression coefficients are given a conjugate normal prior $\boldsymbol{\gamma} \sim \text{N}(0, \sigma^2\boldsymbol{\Sigma}_{0\boldsymbol{\gamma}})$ and the tensor predictor is normalized over all cells to have mean zero and variance 1, allowing one to assume default values for hyper-parameters in the proposed multiway prior.

5.1 Posterior Computation

The proposed multiway prior (9) leads to Gibbs sampling scheme for most parameters of the tensor regression model (12). We rely on marginalization and blocking to reduce auto-correlation for $\big\{(\boldsymbol{\beta}_j^{(r)}, w_{jr}; 1 \leq j \leq D, 1 \leq r \leq R), (\Phi, \tau), (\boldsymbol{\gamma}, \sigma)\big\}$, drawing in sequence from $[\alpha, \Phi, \tau|\boldsymbol{B}, W]$, $[\boldsymbol{B}, W|\Phi, \tau, \boldsymbol{\gamma}, \sigma, \boldsymbol{y}]$ and $[\boldsymbol{\gamma}, \sigma|\boldsymbol{B}, \boldsymbol{y}]$ as follows:

(1) Sample $[\alpha, \Phi, \tau|\boldsymbol{B}, \boldsymbol{W}]$ compositionally as $[\alpha|\boldsymbol{B}, \boldsymbol{W}][\Phi, \tau|\alpha, \boldsymbol{B}, \boldsymbol{W}]$:

(a) Sample from the conditional distribution of Dirichlet concentration parameter $[\alpha|\boldsymbol{B}, \boldsymbol{W}]$ via griddy-Gibbs: form a reference set by drawing M samples from $[\Phi, \tau|\alpha, \boldsymbol{B}, \boldsymbol{W}]$ for each $\alpha \in \mathcal{A}$. Set $w_{j,l} = \pi(\boldsymbol{B}|\alpha, \Phi_l, \tau_l, \boldsymbol{W})\pi(\Phi_l, \tau_l|\alpha)$, $1 \leq l \leq M$, $p(\alpha|\boldsymbol{B}, \boldsymbol{W}) = \pi(\alpha)\sum_{l=1}^M w_{j,l}/M$, and $\Pr(\alpha = \alpha_j|-) = p(\alpha_j|\boldsymbol{B}, \boldsymbol{W})/\sum_{\alpha\in\mathcal{A}} p(\alpha|\boldsymbol{B}, \boldsymbol{W})$.

(b) Sample component-specific scales as $[\Phi, \tau|\alpha^*, \boldsymbol{B}, \boldsymbol{W}] = [\Phi|\boldsymbol{B}, \boldsymbol{W}][\tau|\Phi, \boldsymbol{B}, \boldsymbol{W}]$; define $p_0 = \sum_{j=1}^D p_j$, and recall $a_\tau = \sum_{r=1}^R \alpha_r = R\alpha$ and $b_\tau = \alpha(R/v)^{1/D}$ (see Section 3.3), then

- draw $\psi_r \sim \text{giG}(\alpha - p_0/2, 2b_\tau, 2C_r)$, $C_r = \sum_{j=1}^D \boldsymbol{\beta}_j^{(r)T}\boldsymbol{W}_{jr}^{-1}\boldsymbol{\beta}_j^{(r)}$, and set $\phi_r = \psi_r/\sum_{l=1}^R \psi_l$ in parallel for $1 \leq r \leq R$ (see Appendix A for definition of 'giG')
- draw $\tau \sim \text{giG}(a_\tau - Rp_0/2, 2b_\tau, 2\sum_{r=1}^R D_r)$, $D_r = C_r/\phi_r$.

(2) Sample from $\big\{(\boldsymbol{\beta}_j^{(r)}, w_{jr}, \lambda_{jr}); 1 \leq j \leq D, 1 \leq r \leq R\big\}|\Phi, \tau, \boldsymbol{\gamma}, \sigma, \boldsymbol{y}$ using a back-fitting procedure to produce a sequence of draws from the margin-level conditional distributions across components. For $r = 1, \ldots, R$ and $j = 1, \ldots, D$, sample from conditional distribution $[(\boldsymbol{\beta}_j^{(r)}, w_{jr}, \lambda_{jr})|\boldsymbol{\beta}_{-j}^{(r)}, \boldsymbol{B}_{-r}, \Phi, \tau, \boldsymbol{\gamma}, \sigma, \boldsymbol{y}]$, where $\boldsymbol{\beta}_{-j}^{(r)} = \{\boldsymbol{\beta}_l^{(r)}, l \neq j\}$ and $\boldsymbol{B}_{-r} = \boldsymbol{B} \setminus \boldsymbol{B}_r$;

(a) draw $[w_{jr}, \lambda_{jr}|\boldsymbol{\beta}_j^{(r)}, \phi_r, \tau] = [w_{jr}|\lambda_{jr}, \boldsymbol{\beta}_j^{(r)}, \phi_r, \tau][\lambda_{jr}|\boldsymbol{\beta}_j^{(r)}, \phi_r, \tau]$:

- draw $\lambda_{jr} \sim \text{Ga}\big(a_\lambda + p_j, b_\lambda + ||\boldsymbol{\beta}_j^{(r)}||_1/\sqrt{\phi_r\tau}\big)$; and
- draw $w_{jr,k} \sim \text{giG}\big(\frac{1}{2}, \lambda_{jr}^2, \beta_{j,k}^{2\,(r)}/(\phi_r\tau)\big)$ independently for $1 \leq k \leq p_j$

(b) draw $\boldsymbol{\beta}_j^{(r)} \sim \text{N}(\boldsymbol{\mu}_{jr}, \boldsymbol{\Sigma}_{jr})$: define $h_{i,j,k}^{(r)} = \sum_{d_1=1,\ldots,d_D=1}^{p_1,\ldots,p_D} I(d_j = k)\, x_{d_1,\ldots,d_D}\big(\prod_{l\neq j}\beta_{l,i_l}^{(r)}\big)$, $\boldsymbol{H}_{i,j}^{(r)} = (h_{i,j,1}^{(r)}, \ldots, h_{i,j,p_j}^{(r)})'$, $\tilde{y}_i = y_i - \boldsymbol{z}_i'\boldsymbol{\gamma} - \sum_{l\neq r}\langle \boldsymbol{X}_i, \boldsymbol{B}_l\rangle$ for $1 \leq i \leq n$; then $\boldsymbol{\Sigma}_{jr} = \big(\boldsymbol{H}_j^{(r)T}\boldsymbol{H}_j^{(r)}/\sigma^2 + \boldsymbol{W}_{jr}^{-1}/(\phi_r\tau)\big)^{-1}$, $\boldsymbol{\mu}_{jr} = \boldsymbol{\Sigma}_{jr}\boldsymbol{H}_j^{(r)}\tilde{\boldsymbol{y}}/\sigma^2$

(3) Sample $[\boldsymbol{\gamma}, \sigma|\boldsymbol{B}, \boldsymbol{y}] = [\boldsymbol{\gamma}|\sigma, \tilde{\boldsymbol{y}}][\sigma^2|\tilde{\boldsymbol{y}}]$; define $\tilde{y}_i = y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}\rangle$ for $1 \leq i \leq n$, then

(a) draw $\sigma^2 \sim \text{IG}(a_\sigma, b_\sigma)$, $a_\sigma = (n+v)/2$, $b_\sigma = \big(vs_0^2 + ||\tilde{\boldsymbol{y}}||_2^2 - \tilde{\boldsymbol{y}}^T\boldsymbol{Z}\boldsymbol{\mu}_{\boldsymbol{\gamma}}\big)/2$

(b) draw $\boldsymbol{\gamma} \sim \text{N}\big(\boldsymbol{\mu}_{\boldsymbol{\gamma}}, \sigma^2\boldsymbol{\Sigma}_{\boldsymbol{\gamma}}\big)$, $\boldsymbol{\Sigma}_{\boldsymbol{\gamma}} = \big(\boldsymbol{Z}^T\boldsymbol{Z} + \boldsymbol{\Sigma}_{0\boldsymbol{\gamma}}^{-1}\big)^{-1}$, $\boldsymbol{\mu}_{\boldsymbol{\gamma}} = \boldsymbol{\Sigma}_{\boldsymbol{\gamma}}\boldsymbol{Z}^T\tilde{\boldsymbol{y}}$.

6. Simulation Studies

To illustrate finite-sample performance of the proposed multiway priors, we show results from a simulation study with various dimensionality (p, R) and define $\bar{b} = \max|\boldsymbol{B}^0_{i_1,\ldots,i_D}|$ as the maximum signal size. Throughout, set $p_j = p$, true error variance $\sigma_0^2 = 1$ and $\bar{b} = 1$ for convenience. In addition, we set the true vector coefficient $\boldsymbol{\gamma}_0 = (0, \ldots, 0)$ and focus exclusively on inference for tensor parameter $\boldsymbol{B}$. The following simulated setups are considered:

1. "Generated" tensor: We construct tensor parameters having rank $R_0 = \{3, 5\}$ with $p = \{64, 100\}$ and $D = 2$.

2. "Ready made" tensor: We use three tensor (2D) images without generating them from a parafac decomposition with known rank.

Five replicated datasets with $n = 1000$ are generated according to (12) with $x_{i_1,\ldots,i_D} \sim \text{N}(0, 1)$. The tensor parameters considered are shown in Figure 2, where the magnitude of the non-zero cells is $\bar{b} = 1$. Examples are chosen to demonstrate recovery of cell-level coefficients across varying degrees of complexity (dimension, parafac rank) and sparsity (% of non-zero cells; see Figure 2). The performance of our method with M-DGDP prior (9) (BTR) is compared with (i) frequentist tensor regression with penalization (FTR)(Zhou et al., 2013); and (ii) Lasso (on the vectorized tensor predictor). Comparisons are based on (a) cell mean squared estimation error (true non-zero, true zero, and overall); and (b) frequentist coverage (and length) of 95% credible intervals.

By default, BTR uses $R = 10$ as an upper bound on the tensor parafac rank, minimizing effects of extra dimensions automatically and concentrating on a lower rank coefficient tensor as MCMC proceeds. We ran FTR with various choices of R and found equivalent performance for R between 3 to 15, thus the default value is set to $R = 10$ to ensure comparability with the BTR fitting. MCMC for BTR was run for 1300 iterations, with a 300 iteration burn-in and remaining samples thinned by 5. The latter was chosen to keep runtime between BTR and FTR similar for 3D simulation studies in Section 7. There, the total runtime using non-optimized R code on an x86×64 Intel(R) Core(TM) i7-3770 is between 6.2 - 7.5 hours. In simulation studies, the tuning parameter in FTR is selected

Table 2: Comparison of cell estimation as measured by root mean squared error (RMSE) for the six 2D tensor images portrayed in Figure 2. Results from FTR (Zhou et al., 2013) use $R = 10$. For BTR, $R = 10$ is used as an upper bound to the tensor parafac rank. Subscript shows the standard error over a few replicated simulations.

over a grid of values to minimize RMSE for the tensor predictor[3]. In real applications, cross validation instead would be used to select the tuning parameter that results in lowest hold-out predictive RMSE for FTR. Assuming 10-fold cross validation were used over a vector of 20 tuning parameters, FTR would have a runtime of approximately 8 hours. It also needs to be mentioned that the convergence of parameters in BTR is extremely rapid with an average effective sample size (ESS) ≈ 600 over 1000 iterations.

Cell-level RMSE reported in Table 2 demonstrates that our method (BTR) consistently out performs FTR. When the tensor parameter has a low-rank parafac decomposition ('R3-ex' and 'R5-ex'), BTR and FTR perform best, with BTR having lower RMSE on both true zero and non-zero cells. This validates empirically prior (9) along with our suggested default hyper-parameter choices in Section 3. In particular, the tensor coefficient in BTR has three different types of shrinkage parameters: global, local and shrinkage across ranks. Such a careful construction of shrinkage prior on $\boldsymbol{B}$ adapts to varying degrees of sparsity, shrinking many tensor coefficients close to zero while accurately estimating nonzero cells. FTR shrinkage being dependent on only local parameters suffers in terms of both inferential and predictive performances.

Table 3 demonstrate that BTR yields 95% credible intervals with good frequentist coverage across each of the simulated settings, both overall as well as on the true non-zero coefficients. Our method is one of the first to offer uncertainty quantification for tensor valued predictors.Finally, Table 4 provides evidence of the robustness of our method to increasing predictor dimension using two of the simulated examples. In both cases, RMSE for FTR worsens considerably on the true zero coefficients. For the true nonzero cells, RMSE increases for both methods as the margin dimension increases; however on a relative basis, FTR worsens considerably more, while on an absolute scale, BTR remains the clear winner.

3. To choose initial values, a preliminary analysis was run with a coarsened 16×16 image.

7. Simulated response with a real 3D brain image

We analyze data containing 3D MRI images for 550 adolescents, with information such as age and sex available. Age and sex are treated as ordinary scalar covariates while 3D MRI images act as tensor covariates. Let $\boldsymbol{X}$ denote a $30\times30\times30$ 3D MRI image, Z_1 be the age and Z_2 be the sex of an individual. The response is simulated using $y \sim \text{N}\left(\boldsymbol{Z}'\boldsymbol{\gamma} + \langle \boldsymbol{X}, \boldsymbol{B}_0\rangle, \sigma^2\right)$, where $\boldsymbol{Z}$ denotes $(Z_1, Z_2)'$, $\boldsymbol{\gamma} \in \mathcal{R}^2$ and $\boldsymbol{B}_0 \in \mathcal{R}^{30\times30\times30}$.

We assume the true $\boldsymbol{B}_0$ is a rank 2 tensor, with $\boldsymbol{B}_0 = \boldsymbol{a}_1 \circ \boldsymbol{a}_2 \circ \boldsymbol{a}_3 + \boldsymbol{b}_1 \circ \boldsymbol{b}_2 \circ \boldsymbol{b}_3$. Initialization and standardization of predictors follow exactly as prescribed in Section 5. By varying $\boldsymbol{a}_i$'s and $\boldsymbol{b}_i$'s, the following cases with varying degrees of sparsity in the tensor parameter $\boldsymbol{B}_0$ are considered:
Case 1: $\boldsymbol{b}_1 = \boldsymbol{b}_2 = (0, \ldots, 0, \sin((1:15) * \pi/4))$, $\boldsymbol{b}_3 = (\sin((1:10) * \pi/4), 0, \ldots, 0)$,
$\boldsymbol{a}_1 = (0, \ldots, 0, \sin((1:10) * \pi/4))$, $\boldsymbol{a}_2 = (0, \ldots, 0, \cos((1:15) * \pi/4))$,
$\boldsymbol{a}_3 = (\sin((1:15) * \pi/4), 0, \ldots, 0)$.
Case 2: $\boldsymbol{b}_1 = \boldsymbol{b}_2 = (0, \ldots, 0, \sin((1:15) * \pi/6))$, $\boldsymbol{b}_3 = (\sin((1:20) * \pi/6), 0, \ldots, 0)$,
$\boldsymbol{a}_1 = (0, \ldots, 0, \sin((1:15) * \pi/4))$, $\boldsymbol{a}_2 = (0, \ldots, 0, \cos((1:10) * \pi/6))$,
$\boldsymbol{a}_3 = (\sin((1:15) * \pi/6), 0, \ldots, 0)$.
Case 3: $\boldsymbol{b}_1 = \boldsymbol{b}_2 = (0, \ldots, 0, \sin((1:20) * \pi/6))$, $\boldsymbol{b}_3 = (\sin((1:20) * \pi/6), 0, \ldots, 0)$,
$\boldsymbol{a}_1 = (0, \ldots, 0, \sin((1:10) * \pi/4))$, $\boldsymbol{a}_2 = (0, \ldots, 0, \cos((1:20) * \pi/4))$,
$\boldsymbol{a}_3 = (\sin((1:20) * \pi/6), 0, \ldots, 0)$.

We implement BTR, FTR, and Lasso on the vectorized tensor. As before, we present results for FTR with $R = 10$ (See additional discussion in Section 6 on FTR default setup). Point estimates for coefficients corresponding to age and sex covariates are provided in Table 6. Table 5 summarizes RMSEs for the estimated tensor coefficients for each method. BTR shows at least a 15% improvement over FTR on simulated cases considered. Evidently BTR tends to outperform FTR and vectorized lasso by a greater margin in less sparse settings as well. Importantly, every parameter in BTR is auto-tuned, while the `TensorReg` toolbox used for FTR (Zhou et al., 2013) requires calibrating tuning parameter values specific to each setting. Note that rather than using cross validation, tuning parameters in these experiments were chosen to provide the lowest possible (most optimistic) RMSE for the tensor coefficient. FTR fixes $R = 10$ based on findings discussed in Section 6 while BTR sets $R = 10$ as an upper bound, concentrating on a lower dimension parafac rank via adaptive shrinkage. While vectorized lasso and FTR do not come equipped with parameter uncertainty estimates, Table 7 demonstrates how BTR consistently provides over 95% coverage across examples with varying degrees of sparsity.

Finally, Table 8 provides a measure of mixing efficiency for a single MCMC run in each of the simulated cases considered (post burn-in over the remaining 1000 MCMC samples). All reported RMSE and coverage statistics were computed over these draws as well (thinning by 5 as previously discussed in Section 6).

8. Brain Connectome Data Analysis

Brain connectome data are known by neuroscientists to have low signal-to-noise ratio, and effective modeling is often hindered as the sample size is often very limited compared to the

number of cells in the tensor predictor. In this setting, developing well calibrated predictive models is thus of key importance.

To investigate the performance of competing methods outside the class of fMRI brain image data, we present an analysis using a brain connectome dataset on structural connectivity. Data are extracted from diffusion tensor imaging (DTI) and consist of estimates of the number of "fibers" connecting pairs of brain regions for 109 individuals. For each individual, brain connections among 70 brain regions (following desikan atlas) are encoded by a 70×70 weighted adjacency matrix. The (i, j)-th off-diagonal entry in the adjacency matrix is the estimated number of fiber tracts connecting the i-th and j-th brain region. The data also provides 10 clinical covariates for every individual, including sex, age, openness, agreeableness and conscientiousness.

The focus of this study is on developing a predictive model with Creativity Composite Index (CCI) as a response fitted against clinical covariates and a tensor covariate (i.e., the weighted adjacency matrix). Implementing FTR on this data using the `TensorReg` package was attempted, however, functions in the toolbox require $n > R \times p$. In this example, because $n = 109$ and $p = 70$, it is only possible therefore to fit FTR with $R = 1$, which has previously been found to perform poorly by Zhou et al. (2013). We therefore compare our proposed method (BTR) to the vectorized Lasso on the basis of their predictive performance. To assess the predictive performance, the sample of $n = 109$ individuals are divided into 10 folds. Both vectorized lasso and BTR are fitted on 9 folds as training data and the remaining fold as the hold out sample. This is carried out for each of the 10 folds and predictive inferences are obtained for both vectorized lasso and BTR.

Table 9 reports the root mean squared error (RMSE) and correlation between observed and predicted responses, here average is over the 10 crossvalidated folds. For reference, average RMSE of the null model is 10.03 with a standard deviation of 2.40 across the

Method	avg(RMSE)	sd(RMSE)	avg(cov.)	sd(cov.)	avg(cor.)	sd(cor.)
Lasso	9.21	2.18	63%	20%	0.31	0.11
BTR	9.03	1.64	91%	10%	0.32	0.13

Table 9: mean and standard deviation of RMSEs and cor(y_{obs}, y_{pred}) of Lasso and BTR over 10 folds of the data. It also provides mean and standard deviation of coverages of Lasso and BTR over 10 folds of the data

folds. Given the very high degree of sparsity in the connectome adjacency matrix, it is not surprising that the Lasso is competitive to BTR. However, note that BTR detects this signal with far fewer effective parameters as compared to vectorized lasso. Finally, we measure coverage of 95% predictive intervals for all competitors. The latter is of course a byproduct of our fully Bayesian approach (BTR), while for the Lasso we use a two-staged approach. First we estimate the regression coefficients and subsequently construct approximate 95% predictive intervals based on the normal response-model centered on the predictive mean with variance equal to the estimated residual variance.

9. Discussion

This work develops a novel class of prior distributions on tensor valued predictors which substantially reduces dimensionality relative to vectorizing, providing a multiway analogue of vector shrinkage priors, and enabling high dimensional region selection. The prior on tensor coefficient constructed here imparts shrinkage of the tensor components at global and local levels, while also encouraging shrinkage towards low rank tensor decomposition. In contrast, existing penalization framework on the tensor coefficient shrinks only at the global level. Strong theoretical results are proved for the proposed class of multiway shrinkage priors and a computationally efficient MCMC algorithm is developed in the regression setting. We plan to extend methods developed here to settings where the measured response for each subject is binary (e.g., indicator of a heath outcome) or multivariate, i.e., $\boldsymbol{y} = (y_1, ..., y_d)$. Also, the current framework of Bayesian tensor regression fixes rank R of the PARAFAC decomposition at reasonably large value. It might be of interest to learn the PARAFAC rank R by adding a discrete prior distribution on R.

In various longitudinal studies, monitoring the evolution in the predictor response relationship (i.e., changes to the scalar and tensor parameters) is of fundamental interest. One application involves subjects receiving various treatments (e.g., chemotherapy), with tensor valued predictors corresponding to mRI (fMRI) scans obtained at regular intervals over a period of time. In such settings it is of crucial importance to monitor the progression of the disease in response to the treatment being administered. We plan to extend our method to such settings.

Acknowledgement

The authors would like to thank Joshua T. Vogelstein from Johns Hopkins university for gracefully allowing us to utilize their brain connectome dataset in the real data analysis of our proposed BTR method.

Appendix A

MCMC algorithm

The following derivations concern the M-DGDP prior (9) and the sampling algorithm outlined in Section 5.1.

For step (1b) Recall from Section 3.3 that $\tau \sim \text{Ga}(a_\tau, b_\tau)$ and $\Phi \sim \text{Dirichlet}(\alpha_1, \ldots, \alpha_R)$ and denote $p_0 = \sum_{j=1}^D p_j$. Then,

$$\begin{aligned}
\pi(\Phi|\boldsymbol{B}, \boldsymbol{\omega}) &\propto \pi(\Phi) \int_0^\infty \pi(\boldsymbol{B}|\boldsymbol{\omega}, \Phi, \tau)\pi(\tau)d\tau \\
&\propto \Big[\prod_{r=1}^R \phi_r^{\alpha_r - 1}\Big] \int_0^\infty \prod_{r=1}^R \Big[(\tau\phi_r)^{-p_0/2} \exp\Big(-\frac{1}{\tau\phi_r}\sum_{j=1}^d ||\boldsymbol{\beta}_{jr}||^2/(2\omega_{jr})\Big)\Big] \tau^{a_\tau - 1}\exp(-b_\tau\tau)d\tau \\
&\propto \Big[\prod_{r=1}^R \phi^{\alpha_r - \frac{p_0}{2} - 1}\Big] \int_0^\infty \tau^{a_\tau - R\frac{p_0}{2} - 1} \prod_{r=1}^R \exp\Big(-\frac{C_r}{\tau\phi_r} - b_\tau(\tau\phi_r)\Big)\, d\tau
\end{aligned}$$

with $C_r = \sum_{j=1}^d ||\boldsymbol{\beta}_{jr}||^2/(2\omega_{jr})$. When $a_\tau = \sum_{r=1}^R \alpha_r$, this contains the kernel of a generalized inverse Gaussian (gIG) distribution for $(\tau\phi_r)$. Recall: $X \sim f_X(x) = \text{giG}(p, a, b) \propto x^{p-1}\exp(-(ax + b/x)/2)$. Following Lemma 9 in the Appendix B, for independent random variable $T_r \sim f_r$ on $(0, \infty)$, the joint density of $\{\phi_r = T_r/\sum_{\tilde{r}} T_{\tilde{r}} : r = 1, \ldots, R\}$ has support on $\mathcal{S}^{R-1}$. In particular,

$$f(\phi_1, \ldots, \phi_{R-1}) = \int_0^\infty t^{R-1} \prod_{r=1}^R f_r(\phi_r t)\, dt, \quad \phi_R = 1 - \sum_{r<R} \phi_r.$$

Substituting $f_r(x) \propto x^{-\delta_r}\exp(-C_r/x)\exp(-b_\tau x)$ in the above expression yields

$$\begin{aligned}
f(\phi_1, \ldots, \phi_{R-1}) &\propto \int_0^\infty \tau^{R-1} \prod_{r=1}^R (\phi_r\tau)^{-\delta_r} \exp\Big(-\frac{C_r}{(\phi_r\tau)} - b_\tau(\phi_r\tau)\Big)d\tau \\
&= \Big[\prod_{r=1}^R \phi^{-\delta_r}\Big] \int_0^\infty \tau^{R - \sum_r \delta_r - 1} \prod_{r=1}^R \exp\Big(-\frac{C_r}{(\phi_r\tau)} - b_\tau(\phi_r\tau)\Big)d\tau.
\end{aligned}$$

Matching exponents between this expression and the preceding one implies (1) $a_\tau - R(p_0/2) - 1 = R - \sum_r \delta_r - 1$, and (2) $\delta_r = 1 + p_0/2 - \alpha_r$. Then,

$$a_\tau = R(1 + p_0/2) - \sum_r \delta_r = R(1 + p_0/2) - (R + Rp_0/2 - \sum_r \alpha_r) = \sum_r \alpha_r$$

as previously noted. Hence, draws from $[\Phi|\alpha, \boldsymbol{B}, \boldsymbol{W}]$ are obtained by sampling $T_r \sim f_r = \text{giG}(\alpha_r - p_0/2, 2b_\tau, 2C_r)$ independently for $r = 1, \ldots, R$, and renormalizing.

Proof of lemma 5

Proof Using priors defined in (9), one has $C_\lambda = \mathbb{E}_\lambda(1/\lambda^2) = \frac{b_\lambda^2}{(a_\lambda-1)(a_\lambda-2)}$ for any $a_\lambda > 2$. In addition, the following inequalities are useful to bound the latter quantity:

- If $\alpha_1 = c/R$, $c \in \mathbb{N}_+$, $\Gamma(\alpha_0+D)/\Gamma(\alpha_0) = \alpha_0(\alpha_0+1)\cdots(\alpha_0+D-1)$. Using the fact that $\log(x+1) \leq x$, $x \geq 0$, one has $\log(\alpha_0)+\cdots+\log(\alpha_0+D-1) \leq \alpha_0 D - 1 + \sum_{k=1\vee D-2}^{D-2} k$. Then $\alpha_0^D \leq \Gamma(\alpha_0+D)/\Gamma(\alpha_0) \leq A_\tau \exp(\alpha_0 D)$ where $A_\tau = \exp(-1+\sum_{k=1\vee D-2}^{D-2} k) = \exp\big((D^2-3D)/2\big)$, $D \geq 2$.
- Let $||x||_r$ denote the L^rth norm. Trivially, $||\Phi||_D^D \leq 1$; in addition, by Hölder's inequality, for any $x \in \Re^k$ and $0 < r < p$, one has $||x||_p \geq k^{-\left(\frac{1}{r}-\frac{1}{p}\right)}||x||_r$. In our setting, $D \geq 2$. Taking $r = 1$ in the latter yields $||\Phi||_D^D \geq R^{-(D-1)}$.

Recall $\alpha_0 = \sum_{r=1}^R \alpha_r = \alpha_1 R$. This leads to the lower and upper bounds for the prior voxel-level variance:

$$\begin{aligned}\text{var}(B_{i_1,\ldots,i_D}) &\geq (2C_\lambda)^D (\alpha_1 R)^D R^{-(D-1)}/b_\tau^D \;= (2C_\lambda)^D \alpha_1^D R/b_\tau^D \\ \text{var}(B_{i_1,\ldots,i_D}) &\leq A_\tau (2C_\lambda)^D \exp(\alpha_1 RD)/b_\tau^D.\end{aligned}$$

■

Consistency proofs

The proof of Theorem 1 relies in part on the existence of exponentially consistent tests.

Definition An exponentially consistent sequence of test functions $\Phi_n = I(\boldsymbol{y}_n \in \mathcal{C}_n)$ for testing $H_0 : \boldsymbol{B}_n = \boldsymbol{B}_n^0$ vs. $H_1 : \boldsymbol{B}_n \neq \boldsymbol{B}_n^0$ satisfies

$$\mathbb{E}_{\boldsymbol{B}_n^0}(\Phi_n) \leq c_1 \exp(-b_1 n), \qquad \sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} \mathbb{E}_{\boldsymbol{B}_n}(1-\Phi_n) \leq c_2 \exp(-b_2 n)$$

for some $c_1, c_2, b_1, b_2 > 0$.

Lemma 6 *There exist an exponentially consistent sequence of tests Φ_n for testing H_0 : $\boldsymbol{B}_n = \boldsymbol{B}_n^0$ vs. $H_1 : \boldsymbol{B}_n \neq \boldsymbol{B}_n^0$.*

Proof We begin by stating that $\sum_{i=1}^n \left(y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n^0\rangle\right)^2 \sim \chi_n^2$ under $\boldsymbol{B}_n^0$. We choose the critical region of the test Φ_n as $\mathcal{C}_n = \left\{\boldsymbol{B}_n : \frac{1}{n}\sum_{i=1}^n \left(y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n^0\rangle\right)^2 > \epsilon/4\right\}$. Note that

$$\mathbb{E}_{\boldsymbol{B}_n^0}(\Phi_n) = P_{\boldsymbol{B}_n^0}\Big(\sum_{i=1}^n \left(y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n^0\rangle\right)^2 > n\epsilon/4\Big) \leq \exp\Big(-\frac{n\epsilon}{16}\Big), \text{ for large n,}$$

where the last line follows by simplifying Lemma 1 in Laurent and Massart (2000).

Now we will use the fact that

$$\begin{aligned}&\frac{1}{n}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n^0\rangle)^2 \\ &= \frac{1}{n}\sum_{i=1}^n \left(y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle\right)^2 + \frac{1}{n}\sum_{i=1}^n \left(\langle \boldsymbol{X}_i, \boldsymbol{B}_n - \boldsymbol{B}_n^0\rangle\right)^2 + \frac{2}{n}\sum_{i=1}^n \left(y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle\right)\left(\langle \boldsymbol{X}_i, \boldsymbol{B}_n - \boldsymbol{B}_n^0\right) \\ &= \frac{1}{n}\sum_{i=1}^n \left(\langle \boldsymbol{X}_i, \boldsymbol{B}_n - \boldsymbol{B}_n^0\rangle\right)^2 + \frac{1}{n}\sum_{i=1}^n KL_i + \frac{2}{n}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle)\langle \boldsymbol{X}_i, \boldsymbol{B}_n - \boldsymbol{B}_n^0\rangle.\end{aligned}$$

Note that, under $\boldsymbol{B}_n$,

$$\frac{2}{n}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle)\langle \boldsymbol{X}_i, \boldsymbol{B}_n - \boldsymbol{B}_n^0\rangle \sim N(0, \frac{4}{n^2}\sum_{i=1}^n KL_i),$$

so that, $\frac{2}{n}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle)\langle \boldsymbol{X}_i, \boldsymbol{B}_n - \boldsymbol{B}_n^0\rangle = \sqrt{\frac{4}{n}\sum_{i=1}^n KL_i}\frac{Z}{\sqrt{n}}$, where $Z \sim N(0,1)$. Thus,

$$\begin{aligned}&\sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} \mathbb{E}_{\boldsymbol{B}_n}(1-\Phi_n) = \sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} P_{\boldsymbol{B}_n}\left(\frac{1}{n}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n^0\rangle)^2 \leq \epsilon/4\right) \\ &\leq \sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} P_{\boldsymbol{B}_n}\left(\left|\left|\sqrt{\frac{4}{n}\sum_{i=1}^n KL_i}\frac{Z}{\sqrt{n}} + \frac{1}{n}\sum_{i=1}^n KL_i\right| - \left|\frac{1}{n}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle)^2\right|\right| \leq \epsilon/4\right) \\ &\leq \sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} P_{\boldsymbol{B}_n}\left(\left|\sqrt{\frac{4}{n}\sum_{i=1}^n KL_i}\frac{Z}{\sqrt{n}} + \frac{1}{n}\sum_{i=1}^n KL_i\right| - \epsilon/4 \leq \left|\frac{1}{n}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle)^2\right|\right) \\ &\leq \sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} P_{\boldsymbol{B}_n}\left(\left|\frac{1}{n}\sum_{i=1}^n KL_i + \sqrt{\frac{4\sum_{i=1}^n KL_i}{n}}\frac{Z}{\sqrt{n}}\right| - \epsilon/4 \leq \left|\frac{1}{n}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle)^2\right|\right)\end{aligned}$$

Let $\mathcal{T}_n = \left\{\left|\sqrt{\frac{4\sum_{i=1}^n KL_i}{n}}\frac{Z}{\sqrt{n}}\right| \leq \frac{1}{2n}\sum_{i=1}^n KL_i\right\}$. Using this fact we have

$$\begin{aligned}&\sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} \mathbb{E}_{\boldsymbol{B}_n}(1-\Phi_n) \\ &\leq \sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} P_{\boldsymbol{B}_n}\left(\left\{\left|\frac{1}{n}\sum_{i=1}^n KL_i + \sqrt{\frac{4\sum_{i=1}^n KL_i}{n}}\frac{Z}{\sqrt{n}}\right| - \epsilon/4 \leq \left|\frac{1}{n}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle)^2\right|\right\} \cap \mathcal{T}_n\right) + \sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} P_{\boldsymbol{B}_n}(\mathcal{T}_n) \\ &\leq \sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} P_{\boldsymbol{B}_n}\left(\frac{1}{2n}\sum_{i=1}^n KL_i - \epsilon/4 \leq \left|\frac{1}{n}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle)^2\right|\right) + \sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} P_{\boldsymbol{B}_n}\left(\left|\frac{Z}{\sqrt{n}}\right| \geq \frac{1}{4}\sqrt{\frac{1}{n}\sum_{i=1}^n KL_i}\right) \\ &\leq P_{\boldsymbol{B}_n}\left(\frac{3\epsilon}{4} \leq \left|\frac{1}{n}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle)^2\right|\right) + P_{\boldsymbol{B}_n}\left(|Z| \geq \frac{1}{4}\sqrt{n\epsilon}\right) \\ &\leq P_{\boldsymbol{B}_n}\left(\frac{3n\epsilon}{4} \leq \chi_n^2\right) + P_{\boldsymbol{B}_n}\left(\chi_1^2 \geq \frac{n\epsilon}{4}\right) \leq \exp\left(-\frac{3n\epsilon}{16}\right) + \exp\left(-\frac{n\epsilon}{64}\right) \leq 2\exp\left(-\frac{n\epsilon}{64}\right),\end{aligned}$$

where the last line requires an application of Lemma 1 in Laurent and Massart (2000). ■

Theorem 1

Proof Under Lemma 6 one has

$$\Pi_n(\mathcal{B}_n^c) = \frac{\int_{\mathcal{B}_n^c} f(\boldsymbol{y}_n|\boldsymbol{B}_n)\pi_n(\boldsymbol{F}_n)}{\int f(\boldsymbol{y}_n|\boldsymbol{B}_n)\pi_n(\boldsymbol{F}_n)} = \frac{\int_{\mathcal{B}_n^c} \frac{f(\boldsymbol{y}_n|\boldsymbol{B}_n)}{f(\boldsymbol{y}_n|\boldsymbol{B}_n^0)}\pi_n(\boldsymbol{F}_n)}{\int \frac{f(\boldsymbol{y}_n|\boldsymbol{B}_n)}{f(\boldsymbol{y}_n|\boldsymbol{B}_n^0)}\pi_n(\boldsymbol{F}_n)} = \frac{N}{D} \leq \Phi_n + (1-\Phi_n)\frac{N}{D}.$$

Note that we have

$$P_{\boldsymbol{B}_n^0}\left(\Phi_n > \exp(-b_1 n/2)\right) \leq \mathbb{E}_{\boldsymbol{B}_n^0}\left(\Phi_n\right)\exp(b_1 n/2) \leq c_1 \exp(-b_1 n/2).$$

Therefore $\sum_{n=1}^{\infty} P_{\boldsymbol{B}_n^0}\left(\Phi_n > \exp(-b_1 n/2)\right) < \infty$. Using Borel-Cantelli lemma $P_{\boldsymbol{B}_n^0}\left(\Phi_n > \exp(-b_1 n/2) i.o.\right) = 0$. It follows that

$$\Phi_n \to 0 \quad a.s. \tag{13}$$

In addition, we have

$$\begin{aligned}
\mathbb{E}_{\boldsymbol{B}_n^0}((1-\Phi_n)N) &= \int (1-\Phi_n)\int_{\mathcal{B}_n^c} \frac{f(\boldsymbol{y}_n|\boldsymbol{B}_n)}{f(\boldsymbol{y}_n|\boldsymbol{B}_n^0)}\pi_n(\boldsymbol{F}_n) f(\boldsymbol{y}_n|\boldsymbol{B}_n^0) \\
&= \int_{\mathcal{B}_n^c}\int (1-\Phi_n) f(\boldsymbol{y}_n|\boldsymbol{B}_n)\pi_n(\boldsymbol{F}_n) \\
&\leq \sup_{\boldsymbol{B}_n \in \mathcal{B}_n^c} \mathbb{E}_{\boldsymbol{B}_n}(1-\Phi_n) \leq c_2 \exp(-b_2 n).
\end{aligned}$$

Using a similar technique as above, $P_{\boldsymbol{B}_n^0}\left((1-\Phi_n)N\exp(nb_2/2) > \exp(-nb_2/4) i.o.\right) = 0$ so

$$\exp(bn)(1-\Phi_n)N \to 0 \quad a.s.. \tag{14}$$

By Lemma 6 and (13)-(14) it is enough to show that $M = \exp(\tilde{b}n)\int \frac{f(\boldsymbol{y}_n|\boldsymbol{B}_n)}{f(\boldsymbol{y}_n|\boldsymbol{B}_n^0)}\pi_n(\boldsymbol{F}_n) \to \infty$ for some $\tilde{b} \leq b = \frac{\epsilon}{256}$. We choose $\tilde{b} = b$. Consider the set $\mathcal{H}_n = \left\{\boldsymbol{B}_n : \frac{1}{n}\log\left[\frac{f(\boldsymbol{y}_n|\boldsymbol{B}_n^0)}{f(\boldsymbol{y}_n|\boldsymbol{B}_n)}\right] < \eta\right\}$, for some η which is chosen later.

$$\begin{aligned}
M &\geq \exp(\tilde{b}n)\int_{\mathcal{H}_n} \exp\left(-n\frac{1}{n}\log\frac{f(\boldsymbol{y}_n|\boldsymbol{B}_n^0)}{f(\boldsymbol{y}_n|\boldsymbol{B}_n)}\right)\pi_n(\boldsymbol{F}_n) \\
&\geq \exp((\tilde{b}-\eta)n)\pi_n(\mathcal{H}_n).
\end{aligned}$$

Note that

$$\begin{aligned}
&\frac{1}{n}\log\left[\frac{f(\boldsymbol{y}_n|\boldsymbol{B}_n)}{f(\boldsymbol{y}_n|\boldsymbol{B}_n^0)}\right] \\
&= \frac{1}{n}\left[-\frac{1}{2}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n\rangle)^2 + \frac{1}{2}\sum_{i=1}^n (y_i - \langle \boldsymbol{X}_i, \boldsymbol{B}_n^0\rangle)^2\right].
\end{aligned}$$

Let $\boldsymbol{y}_n = (y_1, ..., y_n)'$, $\boldsymbol{H}_n = (\langle \boldsymbol{X}_1, \boldsymbol{B}_n\rangle, \ldots, \langle \boldsymbol{X}_n, \boldsymbol{B}_n\rangle)$ and $\boldsymbol{H}_n^0 = \left(\langle \boldsymbol{X}_1, \boldsymbol{B}_n^0\rangle, \ldots, \langle \boldsymbol{X}_n, \boldsymbol{B}_n^0\rangle\right)$. Then

$$\begin{aligned}
&\pi_n\Big(\boldsymbol{B}_n : \frac{1}{n}\left[-||\boldsymbol{y}_n - \boldsymbol{H}_n^0||^2 + ||\boldsymbol{y}_n - \boldsymbol{H}_n||^2\right] < 2\eta\Big) \\
&\geq \pi_n\Big(\boldsymbol{B}_n : \frac{1}{n}\left|2||\boldsymbol{y}_n - \boldsymbol{H}_n^0||\left(||\boldsymbol{y}_n - \boldsymbol{H}_n|| - ||\boldsymbol{y}_n - \boldsymbol{H}_n^0||\right) + \left(||\boldsymbol{y}_n - \boldsymbol{H}_n|| - ||\boldsymbol{y}_n - \boldsymbol{H}_n^0||\right)^2\right| < 2\eta\Big) \\
&\geq \pi_n\Big(\boldsymbol{B}_n : \frac{1}{n}\left|2||\boldsymbol{y}_n - \boldsymbol{H}_n^0||||\boldsymbol{H}_n^0 - \boldsymbol{H}_n|| + ||\boldsymbol{H}_n - \boldsymbol{H}_n^0||^2\right| < 2\eta\Big) \\
&\geq \pi_n\Big(\boldsymbol{B}_n : \frac{1}{n}||\boldsymbol{H}_n^0 - \boldsymbol{H}_n|| < \frac{2\eta}{3\zeta_n}, ||\boldsymbol{y}_n - \boldsymbol{H}_n^0||^2 < \zeta_n^2\Big) \\
&\geq \pi_n(\mathcal{A}_{1n} \cap \mathcal{A}_{2n})
\end{aligned}$$

where $\mathcal{A}_{1n} = \left\{\frac{1}{n}||\boldsymbol{H}_n - \boldsymbol{H}_n^0|| < \frac{2\eta}{3\zeta_n}\right\}$, $\mathcal{A}_{2n} = \left\{||\boldsymbol{y}_n - \boldsymbol{H}_n^0||^2 < \zeta_n^2\right\}$.

We will show that $P_{\boldsymbol{B}_n^0}(\mathcal{A}_{2n}) = 1$ for all large n. Assume $\zeta_n = n^{(1+\rho_3)/2}$, $\rho_3 > 0$ so that $\zeta_n^2 > 8n$ for all large n. Then,

$$P_{\boldsymbol{B}_n^0}(\mathcal{A}'_{2n}) = P_{\boldsymbol{B}_n^0}(\chi_n^2 > \zeta_n^2) \leq \exp(-\zeta_n^2/2).$$

Therefore, using Borel-Cantelli lemma $P_{\boldsymbol{B}_n^0}(\mathcal{A}'_{2n}\ i.o.) = 0$. Hence $P_{\boldsymbol{B}_n^0}(\mathcal{A}_{2n}) = 1$ for all large n. It is enough to bound $\pi_n(\mathcal{A}_{1n})$. Let $M_n = \frac{1}{n}\sqrt{\sum_{i=1}^n ||\boldsymbol{X}_i||_2^2}$. Now use the fact that $\frac{1}{n}||\boldsymbol{H}_n - \boldsymbol{H}_n^0|| = \frac{1}{n}\sqrt{\sum_{i=1}^n (\langle \boldsymbol{X}_i, \boldsymbol{B}_n - \boldsymbol{B}_n^0\rangle)^2} \leq \left(\frac{1}{n}\sqrt{\sum_{i=1}^n ||\boldsymbol{X}_i||_2^2}\right)||\boldsymbol{B}_n - \boldsymbol{B}_n^0||_2$ to conclude

$$\left\{||\boldsymbol{B}_n - \boldsymbol{B}_n^0||_2 < \frac{2\eta}{3M_n\zeta_n}\right\} \subseteq \mathcal{A}_{1n}. \tag{15}$$

By (11) one has $\pi_n(\mathcal{A}_{1n}) \geq \pi_n\Big(||\boldsymbol{B}_n - \boldsymbol{B}_n^0||_2 < \frac{2\eta}{3M_n\zeta_n}\Big) \geq \exp(-dn)$ and hence $M \geq \exp\left((\tilde{b} - \eta - d)n\right) \to \infty$ as $n \to \infty$ proving the result. ■

Theorem 2

Proof Define $g : \mathbb{R} \to \mathbb{R}$ s.t.

$$g(\kappa) = R\kappa^D + \kappa^{D-1}\sum_{j=1}^D\sum_{r=1}^R ||\boldsymbol{\beta}_{j,n}^{0(r)}||_2 + \cdots + \kappa\sum_{j=1}^D\sum_{r=1}^R\prod_{l\neq j}||\boldsymbol{\beta}_{l,n}^{0(r)}||_2.$$

Let $\kappa_n > 0$ be s.t. $g(\kappa_n) = \frac{2\eta}{3M_n\zeta_n}$. Note that by Decarte's rule of sign, the equation $g(\kappa) - \frac{2\eta}{3M_n\zeta_n} = 0$ has a unique positive root. Further

$$\frac{1}{\kappa_n} < 1 + \max_{i=1,\ldots,D}\left|\frac{3\sum_{j_1\neq\cdots\neq j_i}\sum_{r=1}^R\prod_{l=1}^i ||\boldsymbol{\beta}_{j_l,n}^{0(r)}||_2}{2\eta/M_n\zeta_n}\right| \tag{16}$$

$$\kappa_n < 1 + \max\left\{\frac{2\eta}{3M_n\zeta_n R}, \max_{i=1,\ldots,D}\left|\frac{\sum_{j_1\neq\cdots\neq j_i}\sum_{r=1}^R\prod_{l=1}^i ||\boldsymbol{\beta}_{j_l,n}^{0(r)}||_2}{R}\right|\right\} \tag{17}$$

by Lemma 8 in Appendix B.

Using Lemma 7 in Appendix B, it is easy to see that

$$\left\{||\boldsymbol{\beta}_{j,n}^{(r)}-\boldsymbol{\beta}_{j,n}^{0(r)}||_2\leq\kappa_n,\ j=1,...,D;\ r=1,...,R\right\}\subseteq\left\{||\boldsymbol{B}_n-\boldsymbol{B}_n^0||_2<\frac{2\eta}{3M_n\zeta_n}\right\}. \quad (18)$$

Using (15), $\pi_n\left(||\boldsymbol{B}_n-\boldsymbol{B}_n^0||_2<\frac{2\eta}{3M_n\zeta_n}\right)\geq\pi_n\left(\left\{||\boldsymbol{\beta}_{j,n}^{(r)}-\boldsymbol{\beta}_{j,n}^{0(r)}||_2\leq\kappa_n,\ j=1,...,D;\ r=1,...,R\right\}\right)$. Note that

$$\begin{aligned}&\pi_n\left(\left\{||\boldsymbol{\beta}_{j,n}^{(r)}-\boldsymbol{\beta}_{j,n}^{0(r)}||_2\leq\kappa_n,\ j=1,...,D;\ r=1,...,R\right\}|\{w_{jr,l}\}_{l=1}^{p_{j,n}},\{\lambda_{jr}\}_{j,r=1}^{D,R-1},\{\phi_r\}_{r=1}^{R-1},\tau\right)\\&\geq\left[\prod_{j=1}^{D}\prod_{r=1}^{R}\pi_n\left(||\boldsymbol{\beta}_{j,n}^{(r)}-\boldsymbol{\beta}_{j,n}^{0(r)}||_2\leq\kappa_n|\{w_{jr,l}\}_{l=1}^{p_{j,n}},\{\lambda_{jr}\}_{j,r=1}^{D,R-1},\{\phi_r\}_{r=1}^{R-1},\tau\right)\right].\end{aligned}$$

Therefore, it is enough to bound $\pi_n(||\boldsymbol{\beta}_{j,n}^{(r)}-\boldsymbol{\beta}_{j,n}^{0(r)}||\leq\kappa_n, j=1,...,D; r=1,...,R)$. For $j=1,...,D$, $r=1,...,R$,

$$\begin{aligned}&\pi_n(||\boldsymbol{\beta}_{j,n}^{(r)}-\boldsymbol{\beta}_{j,n}^{0(r)}||\leq\kappa_n|\{w_{jr,l}\}_{l=1}^{p_{j,n}},\lambda_{jr},\{\phi_r\}_{r=1}^{R-1},\tau)\\&\quad\geq\prod_{l=1}^{p_{j,n}}\pi_n\left(|\beta_{j,n,l}^{(r)}-\beta_{j,n,l}^{0(r)}|\leq\frac{\kappa_n}{\sqrt{p_{j,n}}}|\{w_{jr,l}\}_{l=1}^{p_{j,n}},\lambda_{jr},\{\phi_r\}_{r=1}^{R-1},\tau\right)\\&\quad\geq\prod_{l=1}^{p_{j,n}}\left\{\left(\frac{2\kappa_n}{\sqrt{2p_{j,n}\pi w_{jr,l}\phi_r\tau}}\right)\exp\left(-\frac{|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}}{w_{jr,l}\phi_r\tau}\right)\right\},\end{aligned}$$

where the last step follows from the fact that $\int_a^b e^{-x^2/2}dx\geq e^{-(a^2+b^2)/2}(b-a)$. Thus,

$$\begin{aligned}&\pi_n(||\boldsymbol{\beta}_{j,n}^{(r)}-\boldsymbol{\beta}_{j,n}^{0(r)}||\leq\kappa_n|\lambda_{jr},\{\phi_r\}_{r=1}^{R-1},\tau)\\&=\mathbb{E}\left[\pi_n(||\boldsymbol{\beta}_{j,n}^{(r)}-\boldsymbol{\beta}_{j,n}^{0(r)}||\leq\kappa_n|\{w_{jr,l}\}_{l=1}^{p_{j,n}},\lambda_{jr},\{\phi_r\}_{r=1}^{R-1},\tau)\right]\\&\geq\left(\frac{2\kappa_n}{\sqrt{2p_{j,n}\pi\phi_r\tau}}\right)^{p_{j,n}}\prod_{l=1}^{p_{j,n}}E\left\{\frac{1}{\sqrt{w_{jr,l}}}\exp\left(-\frac{|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}}{w_{jr,l}\phi_r\tau}\right)\right\}\\&\geq\left(\frac{2\kappa_n\lambda_{jr}^2}{2\sqrt{2p_{j,n}\pi\phi_r\tau}}\right)^{p_{j,n}}\prod_{l=1}^{p_{j,n}}\int_{w_{jr,l}}\left\{\frac{1}{\sqrt{w_{jr,l}}}\exp\left(-\frac{|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}}{w_{jr,l}\phi_r\tau}-\frac{\lambda_{jr}^2w_{jr,l}}{2}\right)dw_{jr,l}\right\}.\end{aligned} \quad (19)$$

Use the change of variable $\frac{1}{w_{jr,l}}=z_{jr,l}$ and the normalizing constant from the inverse Gaussian density to deduce

$$\begin{aligned}&\int_{w_{jr,l}}\left\{\frac{1}{\sqrt{w_{jr,l}}}\exp\left(-\frac{|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}}{w_{jr,l}\phi_r\tau}-\frac{\lambda_{jr}^2w_{jr,l}}{2}\right)dw_{jr,l}\right\}\\&=\int_{z_{jr,l}}\left\{\frac{1}{\sqrt{z_{jr,l}^3}}\exp\left(-\frac{(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n})}{\phi_r\tau}z_{jr,l}-\frac{\lambda_{jr}^2}{2z_{jr,l}}\right)dz_{jr,l}\right\}\\&=\sqrt{\left(\frac{2\pi}{\lambda_{jr}^2}\right)}\exp\left(-\lambda_{jr}\frac{\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{\sqrt{\phi_r\tau}}\right).\end{aligned}$$

(19) can be written as

$$\begin{aligned}&\pi_n(||\boldsymbol{\beta}_{j,n}^{(r)}-\boldsymbol{\beta}_{j,n}^{0(r)}||\leq\kappa_n|\lambda_{jr},\{\phi_r\}_{r=1}^{R-1},\tau)\\&\geq\left(\frac{2\kappa_\eta\lambda_{jr}^2}{2\sqrt{2p_{j,n}\pi\phi_r\tau}}\right)^{p_{j,n}}\prod_{l=1}^{p_{j,n}}\left[\sqrt{\left(\frac{2\pi}{\lambda_{jr}^2}\right)}\exp\left(-\lambda_{jr}\frac{\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{\sqrt{\phi_r\tau}}\right)\right]\\&=\left(\frac{2\kappa_n\lambda_{jr}}{2\sqrt{p_{j,n}\phi_r\tau}}\right)^{p_{j,n}}\exp\left(-\lambda_{jr}\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{\sqrt{\phi_r\tau}}\right).\end{aligned}$$

Therefore,

$$\begin{aligned}&\pi_n(||\boldsymbol{\beta}_{j,n}^{(r)}-\boldsymbol{\beta}_{j,n}^{0(r)}||\leq\kappa_n|\{\phi_r\}_{r=1}^{R-1},\tau)\\&\geq\left(\frac{2\kappa_n}{2\sqrt{p_{j,n}\phi_r\tau}}\right)^{p_{j,n}}\frac{b_{\lambda,r}^{a_{\lambda,r}}}{\Gamma(a_{\lambda,r})}\int_{\lambda_{jr}}\lambda_{jr}^{p_{j,n}+a_{\lambda,r}-1}\exp\left(-\lambda_{jr}\left[\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{\sqrt{\phi_r\tau}}+b_{\lambda,r}\right]\right)d\lambda_{jr}\\&=\left(\frac{2\kappa_n}{2\sqrt{p_{j,n}\phi_r\tau}}\right)^{p_{j,n}}\frac{b_{\lambda,r}^{a_{\lambda,r}}}{\Gamma(a_{\lambda,r})}\frac{\Gamma(p_{j,n}+a_{\lambda,r})}{\left[\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{\sqrt{\phi_r\tau}}+b_{\lambda,r}\right]^{p_{j,n}+a_{\lambda,r}}}\\&=\left(\frac{2\kappa_n}{2b_{\lambda,r}\sqrt{p_{j,n}\phi_r\tau}}\right)^{p_{j,n}}\frac{1}{\Gamma(a_{\lambda,r})}\frac{\Gamma(p_{j,n}+a_{\lambda,r})}{\left[\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{b_{\lambda,r}\sqrt{\phi_r\tau}}+1\right]^{p_{j,n}+a_{\lambda,r}}}.\end{aligned}$$

The final expression as in the above yields

$$\pi_n(||\boldsymbol{\beta}_{j,n}^{(r)} - \boldsymbol{\beta}_{j,n}^{0(r)}|| \leq \kappa_n, j = 1, ..., D, r = 1, ..., R | \{\phi_r\}_{r=1}^{R-1}, \tau)$$
$$\geq \mathbb{E}\left\{ \prod_{j=1}^{D}\prod_{r=1}^{R}\left[\left(\frac{2\kappa_n}{2b_{\lambda,r}\sqrt{p_{j,n}\phi_r\tau}}\right)^{p_{j,n}} \frac{1}{\Gamma(a_{\lambda,r})}\lambda_{j,r}^{p_{j,n}+a_{\lambda,r}-1} \frac{\Gamma(p_{j,n}+a_{\lambda,r})}{\left[\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{b_{\lambda,r}\sqrt{\phi_r\tau}}+1\right]^{p_{j,n}+a_{\lambda,r}}} \right] \right\}.$$

We will now use the fact that for $\phi_r \leq 1$,

$$\frac{1}{\left[\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{b_{\lambda,r}\sqrt{\phi_r\tau}}+1\right]^{p_{j,n}+a_{\lambda,r}}} \geq \frac{1}{\left[\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{b_{\lambda,r}\sqrt{\phi_r\tau}}+\frac{1}{\sqrt{\tau\phi_r}}\right]^{p_{j,n}+a_{\lambda,r}}} I_{\tau\in[0,1]}.$$

This inequality is critical to provide a lower bound on $\pi_n(||\boldsymbol{\beta}_{j,n}^{(r)} - \boldsymbol{\beta}_{j,n}^{0(r)}|| \leq \kappa_n, j = 1, ..., D, r = 1, ..., R)$ as following

$$\pi_n(||\boldsymbol{\beta}_{j,n}^{(r)} - \boldsymbol{\beta}_{j,n}^{0(r)}|| \leq \kappa_n, j = 1, ..., D, r = 1, ..., R)$$
$$\geq \frac{\lambda_2^{\lambda_1}\Gamma(Ra)}{\Gamma(\lambda_1)\Gamma(a)^R}\prod_{j=1}^{D}\prod_{r=1}^{R}\left[\left(\frac{\kappa_n}{\sqrt{p_{j,n}}b_{\lambda,r}}\right)^{p_{j,n}}\frac{\Gamma(p_{j,n}+a_{\lambda,r})}{\Gamma(a_{\lambda,r})}\right]\int_\tau \tau^{\lambda_1 - R\sum_{j=1}^{D}\frac{p_{j,n}}{2}-1}\exp(-\lambda_2\tau)$$
$$\int_{\boldsymbol{\phi}\in\mathcal{S}^{R-1}}\frac{\prod_{r=1}^{R}\phi_r^{a-1}}{\prod_{r=1}^{R}\phi_r^{\sum_{j=1}^{D}\frac{p_{j,n}}{2}}}\prod_{j=1}^{D}\prod_{r=1}^{R}\frac{1}{\left[\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{b_{\lambda,r}\sqrt{\phi_r\tau}}+1\right]^{p_{j,n}+a_{\lambda,r}}}d\boldsymbol{\phi}d\tau$$
$$\geq \frac{\lambda_2^{\lambda_1}\Gamma(Ra)}{\Gamma(\lambda_1)\Gamma(a)^R}\prod_{j=1}^{D}\prod_{r=1}^{R}\left[\left(\frac{\kappa_n}{\sqrt{p_{j,n}}b_{\lambda,r}}\right)^{p_{j,n}}\frac{\Gamma(p_{j,n}+a_{\lambda,r})}{\Gamma(a_{\lambda,r})}\right]\prod_{j=1}^{D}\prod_{r=1}^{R}\frac{1}{\left[\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{b_{\lambda,r}}+1\right]^{p_{j,n}+a_{\lambda,r}}}$$
$$\left(\int_{\tau=0}^{1}\tau^{\lambda_1+\sum_{r=1}^{R}a_{\lambda,r}\frac{D}{2}-1}\exp(-\tau\lambda_2)d\tau\right)\int_{\boldsymbol{\phi}\in\mathcal{S}^{R-1}}\prod_{r=1}^{R}\phi_r^{a+a_{\lambda,r}\frac{D}{2}-1}d\boldsymbol{\phi}$$
$$= \frac{\lambda_2^{\lambda_1}\Gamma(Ra)}{\Gamma(\lambda_1)\Gamma(a)^R}\prod_{j=1}^{D}\prod_{r=1}^{R}\left[\left(\frac{\kappa_n}{\sqrt{p_{j,n}}b_{\lambda,r}}\right)^{p_{j,n}}\frac{\Gamma(p_{j,n}+a_{\lambda,r})}{\Gamma(a_{\lambda,r})}\right]\prod_{j=1}^{D}\prod_{r=1}^{R}\frac{1}{\left[\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{b_{\lambda,r}}+1\right]^{p_{j,n}+a_{\lambda,r}}}$$
$$\times\frac{\exp(-\lambda_2)}{(\lambda_1+\sum_{r=1}^{R}a_{\lambda,r}\frac{D}{2})}\frac{\prod_{r=1}^{R}\left[\Gamma(a+a_{\lambda,r}\frac{D}{2})\right]}{\Gamma(Ra+\frac{D}{2}\sum_{r=1}^{R}a_{\lambda,r})}.$$

Denote $C_6 = \frac{\lambda_2^{\lambda_1}\Gamma(Ra)}{\Gamma(\lambda_1)[\Gamma(a)]^R}\frac{\exp(-\lambda_2)}{(\lambda_1+\sum_{r=1}^{R}a_{\lambda,r}\frac{D}{2})}\frac{\prod_{r=1}^{R}\left[\Gamma(a+a_{\lambda,r}\frac{D}{2})\right]}{\Gamma(Ra+\sum_{r=1}^{R}a_{\lambda,r}\frac{D}{2})}$. Then the above expression gives us

$$-\log\left(||\boldsymbol{B}_n - \boldsymbol{B}_n^0||_2 < \frac{2\eta}{3M_n\zeta_n}\right)$$
$$\leq -\log(C_6) + \sum_{j=1}^{D}\sum_{r=1}^{R}p_{j,n}\left[-\log(\kappa_n) + \frac{1}{2}\log(p_{j,n}) + \log(b_{\lambda,r}) + \log(\Gamma(a_{\lambda,r})\right]$$
$$-\sum_{r=1}^{R}\sum_{j=1}^{D}\log(\Gamma(p_{n,j}+a_{\lambda,r})) + \sum_{j=1}^{D}\sum_{r=1}^{R}(p_{j,n}+a_{\lambda,r})\log\left[\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{b_{\lambda,r}}+1\right]. \quad (20)$$

Using (16) and assumption (b), it is easy to see that $\frac{1}{\kappa_n} < G_5 n^{\rho_2+\frac{\rho_3+1}{2}}\prod_{j=1}^{D}p_{j,n}$ for a constant $G_5 > 0$ for all large n. Therefore, $\sum_{j=1}^{D}\sum_{r=1}^{R}p_{j,n}\left[\log\left(\frac{1}{\kappa_n}\right) + \frac{1}{2}\log(p_{j,n}) + \log(b_{\lambda,r}) + \log(\Gamma(a_{\lambda,r})\right] = o(n)$. Also, $\sum_{r=1}^{R}\sum_{j=1}^{D}\log(\Gamma(p_{j,n}+a_{\lambda,r}))] \leq \sum_{j=1}^{D}(p_{j,n}+a_{\lambda,r})\log(p_{j,n}+a_{\lambda,r}) = o(n)$, by assumption (c). Finally, $\sum_{j=1}^{D}\sum_{r=1}^{R}(p_{j,n}+a_{\lambda,r})\log\left[\frac{\sum_{l=1}^{p_{j,n}}\sqrt{2\left(|\beta_{j,n,l}^{0(r)}|^2+\kappa_n^2/p_{j,n}\right)}}{b_{\lambda,r}}+1\right] = o(n)$, by assumptions (b) and (c). Thus, $-\log\left(\pi_n(\boldsymbol{B}_n : ||\boldsymbol{B}_n - \boldsymbol{B}_n^0||_2 < \frac{2\eta}{3M_n\zeta_n})\right) < dn$ for all $d > 0$, for all large n. This proves the result. ■

Appendix B

This Section contains additional Lemmas relevant to the article.

Lemma 7 *Suppose $\boldsymbol{T} = T_1 \circ \cdots \circ T_D$ and $\boldsymbol{F} = F_1 \circ \cdots \circ F_D$ are two rank one tensors of same dimension. Then*

$$\boldsymbol{T} - \boldsymbol{F} = (T_1 - F_1) \circ \cdots \circ (T_D - F_D) + \sum_{l=1}^{D-1}\sum_{\mathcal{I}_1\cup\mathcal{I}_2=1:D, |\mathcal{I}_1|=l, |\mathcal{I}_2|=D-l}\gamma_1 \circ \cdots \circ \gamma_D,$$

where $\gamma_j = F_j$ if $j \in \mathcal{I}_2$; $= T_j - F_j$ if $j \in \mathcal{I}_1$.

Proof We will show it by induction. If $D = 2$ then,

$$\boldsymbol{T} - \boldsymbol{F} = T_1 \circ T_2 - F_1 \circ F_2 = (T_1 - F_1) \circ T_2 + F_1 \circ T_2 - F_1 \circ F_2$$
$$= (T_1 - F_1) \circ (T_2 - F_2) + (T_1 - F_1) \circ F_2 + F_1 \circ (T_2 - F_2).$$

Assume the result to hold for $D-1$. For D,

$$
\begin{aligned}
&T_1 \circ \cdots \circ T_D - F_1 \circ \cdots \circ F_D \\
&= (T_1 - F_1) \circ T_2 \circ \cdots \circ T_D + F_1 \circ [T_2 \circ \cdots \circ T_D - F_2 \circ \cdots \circ F_D] \\
&= (T_1 - F_1) \circ [(T_2 - F_2) \circ \cdots \circ (T_D - F_D) + F_2 \circ \cdots \circ F_D + \\
&\sum_{l=1}^{D-2} \sum_{\mathcal{I}_1 \cup \mathcal{I}_2, |\mathcal{I}_1|=l, |\mathcal{I}_2|=D-1-l} \gamma_2 \circ \cdots \circ \gamma_D] + \\
&F_1 \circ [(T_2 - F_2) \circ \cdots \circ (T_D - F_D) + \sum_{l=1}^{D-2} \sum_{\mathcal{I}_1 \cup \mathcal{I}_2, |\mathcal{I}_1|=l, |\mathcal{I}_2|=D-1-l} \gamma_2 \circ \cdots \circ \gamma_D] \\
&= (T_1 - F_1) \circ \cdots \circ (T_D - F_D) + \sum_{l=1}^{D-1} \sum_{\mathcal{I}_1 \cup \mathcal{I}_2, |\mathcal{I}_1|=l, |\mathcal{I}_2|=D-l} \gamma_1 \circ \cdots \circ \gamma_D].
\end{aligned}
$$

Hence proved. ■

Lemma 8 *Let x^* be a real root of the polynomial $P(x) = a_k x^k + a_{k-1} x^{k-1} + \cdots + a_1 x - a_0$. Then $1/|x^*| < 1 + \max_{i=1,\ldots,k} \left|\frac{a_i}{a_0}\right|$.*

Proof Consider the polynomial $P_1(\zeta) = \zeta^k - \left(\frac{a_1}{a_0}\right)\zeta^{k-1} - \cdots - \left(\frac{a_k}{a_0}\right)$. By making a change of variable with $\zeta = \frac{1}{x}$, we obtain

$$
\begin{aligned}
P_1\left(\frac{1}{x}\right) &= \frac{1}{x^k} - \left(\frac{a_1}{a_0}\right)\frac{1}{x^{k-1}} - \cdots - \left(\frac{a_k}{a_0}\right) \\
&= -\frac{a_k x^k + \cdots + a_1 x - a_0}{a_0 x^k}.
\end{aligned}
$$

Note that $P_1\left(\frac{1}{x}\right) = 0$ is solved by $x = x^*$. Therefore, $P_1(\zeta) = 0$ is solved by $\zeta = \frac{1}{x^*}$. The result follows by using Cauchy bound on the roots of a polynomial. ■

Lemma 9 *Suppose $T_1, \ldots, T_m$ are independent random variables with T_j having density f_j supported in $(0, \infty)$. Let $\phi_j = \frac{T_j}{\sum_{l=1}^m T_m}$. Then the joint density of $(\phi_1, \ldots, \phi_{m-1})$ has a joint density supported on the simplex $\mathcal{S}^{m-1}$ and is given by*

$$
f(\phi_1, \ldots, \phi_{m-1}) = \int_{t=0}^{\infty} t^{m-1} \prod_{l=1}^{m} f_j(\phi_j t) dt,
$$

where $\phi_m = 1 - \sum_{l=1}^{m-1} \phi_l$.

Proof This result is well known in the theory of normalized random measures (Kruijer et al., 2010). ■

Abstract

Clustering high-dimensional data often requires some form of dimensionality reduction, where clustered variables are separated from "noise-looking" variables. We cast this problem as finding a low-dimensional projection of the data which is well-clustered. This yields a one-dimensional projection in the simplest situation with two clusters, and extends naturally to a multi-label scenario for more than two clusters. In this paper, (a) we first show that this joint clustering and dimension reduction formulation is equivalent to previously proposed discriminative clustering frameworks, thus leading to convex relaxations of the problem; (b) we propose a novel sparse extension, which is still cast as a convex relaxation and allows estimation in higher dimensions; (c) we propose a natural extension for the multi-label scenario; (d) we provide a new theoretical analysis of the performance of these formulations with a simple probabilistic model, leading to scalings over the form $d = O(\sqrt{n})$ for the affine invariant case and $d = O(n)$ for the sparse case, where n is the number of examples and d the ambient dimension; and finally, (e) we propose an efficient iterative algorithm with running-time complexity proportional to $O(nd^2)$, improving on earlier algorithms for discriminative clustering with the square loss, which had quadratic complexity in the number of examples.

1. Introduction

Clustering is an important and commonly used pre-processing tool in many machine learning applications, with classical algorithms such as K-means (MacQueen, 1967), linkage algorithms (Gower and Ross, 1969) or spectral clustering (Ng et al., 2002). In high dimensions, these unsupervised learning algorithms typically have problems identifying the underlying optimal discrete nature of the data; for example, they are quickly perturbed by adding a few noisy dimensions. Clustering high-dimensional data thus requires some form of dimensionality reduction, where clustered variables are separated from non-informative "noise-looking" (e.g., Gaussian) variables.

Several frameworks aim at linearly separating noise from signal, that is finding projections of the data that extracts the signal and removes the noise. They differ in the ways signals and noise are defined. A line of work that dates back to projection pursuit (Friedman and Stuetzle, 1981) and independent component analysis (Hyvärinen et al., 2004) defines the noise as Gaussian while the signal is non-Gaussian (Blanchard et al., 2006; Le Roux and Bach, 2013; Diederichs et al., 2013). In this work, we follow De la Torre and Kanade (2006); Ding and Li (2007), along the alternative route where one defines the signal as being clustered while the noise is any non-clustered variable. In the simplest situation with two clusters, we may project the data into a one-dimensional subspace. Given a data matrix $X \in \mathbb{R}^{n\times d}$ composed of n d-dimensional points, the goal is to find a direction $w \in \mathbb{R}^d$ such that $Xw \in \mathbb{R}^n$ is well-clustered, e.g., by K-means. This is equivalent to identifying both a direction to project, represented as $w \in \mathbb{R}^d$ and the labeling $y \in \{-1,1\}^n$ that represents the partition into two clusters.

Most existing formulations are non-convex and typically perform a form of alternating optimization (De la Torre and Kanade, 2006; Ding and Li, 2007), where given $y \in \{-1,1\}^n$, the projection w is found by linear discriminant analysis (or any binary classification method), and given the projection w, the clustering is obtained by thresholding Xw or running K-means on Xw. As shown in Section 2, this alternating minimization procedure happens to be equivalent to maximizing the (centered) correlation between $y \in \{-1,1\}^n$ and the projection $Xw \in \mathbb{R}^d$, that is

$$\max_{w\in\mathbb{R}^d, y\in\{-1,1\}^n} \frac{(y^\top \Pi_n X w)^2}{\|\Pi_n y\|_2^2 \, \|\Pi_n X w\|_2^2},$$

where $\Pi_n = I_n - \frac{1}{n} 1_n 1_n^\top$ is the usual centering projection matrix (with $1_n \in \mathbb{R}^n$ being the vector of all ones, and I_n the $n \times n$ identity matrix). This correlation is equal to one when the projection is perfectly clustered (independently of the number of elements per cluster). Existing methods are alternating minimization algorithms with no theoretical guarantees.

In this paper, we relate this formulation to discriminative clustering formulations (Xu et al., 2004; Bach and Harchaoui, 2007), which consider the problem

$$\min_{v\in\mathbb{R}^d,\ b\in\mathbb{R},\ y\in\{-1,1\}^n} \frac{1}{n}\|y - Xv - b1_n\|_2^2, \tag{1}$$

with the intuition of finding labels y which are easy to predict by an affine function of the data. In particular, we show that given the relationship between the number of positive labels and negative labels (i.e., the squared difference between the respective number of elements), these two problems are equivalent, and hence discriminative clustering explicitly performs joint dimension reduction and clustering.

While the discriminative framework is based on convex relaxations and has led to interesting developments and applications (Zhang et al., 2009; Li et al., 2009; Joulin et al., 2010a,b; Wang et al., 2010; Niu et al., 2013; Huang et al., 2015), it has several shortcomings when used with the square loss: (a) the running-time complexity of the semi-definite formulations is at least quadratic in n, and typically much more, (b) no theoretical analysis has ever been performed, (c) no convex sparse extension has been proposed to handle data with many irrelevant dimensions, (d) balancing of the clusters remains an issue, as it typically adds an extra hyperparameter which may be hard to set. In this paper, we focus on addressing these concerns.

When there are more than two clusters, one considers either the *multi-label* or the *multi-class* settings. The multi-class problem assumes that the data are clustered into distinct classes, i.e., a single class per observation, whereas the multi-label problem assumes the data share different labels, i.e., multiple labels per observation. We show in this work that discriminative clustering framework extends more naturally to multi-label scenarios and that this extension has the same convex relaxation.

A summary of the contributions of this paper follows:

- In Section 2, we relate discriminative clustering with the square loss to a joint clustering and dimension reduction formulation. The proposed formulation takes care of the balancing hyperparameter implicitly.
- We propose in Section 3, a novel sparse extension to discriminative clustering and show that it can still be cast through a convex relaxation.
- When there are more than two clusters, we extend naturally the sparse formulation to a multi-label scenario in Section 4.
- We then proceed to provide a theoretical analysis of the proposed formulations with a simple probabilistic model in Section 5, which effectively leads to scalings over the form $d = O(\sqrt{n})$ for the affine invariant case and $d = O(n)$ for the 1-sparse case.
- Finally, we propose in Section 6 efficient iterative algorithms with running-time complexity for each step equal to $O(nd^2)$, the first to be linear in the number of observations n for discriminative clustering with the square loss.

Throughout this paper we assume that $X \in \mathbb{R}^{n\times d}$ is *centered*, a common pre-processing step in unsupervised (and supervised) learning. This implies that $X^\top 1_n = 0$ and $\Pi_n X = X$.

2. Joint Dimension Reduction and Clustering

In this section, we focus on the single binary label case, where we first study the usual non-convex formulation, before deriving convex relaxations based on semi-definite programming. Some of the following results are already known in the literature; however, we state them here for completeness.

2.1 Non-convex formulation

Following De la Torre and Kanade (2006); Ding and Li (2007); Ye et al. (2008), we consider a cost function which depends on $y \in \{-1,1\}^n$ and $w \in \mathbb{R}^d$, which is such that alternating optimization is exactly (a) running K-means with two clusters on Xw to obtain y given w (when we say "running K-means", we mean solving the vector quantization problem exactly), and (b) performing linear discriminant analysis to obtain w given y.

Proposition 1 (Joint clustering and dimension reduction for two clusters) *Given $X \in \mathbb{R}^{n\times d}$ such that $X^\top 1_n = 0$ and X has rank d, consider the optimization problem*

$$\max_{w\in\mathbb{R}^d, y\in\{-1,1\}^n} \frac{(y^\top Xw)^2}{\|\Pi_n y\|_2^2 \, \|Xw\|_2^2}. \tag{2}$$

Given y, the optimal w is obtained as $w = (X^\top X)^{-1}X^\top y$, while given w, the optimal y is obtained by running K-means on Xw.

This equivalence might be straightforward, however it has not been precisely stated in the literature to the best of our knowledge.

Proof Given y, we need to optimize the Rayleigh quotient $\frac{w^\top X^\top y y^\top Xw}{w^\top X^\top Xw}$ with a rank-one matrix in the numerator, which leads to $w = (X^\top X)^{-1}X^\top y$. Given w, we show in Appendix A, that the averaged distortion measure of K-means once the means have been optimized is exactly equal to $(y^\top Xw)^2/\|\Pi_n y\|_2^2$. ■

Algorithm. The proposition above leads to an alternating optimization algorithm. Note that K-means in one dimension may be run *exactly* in $O(n \log n)$ (Bellman, 1973). After having optimized with respect to w in Eq. (2), we then need to maximize with respect to y the function $\frac{y^\top X(X^\top X)^{-1}X^\top y}{\|\Pi_n y\|_2^2}$, which happens to be exactly performing K-means on the whitened data (which is now in high dimension and not in 1 dimension). At first, it seems that dimension reduction is *simply* equivalent to whitening the data and performing K-means; while this is a formally correct statement, the resulting K-means problem is not easy to solve as the clustered dimension is hidden in noise; for example, algorithms such as K-means++ (Arthur and Vassilvitskii, 2007), which have a multiplicative theoretical guarantee on the final distortion measure, are not provably effective here because the minimal final distortion is not small (since the clusters are corrupted by some noisy dimensions), and the multiplicative guarantee is then meaningless.

2.2 Convex relaxation and discriminative clustering

The discriminative clustering formulation in Eq. (1) may be optimized for any $y \in \{-1,1\}^n$ in closed form with respect to b as $b = \frac{1_n^\top (y - Xv)}{n} = \frac{1_n^\top y}{n}$ since X is centered. Substituting b in Eq. (1) leads us to

$$\min_{v\in\mathbb{R}^d} \frac{1}{n}\|\Pi_n y - Xv\|_2^2 = \frac{1}{n}\|\Pi_n y\|_2^2 - \max_{w\in\mathbb{R}^d} \frac{(y^\top Xw)^2}{\|Xw\|_2^2}, \tag{3}$$

where v is obtained from any solution w as $v = w\frac{y^\top Xw}{\|Xw\|_2^2}$. Thus, given

$$\frac{(y^\top 1_n)^2}{n^2} = \frac{1}{n^2}\big(\#\{i, y_i = 1\} - \#\{i, y_i = -1\}\big)^2 = \alpha \in [0,1], \tag{4}$$

which characterizes the asymmetry between clusters and with $\|\Pi_n y\|^2 = n(1-\alpha)$, we obtain from Eq. (3), an equivalent formulation to Eq. (2) (with the added constraint) as

$$\min_{y\in\{-1,1\}^n,\ v\in\mathbb{R}^d} \frac{1}{n}\|\Pi_n y - Xv\|_2^2 \ \text{ such that } \ \frac{(y^\top 1_n)^2}{n^2} = \alpha. \tag{5}$$

This is exactly equivalent to a discriminative clustering formulation with the square loss (Bach and Harchaoui, 2007) with an explicit cluster balance constraint. Consequently we

have formally established that the discriminative clustering formulation in Eq. (5) is related to the joint clustering and dimension reduction formulation in Eq. (2). Following Bach and Harchaoui (2007), we may optimize Eq. (5) in closed form with respect to v as $v = (X^\top X)^{-1} X^\top y$. Substituting v in Eq. (5) leads us to

$$\min_{y \in \{-1,1\}^n} \frac{1}{n} y^\top \big(\Pi_n - X(X^\top X)^{-1} X^\top \big) y \;\; \text{such that} \;\; \frac{(y^\top 1_n)^2}{n^2} = \alpha. \tag{6}$$

This combinatorial optimization problem is NP-hard in general (Karp, 1972; Garey et al., 1976). Hence in practice, it is classical to consider the following convex relaxation of Eq. (6) (Luo et al., 2010). For any admissible $y \in \{-1, +1\}^n$, the matrix $Y = yy^\top \in \mathbb{R}^{n \times n}$ is a rank-one symmetric positive semi-definite matrix with unit diagonal entries and conversely any such Y may be written in the form $Y = yy^\top$ such that y is admissible for Eq. (6). Moreover by rewriting Eq. (6) as

$$\min_{y \in \{-1,1\}^n} \frac{1}{n} \operatorname{tr} yy^\top \big(\Pi_n - X(X^\top X)^{-1} X^\top \big) \;\; \text{such that} \;\; \frac{1_n^\top (yy^\top) 1_n}{n^2} = \alpha,$$

we see that the objective and constraints are linear in the matrix $Y = yy^\top$ and Eq. (6) is equivalent to

$$\min_{Y \succcurlyeq 0,\ \operatorname{rank}(Y)=1,\ \operatorname{diag}(Y)=1} \frac{1}{n} \operatorname{tr} Y \big(\Pi_n - X(X^\top X)^{-1} X^\top \big) \text{ such that } \frac{1_n^\top Y 1_n}{n^2} = \alpha.$$

Then dropping the non-convex rank constraint leads us to the following classical convex relaxation:

$$\min_{Y \succcurlyeq 0,\ \operatorname{diag}(Y)=1} \frac{1}{n} \operatorname{tr} Y \big(\Pi_n - X(X^\top X)^{-1} X^\top \big) \text{ such that } \frac{1_n^\top Y 1_n}{n^2} = \alpha. \tag{7}$$

This is the standard (unregularized) formulation, which is cast as a semi-definite program. The complexity of interior-point methods is $O(n^7)$, but efficient algorithms in $O(n^2)$ for such problems have been developed due to the relationship with the max-cut problem (Journée et al., 2010; Wen et al., 2012). We note that convex relaxation techniques are also used for semi-supervised methods (De Bie and Cristianini, 2003).

Given the solution Y, one may traditionally obtain a candidate $y \in \{-1, 1\}^n$ by running K-means on the largest eigenvector of Y or by sampling (Goemans and Williamson, 1995). In this paper, we show in Section 5 that it may be advantageous to consider the first two eigenvectors.

2.3 Unsuccessful full convex relaxation

The formulation in Eq. (7) imposes an extra parameter α that characterises the cluster imbalance. It is tempting to find a direct relaxation of Eq. (2). It turns out to lead to a trivial relaxation, which we outline below.

When optimizing Eq. (2) with respect to w, we obtain the following optimization problem

$$\max_{y \in \{-1,1\}^n} \frac{y^\top X (X^\top X)^{-1} X^\top y}{y^\top \Pi_n y},$$

leading to a quasi-convex relaxation as

$$\max_{Y \succcurlyeq 0,\ \operatorname{diag}(Y)=1} \frac{\operatorname{tr} YX(X^\top X)^{-1} X^\top}{\operatorname{tr} \Pi_n Y},$$

whose solution is found by solving a sequence of convex problems (Boyd and Vandenberghe, 2004, Section 4.2.5). As shown in Appendix B, this may be exactly reformulated as a single convex problem:

$$\max_{M \succcurlyeq 0,\ \operatorname{diag}(M) = 1 + \frac{1_n^\top M 1}{n^2}} \operatorname{tr} MX(X^\top X)^{-1} X^\top.$$

Unfortunately, this relaxation always leads to trivial solutions, and we thus need to consider the relaxation in Eq. (7) for several values of $\alpha = 1_n^\top Y 1_n / n^2$ (and then the non-convex algorithm can be run from the rounded solution of the convex problem, using Eq. (2) as a final objective). Alternatively, we may solve the following *penalized* problem for several values of $\nu \geqslant 0$:

$$\min_{Y \succcurlyeq 0,\ \operatorname{diag}(Y)=1} \frac{1}{n} \operatorname{tr} Y \big(\Pi_n - X(X^\top X)^{-1} X^\top \big) + \frac{\nu}{n^2} 1_n^\top Y 1_n. \tag{8}$$

For $\nu = 0$, $Y = 1_n 1_n^\top$ is always a trivial solution. As outlined in our theoretical section and as observed in our experiments, it is sufficient to consider $\nu \in [0, 1]$.

By convex duality (Borwein and Lewis, 2000, Sec. 4.3), both constrained relaxation in Eq. (7) and penalized relaxation in Eq. (8) are formally equivalent for specific choices of constraint parameter α and penalization parameter ν. We will see in Section 6 that the formulation in Eq. (8) is more suitable for algorithmic design (Bach et al., 2012).

2.4 Equivalent relaxations

Optimizing Eq. (5) with respect to v in closed form as in Section 2.2 is feasible with no regularizer or with a quadratic regularizer. However, if one needs to add more complex regularizers, we need a different relaxation. Therefore, we now propose a new formulation of the discriminative clustering framework. We start from the penalized version of Eq. (5),

$$\min_{y \in \{-1,1\}^n,\ v \in \mathbb{R}^d} \frac{1}{n} \| \Pi_n y - Xv \|_2^2 + \nu \frac{(y^\top 1_n)^2}{n^2}, \tag{9}$$

which we expand as:

$$\min_{y \in \{-1,1\}^n,\ v \in \mathbb{R}^d} \frac{1}{n} \operatorname{tr} \Pi_n yy^\top - \frac{2}{n} \operatorname{tr} Xvy^\top + \frac{1}{n} \operatorname{tr} X^\top X vv^\top + \nu \frac{(y^\top 1_n)^2}{n^2}, \tag{10}$$

and relax as, using $Y = yy^\top$, $P = yv^\top$ and $V = vv^\top$,

$$\min_{V,P,Y} \frac{1}{n} \operatorname{tr} \Pi_n Y - \frac{2}{n} \operatorname{tr} P^\top X + \frac{1}{n} \operatorname{tr} X^\top X V + \nu \frac{1_n^\top Y 1_n}{n^2} \text{ s.t. } \begin{pmatrix} Y & P \\ P^\top & V \end{pmatrix} \succcurlyeq 0,\ \operatorname{diag}(Y) = 1. \tag{11}$$

When optimizing Eq. (11) with respect to V and P, we get exactly Eq. (8). Indeed, the optimum is attained for $V = (X^\top X)^{-1} X^\top Y X (X^\top X)^{-1}$ and $P = YX(X^\top X)^{-1}$ as shown in Appendix C.1. Therefore, the convex relaxation in Eq. (11) is equivalent to Eq. (8).

However, we get an interesting behavior when optimizing Eq. (11) with respect to P and Y also in closed form. For $\nu = 1$, we obtain, as shown in Appendix C.2, the following closed form expressions:

$$\begin{aligned} Y &= \operatorname{Diag}(\operatorname{diag}(XVX^\top))^{-1/2} XVX^\top \operatorname{Diag}(\operatorname{diag}(XVX^\top))^{-1/2} \\ P &= \operatorname{Diag}(\operatorname{diag}(XVX^\top))^{-1/2} XV, \end{aligned}$$

leading to the problem:

$$\min_{V \succcurlyeq 0} \quad 1 - \frac{2}{n} \sum_{i=1}^n \sqrt{(XVX^\top)_{ii}} + \frac{1}{n} \operatorname{tr}(VX^\top X). \tag{12}$$

The formulation above in Eq. (12) is interesting for several reasons: (a) it is formulated as an optimization problem in $V \in \mathbb{R}^{d \times d}$, which will lead to algorithms whose running time will depend on n linearly (see Section 6), (b) it allows for easy adding of regularizers (see Section 3), which may be formulated as convex functions of $V = vv^\top$. At first sight this seems to be valid only for $\nu = 1$. However we now propose a reformulation which can handle all possible $\nu \in [0, 1)$ through a simple data augmentation.

Reformulation for any ν When $\nu \in [0, 1)$, we may reformulate the objective function in Eq. (9) as follows:

$$\begin{aligned} \frac{1}{n}\|\Pi_n y - Xv\|_2^2 + \nu \frac{(y^\top 1_n)^2}{n^2} &= \frac{1}{n}\|\Pi_n y - Xv + \nu \frac{y^\top 1_n}{n} 1_n\|_2^2 - \big(\nu \frac{y^\top 1_n}{n}\big)^2 + \nu \big(\frac{y^\top 1_n}{n}\big)^2 \\ &= \frac{1}{n}\|y - Xv - (1-\nu)\frac{y^\top 1_n}{n} 1_n\|_2^2 + \frac{\nu}{1-\nu}\big((1-\nu)\frac{y^\top 1_n}{n}\big)^2 \\ &= \min_{b \in \mathbb{R}} \frac{1}{n}\|y - Xv - b1_n\|_2^2 + \frac{\nu}{1-\nu} b^2, \end{aligned} \tag{13}$$

since $\frac{1}{n}\|y - Xv - b1_n\|_2^2 + \frac{\nu}{1-\nu} b^2$ can be optimized in closed form with respect to b as $b = (1-\nu)\frac{y^\top 1_n}{n}$. Note that the weighted imbalance ratio $(1-\nu)\frac{y^\top 1_n}{n}$ is made as an optimization variable in Eq. (13). Thus we have the following reformulation

$$\begin{aligned} &\min_{v \in \mathbb{R}^d,\ y \in \{-1,1\}^n} \frac{1}{n}\|\Pi_n y - Xv\|_2^2 + \nu \frac{(y^\top 1_n)^2}{n^2} \\ = &\min_{v \in \mathbb{R}^d,\ b \in \mathbb{R},\ y \in \{-1,1\}^n} \frac{1}{n}\|y - Xv - b1_n\|_2^2 + \frac{\nu}{1-\nu} b^2, \end{aligned} \tag{14}$$

which is a non-centered penalized formulation on a higher-dimensional problem in the variable $\binom{v}{b} \in \mathbb{R}^{d+1}$. In the rest of the paper, we will focus on the case $\nu = 1$ for ease of exposition. This enables the use of the formulation in Eq. (12), which is easier to optimize. It is worth noting that this is not an algorithmic restriction. Of course any problem with $\nu \in [0, 1)$ can be treated with equal ease by adding a constant term and a quadratic regularizer.

3. Regularization

There are several natural possibilities. We consider norms Ω such that $\Omega(w)^2 = \Gamma(ww^\top)$ for a certain convex function Γ; all norms have that form (Bach et al., 2012, Proposition 5.1). When $\nu = 1$, Eq. (12) then becomes

$$\max_{V \succcurlyeq 0} \frac{2}{n} \sum_{i=1}^n \sqrt{(XVX^\top)_{ii}} - \frac{1}{n} \operatorname{tr}(VX^\top X) - \Gamma(V). \tag{15}$$

The quadratic regularizers $\Gamma(V) = \operatorname{tr} \Lambda V$ have already been tackled by Bach and Harchaoui (2007). They consider the regularized version of problem in Eq. (3)

$$\min_{v \in \mathbb{R}^d} \frac{1}{n}\|\Pi_n y - Xv\|_2^2 + v^\top \Lambda v, \tag{16}$$

optimize in closed form with respect to v as $v = (X^\top X + n\Lambda)^{-1} X^\top y$. Substituting v in Eq. (16) leads them to

$$\min_{Y \succcurlyeq 0,\ \operatorname{diag}(Y) = 1} \frac{1}{n} \operatorname{tr} Y\big(\Pi_n - X(X^\top X + n\Lambda)^{-1} X\big).$$

In this paper, we propose a novel sparse extension to discriminative clustering framework with the square loss. Specifically we formulate a non-trivial sparse regularizer which is a combination of weighted squared ℓ_1-norm and ℓ_2-norm. It leads to

$$\Gamma(V) = \operatorname{tr}[\operatorname{Diag}(a) V \operatorname{Diag}(a)] + \| \operatorname{Diag}(c) V \operatorname{Diag}(c)\|_1, \tag{17}$$

such that $\Gamma(vv^\top) = \sum_{i=1}^d a_i^2 v_i^2 + \big(\sum_{i=1}^d c_i |v_i|\big)^2$. This allows to treat all situations simultaneously, with $\nu = 1$ or with $\nu \in [0, 1)$. To be more precise, when $\nu \in [0, 1)$, we can consider in Eq. (14), a problem of size $d+1$ with a design matrix $[X, 1_n] \in \mathbb{R}^{n \times (d+1)}$, a direction of projection $\binom{v}{b} \in \mathbb{R}^{d+1}$ and different weights for the last variable with $a_{d+1} = \frac{\nu}{1-\nu}$ and $c_{d+1} = 0$.

Note that the sparse regularizers on V introduced in this paper are significantly different when compared to the sparse regularizers on variable v in Eq. (3), for example, considered by Wang et al. (2013). A straightforward sparse regularizer on v in Eq. (3), despite leading to a sparse projection, does not yield natural generalizations of the discriminative clustering framework in terms of theory or algorithms.

In our analysis and experiments for the balanced clusters (when $\nu = 1$), the sparse regularization $\Gamma(\cdot) = \lambda \|\cdot\|_1$, for $\lambda \in \mathbb{R}$ will often be considered. This is equivalent to setting $a = 0_d$ and $c = \sqrt{\lambda} 1_d$ in Eq. (17). The problem in Eq. (15) then becomes

$$\max_{V \succcurlyeq 0} \frac{2}{n} \sum_{i=1}^n \sqrt{(XVX^\top)_{ii}} - \frac{1}{n} \operatorname{tr}(VX^\top X) - \lambda \|V\|_1. \tag{18}$$

The sparse regularizers considered in this paper have a significant algorithmic appeal for certain applications in computer vision (Bojanowski et al., 2013; Alayrac et al., 2016), audio processing (Lajugie et al., 2016) and natural language processing (Grave, 2014). They also lead to robust cluster recovery under minor assumptions as will be illustrated on a simple example in Section 5. The practical benefits of the sparse regularizers will be further demonstrated using empirical evaluation on synthetic and real data sets in Section 7.

4. Extension to Multiple Labels

The discussion so far has focussed on two clusters. Yet it is key in practice to tackle more clusters. It is worth noting that the discrete formulations in Eq. (2) and Eq. (5) extend directly to more than two clusters. However two different extensions of the initial problems Eq. (2) or Eq. (5) are conceivable. They lead to problems with different constraints on different optimization domains and, consequently, to different relaxations. We discuss these possibilities next.

One extension is the *multi-class* case. The multi-class problem which is dealt with by Bach and Harchaoui (2007) assumes that the data are clustered into K classes and the various partitions of the data points into clusters are represented by the K-class indicator matrices $y \in \{0,1\}^{n\times K}$ such that $y1_K = 1_n$. The constraint $y1_K = 1_n$ ensures that one data point belongs to only one cluster. However as discussed by Bach and Harchaoui (2007), by letting $Y = yy^\top$, it is possible to lift these K-class indicator matrices into the outer convex approximations $\mathcal{C}_K = \{Y \in \mathbb{R}^{n\times n} : Y = Y^\top, \operatorname{diag}(Y) = 1_n, Y \succcurlyeq 0, Y \preccurlyeq \frac{1}{K}1_n 1_n^\top\}$ (Frieze and Jerrum, 1995), which is different for all values of K. Note that letting $K = 2$ corresponds to the previous sections.

In this paper, we consider a different novel extension for discriminative clustering to the *multi-label* case. The multi-label problem assumes that the data share k labels and the data-label membership is represented by matrices $y \in \{-1,+1\}^{n\times k}$. In other words, the multi-class problem embeds the data in the extreme points of a simplex, while the multi-label problem does so in the extreme points of the hypercube.

The discriminative clustering formulation of the multi-label problem is

$$\min_{v\in\mathbb{R}^{d\times k},\ y\in\{-1,1\}^{n\times k}} \frac{1}{n}\|\Pi_n y - Xv\|_F^2, \tag{19}$$

where the Frobenius norm is defined for any vector or rectangular matrix as $\|A\|_F^2 = \operatorname{tr} AA^\top = \operatorname{tr} A^\top A$. Letting $k = 1$ here corresponds to the previous sections. The discrete ensemble of matrices $y \in \{-1,+1\}^{n\times k}$ can be naturally lifted into $\mathcal{D}_k = \{Y \in \mathbb{R}^{n\times n} : Y = Y^\top, \operatorname{diag}(Y) = k1_n, Y \succcurlyeq 0\}$, since $\operatorname{diag}(Y) = \operatorname{diag}(yy^\top) = \sum_{i=1}^k y_{i,i}^2 = k$. As the optimization problems in Eq. (7) and Eq. (8) have linear objective functions, we can change the variable from Y to $\tilde{Y} = Y/k$ to change the constraint $\operatorname{diag}(Y) = k1_n$ to $\operatorname{diag}(\tilde{Y}) = 1_n$ without changing the optimizer of the problem. Thus the problems can be solved over the relaxed domain $\mathcal{D} = \{Y \in \mathbb{R}^{n\times n} : Y = Y^\top, \operatorname{diag}(Y) = 1_n, Y \succcurlyeq 0\}$ which is independent of k.

Note that the domain $\mathcal{D}$ is similar to that considered in the problems in Eq. (8) and Eq. (11) and these convex relaxations are the same regardless of the value of k. Hence the multi-label problem is a more natural extension of the discriminative framework, with a slight change in how the labels y are recovered from the solution Y (we discuss this in Section 5.3).

5. Theoretical Analysis

In this section, we provide the first theoretical analysis for the discriminative clustering framework with the square loss. We start with the 2-clusters situation: the non-sparse case is considered first and analysis is provided for both balanced and imbalanced clusters. Our study for the sparse case currently only provides results for the simple 1-sparse solution. However, the analysis also yields valuable insights on the scaling between n and d. We then derive results for multi-label situation.

For ease of analysis, we consider the constrained problem in Eq. (7), the penalized problem in Eq. (8) or their equivalent relaxations in Eq. (12) or Eq. (18) under various scenarios, for which we use the same proof technique. We first try to characterize the low-rank solutions of these relaxations and then show in certain simple situations the uniqueness of such solutions, which are then non-ambiguously found by convex optimization. Perturbation arguments could extend these results by weakening our assumptions but are not within the scope of this paper, and hence we do not investigate them further in this section.

5.1 Analysis for two clusters: non-sparse problems

In this section, we consider several noise models for the problem, either adding irrelevant dimensions or perturbing the label vector with noise. We consider these separately for simplicity, but they could also be combined (with little extra insight).

5.1.1 Irrelevant dimensions

We consider an "ideal" design matrix $X \in \mathbb{R}^{n\times d}$ such that there exists a direction v along which the projection Xv is perfectly clustered into two distinct real values c_1 and c_2. Since Eq. (2) is invariant by affine transformation, we can rotate the design matrix X to have $X = [y, Z]$ with $y \in \{-1,1\}^n$, which is clustered into $+1$ or -1 along the direction $v = \binom{1}{0_{d-1}}$. Then after being centered, the design matrix is written as $X = [\Pi_n y, Z]$ with $Z = [z_1, \dots, z_{d-1}] \in \mathbb{R}^{n\times(d-1)}$. The columns of Z represent the noisy irrelevant dimensions added on top of the signal y.

5.1.2 Balanced problem

When the problem is well balanced ($y^\top 1_n = 0$), y is already centered and $\Pi_n y = y$. Thus the design matrix is represented as $X = [y, Z]$. We consider here the penalized formulation in Eq. (8) with $\nu = 1$ which is the only scenario where we are able to provide a theoretical analysis.

Let us assume that the columns $(z_i)_{i=1,\dots,d-1}$ of Z are i.i.d. with symmetric distribution z, with $\mathbb{E}z = \mathbb{E}z^3 = 0$ and such that $\|z\|_\infty$ is almost surely bounded by $R \geq 0$. We denote by $\mathbb{E}z^2 = m$ its second moment and by $\mathbb{E}z^4/(\mathbb{E}z^2)^2 = \beta$ its (unnormalized) kurtosis.

Surprisingly the clustered vector y happens to generate a solution $yy^\top$ of the relaxation Eq. (8) for all possible values of Z (see Lemma 11 in Appendix D.2). However the problem in Eq. (8) should have a *unique* solution in order to always recover the correct assignment y. Unfortunately the semidefinite constraint $Y \succcurlyeq 0$ of the relaxation makes the second-order information arduous to study. Due to this reason, we consider the other equivalent relaxation in Eq. (12) for which $V_* = vv^\top$ is also solution with $v \propto (X^\top X)^{-1}X^\top y$ (see Lemma 12 in Appendix D.3). Fortunately the semidefinite constraint $V \succcurlyeq 0$ of the problem in Eq. (12) may be ignored since the second-order information in V of the objective function

already provides unicity for the unconstrained problem. Hence we are able to ensure the uniqueness of the solution with high probability.

Proposition 2 *Let us assume $d \geq 3$, $\beta > 1$ and $m^2 \geq \frac{\beta-3}{2(d+\beta-4)}$:*
(a) If $n \geq d^2 R^4 \frac{1+(d+\beta)m^2}{m^2(\beta-1)}$, V_* is the unique solution of the problem in Eq. (12) with high probability.
(b) If $n \geq \frac{d^2R^4}{\min\{m^2(\beta-1), 2m^2, 2m\}}$, v is the principal eigenvector of any solution of the problem in Eq. (12) with high probability.

Let us make the following observations:

- **Proof technique**: The proof relies on a computation of the Hessian of $f(V) = \frac{2}{n}\sum_{i=1}^n \sqrt{(XVX^\top)_{ii}} - \frac{1}{n}\operatorname{tr} X^\top XV$ which is the objective function in Eq. (12). We first derive the expectation of $\nabla^2 f(V)$ with respect to the distribution of X. By the law of large numbers, it amounts to have n going to infinity in $\nabla^2 f(V)$. Then we expand the spectrum of this operator $\mathbb{E}\nabla^2 f(V)$ to lower-bound its smallest eigenvalue. Finally we use concentration theory on matrices, following Tropp (2012), to bound the Hessian $\nabla^2 f(V)$ for finite n.

- **Effect of kurtosis**: We remind that $\beta \geqslant 1$, with equality if and only if z follows a Rademacher law ($\mathbb{P}(z = +1) = \mathbb{P}(z = -1) = 1/2$). Thus, if the noisy dimensions are clustered, then unsurprisingly, our guarantee is meaningless. Note that the constant β behaves like a distance of the distribution z to the Rademacher distribution. Moreover, $\beta = 3$ if z follows a standard normal distribution.

- **Scaling between d and n**: If the noisy variables are not evenly clustered between the same clusters $\{\pm 1\}$ (i.e., $\beta > 1$), we recover a rank-one solution as long as $n = O(d^3)$; while, as long as $n = O(d^2)$, the solution is not unique but its principal eigenvector recovers the correct clustering. Moreover, as explained in the proof, its spectrum would be very spiky.

- The assumption $m^2 \geq \frac{\beta-3}{2(d+\beta-4)}$ is generally satisfied for large dimensions. Note that $m^2 d$ is the total variance of the irrelevant dimensions, and when it is small, i.e., when $m^2 \leq \frac{\beta-3}{2(d+\beta-4)}$, the problem is particularly simple, and we can also show that V_* is the unique solution of the problem in Eq. (12) with high probability if $n \geq \frac{d^2R^4}{m^2}$. Finally, note that for sub-Gaussian distributions (where $\beta \leq 3$), the extra constraint is vacuous, while for super-Gaussian distributions (where $\beta \geq 3$), this extra constraint only appears for small m.

- This result provides the first guarantee for discriminative clustering. However similar theoretical results have been derived for K-means by Ostrovsky et al. (2006) and Gaussian mixtures by Kalai et al. (2010); Moitra and Valiant (2010), where separation conditions between the two clusters are derived, under which the clustering problem is efficiently solved. It would be of great interest to relate these separation conditions to our condition on n and d but this is outside the scope of this work.

5.1.3 Noise robustness for the one dimensional balanced problem

We assume now that the data are one-dimensional and are perturbed by some noise $\varepsilon \in \mathbb{R}^n$ such that $X = y + \varepsilon$ with $y \in \{-1, 1\}^n$. The solution of the relaxation in Eq. (8) recovers the correct y in this setting only when each component of y and $y + \varepsilon$ have the same sign (this is shown in Appendix D.5). This result comes out naturally from the information on whether the signs of y and $y + \varepsilon$ are the same or not. Further if we assume that y and ε are independent, this condition is equivalent to $\|\varepsilon\|_\infty < 1$ almost surely.

5.1.4 Unbalanced problem

When the clusters are imbalanced ($y^\top 1_n \neq 0$), the natural rank-one candidates $Y_* = yy^\top$ and $V_* = vv^\top$ are no longer solutions of the relaxations in Eq. (8) (for $\nu = 1$) and Eq. (12), as proved in Appendix D.6. Nevertheless we are able to characterize some solutions of the penalized relaxation in Eq. (8) for $\nu = 0$.

Lemma 3 *For $\nu = 0$ and for any non-negative $a, b \in \mathbb{R}$ such that $a + b = 1$,*

$$Y = ayy^\top + b1_n 1_n^\top$$

is solution of the penalized relaxation in Eq. (8).

Hence any eigenvector of this solution Y would be supported by the directions y and 1_n. Moreover when the value $\alpha_* = (\frac{1_n^\top y}{n})^2$ is known, it turns out that we can characterize some solutions of the constrained relaxation in Eq. (7), as stated in the following lemma.

Lemma 4 *For $\alpha \geq \alpha_*$,*

$$Y = \frac{1-\alpha}{1-\alpha_*} yy^\top + \Big(1 - \frac{1-\alpha}{1-\alpha_*}\Big) 1_n 1_n^\top$$

is a rank-2 solution of the constrained relaxation in Eq. (7) with constraint parameter α.

The eigenvectors of Y enable to recover y for $\alpha_* \leq \alpha < 1$. We conjecture (and checked empirically) that this rank-2 solution is unique under similar regimes to those considered for the balanced case. The proof would be more involved since, when $\nu \neq 1$, we are not able to derive an equivalent problem in V for the penalized relaxation in Eq. (8) similar to Eq. (12) for the balanced case. We also note that Lemmas 3 and 4 will be direct consequences of Lemma 8 in Section 5.3.

Thus Y being rank-2, one should really be careful and consider the first two eigenvectors when recovering y from a solution Y. This can be done by rounding the principal eigenvector of $\Pi_n Y \Pi_n = \frac{1-\alpha}{1-\alpha_*} \Pi_n y (\Pi_n y)^\top$ as discussed in the following lemma.

Lemma 5 *Let y_{ev} be the principal eigenvector of $\Pi_n Y \Pi_n$ where Y is defined in Lemma 4, then*

$$\operatorname{sign}(y_{ev}) = y.$$

Proof By definition of Y, $y_{ev} = \sqrt{\frac{1-\alpha}{1-\alpha_*}} \Pi_n y$ thus $\operatorname{sign}(y_{ev}) = \operatorname{sign}(\Pi_n y)$ and since $\alpha \leq 1$ then $\operatorname{sign}(\Pi_n y) = \operatorname{sign}(y - \sqrt{\alpha} 1_n) = y$. ■

In practice, contrary to the standard procedure, we should, for any ν, solve the penalized relaxation in Eq. (8) and then do K-means on the principal eigenvector of the centered solution $\Pi_n Y \Pi_n$ instead of the solution Y to recover the correct y. This procedure is followed in our experiments on real-world data in Section 7.2.

5.2 Analysis for two clusters: one-sparse problems

We assume here that the direction of projection v (such that $Xv = y$) is l-sparse (by l-sparse we mean $\|v\|_0 = l$). The ℓ_1-norm regularized problem in Eq. (18) is no longer invariant by affine transformation and we cannot consider that $X = [y, Z]$ without loss of generality. Yet the relaxation Eq. (18) seems experimentally to only have rank-one solutions for the simple $l = 1$ situation. Hence we are able to derive some theoretical analysis only for this case. It is worth noting the $l = 1$ case is simple since it can be solved in $O(d)$ by using K-means separately on all dimensions and ranking them. Nonetheless the proposed scaling also holds in practice for $l \geqslant 1$ (see Figure 1b).

Thereby we consider data $X = [y, Z]$ with $y \in \{-1, 1\}^n$ and $Z \in \mathbb{R}^{n \times (d-1)}$ which are clustered in the direction $v = [1, 0, \dots, 0]^\top \in \mathbb{R}^d$. When adding a ℓ_1-penalty, the initial problem in Eq. (5) for $\alpha = 0$ is

$$\min_{y \in \{-1,1\}^n,\ v \in \mathbb{R}^d} \frac{1}{n} \|y - Xv\|_2^2 + \lambda \|v\|_1^2. \tag{20}$$

When optimizing in v this problem is close to the Lasso (Tibshirani, 1996) and a solution is known to be $v_i^* = (y^\top y + n\lambda)^{-1} y^\top y = \frac{1}{1+\lambda}$, $\forall i \in J$ and $v_i^* = 0$, $\forall i \in \{1, 2, \dots, d\} \setminus J$, where J is the support of v^*. The candidate $V_* = v^* v^{*\top}$ is still a solution of the relaxation in Eq. (18) (see Lemma 15 in Appendix E.1) and we will investigate under which conditions on X this solution is unique. Let us assume as before $(z_i)_{i=1,\dots,d}$ are i.i.d. with distribution z symmetric with $\mathbb{E}z = \mathbb{E}z^3 = 0$, and denote by $\mathbb{E}z^2 = m$ and $\mathbb{E}z^4/(\mathbb{E}z^2)^2 = \beta$. We also assume that $\|z\|_\infty$ is almost surely bounded by $0 \leq R \leq 1$. We are able to ensure the uniqueness of the solution with high-probability.

Proposition 6 *Let us assume $d \geq 3$.*
(a) If $n \geq dR^2 \frac{1+(d+\beta)m^2}{m^2(\beta-1)}$, V_* is the unique solution of the problem Eq. (12) with high probability.
(b) If $n \geq \frac{dR^2}{m^2(\beta-1)}$, v^* is the principal eigenvector of any solution of the problem Eq. (12) with high probability.

The proof technique is very similar to the one of Proposition 2. With the function $g(V) = \frac{2}{n} \sum_{i=1}^n \sqrt{(XVX^\top)_{ii}} - \lambda \|V\|_1 - \frac{1}{n} \operatorname{tr} X^\top XV$, we can certify that g will decrease around the solution V_* by analyzing the eigenvalues of its Hessian.

The rank-one solution V_* is recovered by the principal eigenvector of the solution of the relaxation Eq. (18) as long as $n = O(d)$. Thus we have a much better scaling when compared to the non-sparse setting where $n = O(d^2)$. We also conjecture a scaling of order $n = O(ld)$ for a projection in a l-sparse direction (see Figure 1b for empirical results).

The proposition does not state any particular value for the regularizer parameter λ. This makes sense since the proposition only holds for the simple situation when $l = 1$. We propose to use $\lambda = 1/\sqrt{n}$ by analogy with the Lasso.

5.3 Analysis for the multi-label extension

In this section, the signals share k labels which are corrupted by some extra noisy dimensions. We assume the centered design matrix to be $X = [\Pi_n y, Z]$ where $y \in \{-1, +1\}^{n \times k}$ and $Z \in \mathbb{R}^{n \times (d-k)}$. We also assume that y is full-rank[1]. We denote by $y = [y_1, \dots, y_k]$ and $\alpha_i = \left(\frac{y_i^\top 1_n}{n}\right)^2$ for $i = 1, \cdots, k$. We consider the discrete constrained problem

$$\min_{v \in \mathbb{R}^{d \times k},\ y \in \{-1,1\}^{n \times k}} \frac{1}{n} \|\Pi_n y - Xv\|_F^2 \text{ such that } \frac{1_n^\top y y^\top 1_n}{n^2} = \alpha^2, \tag{21}$$

and the discrete penalized problem for $\nu = 0$

$$\min_{v \in \mathbb{R}^{d \times k},\ y \in \{-1,1\}^{n \times k}} \frac{1}{n} \|\Pi_n y - Xv\|_F^2. \tag{22}$$

As explained in Section 4, these two discrete problems admit the same relaxations in Eq. (7) and Eq. (8) we have studied for one label. We now investigate when the solution of the problems in Eq. (21) and in Eq. (22) generate solutions of the relaxations in Eq. (7) and Eq. (8).

By analogy with Lemma 3, we want to characterize the solutions of these relaxations which are supported by the constant vector 1_n and the labels $(y_1, \dots, y_k)$. Their general form is $Y = \tilde{y} A \tilde{y}^\top$ where $A \in \mathbb{R}^{k \times k}$ is symmetric semi-definite positive and $\tilde{y} = [1_n, y]$. However the initial y is easily recovered from the solution Y only when A is diagonal. To that end the following lemma derives some condition under which the only matrix A such that the corresponding Y satisfies the constraint of the relaxations in Eq. (7) and Eq. (8) is diagonal.

Lemma 7 *The solutions of the matrix equation $\operatorname{diag}(\tilde{y} A \tilde{y}^\top) = 1_n$ with unknown variable A are diagonal if and only if the family $\{1_n, (y_i)_{1 \leq i \leq k}, (y_i \odot y_j)_{1 \leq i < j \leq k}\}$ is linearly independent where we denoted by $\odot$ the Hadamard (i.e., pointwise) product between matrices.*

In this way we are able to characterize the solution of relaxations in Eq. (7) and Eq. (8) with the following result:

Lemma 8 *Let us assume that the family $\{1_n, (y_i)_{1 \leq i \leq k}, (y_i \odot y_j)_{1 \leq i < j \leq k}\}$ is linearly independent. If $\alpha \geq \alpha_{\min} = \min_{1 \leq i \leq k} \{\alpha_i\}$ with $(\alpha_i)_{1 \leq i \leq k}$ defined above Eq. (21), the solutions of the constrained relaxation in Eq. (7) supported by the vectors $(1_n, y_1, \cdots, y_k)$ are of the form:*

$$Y = a_0^2 1_n 1_n^\top + \sum_{i=1}^k a_i^2 y_i y_i^\top,$$

where $(a_i)_{0 \leq i \leq k}$ satisfies $\sum_{i=0}^k a_i^2 = 1$ and $a_0^2 + \sum_{i=1}^k a_i^2 \alpha_i = \alpha$.

1. This assumption is fairly reasonable since the probability of a matrix whose entries are i.i.d. Rademacher random variables to be singular is conjectured to be $1/2 + o(1)$ (Bourgain et al., 2010).

Moreover the solutions of the penalized relaxation in Eq. (8) for $\nu = 0$ which are supported by the vectors $(1_n, y_1, \cdots, y_k)$ are of the form:

$$Y = a_0^2 1_n 1_n^\top + \sum_{i=1}^k a_i^2 y_i y_i^\top,$$

where $(a_i)_{0\leq i\leq k}$ satisfies $\sum_{i=0}^k a_i^2 = 1$.

In the *multi-label* case, some combinations of the constant matrix $1_n 1_n^\top$ and the rank-one matrices $y_i y_i^\top$ are solutions of constrained or penalized relaxations. Furthermore, under some assumptions on the labels $(y_i)_{1\leq i\leq k}$, these combinations are the only solutions which are supported by the vectors $(1_n, y_1, \cdots, y_k)$. And we conjecture (and checked empirically) that under assumptions similar to those made for the balanced one-label case, all the solutions of the relaxation are supported by the family $(1_n, y_1, \cdots, y_k)$ and consequently share the same form as in Lemma 8. Thus the eigenvector of the solution Y would be in the span of the directions $(1_n, y_1, \cdots, y_k)$.

Let us consider an eigenvalue decomposition of $Y = FF^\top = \sum_{i=0}^k \lambda_i e_i e_i^\top$ and denote by $M = [a_0 1_n, a_1 y_1, \cdots, a_k y_k]$ where $(a_i)_{0\leq i\leq k}$ are defined in Lemma 8. Since $MM^\top = FF^\top$, there is an orthogonal transformation R such that $FR = M$. We also denote the product FR by $FR = [\xi_0, \cdots, \xi_K]$. We propose now an alternating minimization procedure to recover the labels $(y_1, \cdots, y_k)$ from M.

Lemma 9 *Consider the optimization problem*

$$\min_{M\in\mathcal{M},\ R\in\mathbb{R}^{k\times k}:\ R^\top R = I_k} \|FR - M\|_F^2,$$

where $\mathcal{M} = \{[a_0 1_n, a_1 y_1, \cdots, a_k y_k], a \in \mathbb{R}^{k+1} : \|a\|_2 = 1, y_i \in \{\pm 1\}^n\}$.

Given M, the problem is equivalent to the orthogonal Procrustes problem (Schönemann, 1966). Denote by $U\Delta V^\top$ a singular value decomposition of $F^\top M$. The optimal R is obtained as $R = UV^\top$. While given R, the optimal M is obtained as

$$M = \frac{1}{\sqrt{\|\xi_1\|_1^2 + \|\xi_2\|_1^2 + \ldots + \|\xi_k\|_1^2}} [\|\xi_0\|_1 \operatorname{sign}(\xi_0), \cdots, \|\xi_k\|_1 \operatorname{sign}(\xi_k)].$$

Proof We give only the argument for the optimization problem with respect to M. Given R, the optimization problem in M is equivalent to $\max_{a\in\mathbb{R}^{k+1}:\|a\|_2=1,\ y\in\{-1,1\}^{n\times k}} \operatorname{tr}(FR)^\top M$ and $\operatorname{tr}(FR)^\top M = a_0 \xi_0^\top 1_n + \sum_{i=1}^k a_i \xi_i^\top y_i$. Thus by property of the dual norms the solution is given by $y_i = \operatorname{sign}(\xi_i)$ and $a_i = \frac{\|\xi_i\|_1}{\sqrt{\|\xi_1\|_1^2 + \|\xi_2\|_1^2 + \ldots + \|\xi_k\|_1^2}}$. ■

The minimization problem in Lemma 9 is non-convex; however we observe that performing few alternating optimizations is sufficient to recover the correct $(y_1, \ldots, y_k)$ from M.

5.4 Discussion

In this section we studied the tightness of convex relaxations under simple scenarios where the relaxed problem admits low-rank solutions generated by the solution of the original non-convex problem. Unfortunately the solutions lose the characterized rank when the initial problem is slightly perturbed since the rank of a matrix is not a continuous function. Nevertheless, the spectrum of the new solution is really spiked, and thus these results are quite conservative. We empirically observe that the principal eigenvectors keep recovering the correct information outside these scenarios. However this simple proof mechanism is not easily adaptable to handle perturbed problems in a straightforward way since it is difficult to characterize the properties of eigenvectors of the solution of a semi-definite program. Hence we are able to derive a proper theoretical study only for these simple models.

6. Algorithms

In this section, we present an optimization algorithm which is adapted to large n settings, and avoids the n-dimensional semidefinite constraint.

6.1 Reformulation

We aim to solve the general regularized problem which corresponds to Eq. (15)

$$\max_{V\succcurlyeq 0} \frac{2}{n}\sum_{i=1}^n \sqrt{(XVX^\top)_{ii}} - \frac{1}{n}\operatorname{tr} V(X^\top X + n\operatorname{Diag}(a)^2) - \|\operatorname{Diag}(c)V\operatorname{Diag}(c)\|_1. \tag{23}$$

We consider a slightly different optimization problem:

$$\max_{V\succcurlyeq 0} \frac{1}{n}\sum_{i=1}^n \sqrt{(XVX^\top)_{ii}} - \|\operatorname{Diag}(c)V\operatorname{Diag}(c)\|_1 \quad \text{s.t. } \operatorname{tr} V(\frac{1}{n}X^\top X + \operatorname{Diag}(a)^2) = 1. \tag{24}$$

When c is equal to zero, then Eq. (24) is exactly equivalent to Eq. (23); when c is small (as will typically be the case in our experiments), the solutions are very similar—in fact, one can show by Lagrangian duality that by a sequence of problems in Eq. (24), one may obtain the solution to Eq. (23).

6.2 Smoothing

By letting $A = \frac{X^\top X}{n} + \operatorname{Diag}(a)^2$, we consider a strongly-convex approximation of Eq. (24) as:

$$\begin{aligned} \max_{V\succcurlyeq 0} \quad & \frac{1}{n}\sum_{i=1}^n \sqrt{(XVX^\top)_{ii}} - \|\operatorname{Diag}(c)V\operatorname{Diag}(c)\|_1 - \varepsilon \operatorname{tr}[(A^{\frac12}VA^{\frac12})\log(A^{\frac12}VA^{\frac12})] \\ \text{s.t.} \quad & \operatorname{tr}(A^{\frac12}VA^{\frac12}) = 1, \end{aligned} \tag{25}$$

where $-\operatorname{tr} M\log(M)$ is a spectral convex function called the von-Neumann entropy (von Neumann, 1927). The difference in the two problems is known to be $\varepsilon\log(d)$ (Nesterov, 2007). As shown in Appendix G.1, the dual problem is

$$\min_{u\in\mathbb{R}_+^n, C\in\mathbb{R}^{d\times d}:|C_{ij}|\leqslant c_i c_j} \frac{1}{2n}\sum_{i=1}^n \frac{1}{u_i} + \phi^\varepsilon\big(A^{-\frac12}\big(\frac{1}{2n}X^\top\operatorname{Diag}(u)X - C\big)A^{-\frac12}\big), \tag{26}$$

where $\phi^\varepsilon(M)$ is an ε-smooth approximation to the maximal eigenvalue of the matrix M.

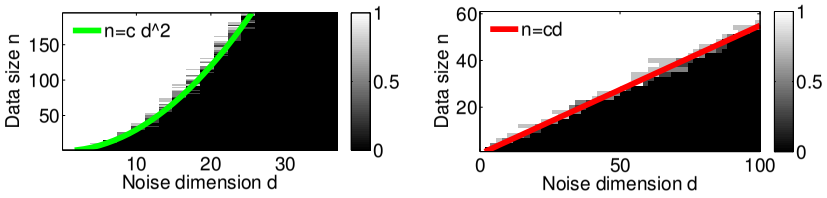
6.3 Optimization algorithm

In order to solve Eq. (26), we split the objective function into a smooth part $F(u,C) = \phi^{\varepsilon}\big(A^{-\frac{1}{2}}\big(\frac{1}{2n}X^\top \operatorname{Diag}(u)X - C\big)A^{-\frac{1}{2}}\big)$ and a non-smooth part $H(u,C) = \mathbb{I}_{|C_{ij}|\leqslant c_i c_j} + \frac{1}{2n}\sum_{i=1}^n \frac{1}{u_i}$. We may then apply FISTA (Beck and Teboulle, 2009) updates to the smooth function $\phi^{\varepsilon}(A^{-\frac{1}{2}}(\frac{1}{2n}X^\top \operatorname{Diag}(u)X - C)A^{-\frac{1}{2}})$, along with a proximal operator for the non-smooth terms $\mathbb{I}_{|C_{ij}|\leqslant c_i c_j}$ and $\frac{1}{2n}\sum_{i=1}^n \frac{1}{u_i}$, which may be computed efficiently. See details in Appendix G.2.

Running-time complexity. Since we need to project on the SDP cone of size d at each iteration, the running-time complexity per iteration is $O(d^3 + d^2 n)$; given that often $n \geqslant d$, the dominating term is $O(d^2 n)$. It is still an open problem to make this linear in d. Our function being $O(1/\varepsilon)$-smooth, the convergence rate is of the form $O(1/(\varepsilon t^2))$. Since we stop when the duality gap is $\varepsilon \log(d)$ (as we use smoothing, it is not useful to go lower), the number of iterations is of order $1/(\varepsilon\sqrt{\log(d)})$. The proposed algorithm is a clear improvement over the existing approach by Bach and Harchaoui (2007) which is quadratic in n.

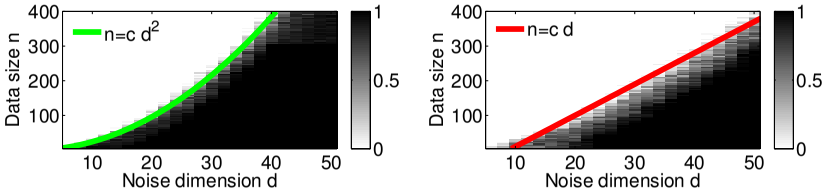
7. Experiments

We implemented the proposed algorithm in Matlab. The code has been made available in `https://drive.google.com/uc?export=download&id=0B5Bx9jrp7celMk5pOFI4UGt0ZEk`. Two sets of experiments were performed: one on synthetically generated data sets and the other on real-world data sets. The details about experiments follow.



7.1 Experiments on synthetic data

In this section, we illustrate our theoretical results and algorithms on synthetic examples. The synthetic data were generated by assuming a fixed clustering with $\alpha_* \in [0,1]$, along a single direction and the remaining variables were whitened. We consider clustering error defined for a predictor $\bar{y}$ as $1 - (\bar{y}^\top y/n)^2$, with values in $[0,1]$ and equal to zero if and only if $y = \bar{y}$.



Phase transition. We first illustrate our theoretical results for the balanced case in Figure 1. We solve the relaxation in Eq. (12) and Eq. (18) for a large range of d and n using the `cvx` solver (Grant and Boyd, 2008, 2014). We show the results averaged over 4 replications and take $\lambda = 1/\sqrt{n}$ for the sparse problems. In Figure 1a, we investigate whether `cvx` finds a rank-one solution for a problem of size (n,d) (the value is 1 if the solution is rank-one and 0 otherwise). We compare the performance of the algorithms without ℓ_1-regularization in the affine invariant case and with ℓ_1-regularization in the 1-sparse case. We observe a phase transition with a scaling over the form $n = O(d^2)$ for the affine invariant case and $n = O(d)$ for the 1-sparse case. This is better than what is expected by the theory and corresponds rather to the performance of the principal eigenvector of the solution. It is worth noting that it may be uncertain to really distinguish between a rank-one solution and a spiked solution.

We also solve the relaxation for 4-sparse problems of different sizes d and n and plot the clustering error. We compare, in Figure 1b, the performance of the formulation in Eq. (12)

(without ℓ_1-regularization) which corresponds to the affine invariant case, against the ℓ_1-regularized formulation in Eq. (18). We notice a phase transition of the clustering error with a scaling over the form $n = O(d^2)$ for the affine invariant case and $n = O(d)$ for the 4-sparse case. It supports our conjecture on the scaling of order $n = O(ld)$ for l-sparse problems. Comparing left plots of Figure 1a and Figure 1b, we observe that the two phase-transitions occur at the same scaling between n and d. Thus there are few values of (n,d) for which the `cvx` solver finds a solution whose rank is strictly larger than one and whose principal eigenvector has a low clustering error. This illustrates, in practice, this solver aims to find a rank-one solution under the improved scaling $n = O(d^2)$.

(b) Phase transition for clustering error. Left: affine invariant case . Right: 4-sparse case.

Figure 1: Phase transition plots.

Unbalanced case. We generate an unbalanced problem for $d = 10$, $n = 80$ and $\alpha_* = 0.25$ and we average the results over 10 replications. We compare the clustering error for the constrained and the penalized relaxations in Eq. (7) and Eq. (8) when we consider the sign of the first or second eigenvector and when we use projection technique defined as $(\Pi_n Y_{(2)} \Pi_n)_{(1)}$ where $Y_{(k)}$ is the best rank-k approximation of Y, to extract the information of y. We see in Figure 2 that (a) for the constrained case, the range of α such that the sign of y is recovered is cut in two parts where one eigenvector is correct, whereas the projection method performs well on the whole set. (b) For the penalized case, the correct sign is

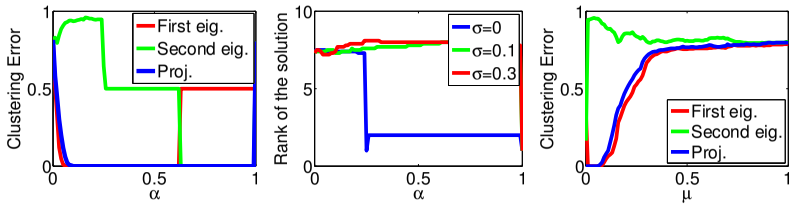

Figure 2: Unbalanced problem for $n = 80$, $d = 10$ and $\alpha_* = 0.25$. Left: Clustering error for the constrained relaxation. Middle: Rank of the solution for different level of noise σ. Right: Clustering error for the penalized relaxation.

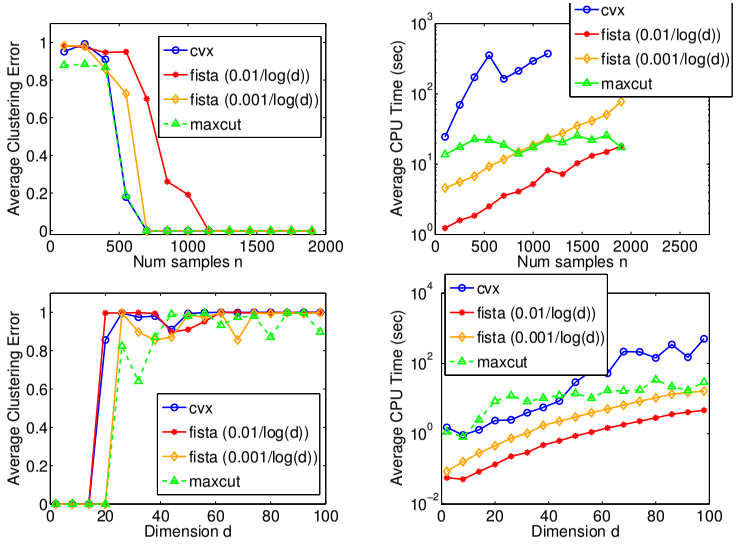
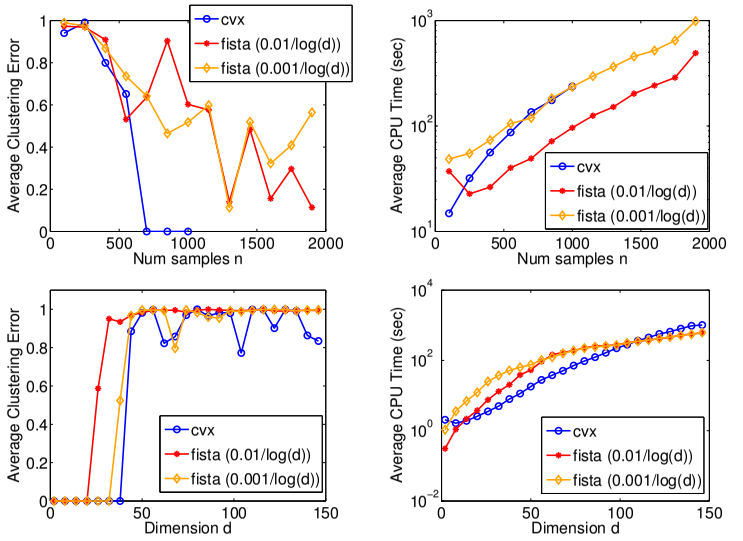


recovered for ν close to 0 by the first eigenvector and the projection method whereas the second one performs always badly. (c) When there is zero noise the rank of the solution is one for $\alpha \in \{\alpha_*, 1\}$, two for $\alpha \in (\alpha_*, 1)$ and greater otherwise. These findings confirm our analysis. However, when y is corrupted by some noise this result is no longer true.

Runtime experiments. We generated data with a k-sparse direction of projection v by adding $d - k$ noise variables to a randomly generated and rotated k-dimension data. The scalability of the FISTA based optimization algorithm illustrated in Section 6.3 to solve Eq. (24) (with $c = \sqrt{\lambda} 1_d$, $a = 0_d$) was compared against a benchmark `cvx` solver (which solves Eq. (18)). Experiments were performed for $\lambda = 0$ and $\lambda = 0.001$, the coefficient associated with the sparse $\|V\|_1$ term. For a fixed d, `cvx` breaks down for large n values (typically $n \geqslant 1000$). Similarly, the runtime required by `cvx` is generally high for $\lambda = 0$ and is comparable to our method for $\lambda = 0.001$. This behavior is illustrated in Figure 3.

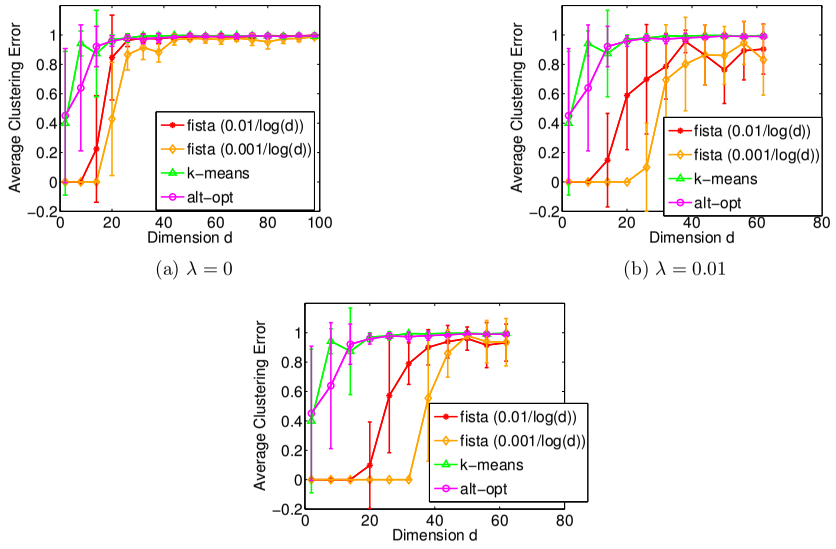


When $\lambda = 0$, the problem reduces exactly to the original Diffrac problem (Bach and Harchaoui, 2007). In the plots in Figure 3a our implementation using FISTA is compared to the baseline Diffrac which is solved with max-cut SDP (Boumal et al., 2014). We observed that our method is comparable in terms of runtime and clustering performance of low-rank methods for max-cut. However, for $\lambda > 0$, the equivalence with max-cut disappears.

The plots in these figures show the behavior of FISTA for two different stopping criteria: $\varepsilon = 10^{-2}/\log(d)$ and $\varepsilon = 10^{-3}/\log(d)$. It is observed that the choice $10^{-3}/\log(d)$ gives a better accurate solution at the cost of more number of iterations (and hence higher runtime). For sparse problems in Figure 3b, we see that cvx gets a better clustering performance (while crashing for large n); the difference would be reduced with a smaller duality gap for FISTA.

Clustering performance. Experiments comparing the proposed method (Eq. (24) with $c = \sqrt{\lambda} 1_d$ and $a = 0_d$ solved using FISTA based optimization algorithm, and Eq. (18) solved using benchmark `cvx` solver) with K-means and alternating optimization are given in Figure 4. K-means is run on the whitened variables in $\mathbb{R}^d$. Alternating optimization is another popular method proposed by Ye et al. (2008) for dimensionality reduction with clustering (where alternating optimization of w and y is performed to solve the non-convex formulation (2)). The plots show that both K-means and alternating optimization fail when only a few dimensions of noise variables are present. The plots also show that with the introduction of a sparse regularizer (corresponding to the non-zero λ) the proposed

(a) `cvx`, max-cut comparison with $\lambda = 0$. Top: n varied with $d = 50$, $k = 6$. `cvx` crashed for $n \approx 1000$. Bottom: d varied with $n = 100$, $k = 2$.



(b) `cvx` comparison with $\lambda = 0.001$. Top: n varied with $d = 50$, $k = 6$. `cvx` crashed for $n \approx 1000$. Bottom: d varied with $n = 100$, $k = 2$.

Figure 3: Scalability experiments.

method becomes more robust to noisy dimensions. As observed earlier, the performance of FISTA is also sensitive to the choice of ε.

Finally we give a comparison of sparse discriminative clustering (cvx and FISTA) with max-margin clustering (Li et al., 2009) in Figure 5. We note that square loss is used in our framework whereas hinge loss is used in max-margin clustering. We have also included the behavior of K-means and alternating optimization methods in Figure 5 for completeness. From this plot, it is clear that the max-margin clustering is sensitive to noisy dimensions present in the data. Sparse discriminative clustering with square loss is able to maintain zero cluster error for a large number of noisy dimensions, while the performance of max-margin clustering starts deteriorating after adding a few noisy dimensions. However, we note from Figure 5 that for large dimensions, the hinge loss used in max-margin clustering is observed to provide a better solution than the square loss used in our framework.

7.2 Experiments on real-world data

Experiments on two-class data. Experiments were conducted on real two-class classification datasets[2] to compare the performance of sparse discriminative clustering against non-sparse discriminative clustering, alternating optimization, K-means and max-margin

2. The data sets were obtained from `https://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/`

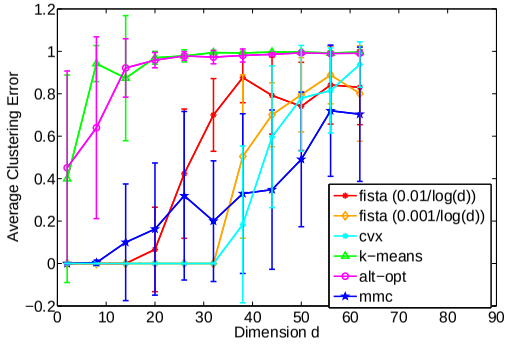

Figure 5: Comparison with k-means, alternating optimization and max-margin clustering (mmc), $n = 100$. The plots for FISTA, `cvx` and mmc correspond to the best choice of regularization parameters.

clustering algorithms. For sparse and non-sparse discriminative clustering, we consider the problem in Eq. (24) and the algorithm detailed in Section 6.3 (with the regularization $c = 0$ for the non-sparse case). The alternating optimization method is described in Proposition 1. For the two-class datasets, the clustering performance for a cluster $\bar{y} \in \{+1, -1\}^n$ obtained from an algorithm under comparison, was computed as $1-(\bar{y}^\top y/n)^2$, where y is the original labeling. Here we explicitly compare the output of clustering with the original labels of the data points.

The dataset details and clustering performance results are summarized in Table 1. The experiments for discriminative clustering were conducted for different values of $a, c \in \{10^{-3}, 10^{-2}, 10^{-1}\}1_d$ associated with the ℓ_2-regularizer and ℓ_1-regularizer respectively. The range of cluster imbalance parameter was chosen to be $\nu \in \{0.01, 0.25, 0.5, 0.75, 1\}$. Note that for $\nu \neq 1$, the reformulation given in Eq. (14) was used, as explained after Eq. (17) in Section 3. The results given in Table 1 pertain to the best choices of these parameters. Similarly, the values of regularization parameter for max-margin clustering (Li et al., 2009) were chosen from the set $\{10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}, 0.1, 1, 10\}$ and the cluster balance parameter was chosen from $\{0.1, 0.2, \ldots, 0.9\}$. The results for alternating optimization and K-means show the average cluster error (and standard deviation) over 10 different runs. These results show that the cluster error is quite high for many datasets. This is primarily due to the absence of an ambient low-dimensional clustering of the two-class data, which can be identified by the simple linear model presented in this paper. Since K-means does not provide explicit dimensionality reduction, it might not be able to take advantage of the existence of an ambient low-dimensional clustering of the two-class data and its performance is poor. The results show that max-margin clustering achieves best clustering performance on most datasets. This improved performance of max-margin clustering may be due to the use of hinge loss, as opposed to square loss used in discriminative clustering in this paper. However for the heart dataset, we note that the sparse version with the square loss performs

significantly better than the non-sparse version with the hinge loss (see additional experiments in Figure 5). The results also show that adding sparse regularizers to discriminative clustering helps in a better cluster identification when compared to the non-sparse case.

Table 1: Experiments on two-class datasets

Dataset	n	d	Cluster Error				
			Sparse Discriminative Clustering	Non-sparse Discriminative Clustering	Alternating Optimization	K-means	Max-margin Clustering

Experiments on real multi-label data. Experiments were also conducted on the Microsoft COCO dataset[3] to demonstrate the effectiveness of the proposed method in discovering multiple labels. We considered $n = 2000$ images from the dataset, each of which was labeled with a subset of $K = 80$ labels. The labels identified the objects in the images like person, car, chair, table, etc. and the corresponding features for each image were extracted from the last layer of a conventional convolutional neural network (CNN). The CNN was originally trained over the imagenet data (Krizhevsky et al., 2012).

For each image in the dataset, we obtained $d = 1000$ features. We then performed discriminative clustering on the 2000×1000 data matrix X and obtained the label matrix Y which was then subjected to the alternating optimization procedure (see Section 5.3).

It is clearly unlikely to recover perfect labels; therefore we now describe a way of measuring the amount of information which is recovered. In order to extract meaningful cluster information from the result so-obtained, we computed the correlation matrix $Y_k^\top \Pi_n Y_{true}$ where Y_{true} is the $n \times K$ label matrix containing actual labels and Π_n is the $n \times n$ centering matrix $I_n - \frac{1}{n} 1_n 1_n^\top$. The k predicted labels for the examples are present in the Y_k matrix of size $n \times k$. In order to choose an appropriate value of k, we plotted $\mathrm{Tr}(\Phi_{Y_{true}} \Phi_{Y_k})$ (shown in Figure 6 along with a K-means baseline), where $\Phi_{Y_k} = Y_k (Y_k{}^\top Y_k)^{-1} Y_k^\top$. From these plots, we chose $k = 30$ to be a suitable value for our interpretation purposes.

After choosing an arbitrary value of $k = 30$, we plotted the correlations between the actual and predicted labels. The heat map of the normalized absolute correlations is given in Figure 7, where the columns and rows corresponding to the 80 true labels and 30 predicted labels respectively, are ordered according to the sum of squared correlations (the top-scoring labels appear to the left-bottom). From this plot, we extract following highly correlated

3. Dataset obtained from `http://mscoco.org/dataset`

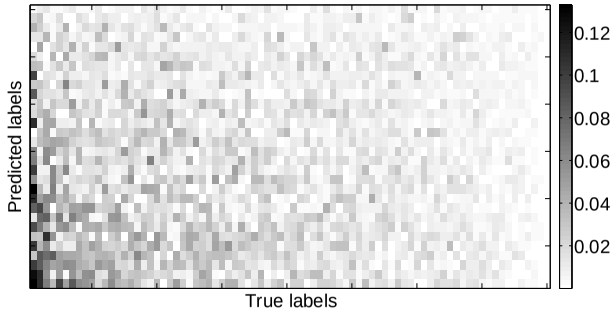

Figure 7: Heat map of correlations, $Y_k^\top \Pi_n Y_{true}$ with $k = 30$, with columns and rows ordered according to the sum of squared correlations.

labels: person, dining table, car, chair, cup, tennis racket, bowl, truck, fork, pizza, showing that these labels were partially recovered by our unsupervised technique (note that the CNN features are learned with supervision on the different dataset Imagenet, hence there is still some partial supervision).

8. Conclusion

In this paper, we provided a sparse extension of the discriminative clustering framework, and gave a first analysis of its theoretical performance in the totally unsupervised situation, highlighting provable scalings between ambient dimension d, number of observations and "clusterability" of irrelevant variables. We also proposed an efficient algorithm which is the first of its kind to be linear in the number of observations for discriminative clustering with the square loss. Our work could be extended in a number of ways, e.g., extending the sparse

analysis to l-sparse case with higher l, extending the framework to nonlinear clustering using kernels, considering related weakly supervised learning extensions (Joulin and Bach, 2012), going beyond uniqueness of rank-one solutions, and improving the complexity of our algorithm to $O(nd)$, for example using stochastic gradient techniques.

Acknowledgments

The authors would like to thank Nicolas Boumal for interesting discussions and for his advice on max-cut implementation, Piotr Bojanowski for his help with multi-label datasets and the reviewers for their constructive and helpful comments which helped to significantly improve the paper.

Appendix A. Joint clustering and dimension reduction

Given y, we need to optimize the Rayleigh quotient $\frac{w^\top X^\top y y^\top X w}{w^\top X^\top X w}$ with a rank-one matrix in the numerator, which leads to $w = (X^\top X)^{-1} X^\top y$. Given w, we will show that the averaged distortion measure of K-means once the means have been optimized is exactly equal to $(y^\top \Pi_n X w)^2 / \|\Pi_n y\|_2^2$. Given the data matrix $X \in \mathbb{R}^{n \times d}$, K-means to cluster the data into two components will tend to approximate the data points in X by the centroids $c_+ \in \mathbb{R}^d$ and $c_- \in \mathbb{R}^d$ such that

$$\begin{aligned} X &\approx \frac{(y+1_n)}{2} c_+^\top - \frac{(y-1_n)}{2} c_-^\top \text{ (since } y \in \{-1,1\}^n) \\ &= \frac{y}{2}(c_+^\top - c_-^\top) + \frac{1}{2} 1_n (c_+^\top + c_-^\top). \end{aligned}$$

The objective of K-means can now be written as problem $\mathcal{KM}$:

$$\begin{aligned} &\min_{y, c_+, c_-} \left\| X - \frac{y}{2}(c_+^\top - c_-^\top) - \frac{1}{2} 1_n (c_+^\top + c_-^\top) \right\|_F^2 \\ &= \min_{y, c_+, c_-} \left\| X - \frac{(y+1_n)}{2} c_+^\top - \frac{(1_n - y)}{2} c_-^\top \right\|_F^2 \\ &= \min_{y, c_+, c_-} \|X\|_F^2 + \|c_+^\top\|_F^2 \left\| \frac{(y+1_n)}{2} \right\|^2 + \|c_-^\top\|_F^2 \left\| \frac{(1-y_n)}{2} \right\|^2 + 2 c_-^\top c_+ \frac{(y+1_n)}{2}^\top \frac{(1_n - y)}{2} \\ &\qquad -2 \operatorname{tr} X^\top \left(\frac{(y+1_n)}{2} c_+^\top + \frac{(1_n - y)}{2} c_-^\top \right) \\ &= \min_{y, c_+, c_-} \|X\|_F^2 + \|c_+^\top\|_F^2 \frac{1}{2}(n + 1_n^\top y) + \|c_-^\top\|_F^2 \frac{1}{2}(n - 1_n^\top y) - 2 c_+^\top X^\top \left(\frac{y+1_n}{2} \right) \\ &\qquad -2 c_-^\top X^\top \left(\frac{1_n - y}{2} \right). \end{aligned}$$

Fixing y and minimizing with respect to c_+ and c_-, we get closed-form expressions for c_+ and c_- as

$$c_+ = \frac{X^\top (y + 1_n)}{(n + 1_n^\top y)} \quad \text{and} \quad c_- = \frac{X^\top (1_n - y)}{(n - 1_n^\top y)}.$$

Substituting these expressions in $\mathcal{KM}$, we have the following optimization problem in y:

$$\begin{aligned}
&\min_y \|X\|_F^2 - \frac{1}{2}\frac{\|X^\top(y+1_n)\|_F^2}{(n+1_n^\top y)} - \frac{1}{2}\frac{\|X^\top(1_n-y)\|_F^2}{(n-1_n^\top y)} \\
&= \min_y \|X\|_F^2 - \frac{1}{2}\frac{\operatorname{tr} XX^\top(y+1_n)(y+1_n)^\top}{(n+1_n^\top y)} - \frac{1}{2}\frac{\operatorname{tr} XX^\top(1_n-y)(1_n-y)^\top}{(n-1_n^\top y)} \\
&= \min_y \|X\|_F^2 - \frac{2}{(n+1_n^\top y)}\operatorname{tr} XX^\top\left(\frac{y+1_n}{2}\right)\left(\frac{y+1_n}{2}\right)^\top \\
&\qquad - \frac{2}{(n-1_n^\top y)}\operatorname{tr} XX^\top\left(\frac{1_n-y}{2}\right)\left(\frac{1_n-y}{2}\right)^\top \\
&= \min_y \ \operatorname{tr} XX^\top - \frac{2}{(n+1_n^\top y)}\operatorname{tr} XX^\top\left(\frac{y+1_n}{2}\right)\left(\frac{y+1_n}{2}\right)^\top \\
&\qquad - \frac{2}{(n-1_n^\top y)}\operatorname{tr} XX^\top\left(\frac{1_n-y}{2}\right)\left(\frac{1_n-y}{2}\right)^\top \\
&= \min_y \ \operatorname{tr} XX^\top\Big(I - \frac{1}{2(n+1_n^\top y)}(yy^\top + 1_n1_n^\top + y1_n^\top + 1_ny^\top) \\
&\qquad - \frac{1}{2(n-1_n^\top y)}(1_n1_n^\top + yy^\top - 1_ny^\top - y1_n^\top)\Big).
\end{aligned}$$

By the centering of X, we have $1_n^\top X = 0$ and hence $\operatorname{tr} XX^\top 1_n1_n^\top = \operatorname{tr} XX^\top 1_ny^\top = \operatorname{tr} XX^\top y1_n^\top = 0$. Therefore, we obtain

$$\begin{aligned}
&\min_y \ \operatorname{tr} XX^\top\Big(I - \frac{1}{2(n+1_n^\top y)}(yy^\top) - \frac{1}{2(n-1_n^\top y)}(yy^\top)\Big) \\
&= \min_y \ \operatorname{tr} XX^\top\Big(I - (yy^\top)\Big(\frac{1}{2(n+1_n^\top y)} + \frac{1}{2(n-1_n^\top y)}\Big)\Big) \\
&= \min_y \ \operatorname{tr} XX^\top\Big(I - (yy^\top)\Big(\frac{n}{n^2-(1_n^\top y)^2)}\Big)\Big) \\
&= \min_y \ \operatorname{tr} XX^\top\Big(I - \frac{nyy^\top}{n^2-(1_n^\top y)^2}\Big).
\end{aligned}$$

Thus we have the equivalent K-means problem as

$$\min_{y\in\{-1,1\}^n} \frac{1}{n}\operatorname{tr} Xww^\top X^\top\Big(I - \frac{n}{n^2-(y^\top 1)^2}yy^\top\Big) = 1 - \max_{y\in\{-1,1\}^n}\frac{(w^\top X^\top y)^2}{n^2-(y^\top 1)^2}.$$

Thus the averaged distortion measure of K-means with the optimized means is $\frac{(y^\top\Pi_nXw)^2}{\|\Pi_ny\|_2^2}$.

Appendix B. Full (unsuccessful) relaxation

It is tempting to find a direct relaxation of Eq. (2). It turns out to lead to a trivial relaxation, which we outline in this section. When optimizing Eq. (2) with respect to w, we obtain $\max_{y\in\{-1,1\}^n}\frac{y^\top X(X^\top X)^{-1}X^\top y}{y^\top\Pi_ny}$, leading to a quasi-convex relaxation as $\max_{\substack{Y\succcurlyeq 0,\\ \operatorname{diag}(Y)=1}}\frac{\operatorname{tr} YX(X^\top X)^{-1}X^\top}{\operatorname{tr}\Pi_nY}$. Unfortunately, this relaxation always leads to trivial solutions as described below.

Consider the quasi-convex relaxation

$$\max_{Y\succcurlyeq 0,\operatorname{diag}(Y)=1}\frac{\operatorname{tr} YX(X^\top X)^{-1}X^\top}{\operatorname{tr}\Pi_nY}. \tag{27}$$

By definition of Π_n this relaxation is equal to:

$$\max_{Y\succcurlyeq 0,\operatorname{diag}(Y)=1}\frac{1}{n}\frac{\operatorname{tr} YX(X^\top X)^{-1}X^\top}{1-\frac{1_n^\top Y1_n}{n^2}}.$$

Let $\mathcal{A} = \{Y \succcurlyeq 0,\ \operatorname{diag}(Y) = 1\}$ the feasible set of this problem and define $\mathcal{B} = \{M \succcurlyeq 0,\ \operatorname{diag}(M) = 1 + \frac{1_n^\top M1_n}{n^2}\}$. Let $Y \in \mathcal{A}$, then M defined by $M = \frac{Y}{1-\frac{1_n^\top Y1_n}{n^2}}$ belongs to $\mathcal{B}$ since $1 + \frac{1_n^\top M1_n}{n^2} = 1 + \frac{1_n^\top Y1_n}{n^2-1_n^\top Y1_n} = \frac{1}{1-\frac{1_n^\top Y1_n}{n^2}} = \operatorname{diag}(M)$. Reciprocally for $M \in \mathcal{B}$, we can define $Y = \frac{M}{1+\frac{1_n^\top M1_n}{n^2}}$, such that $\operatorname{diag}(Y) = 1$ and $Y \in \mathcal{A}$ and then verify that $M = \frac{Y}{1-\frac{1_n^\top Y1_n}{n^2}}$. Thus the problem Eq. (27) is equivalent to the relaxation

$$\max_{M\succcurlyeq 0,\operatorname{diag}(M)=1+\frac{1_n^\top M1_n}{n^2}}\frac{1}{n}\operatorname{tr} MX(X^\top X)^{-1}X^\top. \tag{28}$$

The Lagrangian function of this problem can be written as:

$$\begin{aligned}
L(\mu) &= \operatorname{tr} MX(X^\top X)^{-1}X^\top - \frac{\mu}{n}^\top[\operatorname{diag}(M) - 1_n - \frac{1_n^\top M1_n}{n^2}1_n] \\
&= \operatorname{tr} M[X(X^\top X)^{-1}X^\top - \operatorname{Diag}(\mu) + \frac{1_n^\top\mu}{n^2}1_n1_n^\top] + \frac{1}{n}\mu^\top 1_n.
\end{aligned}$$

Using $L(\mu)$ and the PSD constraint $M \succcurlyeq 0$, the dual problem is given by

$$\min_\mu \frac{\mu^\top 1_n}{n} \quad \text{s.t. } \operatorname{Diag}(\mu) - \frac{1_n^\top\mu}{n^2}1_n1_n^\top \succcurlyeq X(X^\top X)^{-1}X^\top.$$

Since $X(X^\top X)^{-1}X^\top \succcurlyeq 0$, this implies for the dual variable μ:

$$\begin{aligned}
\operatorname{Diag}(\mu) - \frac{1_n^\top\mu}{n^2}1_n1_n^\top \succcurlyeq 0 \ &\Leftrightarrow\ 1_n^\top\operatorname{Diag}(\mu)^{-1}1_n \le \frac{n^2}{\mu^\top 1_n} \\
&\Leftrightarrow\ \sum_{i=1}^n\frac{1}{\mu_i} \le \frac{n^2}{\sum_{i=1}^n\mu_i} \\
&\Leftrightarrow\ \frac{1}{n}\sum_{i=1}^n\frac{1}{\mu_i} \le \frac{1}{\frac{1}{n}\sum_{i=1}^n\mu_i}.
\end{aligned}$$

However for $\nu \in \mathbb{R}^n$, the harmonic mean $\big[\frac{1}{n}\sum_{i=1}^n\frac{1}{\nu_i}\big]^{-1}$ is always smaller than the arithmetic mean $\frac{1}{n}\sum_{i=1}^n\nu_i$ with equality if and only if $\nu = c1_n$ for $c \in \mathbb{R}$.

Thus the dual variable μ is constant and the diagonal constraint in problem Eq. (28) simplifies itself as a trace constraint. Therefore the problem is equivalent to the trivial relaxation below for which each eigenvector of $X(X^\top X)^{-1}X^\top$ is a solution:

$$\max_{M\succcurlyeq 0,\ \operatorname{tr}(M)=n+\frac{1_n^\top M1_n}{n}}\operatorname{tr} MX(X^\top X)^{-1}X^\top.$$

Appendix C. Equivalent relaxations

In this section, we give details about two equivalent relaxations.

C.1 First equivalent relaxation

We start from the penalized version of Eq. (5),

$$\min_{y\in\{-1,1\}^n,\ v\in\mathbb{R}^d} \frac{1}{n}\|\Pi_n y - Xv\|_2^2 + \nu\frac{(y^\top 1_n)^2}{n^2}, \tag{29}$$

which we expand as:

$$\min_{y\in\{-1,1\}^n,\ v\in\mathbb{R}^d} \frac{1}{n}\operatorname{tr}\Pi_n yy^\top - \frac{2}{n}\operatorname{tr}Xvy^\top + \frac{1}{n}\operatorname{tr}X^\top Xvv^\top + \nu\frac{(y^\top 1_n)^2}{n^2}, \tag{30}$$

and relax as, using $Y = yy^\top$, $P = yv^\top$ and $V = vv^\top$,

$$\min_{V,P,Y} \frac{1}{n}\operatorname{tr}\Pi_n Y - \frac{2}{n}\operatorname{tr}P^\top X + \frac{1}{n}\operatorname{tr}X^\top XV + \nu\frac{1_n^\top Y 1_n}{n^2} \text{ s.t. } \begin{pmatrix} Y & P \\ P^\top & V\end{pmatrix} \succcurlyeq 0,\ \operatorname{diag}(Y) = 1. \tag{31}$$

When optimizing Eq. (31) with respect to V and P, we get exactly Eq. (8). Indeed we solve this problem by fixing the matrix Y such that $Y = Y_0$ and $\operatorname{diag}(Y_0) = 1_n$. Then the Lagrangian function of the problem in Eq. (31) can be written as

$$\begin{aligned} L(A) &= \frac{1}{n}\operatorname{tr}\Pi_n Y - \frac{2}{n}\operatorname{tr}P^\top X + \frac{1}{n}\operatorname{tr}X^\top XV + \nu\frac{1_n^\top Y 1_n}{n^2} + \operatorname{tr}A(Y - Y_0) \\ &= \begin{pmatrix} Y & P \\ P^\top & V\end{pmatrix}\begin{pmatrix} \frac{1}{n}\Pi_n + \frac{\nu}{n^2}1_n 1_n^\top + A & \frac{-1}{n}X \\ \frac{-1}{n}X^\top & \frac{1}{n}X^\top X\end{pmatrix} - \operatorname{tr}AY_0. \end{aligned}$$

Using $L(A)$ and the psd constraint $\begin{pmatrix} Y & P \\ P^\top & V\end{pmatrix} \succcurlyeq 0$, we write the dual problem as

$$\min_A \operatorname{tr}AY_0 \text{ s.t. } \begin{pmatrix} \frac{1}{n}\Pi_n + \frac{\nu}{n^2}1_n 1_n^\top + A & \frac{-1}{n}X \\ \frac{-1}{n}X^\top & \frac{1}{n}X^\top X\end{pmatrix} \succcurlyeq 0.$$

From the Schur's complement condition of $\begin{pmatrix} \frac{1}{n}\Pi_n + \frac{\nu}{n^2}1_n 1_n^\top + A & \frac{-1}{n}X \\ \frac{-1}{n}X^\top & \frac{1}{n}X^\top X\end{pmatrix} \succcurlyeq 0$, we obtain $\frac{1}{n}\Pi_n + \frac{\nu}{n^2}1_n 1_n^\top + A \succcurlyeq \frac{1}{n}X(X^\top X)^{-1}X^\top$. Substituting the bound for A we get the optimal objective function value

$$\mathcal{D}^* = \frac{1}{n}\operatorname{tr}X(X^\top X)^{-1}X^\top Y_0 - \frac{1}{n}\operatorname{tr}\Pi_n Y_0 - \frac{\nu}{n^2}1_n^\top Y_0 1_n.$$

Note that the optimal dual objective value $\mathcal{D}^*$ corresponds to a fixed Y_0. Hence by maximizing with respect to Y we obtain exactly Eq. (8) and therefore, the convex relaxation in Eq. (11) is equivalent to Eq. (8). Moreover the Karush-Kuhn-Tucker (KKT) conditions gives

$$P^\top - X + VX^\top X = 0 \text{ and } -YX + PX^\top X = 0$$

Thus the optimum is attained for $P = YX(X^\top X)^{-1}$ and $V = (X^\top X)^{-1}X^\top YX(X^\top X)^{-1}$.

C.2 Second equivalent relaxation

For $\nu = 1$, we solve the problem in Eq. (31) by fixing the matrix $V = V_0$. Then the Lagrangian function of this problem can be written as

$$\begin{aligned} \hat{L}(\mu, B) &= \frac{1}{n}\operatorname{tr}\Pi_n Y - \frac{2}{n}\operatorname{tr}P^\top X + \frac{1}{n}\operatorname{tr}X^\top XV + \nu\frac{1_n^\top Y 1_n}{n^2} + \mu^\top(\operatorname{diag}(Y) - 1_n) + \operatorname{tr}B(V - V_0) \\ &= \begin{pmatrix} Y & P \\ P^\top & V\end{pmatrix}\begin{pmatrix} \frac{1}{n}I_n + \operatorname{diag}(\mu) & \frac{-1}{n}X \\ \frac{-1}{n}X^\top & \frac{1}{n}X^\top X + B\end{pmatrix} - \mu^\top 1_n - \operatorname{tr}BV_0. \end{aligned}$$

Using $\hat{L}(\mu, B)$ and the psd constraint $\begin{pmatrix} Y & P \\ P^\top & V\end{pmatrix} \succcurlyeq 0$, the dual problem is given by

$$\min_{\mu,B} \mu^\top 1_n + \operatorname{tr}BV_0 \text{ s.t.} \begin{pmatrix} \frac{1}{n}I_n + \operatorname{diag}(\mu) & \frac{-1}{n}X \\ \frac{-1}{n}X^\top & \frac{1}{n}X^\top X + B\end{pmatrix} \succcurlyeq 0.$$

From the Schur's complement condition of $\begin{pmatrix} \frac{1}{n}I_n + \operatorname{diag}(\mu) & \frac{-1}{n}X \\ \frac{-1}{n}X^\top & \frac{1}{n}X^\top X + B\end{pmatrix} \succcurlyeq 0$, we obtain $B \succcurlyeq \frac{1}{n^2}X^\top \operatorname{diag}(\mu + 1_n/n)^{-1}X - \frac{1}{n}X^\top X$. Substituting the bound for B we get the dual problem as

$$\begin{aligned} &\min_\mu \mu^\top 1_n + \frac{1}{n^2}\operatorname{tr}V_0X^\top \operatorname{diag}(\mu + 1_n/n)^{-1}X - \frac{1}{n}\operatorname{tr}V_0X^\top X \\ \implies &\min_\mu \sum_{i=1}^n \left(\mu_i + \frac{1}{n^2\mu_i + n}x_i^\top V_0 x_i\right) - \frac{1}{n}\operatorname{tr}V_0X^\top X. \end{aligned}$$

Solving for μ_i, we get

$$\mu_i^* = \frac{1}{n}\sqrt{x_i^\top V_0 x_i} - \frac{1}{n}.$$

Substituting μ_i^* into the dual objective function, we get the optimal objective function value

$$\hat{D} = \frac{2}{n}\sum_{i=1}^n \sqrt{(XVX^\top)_{ii}} - 1 - \frac{1}{n}\operatorname{tr}V_0X^\top X.$$

Furthermore the KKT conditions give

$$Y\operatorname{diag}(\nu + 1_n/n) - \frac{1}{n}PX^\top = 0 \text{ and } P^\top \operatorname{diag}(\nu + 1_n/n) - \frac{1}{n}VX^\top = 0.$$

Thus we obtain the following closed form expressions:

$$\begin{aligned} P &= \operatorname{Diag}(\operatorname{diag}(XVX^\top))^{-1/2}XV \\ Y &= \operatorname{Diag}(\operatorname{diag}(XVX^\top))^{-1/2}XVX^\top \operatorname{Diag}(\operatorname{diag}(XVX^\top))^{-1/2}. \end{aligned}$$

The optimal dual objective value $\hat{D}$ corresponds to a fixed V_0. Therefore, maximizing with respect to V leads to the problem:

$$\min_{V\succcurlyeq 0}\ 1 - \frac{2}{n}\sum_{i=1}^n \sqrt{(XVX^\top)_{ii}} + \frac{1}{n}\operatorname{tr}(VX^\top X). \tag{32}$$

Appendix D. Auxiliary results for Section 5.1

Here we provide auxiliary results for Section 5.1.

D.1 Auxiliary lemma

The matrix $X(X^\top X)^{-1}X^\top$ has the following properties (see e.g., (Freedman, 2009)).

Lemma 10 *The matrix $H = X(X^\top X)^{-1}X^\top$ is the orthogonal projection onto the column space of the design matrix X since:*

- *H is symmetric.*
- *H is idempotent ($H^2 = H$.*
- *X is invariant under H, that is $HX = X$.*

D.2 Rank-one solution of the relaxation Eq. (8)

We denote by $(x_i)_{i=1\dots n}$ the lines (or rows) of X.

Lemma 11 *The rank-one solution $Y_* = yy^\top$ is always a solution of the relaxation Eq. (8).*

Proof We give an elementary proof of this result without using convex optimization tools. Using Proposition 1 and Lemma 10 we have $Hy = y$, thus

$$\operatorname{tr} HY_* = \operatorname{tr} Hyy^\top = \operatorname{tr} yy^\top = n.$$

Moreover all $M \succcurlyeq 0$ can always be decomposed as $\sum_{i=1}^n \lambda_i u_i u_i^\top$ with $\lambda_i \geq 0$ and $(u_i)_{i=1,\dots,n}$ an orthonormal family. Since H is an orthogonal projection $(u_i)^\top H u_i = (Hu_i)^\top H u_i = \|Hu_i\|^2 \leq \|u_i\|^2 \leq 1$. Thus $\operatorname{tr} HM = \sum_{i=1}^n \lambda_i \operatorname{tr} Hu_i(u_i)^\top = \sum_{i=1}^n \lambda_i (u_i)^\top H u_i \leq \sum_{i=1}^n \lambda_i = \operatorname{tr} M$.

Then for all matrix M feasible we have $\operatorname{tr} HM \leq n$ since $\operatorname{diag}(M) = 1_n$ and $\operatorname{tr} HY_* = n$ which conclude the lemma. ■

D.3 Rank-one solution of the relaxation Eq. (12)

Lemma 12 *The rank-one solution $V_* = vv^\top$ is always a solution of the relaxation Eq. (12).*

Proof The Karush-Kuhn-Tucker (KKT) optimality conditions for the problem are for the dual variable $A \preccurlyeq 0$:

$$\frac{1}{n}\sum_{i=1}^n \frac{x_i x_i^\top}{\sqrt{x_i^\top V x_i}} - \frac{1}{n}XX^\top = A \text{ and } AV = 0 \quad \text{(Complementary Slackness)}.$$

Since $x_i^\top w = y_i$, $\sqrt{x_i^\top V_* x_i} = |y_i| = 1$, V_* and the dual variable $A = 0$ satisfy the KKT conditions and then V_* is solution of this problem. ■

D.4 Proof of Proposition 2

In the following lemma, we use a Taylor expansion to lower-bound f around its minimum.

Lemma 13 *For $d \geq 3$ and $\delta \in [0,1)$.*

If $\beta \geq 3$ and $m^2 \leq \frac{\beta-3}{2(d+\beta-4)}$, then with probability at least $1 - d\exp\big(-\frac{\delta^2 n m^2}{2R^4 d^2}\big)$, for any symmetric matrix Δ:

$$f(V_*) - f(V_* + \Delta) > 2(1-\delta)m^2\|\Delta\|_F^2 + o(\|\Delta\|^2) \geq 0.$$

Otherwise with probability at least $1 - d\exp\big(-\frac{\delta^2 n \mu_1}{4R^4 d^2}\big)$, for any symmetric matrix Δ:

$$f(V_*) - f(V_* + \Delta) > (1-\delta)\mu_1\|\Delta\|_F^2 + o(\|\Delta\|^2) \geq 0,$$

with $\mu_1 \geq \frac{m^2(\beta-1)}{1+(d+\beta-2)m^2}$. Moreover we also have with probability at least $1 - d\exp\big(-\frac{\delta^2 n \mu_2}{4R^4 d^2}\big)$, for any symmetric matrix $\Delta \in \Delta_{\min}^\perp$:

$$f(V_*) - f(V_* + \Delta) > (1-\delta)\mu_2\|\Delta\|_F^2 + o(\|\Delta\|^2) \geq 0,$$

where $\mu_2 = \min\{2m^2, m^2(\beta-1), 2m\}$ and $\Delta_{\min} = \begin{pmatrix} 1 & 0 \\ 0 & c_{\min} I_{d-1} \end{pmatrix}$ is defined in the proof and satisfies

$$|c_{\min}| \leq \frac{m}{|(d+\beta-2)m^2 - 1|}.$$

This lemma directly implies Proposition 2.

Proof

For $\Delta \in \mathcal{S}(d)$ and $\delta \in \mathbb{R}$ we compute for $f(V) = \frac{1}{n}\sum_{i=1}^n \sqrt{x_i^\top V x_i}$,

$$\frac{d^2}{d\delta^2} f(V + \delta\Delta) = -\frac{1}{4n}\sum_{i=1}^n \frac{(x_i^\top \Delta x_i)^2}{\sqrt{x_i^\top (V+\delta\Delta) x_i}^3}.$$

Thus the second directional derivative in $V = V_*$ along Δ is

$$\nabla^2_\Delta f(V_*) = \lim_{\delta\to 0} \frac{d^2}{d\delta^2} f(V + \delta\Delta) = -\frac{1}{4n}\sum_{i=1}^n (x_i^\top \Delta x_i)^2.$$

Let $\mathcal{T}_x$ be the semidefinite positive quadratic form of $\mathcal{S}(d)$ defined for $\Delta \in \mathcal{S}(d)$, by

$$\mathcal{T}_x : \Delta \mapsto (x^\top \Delta x)^2. \tag{33}$$

Then there exists a positive linear operator T_x from $\mathcal{S}(d)$ to $\mathcal{S}(d)$ such that $\mathcal{T}_x(\Delta) = \langle \Delta, T_x \Delta \rangle$.

Therefore the function f will be strictly concave if for all directions $\Delta \in \mathcal{S}(d)$

$$\frac{1}{n}\sum_{i=1}^n \mathcal{T}_{x_i}(\Delta) > 0. \tag{34}$$

We will bound the empirical expectation in Eq. (34) by first showing that its expectation remains away from 0. Then we will use a concentration inequality for matrices to control the distance between the sum in Eq. (34) and its expectation.

We first derive conditions so that the result is true in expectation, i.e., for the operator $\mathcal{T}$ defined by $\mathcal{T} = \mathbb{E}\mathcal{T}_x$ for x following the same law as $(y, z^\top)^\top$. We denote by $m = \mathbb{E}z^2$ and by $\beta = \mathbb{E}z^4/m^2$ its kurtosis.

We let $\Delta = \begin{pmatrix} a & b^\top \\ b & C \end{pmatrix}$ and then have $x^\top \Delta x = a + 2yb^\top z + z^\top Cz$. Thus

$$\mathcal{T}_x(\Delta) = a^2 + 4ayb^\top z + 2az^\top Cz + 4b^\top(zz^\top)b + (z^\top Cz)^2 + 4yb^\top z(z^\top Cz).$$

Therefore we can express the value of the operator $\mathcal{T}$ only in function of the elements of Δ:

$$\mathcal{T}(\Delta) = (a + m\operatorname{tr} C)^2 + 4m\|b\|_2^2 + 2m^2\|C - \operatorname{Diag}(\operatorname{diag}(C))\|_F^2 + m^2(\beta-1)\|\operatorname{diag}(C)\|^2,$$

where we have used

$$\begin{aligned}
\mathbb{E}(z^\top Cz)^2 &= \mathbb{E}\sum_{i,j,k,l} z_i z_j z_k z_l c_{i,j} c_{k,l} \\
&= \mathbb{E}\sum_i (z_i)^4 c_{i,i}^2 + \mathbb{E}\sum_{i,k\neq i} z_i^2 z_k^2 c_{i,i} c_{k,k} + 2\mathbb{E}\sum_{i,j\neq i} z_i^2 z_j^2 c_{i,j}^2 \\
&= \beta m^2 \sum_i c_{i,i}^2 + m^2 \sum_{i,k\neq i} c_{i,i} c_{k,k} + 2m^2 \sum_{i,j\neq i} c_{i,j}^2 \\
&= m^2(\beta-3)\sum_i c_{i,i}^2 + m^2 \sum_{i,k} c_{i,i} c_{k,k} + 2m^2 \sum_{i,j} c_{i,j}^2 \\
&= m^2(\beta-3)\|\operatorname{diag}(C)\|^2 + m^2\big(2\|C\|_F^2 + \operatorname{tr}(C)^2\big) \\
&= m^2(\beta-3)\|\operatorname{diag}(C)\|^2 + m^2\big(2\|C - \operatorname{Diag}(\operatorname{diag}(C))\|_F^2 + \operatorname{tr}(C)^2\big).
\end{aligned}$$

Since $\beta \geq 1$, we get

$$\mathcal{T}(\Delta) \geq (a + m\operatorname{tr} C)^2 + 4m\|b\|_2^2 + 2m^2(\|C\|_F^2 - \|\operatorname{diag}(C)\|^2).$$

Thus $\mathcal{T}(\Delta) = 0$ if and only if $\beta = 1$ with $b = 0_{d-1}$ and $C = \operatorname{diag}(c)$ with $c^\top 1_d = -\frac{a}{m_2}$. With the condition $\beta = 1$ meaning that $\operatorname{var}(z^2) = 0$ and thus z^2 is constant a.s., i.e., z follows a Rademacher law.

However we would like to bound $\mathcal{T}(\Delta)$ away from zero by some constant and for that we are looking for the smallest eigenvalue of the operator $\mathbb{E}T_x$. Unfortunately we are not able to solve the optimization problem

$$\min_{\Delta \in \mathcal{S}(d), \|\Delta\|_F^2 = 1} \mathcal{T}(\Delta),$$

and we have to compute all the spectrum of this operator to be able to find the smallest using $\mathbb{E}T_x\Delta = 1/2\nabla\mathcal{T}(\Delta)$.

We have

$$1/2\nabla\mathcal{T}(\Delta) = \begin{pmatrix} a + m\operatorname{tr}(C) & 2mb^\top \\ 2mb & (a + m\operatorname{tr}(C))m_2 I_{d-1} + 2m^2 C \\ & \quad + m^2(\beta-3)\operatorname{Diag}(\operatorname{diag}(C)) \end{pmatrix}.$$

- For all $b \in \mathbb{R}^{d-1}$ we have for $\Delta = \begin{pmatrix} 0 & b^\top \\ b & 0 \end{pmatrix}$, $1/2\nabla\mathcal{T}(\Delta) = 2m\Delta$. Thus $2m$ is an eigenvalue of multiplicity $d-1$.
- For all $C \in \mathbb{R}^{(d-1)\times(d-1)}$ with $\operatorname{diag}(C) = 0_{d-1}$ we have for $\Delta = \begin{pmatrix} 0 & 0 \\ 0 & C \end{pmatrix}$, $1/2\nabla\mathcal{T}(\Delta) = 2m^2\Delta$. Thus $2m^2$ is an eigenvalue of multiplicity $\frac{(d-1)(d-2)}{2}$.
- For all $c \in \mathbb{R}^{d-1}$ with $c^\top 1_{d-1} = 0$ we have for $\Delta = \begin{pmatrix} 0 & 0 \\ 0 & \operatorname{diag}(C) \end{pmatrix}$, $1/2\nabla\mathcal{T}(\Delta) = m^2(\beta-1)\Delta$. Thus $m^2(\beta-1)$ is an eigenvalue of multiplicity $d-2$.
- For all $a, c \in \mathbb{R}^2$ we have for $\Delta = \begin{pmatrix} a & 0 \\ 0 & cI_{d-1} \end{pmatrix}$,

$$\begin{aligned}
1/2\nabla\mathcal{T}(\Delta) &= \begin{pmatrix} a + m(d-1)c & 0 \\ 0 & [ma + m^2(d+\beta-2)c]I_{d-1} \end{pmatrix} \\
&= \operatorname{Diag}\Big[\begin{pmatrix} 1 & m1_{d-1}^\top \\ m1_{d-1} & (d+\beta-2)m^2 I_{d-1} \end{pmatrix}\begin{pmatrix} a \\ c1_{d-1} \end{pmatrix}\Big].
\end{aligned}$$

  Thus an eigenvalue of $\begin{pmatrix} 1 & (d-1)m \\ m & (d+\beta-2)m^2 \end{pmatrix}$ with an eigenvector $[a, c]^\top$ would be an eigenvalue of the operator $\mathbb{E}T_x$ with a corresponding eigenvector $\begin{pmatrix} a & 0 \\ 0 & cI_{d-1} \end{pmatrix}$. This matrix has two simple eigenvalues

$$\mu_\pm = \frac{1 + (d+\beta-2)m^2 \pm \sqrt{(1 + (d+\beta-2)m^2)^2 - 4m^2(\beta-1)}}{2}. \tag{35}$$

Moreover when we add all the multiplicity of the found eigenvalues we get $d-1+\frac{(d-1)(d-2)}{2} + d-2+2 = \frac{d(d+1)}{2}$ which is the dimension of $S(d)$, therefore we have found all the eigenvalues of the linear operator $\mathbb{E}T_x$.

We will prove now than the smallest eigenvalue is μ_- when the dimension d is large enough with regards to m^2 and $2m^2$ otherwise.

Lemma 14 *Let μ_1 and μ_2 be the two smallest eigenvalues of the operator $\mathbb{E}T_x$. Let us assume that $d \geq 3$ (the case $d = 2$ will also be done in the proof).*

If $\beta \geq 3$ and $m^2 \leq \frac{\beta-3}{2(d+\beta-4)}$ then

$$\mu_1 = 2m^2.$$

Otherwise

$$\mu_1 = \mu_- \geq \frac{m^2(\beta-1)}{1 + (d+\beta-2)m^2} \text{ and } \mu_2 = \min\{2m^2, m^2(\beta-1), 2m\}.$$

Moreover we denote by $\Delta_{\min} = \begin{pmatrix} 1 & 0 \\ 0 & c_{\min} I_{d-1} \end{pmatrix}$ the eigenvector associated to μ_- for which we have set without loss of generality the first component $a = 1$. Then

$$|c_{\min}| \leq \frac{m}{|(d+\beta-2)m^2 - 1|}.$$

Unfortunately μ_- can become small when the dimension increases as explained by the tight bound $\mu_- \geq \frac{m^2(\beta-1)}{1+(d+\beta-2)m^2}$. However the corresponding eigenvector has a particular structure we will be able to exploit.

Proof First we note that $\mu_- \leq m^2(\beta-1)$ and compute

$$\begin{aligned}
\mu_- \geq 2m^2 &\Leftrightarrow 1+(d+\beta-2)m^2 - \sqrt{(1+(d+\beta-2)m^2)^2 - 4m^2(\beta-1)} - 4m^2 \geq 0 \\
&\Leftrightarrow 1+(d+\beta-2)m^2 - 4m^2 \geq \sqrt{(1+(d+\beta-2)m^2)^2 - 4m^2(\beta-1)} \\
&\Leftrightarrow (1+(d+\beta-2)m^2-4m^2)^2 \geq (1+(d+\beta-2)m^2)^2 - 4m^2(\beta-1) \\
&\quad \text{and } 1+(d+\beta-6)m^2 \geq 0 \\
&\Leftrightarrow 16m^4 - 8m^2(1+(d+\beta-2)m^2) \geq -4m^2(\beta-1) \\
&\quad \text{and } 1+(d+\beta-6)m^2 \geq 0 \\
&\Leftrightarrow \underbrace{2(d+\beta-4)m^2 \leq \beta-3}_{\text{R1}} \text{ and } \underbrace{1+(d+\beta-6)m^2 \geq 0}_{\text{R2}}.
\end{aligned}$$

- If $d=2$,
  - If $\beta \leq 3$ we have necessary that $\beta \leq 2$ and the first term R1 implies $m^2 \geq \frac{3-\beta}{2(2-\beta)}$ and the second term R2 implies $m^2 \leq 1/(4-\beta)$. Thus we should have $(4-\beta)(3-\beta) \leq 2(2-\beta)$ which is not possible since the polynomial $\beta^2-5\beta+8 \geq 0$.
  - If $\beta \geq 3$, the first term R1 implies $m^2 \leq \frac{\beta-3}{2(\beta-2)} \leq 1$ and the second term R2 implies $m^2 \leq 1/(4-\beta) \leq \frac{\beta-3}{2(\beta-2)} \leq 1$ for $\beta \leq 4$ and is always satisfied otherwise.
- If $d \geq 3$, the first term R1 implies that $\beta \geq 3$ for which the second term R2 is always satisfied. It also implies that $m^2 \leq \frac{\beta-3}{2(d+\beta-4)} \leq 1$.

We denote by $\Delta_{\min} = \begin{pmatrix} 1 & 0 \\ 0 & c_{\min} I_{d-1} \end{pmatrix}$ the eigenvector for which we have set without loss of generality $a=1$ and

$$c_{\min} = \frac{-1}{2(d-1)m}\Big[\sqrt{((d+\beta-2)m^2-1)^2+4(d-1)m^2} - (d+\beta-2)m^2+1\Big].$$

Consequently $c_{\min} \leq 0$ and by convexity of the square root we have

$$\sqrt{((d+\beta-2)m^2-1)^2+4(d-1)m^2} \leq ((d+\beta-2)m^2-1) + \frac{2(d-1)m^2}{|(d+\beta-2)m^2-1|}.$$

Therefore

$$|c_{\min}| \leq \frac{m}{|(d+\beta-2)m^2-1|}.$$

■

We will control now the behavior of the empirical expectation by its expectation thanks to concentration theory. By definition T_x is a symmetric positive linear operator as its projection $T_x^\perp$ onto the orthogonal space of $\Delta_{\min}$. We can thus apply the Matrix Chernoff inequality from Tropp (2012, Theorem 5.1.1) to these two operators using $\|T_x\|_{op} \leq \|xx^\top\|^2 \leq \mathrm{tr}(xx^\top)^2 \leq \|x\|_2^4 \leq R^4 d^2$. Then:

$$\mathbb{P}\left(\lambda_{\min}\Big(\sum_{k=1} T_{x_k}\Big) \leq n\delta\mu_1\right) \leq d\Big[\frac{e^{-(1-\delta)}}{\delta^\delta}\Big]^{n\mu_1/(2R^4d^2)} \leq de^{-(1-\delta)^2 n\mu_1/(4R^4d^2)},$$

$$\mathbb{P}\left(\lambda_{\min}\Big(\sum_{k=1} T^\perp_{x_k}\Big) \leq n\delta\mu_2\right) \leq d\Big[\frac{e^{-(1-\delta)}}{\delta^\delta}\Big]^{n\mu_2/(2R^4d^2)} \leq de^{-(1-\delta)^2 n\mu_2/(4R^4d^2)},$$

For $m=1$ and $d \geq 3$ we have $\mu_1 = \mu_- \geq \frac{\beta-1}{\beta+d} \geq \min\{\frac{\beta-1}{2\beta}, \frac{\beta-1}{2d}\} \geq \min\{1/3, \frac{\beta-1}{2d}\}$. ■

D.5 Noise robustness for the one dimensional balanced problem

We want a condition on ε such that the solution of the relaxation Eq. (8) recovers the right y. We recall the dual problem of the relaxation Eq. (8)

$$\min \mu^\top 1_n \text{ s.t. } \mathrm{Diag}(\mu) \succcurlyeq X(X^\top X)^{-1}X^\top.$$

The KKT conditions are:

- Dual feasibility: $\mathrm{Diag}(\mu) \succcurlyeq X(X^\top X)^{-1}X^\top$.
- Primal feasibility: $\mathrm{Diag}(Y) = 1_n$ and $Y \succcurlyeq 0$.
- Complimentary slackness : $Y[\mathrm{Diag}(\mu) - X(X^\top X)^{-1}X^\top] = 0$

For $Y = yy^\top$ a rank one matrix, the last condition implies $\mathrm{Diag}(\mu)y = Hy$ and

$$\mu_i = \frac{(X(X^\top X)^{-1}X^\top y)_i}{y_i}.$$

For $X = y+\varepsilon$, we denote by $\tilde{y} = y+\varepsilon$, then $X(X^\top X)^{-1}X^\top = \frac{\tilde{y}\tilde{y}^\top}{\|\tilde{y}\|^2}$ and $X(X^\top X)^{-1}X^\top y = \frac{\tilde{y}^\top y}{\|\tilde{y}\|^2}\tilde{y}$. Thus

$$\mu_i = \frac{\tilde{y}^\top y}{\|\tilde{y}\|^2}\frac{\tilde{y}_i}{y_i}.$$

Assume that all $\tilde{y}_i y_i$ have the same sign, without loss of generality we assume $\tilde{y}_i y_i > 0$. By definition of μ, $\mu \geq 0$. To show the dual feasibility we have to show that $\mathrm{Diag}(\mu) \succcurlyeq H$ which is equivalent to $\mathrm{Diag}(\frac{\tilde{y}_i}{y_i}) \succcurlyeq \frac{\tilde{y}\tilde{y}^\top}{\tilde{y}^\top y}$, to $I_n - \mathrm{Diag}(\sqrt{\frac{y_i}{\tilde{y}_i}})\frac{\tilde{y}\tilde{y}^\top}{\tilde{y}^\top y}\mathrm{Diag}(\sqrt{\frac{y_i}{\tilde{y}_i}}) \succcurlyeq 0$ and to $\sum y_i\tilde{y}_i \leq \tilde{y}^\top y$ which is obviously true. Reciprocally if μ is dual feasible then $\mathrm{Diag}(\mu) \succcurlyeq 0$ and all the $\tilde{y}_i y_i$ have the same sign.

Therefore we have shown that y is solution of the relaxation Eq. (8) if and only if all the $\tilde{y}_i y_i$ have the same sign. If ε and y are independent this is equivalent to $\|\varepsilon\|_\infty \leq 1$ a.s.

D.6 The rank-one candidates are not solutions of the relaxation Eq. (12)

We assume now that $1_n^\top y \neq 0$ thus $y \neq \Pi_n y$, which means we do not have the same proportion in the two clusters. Let us assume that $\Pi_n y$ takes two values $\{\pi y_-, \pi y_+\}$ that is by definition of Π_n: $\pi y_+ = 1 - \frac{1_n^\top y}{n}$ and $\pi y_- = -1 - \frac{1_n^\top y}{n}$. For V_* defined as before, we get $x_i^\top V_* x_i = (\pi y_i)^2$ and with $I_\pm$ the set of indices such that $\Pi_n y_i = \pi y_\pm$ respectively, the KKT conditions for $V = V_*$ can be written as

$$\frac{1}{n}\Big[\sum_{i\in I_+}\Big(\frac{1}{\pi y_+}-1\Big)x_i x_i^\top + \sum_{i\in I_-}\Big(\frac{1}{-\pi y_-}-1\Big)x_i x_i^\top\Big] = A_n \preccurlyeq 0 \text{ and } A_n V_* = 0.$$

We check that with $n_\pm = \#\{I_\pm\}$:

$$\begin{aligned} w^\top A_n w = 0 &= \sum_{i\in I_+}\Big(\frac{1}{\pi y_+}-1\Big)(\pi y_+)^2 + \sum_{i\in I_-}\Big(\frac{1}{-\pi y_-}-1\Big)(\pi y_-)^2 \\ &= n_+\Big(\frac{1}{\pi y_+}-1\Big)(\pi y_+)^2 + n_-\Big(\frac{1}{-\pi y_-}-1\Big)(\pi y_-)^2 \\ &= n_+\pi y_+ - n_-\pi y_- - \big(n_+(\pi y_+)^2 + n_-(\pi y_-)^2\big) \\ &= y^\top \Pi_n y - (\Pi_n y)^\top \Pi_n y = y^\top \Pi_n y - y^\top \Pi_n y = 0. \end{aligned}$$

And $A_n = \frac{1}{2n}\big[\sum_{i\in I_+}\alpha_+ x_i x_i^\top + \sum_{i\in I_-}\alpha_- x_i x_i^\top\big]$ with $\alpha_+ = \big(\frac{1}{\pi y_+}-1\big)$ and $\alpha_- = \big(\frac{1}{-\pi y_-}-1\big)$. Unfortunately $\alpha_+\alpha_- \leq 0$, and A_n is not necessary negative. Even worse we will show that $\mathbb{E}A$ is not semi-definite negative which will conclude the proof since by the law of large number $\lim_{n\to\infty}\frac{1}{n}A_n = \mathbb{E}A$. Assume that the proportions of the two clusters stay constant with $n_\pm = \rho_\pm n$, then

$$\mathbb{E}A = \rho_+\alpha_+\begin{pmatrix}(\pi y_+)^2 & 0\\ 0 & I\end{pmatrix} + \rho_-\alpha_-\begin{pmatrix}(\pi y_-)^2 & 0\\ 0 & I\end{pmatrix}.$$

And $\rho_+\alpha_+(\pi y_+)^2 + \rho_-\alpha_-(\pi y_-)^2 = 0$ since $w^\top A_n w = 0$. Then

$$\begin{aligned} \rho_+\alpha_+ + \rho_-\alpha_- &= \frac{\rho_+\pi y_- - \rho_-\pi y_+ - \pi y_+\pi y_-}{\pi y_+\pi y_-} \\ &= \frac{-(\rho_+ + \rho_-) - \frac{1_n^\top y}{n}(\rho_+ - \rho_-) + (1-(1_n^\top y)^2)}{-(1-(\frac{1_n^\top y}{n})^2)} \\ &= \frac{\frac{1_n^\top y}{n}(\rho_+ - \rho_-) + (\frac{1_n^\top y}{n})^2)}{(1-(\frac{1_n^\top y}{n})^2)} = \frac{2(\frac{1_n^\top y}{n})^2}{(1-(\frac{1_n^\top y}{n})^2)} \geq 0. \end{aligned}$$

Thus $A = \frac{2(1_n^\top y)^2}{(n^2-(1_n^\top y)^2)}\begin{pmatrix}0 & 0\\ 0 & I\end{pmatrix}$ is not semi-definite negative and V_* is not solution of the relaxation Eq. (12).

Appendix E. Auxiliary results for sparse extension

In this section, we provide some results for sparse extension.

E.1 There is a rank-one solution of the relaxation Eq. (18)

Lemma 15 *The rank-one solution $V_* = v^* v^{*\top}$ is solution of the relaxation Eq. (18) if the design matrix X is such that $\frac{1}{n}X^\top X$ has all its diagonal entries less than one.*

Proof The KKT conditions for problem Eq. (18) are

$$\frac{1}{n}\sum_{i=1}^n \frac{x_i x_i^\top}{\sqrt{x_i^\top V x_i}} - \lambda U - \frac{1}{n}X^\top X = A \preccurlyeq 0 \text{ and } AV = 0,$$

with U such that $U_{ij} = \operatorname{sign}(V_{ij})$ if $V_{ij} \neq 0$ and $U_{ij} \in [-1,1]$ otherwise. For $V_* = v^* v^{*\top}$ this gives

$$A = \frac{(1+\lambda)}{n}X^\top X - \lambda U - \frac{1}{n}X^\top X = \lambda\Big[\frac{X^\top X}{n} - U\Big] \text{ with } U_{1,1} = 1 \text{ and } U_{i,j} \in [-1,1] \text{ otherwise.}$$

We check that $AV_* = 0$. If the design matrix X is such that $\frac{1}{n}X^\top X$ has all its diagonal entries less than one, we can choose a sub-gradient U such that the dual variable $A = 0$ and thus V_* is solution. Otherwise by property of semi-definite matrices, there is a diagonal entry of $\frac{1}{n}X^\top X$ which is bigger than 1 which prevents A to be semi-definite negative since the corresponding diagonal entry of $\frac{X^\top X}{n} - U$ will be positive. This shows that V_* does not solve the problem. ■

E.2 Proof of proposition 6

Lemma 16 *For $\delta \in [0,1)$, with probability $1 - 5d^2\exp\big(-\frac{\delta^2 n(\beta-1)}{2dR^4(1/m^2+\beta+d)}\big)$, for any direction Δ such that $V_* + \Delta \succcurlyeq 0$, we have:*

$$g(V_*) - g(V_*+\Delta) > (1-\delta)\Big[\lambda\|\Delta - \operatorname{Diag}(\Delta)\|_1 + \frac{\beta-1}{\beta+d+1/m^2}\frac{(1+\lambda)^3}{4}\|\operatorname{Diag}(\Delta)\|_2^2\Big] + o(\|\Delta\|^2) \geq 0.$$

Moreover we also have with probability at least $1 - 5d^2\exp\big(-\frac{\delta^2 n m^2(\beta-1)}{2dR^4}\big)$, for any symmetric matrix Δ such that $V_* + \Delta \succcurlyeq 0$ and $\operatorname{Diag}(\Delta) \in (e_{\min})^\perp$:

$$g(V_*) - g(V_*+\Delta) > (1-\delta)\Big[\lambda\|\Delta - \operatorname{Diag}(\Delta)\|_1 + m^2(\beta-1)\frac{(1+\lambda)^3}{4}\|\operatorname{Diag}(\Delta)\|_2^2\Big] + o(\|\Delta\|^2) \geq 0,$$

where $e_{\min} = [1, c_{\min} 1_{d-1}]$ is defined in the proof and $c_{\min}$ satisfies

$$|c_{\min}| \leq \frac{m}{|(d+\beta-2)m^2 - 1|}.$$

E.2.1 Proof outline

We will investigate under which conditions on X the solution is unique, first for a deterministic design matrix. We make the following deterministic assumptions on X for $\delta, \zeta \geq 0$ and $\mathcal{S} \subset \mathbb{R}^d$:

(A1) $\|\frac{X^\top X}{n}\|_\infty \leq 1$ **(A3)** $\|\frac{Z^\top Z}{n} - \mathrm{Diag}(\mathrm{diag}(\frac{1}{n}Z^\top Z))\|_\infty \leq \delta$
(A2) $\|\frac{Z^\top y}{n}\|_\infty \leq \delta$ **(A4)** $\lambda^{\mathcal{S}}_{\min}\big(\frac{X^{\odot 2}(X^{\odot 2})^\top}{n}\big) \geq \zeta > 0,$

where we denoted by $\odot$ the Hadamard (i.e., pointwise) product between matrices and $\lambda^{\mathcal{S}}_{\min}$ the minimum eigenvalue of a linear operator restricted to a subspace $\mathcal{S}$. Then with $g(V) = \frac{2}{n}\sum_{i=1}^n \sqrt{x_i^\top V x_i} - \lambda\|V\|_1 - \frac{1}{n}\operatorname{tr} X^\top XV$, we can certify that g will decrease around the solution V_*.

Lemma 17 *Let us assume that the noise matrix verifies assumptions (A1,A2,A3,A4), then for any direction Δ such that $V_* + \Delta \succcurlyeq 0$ and $\mathrm{diag}(\Delta) \in \mathcal{S}$ we have:*

$$g(V_*) - g(V_* + \Delta) \geq \lambda(1-\delta)\|\Delta - \mathrm{Diag}(\mathrm{diag}(\Delta))\|_1 + \zeta\frac{(1+\lambda)^3}{4}\|\mathrm{Diag}(\Delta)\|_2^2 + o(\|\Delta\|^2) > 0.$$

Let us assume now that $(z^i)_{i=1,.,d}$ are i.i.d of law z symmetric with $\mathbb{E}z = \mathbb{E}z^3 = 0$, $\mathbb{E}z^2 = m = 1$, $\mathbb{E}z^4/(\mathbb{E}z^2)^2 = \beta$ and such that $\|z\|_\infty$ is a.s. bounded by $0 \leq R \leq 1$. Then the matrix X satisfies a.s. assumption (A1). Using multiple Hoeffding's inequalities we will prove lemma 17.

Lemma 18 *If z does not follow a Rademacher law, the design matrix X satisfies assumptions (A1,A2,A3,A4) with probability greater than $1 - 8d^2\exp\big(-\frac{\delta^2 n(\beta-1)}{2d(\beta+d)R^4}\big)$ for $\mathcal{S} = \mathbb{R}^d$, and with probability greater than $1 - 8d^2\exp\big(-\frac{\delta^2 n\min\{\beta-1,2\}}{2dR^4}\big)$ for $\mathcal{S} = [1, c_{\min}1_{d-1}]^\perp$ where c_{min} is defined in the proof and satisfies*

$$|e_{\min}| \leq \frac{1}{d+\beta-3}.$$

This lemma concludes the proof of proposition 6. We will now prove these two lemmas.

E.2.2 Proof of lemma 17

Proof Since the dual variable A for the PSD constraint is 0 (see the proof of lemma 15), this constraint $V \succcurlyeq 0$ is not active and we will show that the function decreases in a set of directions Δ which include the one for which $V_* + \Delta \succcurlyeq 0$.

Therefore we consider a direction $\Delta = \begin{pmatrix} a & b^\top \\ b & C \end{pmatrix}$, with $C \succcurlyeq 0$, which is slightly more general than $V_* + \Delta \succcurlyeq 0$. We denote by $f(W) = \frac{2}{n}\sum_{i=1}^n \sqrt{x_i^\top W x_i} - \frac{1}{n}\operatorname{tr} X^\top XW$ the smooth part of g. By Taylor-Young, we have for all W:

$$f(W) - f(W+\Delta) = -\langle f'(W), \Delta\rangle - \frac{1}{2}\langle \Delta, f''(W)\Delta\rangle + o(\|\Delta\|^2).$$

Thus:

$$g(W) - g(W+\Delta) = -\langle f'(W), \Delta\rangle - \frac{1}{2}\langle \Delta, f''(W)\Delta\rangle + \lambda(\|W+\Delta\|_1 - \|W\|_1) + o(\|\Delta\|^2).$$

Letting $W = V_*$ this gives with $X^\top X = \begin{pmatrix} n & y^\top Z \\ Z^\top y & Z^\top Z \end{pmatrix}$,

$$\begin{aligned} g(W) - g(W+\Delta) &= -\lambda\langle \frac{X^\top X}{n}, \Delta\rangle - \frac{1}{2}\langle \Delta, f''(V_*)\Delta\rangle + \lambda(a + 2\|b\|_1 + \|C\|_1) + o(\|\Delta\|^2) \\ &= \lambda\big[2(\|b\|_1 - \frac{1}{n}b^\top Z^\top y) + \|C\|_1 - \frac{1}{n}\operatorname{tr}(Z^\top ZC)\big] - \frac{1}{2}\langle \Delta, f''(V_*)\Delta\rangle + o(\|\Delta\|^2). \end{aligned}$$

And with Hölder's inequality and assumption (A2)

$$\|b\|_1 - \frac{1}{n}b^\top Z^\top y \geq \|b\|_1(1 - \|\frac{1}{n}Z^\top y\|_\infty) \geq (1-\delta)\|b\|_1.$$

Nevertheless we will show in lemma 19 that $\|C\|_1 - \frac{1}{n}\operatorname{tr}(Z^\top ZC) \geq (1-\delta)\|C - \mathrm{diag}(C)\|_1$, thus

$$g(W) - g(W+\Delta) \geq \lambda(1-\delta)(2\|b\|_1 + \|C - \mathrm{diag}(C)\|_1) + o(\|\Delta\|^2). \tag{36}$$

However in Eq. (36), $g(W) - g(W+\Delta) = 0$ for $b = 0$ and C diagonal, therefore we have to investigate second order conditions, i.e., to show for $\Delta = \mathrm{diag}(e)$ with $e \in \mathbb{R}^d$ that $-\langle \Delta, f''(V_*)\Delta\rangle > 0$.

And with assumption (A4)

$$\begin{aligned} -\frac{4}{(1+\lambda)^3}\langle \mathrm{diag}(e), f''(V_*)\,\mathrm{diag}(e)\rangle &= \frac{1}{n}\sum_{i=1}^n (x_i^\top \mathrm{diag}(e) x_i)^2 \\ &= \frac{1}{n}\sum_{i=1}^n (\sum_{j=1}^d e_j (x_i^j)^2)^2 \\ &= \frac{1}{n}\sum_{i=1}^n e^\top [x_i^{\odot 2}(x_i^{\odot 2})^\top] e \\ &\geq \lambda_{\min}\big(\frac{X^{\odot 2}(X^{\odot 2})^\top}{n}\big)\|e\|^2 \geq \zeta\|e\|_2^2. \end{aligned}$$

Thus we can conclude:

$$g(W) - g(W+\Delta) \geq \lambda(1-\delta)(2\|b\|_1 + \|C - \mathrm{diag}(C)\|_1) + \zeta\frac{(1+\lambda)^3}{4}\|e\|_2^2 + o(\|\Delta\|^2).$$

■

E.2.3 Auxiliary lemma

Lemma 19 *For all matrix C symmetric semi-definite positive we have under assumptions (A1) and (A3):*

$$\operatorname{tr}\Big(S - \frac{Z^\top Z}{n}\Big)C \geq (1-\delta)\|C - \mathrm{diag}(C)\|_1 > 0.$$

Proof We denote by $\Sigma^n = \frac{Z^\top Z}{n}$. We always have $\|C\|_1 - \mathrm{tr}(\Sigma^n C) = \mathrm{tr}(S - \Sigma^n)C$ where $S_{i,j} = \mathrm{sign}(C_{i,j})$, thus if $\mathrm{diag}(C) > 0$ then $\mathrm{diag}(S) = 1$ and $\mathrm{diag}(S - \Sigma^n) \geq 0$ from assumption (A1). Moreover since $\Sigma^n{}_{i,j} \in [-1, 1]$ then $\mathrm{sign}(S - \Sigma^n) = \mathrm{sign}(S)$.

Thus $\mathrm{tr}(S-\Sigma^n)C = \sum_i C_{i,i}(S-\Sigma^n)_{i,i} + \sum_{i\neq j} C_{i,j}(S-\Sigma^n)_{i,j} \geq \sum_{i\neq j} C_{i,j}(S-\Sigma^n)_{i,j} \geq 0$. Furthermore from assumption (A3), $|(\Sigma^n)_{i,j}| \leq \delta$ for $i \neq j$. Therefore

$$\mathrm{tr}(S - \Sigma^n)C \geq \sum_{i\neq j} C_{i,j}(S - \Sigma^n)_{i,j} \geq \sum_{i\neq j} |C_{i,j}|(1 - \delta) \geq (1 - \delta)\|C - \mathrm{diag}(C)\|_1 > 0.$$

If there is a diagonal element of C which is 0, then the corresponding row and column in C will also be 0 and we can look at the same problem as before by erasing off from C and Σ^n the corresponding column and row. ■

E.2.4 Proof of lemma 18

Proof We will first show that the noise matrix Z satisfies assumptions (A2,A3). By Hoeffding's inequality we have with probability $1 - 2\exp(-\delta^2 n/(2R^2))$

$$\frac{1}{n}|\sum_{i=1}^n z_i^j| \leq \delta.$$

Then, since the law of z is symmetric $y_i z_i$ will have the same law as z_i and with probability $1 - 2\exp(-\delta^2 n/(2R^2))$, the design matrix Z satisfies assumption (A2):

$$\|\frac{Z^\top y}{n}\|_\infty \leq \delta.$$

Likewise we have with probability $1 - 2\exp(-\delta^2 n/(2R^4))$ that for $j \neq j'$

$$|\frac{1}{n}\sum_{i=1}^n z_i^j z_i^{j'}| \leq \delta.$$

Thus we also have with probability $1 - 2d^2\exp(-\delta^2 n/(2R^4))$ that Z satisfies assumption (A3):

$$\|\frac{1}{n}Z^\top Z - \mathrm{diag}(\frac{1}{n}Z^\top Z)\|_\infty \leq \delta.$$

Thus with probability $1 - 4d^2\exp(-\delta^2 n/(2R^4))$, the noise matrix Z satisfies assumptions (A1, A2, A3).

We proceed as in the proof of proposition 2 to show that X satisfies assumption (A4). We first derive a condition to have the result in expectation, then we use an inequality concentration on matrix to bound the empirical expectation. This will be very similar, but we will get a better scaling since Δ is diagonal.

Using the same arguments as in the proof of proposition 2 we have for the diagonal matrix $\Delta = \mathrm{diag}(e)$ with $e = (a, c) \in \mathbb{R}^d$:

$$e^\top \mathbb{E}(x^{\odot 2}(x^{\odot 2})^\top)e = \mathbb{E}(x^\top \Delta x)^2 = (a + mc^\top 1_{n-1})^2 + m^2(\beta - 1)\|c\|_2^2 > 0 \;\text{ if }\; \beta > 1.$$

We can show that $m^2(\beta - 1)$ is an eigenvalue of multiplicity $d - 2$ and $\mu_\pm$ are eigenvalues of multiplicity one of the operator $\Delta \mapsto \mathbb{E}(x^\top \Delta x)^2$ with eigenvectors $e_\pm$. Thus we have

$$\begin{aligned}\lambda_{\min}(\mathbb{E}x^{\odot 2}(x^{\odot 2})^\top) &= \frac{1 + (d + \beta - 2)m^2 - \sqrt{(1 + (d + \beta - 2)m^2)^2 - 4m^2(\beta - 1)}}{2} \quad (37)\\ &\geq \frac{m^2(\beta - 1)}{1 + (d + \beta - 2)m^2},\end{aligned}$$

and

$$\lambda_{\min}^{e_-^\perp}(\mathbb{E}x^{\odot 2}(x^{\odot 2})^\top) = m^2(\beta - 2).$$

Moreover

$$\lambda_{\max}\Big(x^{\odot 2}(x^{\odot 2})^\top\Big) = (x^{\odot 2})^\top x^{\odot 2} = \sum_{j=1}^d (x_i)^4 \leq dR^4.$$

Thus we can apply the Matrix Chernoff inequality from (Tropp, 2012) for $\mu_{\mathcal{S}} = \lambda_{\min}^{\mathcal{S}}(\mathbb{E}x^{\odot 2}(x^{\odot 2})^\top)$:

$$\mathbb{P}\left(\lambda_{\min}^{\mathcal{S}}\Big(\frac{X^{\odot 2}(X^{\odot 2})^\top}{n}\Big) \leq (1 - \delta)\mu_{\mathcal{S}}\right) \leq de^{-\delta^2 n\mu_{\mathcal{S}}/(2dR^4)}.$$

Thus with probability $1 - 5d^2\exp(-\delta^2 n\mu_-/(2dR^4))$ the design matrix X satisfies assumptions (A1,A2,A3,A4) with $\zeta = (1 - \delta)\mu_-$ and $\mathcal{S} = \mathbb{R}^d$. And with probability $1 - 5d^2\exp(-\delta^2 n\min\{\beta - 1, 2\}/(2dR^4))$ the design matrix X satisfies assumptions (A1,A2,A3,A4) with $\zeta = (1 - \delta)\min\{\beta - 1, 2\}$ and $\mathcal{S} = e_-^\perp$. ■

Appendix F. Proof of multi-label results

We first prove lemma 7:

Proof Let $A \in \mathbb{R}^{k\times k}$ symmetric semi-definite positive such that $\mathrm{diag}(\tilde{y}A\tilde{y}^\top) = 1_n$, then

$$\mathrm{diag}(\tilde{y}A\tilde{y}^\top) = \sum_{i=0}^k a_{i,i}1_n + 2\sum_{i=1}^k a_{0,i}y_i + 2\sum_{1\leq i<j\leq k} a_{i,j}y_i \odot y_j$$

thus

$$2\sum_{i=1}^k a_{0,i}y_i + 2\sum_{1\leq i<j\leq k} a_{i,j}y_i \odot y_j = (1 - \sum_{i=0}^k a_{i,i})1_n$$

And this system admits as unique solution 0_n if and only if the family $\{1_n, (y_i)_{1\leq i\leq k}, (y_i y_j)_{1\leq i<j\leq k}\}$ is *linearly independent.* ■

Then we prove the lemma 8:

Proof Since $a_0 + \sum_{i=1}^k a_i^2\alpha_i \geq \alpha_{\min}\sum_{i=0}^k a_i^2 = \alpha_{\min}$ we should have $\alpha \geq \alpha_{\min}$. We have already seen that such Y satisfies the constraint. The KKT conditions are: $B =$

$\operatorname{diag}(\mu) - H - \nu 11^\top \succcurlyeq 0$ and $BY = 0$. Since $y_i = \Pi_n y_i + \frac{(y_i^\top 1_n)}{n} 1_n$.

$$\begin{aligned} Hy_i &= H\Pi_n y_i + (y_i^\top 1_n) H 1_n \\ &= \Pi_n y \\ &= (y_i - \frac{1_n^\top y_i}{n} 1_n). \end{aligned}$$

Thus

$$\begin{aligned} HY &= \sum_{i=1}^k a_i^2 H y_i y_i^\top \\ &= \sum_{i=1}^k a_i^2 (y_i - \frac{1_n^\top y_i}{n} 1_n) y_i^\top \\ &= \sum_{i=1}^k a_i^2 (y_i y_i^\top - \frac{1_n^\top y_i}{n} 1_n y_i^\top) \end{aligned}$$

and $\operatorname{tr}(HY) = \sum_{i=1}^k a_i^2 (n - n\alpha_i) = n(1 - a_0^2 + a_0^2 - \alpha) = n(1-\alpha)$.

Furthermore since $1_n^\top \operatorname{diag}(Y) = n$ and $1_n^\top M 1_n = n^2\alpha$, for $\mu = 1_n$ and $\nu = 1/n$, $B.Y = n - n(1-\alpha) - n\alpha = 0$. And since $B = I_n - \frac{1}{n} 1_n 1_n^\top - H$, $B^2 = B$ and $B^\top = B$, thus B is a symmetric projection and consequently symmetric semi-definite positive.

Hence the primal variable Y and the dual variables $\mu = 1_n$ and $\nu = 1/n$ satisfy the KKT conditions, thus Y is solution of this problem. ■

Appendix G. Efficient optimization problem

We now give the details of an efficient optimization algorithm.

G.1 Dual computation

We consider the following strongly-convex approximation of Eq. (24), augmented with the von-Neumann entropy:

$$\max_{V \succcurlyeq 0} \frac{1}{n} \sum_{i=1}^n \sqrt{(XVX^\top)_{ii}} - \|\operatorname{Diag}(c) V \operatorname{Diag}(c)\|_1 - \varepsilon \operatorname{tr}[(A^{\frac{1}{2}} V A^{\frac{1}{2}}) \log (A^{\frac{1}{2}} V A^{\frac{1}{2}})] \text{ s.t. } \operatorname{tr}(A^{\frac{1}{2}} V A^{\frac{1}{2}}) = 1.$$

Introducing dual variables, we have

$$\begin{aligned} \min_{u \in \mathbb{R}_+^n, C : |C_{ij}| \leqslant c_i c_j} \max_{V \succcurlyeq 0} \quad & \frac{1}{2n} \sum_{i=1}^n \Big(u_i ((XVX^\top)_{ii}) + \frac{1}{u_i} \Big) - \operatorname{tr} CV - \varepsilon \operatorname{tr}[(A^{\frac{1}{2}} V A^{\frac{1}{2}}) \log (A^{\frac{1}{2}} V A^{\frac{1}{2}})] \\ \text{s.t.} \quad & \operatorname{tr}(A^{\frac{1}{2}} V A^{\frac{1}{2}}) = 1. \end{aligned}$$

By fixing u and C, and letting $Q = A^{\frac{1}{2}} V A^{\frac{1}{2}}$, we can write the max problem as

$$\begin{aligned} \max_{Q \succcurlyeq 0} \quad & \operatorname{tr} A^{-\frac{1}{2}} (\frac{1}{2n} X^\top \operatorname{Diag}(u) X - C) A^{-\frac{1}{2}} Q - \varepsilon \operatorname{tr}[Q \log(Q)] \\ \text{s.t.} \quad & \operatorname{tr} Q = 1. \end{aligned}$$

This problem is of the form

$$\begin{aligned} \max_{Q \succcurlyeq 0} \operatorname{tr} DQ - \varepsilon \sum_{i=1}^n \sigma_i(Q) \log \sigma_i(Q) \\ \text{s.t. } \operatorname{tr} Q = 1 \end{aligned}$$

where $D = A^{-\frac{1}{2}} (\frac{1}{2n} X^\top \operatorname{Diag}(u) X - C) A^{-\frac{1}{2}}$ and $\sigma_i(Q)$ denotes the i-th largest eigen value of the matrix Q. If we consider the matrix D to be of the form $D = U \operatorname{Diag}(\theta) U^\top$ with θ denoting the vector of ordered eigen values of D, then it turns out that at optimality Q has the form $Q = U \operatorname{Diag}(\sigma) U^\top$, with σ denoting the ordered vector of eigen values of Q.

Therefore the above optimization problem can be cast in terms of σ as:

$$\begin{aligned} \max_{\sigma \in \mathbb{R}^n} \theta^\top \sigma - \varepsilon \sum_{i=1}^n \sigma_i \log \sigma_i \\ \text{s.t. } \sum_{i=1}^n \sigma_i = 1. \end{aligned}$$

The solution of this problem is $\sigma_i = \frac{e^{\theta_i/\varepsilon}}{\sum_{j=1}^n e^{\theta_j/\varepsilon}}$, which leads to

$$\min_{\theta \in \mathbb{R}^n} \phi^\varepsilon(\theta) = \varepsilon \log \sum_{i=1}^n \Big(e^{\frac{\theta_i}{\varepsilon}} \Big).$$

In terms of the original matrix variables, we have

$$\min \phi^\varepsilon(D) = \varepsilon \log \operatorname{tr} e^{\frac{D}{\varepsilon}}.$$

Using the appropriate expansion of D, we have the overall optimization problem as

$$\min_{u \in \mathbb{R}_+^n, C : |C_{ij}| \leqslant c_i c_j} \frac{1}{2n} \sum_{i=1}^n \frac{1}{u_i} + \phi^\varepsilon (A^{-\frac{1}{2}} (\frac{1}{2n} X^\top \operatorname{Diag}(u) X - C) A^{-\frac{1}{2}}). \tag{38}$$

At optimality, we have

$$A^{\frac{1}{2}} V A^{\frac{1}{2}} = \Big(e^{\frac{(A^{-\frac{1}{2}} (\frac{1}{2n} X^\top \operatorname{Diag}(u) X - C) A^{-\frac{1}{2}})}{\varepsilon}} \Big) / \operatorname{tr} \Big(e^{\frac{(A^{-\frac{1}{2}} (\frac{1}{2n} X^\top \operatorname{Diag}(u) X - C) A^{-\frac{1}{2}})}{\varepsilon}} \Big).$$

The error of approximation is at most $\varepsilon \log d$ and the Lipschitz constant associated with the function $\phi^\varepsilon(\cdot)$ is $\frac{1}{\varepsilon}$.

G.2 Algorithm details

We write the optimization problem Eq. (38) as:

$$\min_{u \in \mathbb{R}_+^n} F(u, C) + H(u, C)$$

where

$$H(u,C) = \phi^{\varepsilon}(A^{-\frac{1}{2}}(\frac{1}{2n}X^{\top}\operatorname{Diag}(u)X - C)A^{-\frac{1}{2}})$$

is the smooth part and

$$F(u,C) = \mathbb{I}_{C:|C_{ij}|\leqslant c_i c_j} + \frac{1}{2n}\sum_{i=1}^{n}\frac{1}{u_i}$$

is the non-smooth part.

The gradient ∇_u of $H(u,C)$ with respect to u is

$$\nabla_u = \operatorname{diag}(B^{\top}U\operatorname{Diag}(\sigma)U^{\top}B).$$

where $B = \frac{1}{\sqrt{2n}}A^{-\frac{1}{2}}X^{\top}$ and the gradient of $H(u,C)$ with respect to C is

$$\nabla_C = (A^{-\frac{1}{2}}U\operatorname{Diag}(\sigma)U^{\top}A^{-\frac{1}{2}}).$$

The Lipschitz constant L associated with the gradient $\nabla H(u,C)$ is

$$L = \frac{2}{\varepsilon}\max\Big(\lambda_{max}(B^{\top}B \odot B^{\top}B), \lambda^2_{max}(A^{-1})\Big), \tag{39}$$

where $\lambda_{max}(M)$ denotes the maximum eigen value of matrix M. Computing L takes $O(\max(n,d)^3)$ time and L needs to be computed once at the beginning of the algorithm.

The resultant FISTA procedure is described in Algorithm 1. Note that the FISTA procedure first computes intermediate iterates $(\bar{u}^{k-\frac{1}{2}}, \bar{C}^{k-\frac{1}{2}})$ (Step 7, Algorithm 1) by taking descent steps along the respective gradient directions. Then two distinct problems in u and C (respectively Steps 8 and 9 in Algorithm 1) are solved. The sub-problem in u (Step 8) can be efficiently solved using a Newton procedure followed by a thresholding step, as illustrated in Algorithm 2. The sub-problem in C (Step 9) can also be solved using a simple thresholding step.

Algorithm 1 *FISTA Algorithm to solve Eq. (38)*

1: Input X.
2: Compute Lipschitz constant L.
3: Let (u^0, C^0) be an arbitrary starting point.
4: Let $(\bar{u}^0, \bar{C}^0) = (u^0, C^0)$, $t_0 = 1$.
5: Set the maximum iterations to be K.
6: **for** $k = 1, 2, \ldots, K$ **do** ▷ The loop can also be terminated based on duality gap.
7: $(\bar{u}^{k-\frac{1}{2}}, \bar{C}^{k-\frac{1}{2}}) = \Big(\bar{u}^k - \frac{1}{L}\nabla_{\bar{u}^k}, \bar{C}^k - \frac{1}{L}\nabla_{\bar{C}^k}\Big)$.
8: Obtain $u^k = \operatorname{argmin}_{u\in\mathbb{R}^n_+}\Big\{\frac{L}{2}\|u - \bar{u}^{k-\frac{1}{2}}\|^2 + \frac{1}{2n}\sum_{i=1}^{n}\frac{1}{u_i}\Big\}$ by Algorithm 2.
9: Obtain $C^k = \operatorname{argmin}_C\Big\{\mathbb{I}_{C:|C_{ij}|\leqslant c_i c_j} + \frac{L}{2}\|C - \bar{C}^{k-\frac{1}{2}}\|_F^2\Big\}$ by thresholding.
10: $t_k = \frac{1+\sqrt{1+4t_{k-1}^2}}{2}$.
11: $(\bar{u}^k, \bar{C}^k) = (u^k, C^k) + \frac{(t_{k-1}-1)}{t_k}\Big((u^k, C^k) - (u^{k-1}, C^{k-1})\Big)$.
12: **end for**
13: Output (u^K, C^K).

Algorithm 2 *Newton method to solve u sub-problem*

1: Input $u^{k-\frac{1}{2}}$, n, L.
2: $u_i^0 = \max(u_i^{k-\frac{1}{2}}, \frac{1}{(2nL)^{\frac{1}{3}}})$, $i = 1, 2, \ldots, n$.
3: Set $\mathcal{M}$ to be the max number of Newton steps.
4: **for** $t = 1, 2, \ldots, \mathcal{M}$ **do**
5: **for** $i = 1, 2, \ldots, n$ **do**
6: $u_i^t = \frac{2nL(u_i^{t-1})^3 u_i^{k-\frac{1}{2}} + 3u_i^t}{2(nL(u_i^{t-1})^3+1)}$.
7: **end for**
8: **end for**
9: Output $\max(u^{\mathcal{M}}, 0)$.

Abstract

Due to the non-linear but highly interpretable representations, decision tree (DT) models have significantly attracted a lot of attention of researchers. However, it is difficult to understand and interpret DT models in ultrahigh dimensions and DT models usually suffer from the curse of dimensionality and achieve degenerated performance when there are many noisy features. To address these issues, this paper first presents a novel data-dependent generalization error bound for the perceptron decision tree (PDT), which provides the theoretical justification to learn a sparse linear hyperplane in each decision node and to prune the tree. Following our analysis, we introduce the notion of budget-aware classifier (BAC) with a budget constraint on the weight coefficients, and propose a supervised budgeted tree (SBT) algorithm to achieve non-linear prediction performance. To avoid generating an unstable and complicated decision tree and improve the generalization of the SBT, we present a pruning strategy by learning classifiers to minimize cross-validation errors on each BAC. To deal with ultrahigh label dimensions, based on three important phenomena of real-world data sets from a variety of application domains, we develop a sparse coding tree framework for multi-label annotation problems and provide the theoretical analysis. Extensive empirical studies verify that 1) SBT is easy to understand and interpret in ultrahigh dimensions and is more resilient to noisy features. 2) Compared with state-of-the-art algorithms, our proposed sparse coding tree framework is more efficient, yet accurate in ultrahigh label and feature dimensions.

1. Introduction

Decision tree (DT) (Moret, 1982; Safavian and Landgrebe, 1991) has been identified as one of the top 10 data mining and machine learning algorithms (Wu et al., 2008). Due to the non-linear, but highly interpretable representations (Murthy et al., 1994), DT has played a vital role in various data mining and machine learning applications, ranging from Agriculture (McQueen et al., 1995), Astronomy (Salzberg et al., 1995), Medicine (Czajkowski et al., 2014) and Molecular Biology (Shimozono et al., 1994) to Financial analysis (Mezrich, 1994).

Many early works focus on the DT, in which each node uses the value of a single feature (attribute) (Breiman et al., 1984; Quinlan, 1993) for decision. Since the decision of these methods at each node is equivalent to an axis-parallel hyperplane in the feature space, they are called axis-parallel DT, which suffer from the curse of dimensionality. To improve the performance of axis-parallel DT, researchers developed perceptron decision tree (PDT) (Bennett et al., 2000; Liu and Tsang, 2016) in which the test at each decision node uses the linear combinations of features. Clearly, PDT is the general form of axis-parallel DT. This paper first studies two emerging challenges for decision trees – ultrahigh feature dimensionality and ultrahigh label dimensionality. Then, we develop budget-aware classifier (BAC) and supervised budgeted tree to address ultrahigh feature dimensionality. Under the BAC framework, we further propose a sparse coding tree to address the second challenge.

1.1 Challenges of Ultrahigh Feature Dimensionality

Recently, the emerging trends of ultrahigh feature dimensionality have been analyzed in Mitchell et al. (2004), Fan et al. (2009) and Zhai et al. (2014). For example, the Web continues to generate quintillion bytes of data daily (Zikopoulos et al., 2012; Zhai et al., 2014), leading to three key challenges for PDT classification on the webspam data set with 16,609,143 features (which is collected from Wang et al. (2012)) :

1. It is difficult to understand and interpret PDT on this data set. How to make PDT interpretable in ultrahigh dimensions poses a critical challenge;

2. Many features in high dimensional space are usually non-informative or noisy. Those noisy features will decrease the generalization performance of PDT and derogate from their promising results for dealing with non-linear separable data, especially when there are many noisy features;

3. It is desired to identify a small set of features that is able to represent the original feature space in this ultrahigh dimensional data set.

To overcome these challenges, it is imperative to develop a sparse PDT with respect to input features and its corresponding theory.

1.2 Challenges of Ultrahigh Label Dimensionality

Annotation, which aims to tag objects with some labels to enhance the semantic understanding of the objects, has arisen in various applications. For example, in image annotation (Boutell et al., 2004; Guillaumin et al., 2009), one needs to predict some relevant keywords, such as *beach*, *sky* and *tree*, to describe a natural scene image. When annotating documents

(Schapire and Singer, 2000; Paralic and Bednar, 2003), one may need to classify them into different groups according to their annotations, such as *News*, *Finance* and *Education*. In video annotation (Song et al., 2005; Tang et al., 2008), some labels, such as *Government*, *Policy* and *Election* are needed to describe the subject of the video. In these real-world applications, the object needs to be annotated with multiple labels. Thus, it can be formulated as a multi-label annotation problem (Tsoumakas et al., 2010; Chen and Lin, 2012; Deng et al., 2014; Zhang and Zhou, 2014; Liu and Tsang, 2015b; Koyejo et al., 2015; Yen et al., 2016), which aims to annotate multiple labels for each input instance.

One central challenging issue for practical multi-label annotation is scalability in ultrahigh label and feature dimensions. Suppose one needs to annotate the presence or absence of q labels for each testing instance with m features, early approaches, such as Tsoumakas et al. (2010) and Read et al. (2011), scaling the number of annotations to be linear with the number of labels, take $\mathcal{O}(q \times m)$ time for annotation. We cannot get the results of these exhaustive approaches on the large-scale data sets within one week, such as amazon data set with 2,812,281 labels and 337,067 features, which is collected from McAuley et al. (2015a,b).

Recently, many works (Tsoumakas et al., 2008; Agrawal et al., 2013; Prabhu and Varma, 2014) have put more effort in exploring tree-based algorithms to minimize the number of annotations for multi-label annotations with ultrahigh label dimensions. Among them, FastXML (Prabhu and Varma, 2014) is the most recently advanced technique, which has shown state-of-the-art rapid annotations. However, there is no generalized performance guarantee for FastXML and our extensive empirical study verifies that FastXML generally underperforms in terms of annotation performance. Moreover, some literature (Tsoumakas et al., 2008; Madjarov et al., 2012) has shown Homer (Tsoumakas et al., 2008) achieves good annotation performance. Unfortunately, Homer requires at least $\mathcal{O}(q^2)$ time for training. Thus, we cannot get the results of Homer even on medium-sized data sets within one week. The question is: can we design some efficient, yet accurate multi-label annotation algorithms in ultrahigh label and feature dimensions?

1.3 Our Contributions and Organization

To address these challenges, we first revisit the PDT model. Specifically, we first present a novel generalization error bound for the PDT, which takes into account the distribution of the data, and provides the theoretical justification to learn a sparse hyperplane classifier in each decision node and prune the tree. From the analysis of our bound, the training error loss, the margin, the capacity of the kernel matrix defined on the training data, and the complexity of the tree are the dominant factors that affect the generalization performance of PDTs. In particular, our bound indicates that decreasing training error loss and the capacity of the kernel matrix, and enlarging the margin can yield better generalization performance. Suppose linear kernel is used, decreasing the capacity of the kernel matrix can be done via feature selection. Thereafter, we introduce the notion of budget-aware classifier (BAC) to perform feature selection and optimize training error loss and margin simultaneously, and then develop a supervised budgeted tree (SBT) to achieve non-linear prediction performance. To obtain a stable DT structure, instead of conducting ensemble, we propose an objective to learn classifiers and to identify a universal feature subset that

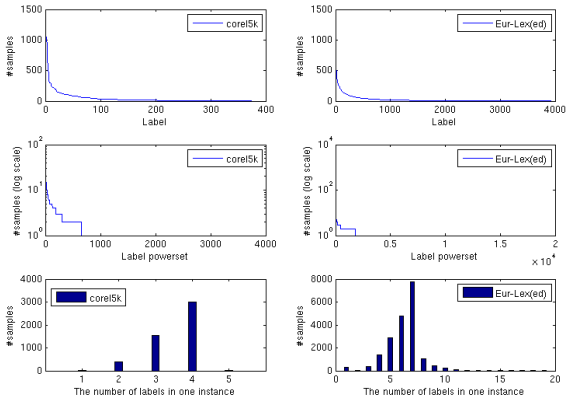

Figure 1: **Top**: Frequency of each label on the corel5k and Eur-Lex(ed) data sets. **middle**: Frequency of each label powerset on the corel5k and Eur-Lex(ed) data sets. **bottom**: Frequency of samples with the specific number of labels on the corel5k and Eur-Lex(ed) data sets.

minimizes the cross validation errors on each BAC. After that, we further diminish the generalization error by pruning the tree.

Based on BAC, we can design the tree-based algorithm to handle ultrahigh feature dimensions. How can one deal with ultrahigh label dimensions? To answer this question, we first use Figure 1 to demonstrate three important phenomena of real-world multi-label annotation data sets from various application domains[1]. We use corel5k and Eur-Lex(ed) data sets as examples. The details of these data sets are shown in Table 7.

Observations of Label Distribution: The labels of instances usually follow the distribution of Power Law (Barabási et al., 2000) which is shown in (Bhatia et al., 2015), as shown at the top of Figure 1, where many labels have very low label frequency. The bottom of Figure 1 shows the sparsity of labels in each instance, which means that the average number of labels in the data set is small. The middle of Figure 1 shows that very few label powersets have high frequency. Note that similar observations can also be found in image annotation tasks (Mao et al., 2013).

In real-world problems, although the number of labels would be very large, the first observation indicates that only a few labels appear very frequently; many others are rare. Based on this property, we design a tree-based algorithm to reduce the overall annotations as follows. Frequent labels should be predicted first in the decision tree, so there will be fewer annotations involved to predict the frequent labels, and more annotations for rare labels. To achieve this, we develop a novel annotation tree (AT) algorithm, which is analogous to the Shannon-Fano coding (Shannon, 1948) strategy, to deal with multi-label annotation problems. Moreover, the second observation shows that each instance typically

1. http://mulan.sourceforge.net

has few labels, which enables early stopping of our tree model. Thus, fewer annotations will be made along shorter paths in our tree model for most testing instances. Based on the property of the last observation, we also develop the powerset tree (PT) algorithm to deal with the transformed multi-class annotation task.

This paper is organized as follows. Section 2 reviews related work. Section 3 introduces a novel data-dependent generalization error bound for PDT. Based on our analysis, Section 4 develops the budget-aware classifier (BAC) to handle ultrahigh feature dimensions. Section 5 proposes the supervised budgeted tree (SBT) to construct a powerful non-linear classifier by arranging BAC in a tree-structure. Furthermore, based on BAC, Section 6 introduces the sparse coding tree framework for multi-label annotation with ultrahigh label and feature dimensions and provides generalization error bound for our proposed powerset tree (PT) and annotation tree (AT). Section 7 and Section 8 present the implementation issues and evaluate the performance of our proposed methods in ultrahigh dimensions, respectively. Lastly, Section 9 concludes the work.

2. Related Work

In this section, we introduce some backgrounds about the perceptron decision tree, multi-label annotation, multiple kernel learning, Huffman coding and Shannon-Fano coding.

2.1 Perceptron Decision Tree

OC1 (Murthy et al., 1994) is a popular PDT, which belongs to a randomized algorithm that performs a randomized hill-climbing search to learn the classifiers and builds the tree in a top-down approach. Murthy et al. (1994) show the competitive results of OC1 compared with C4.5 (Quinlan, 1993) (which is the famous axis-parallel DT) and other baselines. The authors in (Bennett et al., 2000) first provide the margin bound for the perceptron decision tree (PDT), then update the weights of OC1 with the maximum margin for each node. However, the results of Bennett et al. (2000) show that the performance of modified-OC1 with the maximum margin for each node is similar with OC1. The main reason may be the data dependency of the bound comes from the margin only.

The combination of bagging and building ensembles of trees (Breiman, 2001) is a popular strategy to control the generalization error of decision trees. Moreover, due to PDT's performance is sensitive to the tree structure, which is determined by the distribution of features, ensembles offer an effective technique for obtaining increased accuracy by combining the predictions of many different trees, such as random forest feature selection (RFFS) (Hastie et al., 2001) and Gradient boosted feature selection (GBFS) (Xu et al., 2014). GBFS is an advanced gradient boosted DT (Friedman, 2000), which employs gradient boosting to do feature selection in DT. GBFS, which belongs to axis-parallel DT, shows its state-of-the-art feature selection performance compared with l_1-regularized logistic regression (Lee et al., 2006), RFFS, and some other promising baselines. Cost-Sensitive Tree of Classifiers (CSTC) (Xu et al., 2013) is another state-of-the-art approach for feature selection in DT, which follows the PDT. Both are based on the l_1-regularized model (Zhu et al., 2003). Unfortunately, these l_1-regularized methods suffer from three major limitations:

1. Because the scale variation of weight parameters, it is non-trivial for these methods to control the number of features to be selected meanwhile to regulate the decision function;

2. Since l_1-norm regularization shrinks the regressors, the feature selection bias inevitably exists in the l_1-norm methods (Zhang and Huang, 2008; Zhang, 2010a,b);

3. l_1-norm regularized methods are inefficient or infeasible for handling the data sets with ultrahigh dimensions. Moreover, the theoretical and empirical analysis in Zhang and Huang (2008), Zhang (2010a), Zhang (2010b), and Tan et al. (2014) have shown that l_1-regularized methods achieve suboptimal performance in feature selection, compared with the sparse model with an explicit budget constraint on the weights.

Region-specific and locally linear models (Jose et al., 2013; Oiwa and Fujimaki, 2014) are an advanced technique for dealing with the non-linear problem. Local deep kernel learning (LDKL) (Jose et al., 2013) formulates the problem from a local kernel learning perspective where they learn tree-structured primal feature embedding and has shown its superior performance in (Jose et al., 2013). Partition-wise linear models (Oiwa and Fujimaki, 2014) assign linear models to partitions and represent region-specific linear models by linear combinations of partition-specific models. They first formalize the problem as l_0 penalizing problem and then apply a convex relaxation with a combination of l_1 penalties. The model is similar with GBFS and CSTC, which is different in penalizing terms. In this paper, we select GBFS and CSTC as the representatives of these kinds of methods for comparison.

2.2 Multi-Label Annotation

Much effort has been focused on annotation tasks, such as image annotation (Boutell et al., 2004) and video annotation (Song et al., 2005). Usually, annotation tasks can be formulated as a multi-label annotation problem (Tsoumakas et al., 2010; Chen and Lin, 2012; Deng et al., 2014; Zhang and Zhou, 2014; Koyejo et al., 2015; Liu and Tsang, 2015a; Gong et al., 2017). According to the annotation complexity, we divide these methods into several categories:

The first category includes some popular methods, such as Binary Relevance (BR) (Tsoumakas et al., 2010) and Classifier Chain (CC) (Read et al., 2011), the number of annotations scale linearly with the length of label vector. All these methods cannot handle ultrahigh label dimensions.

The second category includes the encoding-decoding strategy. For example, (Zhang and Schneider, 2011, 2012) first use different projection methods to transform the original label space into another space, and recover the original multiple labels using an expensive decoding process, which involves solving a quadratic programming (QP) problem on a space with a combinatorial nature.

The third category includes Label Powerset (LP) (Tsoumakas et al., 2010) and its variant (Tsoumakas and Vlahavas, 2007). LP reduces a multi-label annotation problem into a multi-class annotation problem by treating each distinct label set as one of the classes for a transformed multi-class learning task. One can then train a single multi-class classifier (Tsoumakas et al., 2010) or many binary classifiers (for example one-vs-all or one-vs-one) for the transformed multi-class annotation problem. The number of transformed classes

is upper bounded by $\min(n, 2^q)$ where n means the size of training data set and q means the number of labels. For large values of n and q, it imposes an extremely high training complexity.

The last category is tree-based algorithms, which have annotation costs that are logarithmic in the number of labels. FastXML (Prabhu and Varma, 2014) is one of the most advanced tree-based algorithms. However, there is no generalized performance guarantee for FastXML and our extensive empirical study verifies that FastXML generally underperforms in terms of annotation performance. Homer (Tsoumakas et al., 2008) is developed to use a divide-and-conquer-strategy to divide original problem into k sub-problems. Some literature (Tsoumakas et al., 2008; Madjarov et al., 2012) has shown Homer achieves good annotation performance. However, Homer requires at least $\mathcal{O}(q^2)$ time for training. Thus, we cannot get the results of Homer even on medium-sized data sets within one week.

2.3 Multiple Kernel Learning

By combining multiple sets of features, multiple kernel learning (MKL) (Lanckriet et al., 2004b; Rakotomamonjy et al., 2008) has become a powerful learning paradigm to enhance the interpretability of the decision function and improve performances of single kernel methods. MKL has been successfully applied in many tasks, such as object recognition (Bucak et al., 2014), signal processing (Subrahmanya and Shin, 2010), and genomic data fusion (Lanckriet et al., 2004a).

Many efficient MKL algorithms (Lanckriet et al., 2004b; Bach et al., 2004; Sonnenburg et al., 2006; Rakotomamonjy et al., 2008; Liu et al., 2015) are developed. SimpleMKL (Rakotomamonjy et al., 2008) is one of the most popular MKL solvers. SimpleMKL uses a sub-gradient method to solve the non-smooth optimization problem. However, it is expensive to calculate the sub-gradient for large-scale problems. Tan et al. (2014) develop an up-to-date MKL solver, which modifies accelerated proximal gradient method to solve the primal form of MKL and shows promising results. This paper will adapt this method to solve our subproblems.

2.4 Huffman Coding and Shannon-Fano Coding

Huffman coding (Huffman, 1952) is one of the most widespread bottom-up encoding algorithm for data compression. Huffman coding uses a specific method for choosing the representation for each symbol, resulting in a prefix code, that is, the bit string representing some particular symbol is never a prefix of the bit string representing any other symbol. Given a set of symbols and their weights (usually proportional to probabilities), Huffman coding aims to find a set of prefix codewords with minimum expected codeword length. Based on the frequency of occurrence of each symbol, the principle of Huffman coding is to use a lower number of bits to encode the symbol that occurs more frequently. The detailed procedure of Huffman coding can be referred to Huffman (1952). This work first uses the idea of Huffman coding to deal with the label powerset annotation problems.

Shannon-Fano coding (Shannon, 1948) is a top-down encoding technique for constructing a prefix code based on a set of symbols and their weights. Shannon-Fano coding arranges the symbols in order from biggest weight to smallest weight, and then divides them into two sets whose total weights are roughly comparable. Then, we encode symbols in the first

Table 1: Important notations used in this paper.

Notation	description
n	number of instances
m	dimensionality of the input space
q	dimensionality of the output space
$\mathcal{X}$	the input space over $\mathbb{R}^m$
$\mathcal{Y}$	the output space ($\mathcal{Y} = \{-1, 1\}$ for binary classification, while $\mathcal{Y} \subseteq \{1, 2, \cdots, q\}$ for multi-label classification)
x_i	$x_i \in \mathbb{R}^m$ is a real vector representing the i-th input or instance
y_i	$y_i \in \{-1, 1\}$ is used to represent the i-th label for binary classification
$\mathbf{y}_i$	$\mathbf{y}_i \in \{0, 1\}^q$ is used to represent the i-th label set for multi-label classification, where $\mathbf{y}_i(j) = 1$ if and only if $j \in \mathcal{Y}_i$
X	instance matrix, where $X = [x_1, \cdots, x_n]'$
Y	binary label matrix, where $Y = [y_1, \cdots, y_n]'$
ϱ	$\varrho = [\varrho_1, \cdots, \varrho_m]' \in [0, 1]^m$ represents a feature selection vector, and $\sqrt{\varrho}$ denotes the elementwise square root operator
B	budget constraint on the weight coefficients
$\mathcal{A}$	domain of dual variable α, where $\mathcal{A} = \{\alpha \mid \sum_{i=1}^n \alpha_i \geq 1, 0 \leq \alpha_i \leq C, i = 1, \cdots, n\}$
$\mathcal{E}$	domain of ϱ, where $\mathcal{E} = \{\varrho \in [0, 1]^m \mid \sum_{j=1}^m \varrho_j \leq B\}$

set as zero and symbols in the second set as one. As long as any sets with more than one member remain, the same process is repeated on these sets. The detailed procedure of Shannon-Fano coding can be referred to Shannon (1948). Analogous to the Shannon-Fano coding strategy, this work first proposes a novel annotation tree algorithm to deal with multi-label annotation problems.

3. Data-Dependent Generalization Error Bound for PDT

Inspired by Bartlett and Mendelson (2002) and Shawe-Taylor and Cristianini (2004), this section provides the generalization error bound for the PDT, which takes into account the distribution of the data. We begin with some basic definitions. We denote the transpose of vector/matrix by the superscript $'$. Let $\odot$ represent the elementwise product sign. $\|\cdot\|$ denotes the l_2 norm. If $\mathcal{S}$ is a set, $|\mathcal{S}|$ denotes its cardinality. Let $\mathbb{R}$ represent real number, $\mathcal{X}$ be the input space over $\mathbb{R}^m$ and $\mathcal{Y} = \{-1, 1\}$ be the output space. Suppose $sign(\cdot)$ represents sign function; $tr(\cdot)$ denotes the trace of matrix argument; $ln(\cdot)$ represents the natural logarithm and $\Theta(\cdot)$ returns 1 if its argument is greater than 0, and zero otherwise. $\hat{E}_n$ denotes the empirical risk over n training samples $(x_1, y_1), \cdots, (x_n, y_n)$. Let F be a class of functions mapping from $\mathcal{X}$ to $\mathbb{R}$. We follow the definitions in Koltchinskii (2001), Bartlett and Mendelson (2002) and Mendelson (2002), and use $R_n(F)$ and $G_n(F)$ to denote the Rademacher and Gaussian complexity of F, respectively. The important notations in this paper are summarized in Table 1.

Definition 1 (Generalized Decision Trees (GDT), Bennett et al. (2000)) *Given $\mathcal{X} = \mathbb{R}^m$, and a set of Boolean functions $F_{GDT} = \{f_{GDT} : \mathcal{X} \to \{0, 1\}\}$, the class of Generalized Decision Trees over F_{GDT} is the set of functions that can be implemented using a binary*

tree where each internal node is labeled with an element of F_{GDT}, and each leaf is labeled with either 1 or 0.

Definition 2 (Perceptron Decision Tree (PDT), Bennett et al. (2000)) *Given $\mathcal{X} = \mathbb{R}^m$, and assume g is a linear real function over $\mathcal{X}$ and $w \in \mathbb{R}^m$, a Perceptron Decision Tree (PDT) is a GDT over*

$$F_{PDT} = \{h_w : h_w(x) = \Theta(g_w(x)), g_w(x) = w'x + b\}$$

Next, we introduce two important Theorems.

Theorem 3 (Bartlett and Mendelson (2002)) *Let D be a probability distribution on $\mathcal{X} \times \mathcal{Y}$ and let F be a set of real valued functions defined on $\mathcal{X}$, with $\sup\{|\mathfrak{F}(x)| : \mathfrak{F} \in F\}$ finite for all $x \in \mathcal{X}$. Suppose that $\phi : \mathbb{R} \to [0,1]$ satisfies $\phi(\alpha) \geq \Theta(-\alpha)$ and is Lipschitz with constant L, then with probability at least $1-\delta$ with respect to n training samples $(x_1, y_1), \cdots, (x_n, y_n)$ drawn independently according to D, every function in F satisfies*

$$P_D(y \neq sign(\mathfrak{F}(x))) \leq \hat{E}_n(\phi(y\mathfrak{F}(x))) + 2LR_n(F) + \sqrt{\frac{ln(2/\delta)}{2n}}$$

Theorem 4 (Shawe-Taylor and Cristianini (2004)) *Fix margin γ and let $\mathcal{F}$ be the class of functions mapping from $\mathcal{X} \times \mathcal{Y}$ to $\mathbb{R}$ given by $f(x,y) = -yg(x)$ ($x \in \mathcal{X}$, $y \in \mathcal{Y}$), where g is a linear function in a feature space induced by a kernel $k(\cdot,\cdot)$ with Euclidean norm at most 1. Then, with probability at least $1-\delta$ with respect to n training samples $(x_1, y_1), \cdots, (x_n, y_n)$ drawn independently according to D, we have*

$$P_D(y \neq sign(g(x))) \leq \frac{1}{n\gamma}\sum_{i=1}^{n}\xi_i + \frac{4}{n\gamma}\sqrt{tr(K)} + 3\sqrt{\frac{ln(2/\delta)}{2n}}$$

where K is a kernel matrix defined on the training data with $k(\cdot,\cdot)$ and $\xi_i = \max(0, \gamma - y_i g(x_i))$.

We provide the data-dependent generalization error bound for PDT as follows:

Theorem 5 *Let T be a PDT, where the Euclidean norm of the linear functions in T is at most 1. Suppose that the depth of T is no more than d, and it contains no more than M leaves. Let $(x_1, y_1), \cdots, (x_n, y_n)$ be n training samples, which is generated independently according to a probability distribution D. Then, we can bound the generalization error with probability greater than $1-\delta$ to be less than*

$$\sum_{l}\sum_{i=1}^{d_l}\mathcal{D}_i^l + \frac{5cdMG_n(T)}{2} + \big((3d+1)\sqrt{n}M + 1\big)\sqrt{\frac{ln(6/\delta)}{2n}}$$

where c is a universal small constant, $d_l (d_l \leq d)$ is the depth of leaf l, $\mathcal{D}_i^l = \frac{1}{n_l\gamma_i^l}\sum_{j=1}^{n_l}\xi_{i,j}^l + \frac{4}{n_l\gamma_i^l}\sqrt{tr(K_l)}$, n_l denotes the number of samples $(x_1^l, y_1^l), \cdots, (x_{n_l}^l, y_{n_l}^l)$ reaching leaf l, K_l is the kernel matrix for $\{x_1^l, \cdots, x_{n_l}^l\}$, $\xi_{i,j}^l = \max\big(0, \gamma_i^l - y_{i,j}^l g_i^l(x_j^l)\big)$, where $y_{i,j}^l$ represents the correct output for input x_j^l in decision node i and γ_i^l denotes the corresponding margin.

Proof For a tree of depth d, the indicator function of a leaf is a conjunction of no more than d decision functions. More specifically, if the decision tree consists of decision nodes chosen from a class T of Boolean functions, the indicator function of leaf l (which takes value 1 at a point x if x reaches l and 0 otherwise) is a conjunction of d_l functions from T, where d_l is the depth of leaf l. We can represent the function computed by the tree as follows:

$$f(x) = \sum_l \sigma_l \bigwedge_{i=1}^{d_l} h_{l,i}(x)$$

where the sum is over all leaves l, $\sigma_l \in \{\pm 1\}$ is the label of leaf l, $h_{l,i} \in T$, and the conjunction is understood to map to $\{0,1\}$. Let F be this class of functions. Choose a family $\{\phi_L : L \in \mathbb{N}\}$ of cost functions such that each ϕ_L dominates the step function $\Theta(-yf(x))$ and has a Lipschitz constant L. For each L, Theorem 3 implies that with probability at least $1-\delta_1$:

$$P(y \neq f(x)) \leq \hat{E}_n(\phi_L(yf(x))) + 2LR_n(F) + \sqrt{\frac{ln(2/\delta_1)}{2n}}$$

Define $\phi_L(\alpha)$ to be 1 if $\alpha \leq 0$, $1 - L\alpha$ if $0 < \alpha \leq 1/L$, and 0 otherwise. Let $\tilde{P}_n(l)$ denotes the proportion of all the samples in S which reach leaf l and are correctly classified. Assume $(x_1^l, y_1^l), \cdots, (x_{n_l}^l, y_{n_l}^l)$ reach leaf l with $|S_l| = n_l$. Then we have

$$\begin{aligned}
&\hat{E}_n(\phi_L(yf(x))) \\
&= \sum_l \frac{\sum_{(x^l,y^l)\in S_l}\Theta(-y^l f(x^l))}{n} + \sum_l \tilde{P}_n(l)\phi_L(1) \\
&= \sum_l \frac{\sum_{(x^l,y^l)\in S_l}\Theta(-y^l f(x^l))}{n} + \sum_l \tilde{P}_n(l)max(0, 1\text{–}L)
\end{aligned} \tag{1}$$

If no sample reaches leaf l, the sum term of leaf l in the Eq.(1) is zero. Here we consider $1 \leq n_l < n$. As $L \in \mathbb{N}$, the second term in Eq.(1) is zero. Following Theorem 5 in (Bartlett and Mendelson, 2002), with probability at least $1-\delta_2$, we get:

$$\begin{aligned}
&\frac{\sum_{(x^l,y^l)\in S_l}\Theta(-y^l f(x^l))}{n} \leq \frac{\sum_{(x^l,y^l)\in S_l}\Theta(-y^l f(x^l))}{n_l} \\
&\leq P(y^l \neq f(x^l)) + \frac{R_n(F)}{2} + \sqrt{\frac{ln(2/\delta_2)}{2n_l}}
\end{aligned} \tag{2}$$

The probability of x^l misclassified is equal to the probability of at least one decision node from the root to a leaf l making the errors. Suppose $\{g_1^l, \cdots, g_{d_l}^l\}$ are the linear functions with the Euclidean norm at most 1 and associated with each decision node from the root to a leaf l. The corresponding margins are $\{\gamma_1^l, \cdots, \gamma_{d_l}^l\}$. For input $x^l \in \{x_1^l, \cdots, x_{n_l}^l\}$, the correct output of each decision node from the root to a leaf l is denoted by $\{y_1^l, \cdots, y_{d_l}^l\}$, where $y_i^l \in \{y_{i,1}^l, \cdots, y_{i,n_l}^l\}$. By the union bound and Theorem 4, with probability at least

$1-\delta_3$, we get the following:

$$\begin{aligned}
&P(y^l \neq f(x^l)) \\
=&P\Big(\bigcup_{i=1}^{d_l}(y_i^l \neq sign(g_i^l(x^l)))\Big) \\
\leq&\sum_{i=1}^{d_l} P(y_i^l \neq sign(g_i^l(x^l))) \\
\leq&\sum_{i=1}^{d_l}\Big(\frac{1}{n_l\gamma_i^l}\sum_{j=1}^{n_l}\xi_{i,j}^l + \frac{4}{n_l\gamma_i^l}\sqrt{tr(K_l)}\Big) + 3d_l\sqrt{\frac{ln(2/\delta_3)}{2n_l}}
\end{aligned} \tag{3}$$

Let $\delta_1 = \delta_2 = \delta_3 = \delta/3$ and $L = M$. The results of Eq.(1), Eq.(2) and Eq.(3) imply that with probability at least $1-\delta$:

$$P(y \neq f(x)) \leq \sum_l\sum_{i=1}^{d_l}\mathcal{D}_i^l + \frac{5MR_n(F)}{2} + \big((3d+1)\sqrt{n}M+1\big)\sqrt{\frac{ln(6/\delta)}{2n}}$$

where $\mathcal{D}_i^l = \frac{1}{n_l\gamma_i^l}\sum_{j=1}^{n_l}\xi_{i,j}^l + \frac{4}{n_l\gamma_i^l}\sqrt{tr(K_l)}$. Let c is a constant. Theorem 12, Theorem 16 and Lemma 4 in (Bartlett and Mendelson, 2002) imply that $R_n(F) \leq cdG_n(T)$, which implies the result. ■

4. Budget-Aware Classifier

Theorem 5 reveals important factors to reduce the generalization error bound for the PDT model: the first is to decrease the training error loss and the capacity of the kernel matrix for each node, and the second is to enlarge the margin for each node. We first enforce an upper bound budget $\mathfrak{B}$ for the capacity of the kernel matrix, that is $tr(K_l) \leq \mathfrak{B}$. Suppose there are n samples $(x_1, y_1), \cdots, (x_n, y_n)$, $x_i \in \mathbb{R}^m$ ($x_i = [x_{i,1}, \cdots, x_{i,m}]'$). Let $X = [x_1, \cdots, x_n]'$ and $Y = [y_1, \cdots, y_n]'$. Since we use linear kernel here, decreasing the capacity of the kernel matrix can be transformed to a budget constraint on the weight coefficients, which leads to a feature selection problem for the linear decision function. Mathematically, let $\hat{K}$ denote the kernel matrix on the re-scaled instance: $\hat{x}_i = x_i \odot \sqrt{\varrho}$, where $\varrho = [\varrho_1, \cdots, \varrho_m]' \in [0,1]^m$ represents a feature selection vector and $\sqrt{\varrho}$ denotes the elementwise square root operator. The capacity constraint on the kernel matrix is $tr(\hat{K}) \leq \mathfrak{B}$, then $tr(\hat{K}) = \sum_{i=1}^n \varrho'(x_i \odot x_i) \leq n\tilde{x}_{max}\sum_{j=1}^m \varrho_j$, where $\tilde{x}_{max}$ be the maximum element in $[x_1 \odot x_1, \cdots, x_n \odot x_n]$. Let $\mathfrak{B}/n\tilde{x}_{max} = B$, where B is a budget constraint on the weight coefficients. Thus $tr(\hat{K}) \leq \mathfrak{B}$ can be transformed to $\sum_{j=1}^m \varrho_j \leq B, \varrho \in [0,1]^m$. Then we learn a sparse linear decision function on each node by minimizing the training error loss and maximizing the margin at the same time. Based on Theorem 5, we hereinafter introduce the notion of budget-aware classifier (BAC).

Definition 6 (Budget-Aware Classifier (BAC)) *Assume there are n samples $(x_1, y_1), \cdots, (x_n, y_n)$ drawn independently according to a probability distribution D, where $x_i \in \mathbb{R}^m$ and $y_i \in \{\pm 1\}$. $\varrho = [\varrho_1, \cdots, \varrho_m]' \in [0,1]^m$ represents a feature selection vector. Let $\hat{K}$ denote the kernel matrix on the re-scaled instance: $\hat{x}_i = x_i \odot \sqrt{\varrho}$ and the capacity constraint on the kernel matrix can be transformed as $\sum_{j=1}^m \varrho_j \leq B$ with a budget B. A budget-aware classifier contains a linear decision function $g_w(x) = w'(x_i \odot \sqrt{\varrho} + b), ||w||^2 = 1$, where the parameters are obtained by solving the following problem :*

$$\begin{aligned}
\min_{\varrho\in\mathcal{E}, w, \xi, \gamma} \; & -\gamma + C\sum_{i=1}^n \xi_i \\
s.t. \quad & y_i w'(x_i \odot \sqrt{\varrho} + b) \geq \gamma - \xi_i, \xi_i \geq 0, i = 1, \cdots, n \\
& ||w||^2 = 1, \gamma \geq 0
\end{aligned} \tag{4}$$

where $\mathcal{E} = \{\varrho \in [0,1]^m | \sum_{j=1}^m \varrho_j \leq B\}$ and B is a budget constraint on the weight coefficients.

4.1 Learning the BAC

For the sake of clarity, we consider the function without an offset, although the model can be extended to the function with the offset. For problem (4) with respect to w, ξ, γ, the corresponding Lagrangian function is: $\mathcal{L}(w, \xi, \gamma, \alpha, \lambda, \psi, \nu) = -\gamma + C\sum_{i=1}^n \xi_i - \sum_{i=1}^n \alpha_i(y_i w'(x_i \odot \sqrt{\varrho}) - \gamma + \xi_i) + \lambda(\|w\|^2 - 1) - \sum_{i=1}^n \psi_i\xi_i - \nu\gamma$, with $\alpha_i, \psi_i, \nu \geq 0$. Differentiating with respect to the primal variables and substituting the relations obtained into the primal, we obtain the following dual objective function: $\mathcal{L}(\alpha, \lambda, \varrho) = -\frac{1}{4\lambda}\big\|\sum_{i=1}^n \alpha_i y_i (x_i \odot \sqrt{\varrho})\big\|^2 - \lambda$. Optimizing λ gives $\lambda^* = \frac{1}{2}\|\sum_{i=1}^n \alpha_i y_i (x_i \odot \sqrt{\varrho})\|$, resulting in $\mathcal{L}(\alpha, \varrho) = -\big\|\sum_{i=1}^n \alpha_i y_i (x_i \odot \sqrt{\varrho})\big\|$. Optimizing the squared l_2-norm objective and l_2-norm objective yields the same solution. To simplify the optimization, we use the squared l_2-norm as the objective. Thus, problem (4) can be equivalently reformulated as the following problem:

$$\min_{\varrho\in\mathcal{E}}\max_{\alpha\in\mathcal{A}} -\frac{1}{2}\Big\|\sum_{i=1}^n \alpha_i y_i (x_i \odot \sqrt{\varrho})\Big\|^2 \tag{5}$$

where $\mathcal{A} = \{\alpha | \sum_{i=1}^n \alpha_i \geq 1, 0 \leq \alpha_i \leq C, i = 1, \cdots, n\}$.

Let $\mathbb{G}(\alpha, \varrho) = \frac{1}{2}\Big\|\sum_{i=1}^n \alpha_i y_i (x_i \odot \sqrt{\varrho})\Big\|^2$. According to the minimax saddle-point theorem (Sion, 1958), we have the following theorem:

Theorem 7 *According to the minimax saddle-point theorem in (Sion, 1958), the following equality holds:*

$$\min_{\varrho\in\mathcal{E}}\max_{\alpha\in\mathcal{A}} -\mathbb{G}(\alpha, \varrho) = \max_{\alpha\in\mathcal{A}}\min_{\varrho\in\mathcal{E}} -\mathbb{G}(\alpha, \varrho)$$

Proof Recall that both $\mathcal{A}$ and $\mathcal{E}$ are convex compact set. It can be easily verified that the objective function is concave with respect to α. As shown in Section 4.1.1, the objective function is linear with respect to ϱ, and also is convex in ϱ. Therefore, the conditions in minimax saddle-point theorem in (Sion, 1958) are satisfied here. ■

Algorithm 1 Cutting Plane Algorithm for Solving Problem (7)

Input: Data set $\{x_i, y_i\}_{i=1}^n$. Initialize α_0.

1: $t = 0$, $\mathcal{C}_t = \emptyset$.
2: **repeat**
3: $t = t + 1$.
4: Worst-case analysis: Finding the most violated ϱ_t based on α_{t-1} and set $\mathcal{C}_t = \mathcal{C}_{t-1} \cup \{\varrho_t\}$. The details can be referred to Section 4.1.1.
5: Master-problem optimization: Solving problem (8) over $\mathcal{C}_t$ and obtaining the optimal solution α_t. The details can be referred to Section 4.1.2.
6: **until** ϵ-optimal

Based on Theorem 7, instead of directly solving problem (5), we address the following problem instead:

$$\min_{\alpha\in\mathcal{A}} \max_{\varrho\in\mathcal{E}} \mathbb{G}(\alpha, \varrho) \tag{6}$$

where we drop the negative sign of problem (6) for the clarity of our optimization procedure. By introducing variable $\theta \in \mathbb{R}$, problem (6) can be further formulated as a semi-infinite programming (SIP) (Pee and Royset, 2011) problem:

$$\min_{\alpha\in\mathcal{A},\theta\in\mathbb{R}} \theta \;\; s.t. \;\; \theta \geq \mathbb{G}(\alpha, \varrho), \forall \varrho \in \mathcal{E} \tag{7}$$

Problem (7) involves infinite number of constraints. Inspired by the cutting plane algorithm (Kelley, 1960), which iteratively refines a feasible constraint set and then solves a sequence of approximating linear programs, we propose Algorithm 1 to solve problem (7). Specifically, given α_{t-1}, the worst-case analysis is to infer the most-violated ϱ_t, and add it into the active constraint set $\mathcal{C}_t$. Then, we update α_t by solving the following problem:

$$\min_{\alpha\in\mathcal{A},\theta\in\mathbb{R}} \theta \;\; s.t. \;\; \theta \geq \mathbb{G}(\alpha, \varrho_h), \forall \varrho_h \in \mathcal{C}_t \tag{8}$$

The following convergence theorem indicates that Algorithm 1 gradually approaches to the optimal solution:

Theorem 8 *Algorithm 1 stops after a finite number of steps with the globally optimal solution of Problem (7).*

The proof can be adapted from Tan et al. (2014). Algorithm 1 involves two major steps: **worst-case analysis** and **master-problem optimization**, which will be discussed in the following subsections:

4.1.1 Worst-case analysis

The worst-case analysis is to solve the following maximization problem:

$$\max_{\varrho} \frac{1}{2}\Big\|\sum_{i=1}^{n} \alpha_i y_i (x_i \odot \sqrt{\varrho})\Big\|^2 s.t. \sum_{j=1}^{m} \varrho_j \leq B, \varrho \in [0,1]^m \tag{9}$$

Note that $\Big\|\sum_{i=1}^{n} \alpha_i y_i (x_i \odot \sqrt{\varrho})\Big\|^2 = \sum_{j=1}^{m} (\sum_{i=1}^{n} \alpha_i y_i x_{i,j})^2 \varrho_j$. Let $\Xi = (\sum_{i=1}^{n} \alpha_i y_i x_i)^2 \in \mathbb{R}^m$. Then, problem (9) can be transformed to $\max_{\varrho} \frac{1}{2}\sum_{j=1}^{m} \Xi_j \varrho_j$ subjected to $\sum_{j=1}^{m} \varrho_j \leq B, \varrho \in [0,1]^m$, which is a simple linear programming (LP) problem. We obtain the optimal solution for this LP problem by first sorting Ξ_j's and then setting the first B numbers corresponding to ϱ_j to one and the rests to zero. This procedure takes $\mathcal{O}(mlogB)$ time complexity, which is very efficient.

4.1.2 Master-problem optimization

Note that any $\varrho_h \in \mathcal{C}_t$ indexes a set of features. For simplicity, we define $X_h = [x_{1,h}, \cdots, x_{n,h}]' \in \mathbb{R}^{n\times B}$, where $x_{i,h}$ denotes the i-th instance with the features indexed by ϱ_h. By introducing dual variable $\mu_h \geq 0$ for each constraint defined by ϱ_h, the Lagrangian function of problem (8) can be written as: $\mathcal{L}(\theta, \alpha, \mu) = \theta + \sum_{\varrho_h\in\mathcal{C}_t} \mu_h(\mathbb{G}(\alpha, \varrho_h) - \theta)$. By setting its derivative with respect to θ to zero, we have $\sum \mu_h = 1$. By applying the minimax saddle-point theorem, problem (8) with the negative sign can be transformed to the following problem:

$$\max_{\alpha\in\mathcal{A}} \min_{\mu\in\mathcal{M}} -\sum_{\varrho_h\in\mathcal{C}_t} \mu_h \mathbb{G}(\alpha, \varrho_h) = \min_{\mu\in\mathcal{M}} \max_{\alpha\in\mathcal{A}} -\frac{1}{2}(\alpha \odot Y)'(\sum_{\varrho_h\in\mathcal{C}_t} \mu_h X_h X_h')(\alpha \odot Y) \tag{10}$$

where $\mathcal{M} = \{\mu | \sum \mu_h = 1, \mu_h \geq 0\}$.

Problem (10) is a multiple kernel learning (MKL) problem (Lanckriet et al., 2004b; Rakotomamonjy et al., 2008; Li et al., 2013), where the kernel matrix $\sum_{\varrho_h\in\mathcal{C}_t} \mu_h X_h X_h'$ is a convex combination of $|\mathcal{C}_t|$ base kernel matrices $X_h X_h'$. The resultant MKL problem can be solved efficiently by the modified accelerating proximal gradient (APG) method developed in (Tan et al., 2014), which takes $\mathcal{O}(n\varsigma B)$ time complexity, where ς is the number of the worst-case analyses. Thus, the time complexity of Algorithm 1 is $\mathcal{O}(n\varsigma B + mlogB)$, which is computationally efficient for large-scale and very high dimensional problems. Next sections will present what can we do with BAC.

5. Supervised Budgeted Tree

Due to the non-linear but highly interpretable representations, PDT has played a vital role in various data mining and machine learning applications. Unfortunately, PDT suffers from three limitations on ultrahigh dimensions which are described in introduction. To break the bottlenecks of PDT on ultrahigh dimensions, we first perform supervised learning based on our theoretical results and BAC, and construct a powerful non-linear classifier by arranging BAC in a tree-structure. In this section, we first present an algorithm for supervised budgeted tree (SBT), and propose pruning strategy to improve the generalization of SBT.

5.1 Algorithm for SBT

We build a SBT in a top-down approach. Starting from the root, we train the BAC on each node and use it to split the training data into two child nodes. This process continues until the remaining data at the node cannot be further split by the induced classifier. The details are stated in Algorithm 2.

Algorithm 2 Supervised Budgeted Tree (SBT)

Input: Training data $(x_1, y_1), \cdots, (x_n, y_n)$, where $x_i \in \mathbb{R}^m$ and $y_i \in \{\pm 1\}$.
Output: A supervised budgeted tree

while BAC contains more than one class **do**
  train the BAC on this node.
  split the training data of this node into left child if these instances are predicted to be positive by the BAC and call Algorithm 2 with split data as the input.
  split the rest of training data of this node into right child and call Algorithm 2 with the remaining data as the input.
end while
Return the complete supervised budgeted tree.

5.2 SBT Pruning

Theorem 5 reveals that the generalized bound also depends on the depth and leaves of the tree, which appear in the second and third terms of the bound. Inspired by this, we can reduce the depth and leaves of the tree by pruning the tree to further diminish the generalization error. We follow the pruning strategy in (Xu et al., 2013) to conduct pruning for SBT. To this end, we present to use the cross validation (CV) for each node to estimate the generalization error. If the sum of CV errors of child nodes is bigger than that of the parent node, we remove these child nodes.

It is obvious that any slight changes in the data distribution result in generating different feature subsets for many feature selection methods, such as (Xu et al., 2013, 2014). To identify a stable and unique feature subset across different folds of CV, we introduce the universal feature selection vector ϱ^{uni}, which is selected by the following formulation:

$$\min_{w^v, \varrho^{uni}} \sum_v BAC(w^v, \varrho^{uni}, S^v) \tag{11}$$

where S^v represents the $v-th$ fold of training data, w^v is the corresponding weight vector, and $BAC(w^v, \varrho^{uni}, S^v)$ denotes problem (4). To solve problem (11), we first conduct the worst-case analysis using the sum of objectives of each data fold. Then, we get the universal feature selection vector ϱ^{uni} and based on this, we adapt the efficient Master-problem solvers in (Tan et al., 2014) to get the w^v for each data fold separately. We repeat these procedures until convergence. This framework is called embedded cross validation. By using this method, we can find an intrinsic set of features.

For prediction, we aggregate the outputs from classifiers, which is generated from each data fold, by means of voting.

6. Sparse Coding Tree

In this section, based on BAC, we present sparse coding tree framework for multi-label annotation problem and the transformed multi-class (label powerset) annotation tasks.

Algorithm 3 Powerset Tree (PT) for Label Powerset Annotation

Input: Given ϖ transformed classes S, corresponding frequencies P, and $T_{s_i}(i = 1, \cdots, \varpi)$.
Output: Powerset Tree.

Initialize a priority queue $Q = \emptyset$ with the ascending order of the frequency.
Create a leaf node for each transformed class s_i and insert it to Q.
while $|Q| > 1$ **do**
  remove the two nodes s_i and s_j of the lowest frequency from Q.
  create a new internal node s_k with s_i and s_j as children and its frequency equals to the sum of the two nodes' frequency.
  set the instance T_{s_i} as positive sample and T_{s_j} as negative sample, then construct a BAC for the node s_k.
  insert the new node s_k to Q.
end while
The remaining node is the root node and the tree is complete.

6.1 Label Powerset Annotation

Our goal is to minimize the number of classifiers for binary decisions to enable rapid label powerset annotation for a number of testing instances. Recall that, to minimize the expected codeword length of information, Huffman coding uses shorter codewords to encode more frequent symbols and longer codewords to encode less frequent symbols. The idea of Huffman coding can be easily adapted to deal with the label powerset annotation problems.

Given a random n multi-labeled training sample, we first transform multi-label annotation to multi-class annotation by treating each unique set of labels as one of the classes for transformed multi-class learning task and record the frequency of each transformed class. Let ϖ be the number of transformed classes. A powerset tree is built based on the ϖ classes and their corresponding frequencies. Leaf nodes of this powerset tree are the set of transformed classes, denoted by $S = \{s_1, \cdots, s_\varpi\}$, and the corresponding frequencies are represented by $P = \{p(s_1), \cdots, p(s_\varpi)\}$. $T_{s_i}(i = 1, \cdots, \varpi)$ denotes the training instances associated with each transformed class. In each decision node, we construct a BAC and then build a powerset tree dealing with the label powerset case in a bottom-up manner. The details of the algorithm are presented in Algorithm 3.

More frequent classes are close to the root and less frequent classes are close to the leaf node layer. Thus, the annotation for most testing instances only require a few binary decisions along some shorter paths in our algorithm.

6.2 Multi-label Annotation

For multi-label annotation problems, the hypothesis space is exponential and we cannot observe some combinations of labels in the training data. Thus Huffman coding cannot be used to tackle the multi-label annotation problem. To reduce the number of annotations, we develop a novel annotation tree algorithm, which is analogous to the Shannon-Fano coding strategy. We first construct a BAC to predict the frequent label that have more examples. Then, we can leverage the annotations of such classifier to divide the remaining labels into two sets whose cardinality are roughly comparable. As long as any sets with

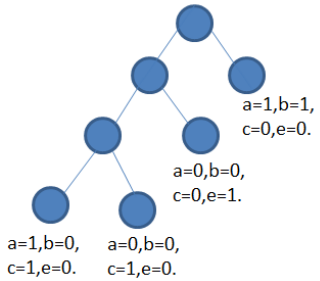

Figure 2: Schematic illustration of PT. We use a simple example to demonstrate our powerset tree. Assume one needs to annotate the presence or absence of four labels (a, b, c, e) for 8 input instances. Suppose $(1, 1, 0, 0)$, $(1, 0, 1, 0)$, $(0, 0, 0, 1)$ and $(0, 0, 1, 0)$ appear 3, 1, 3 and 1 times, respectively. Following Algorithm 3, we build the tree structure as shown in Figure 2.

more than one member remain, the same process is repeated on these sets. Our algorithm makes annotations for the ordered labels which accord to the arrangement with the label frequency ranging from high to low. The second observation shows that each instance has very few labels, based on our algorithm, so only a few annotations will be made for most testing instances. We start with some definitions associated with the specific nodes in a tree.

Let g represent the node in a tree, assume the label set associated with the node g is $G_g = \{1, 2, \cdots, q\}$, given a set of training instances $T_g = \{x_i\}_{i=1}^n$ and the corresponding labels $L_g = \{\mathbf{y}_i\}_{i=1}^n$.

Definition 9 *(Zero Label Set) refers to the situation where all the training instances at the node g do not belong to this label set. It defined as: $Zero_g = \{j|$ where all the training instances at the node g do not belong to label j $\}$.*

Definition 10 *(One Label Set) refers to the situation where all the training instances at the node g belong to this label set. It defined as: $One_g = \{j|$ where all the training instances at the node g belong to label j $\}$.*

To accelerate the learning process, these zero and one label sets will be thrown away. Thus we define the working label set for node g: $W_g = G_g - Zero_g - One_g$. Now, we introduce the learning process for the tree in three cases.

1. **Root node:** Assume g is the root node. We select label $l_g \in W_g$ with the highest frequency among W_g and build a BAC for l_g. g's left and right child are denoted as g_1 and g_0, respectively. The training instances of node g will be partitioned into left child g_1 if the values of label l_g of these instances is 1, otherwise the instances will be partitioned into right child g_0. The label set associated with node g_1 and g_0 will be reduced as $W_g \backslash l_g$. The training instance sets for g_1 and g_0 are denoted by T_{g_1} and T_{g_0}.

2. **Internal node:** The training procedure for internal (child) nodes are the same with that for the root node but uses a subset of training instances. The training instances are split recursively into two smaller subsets until our algorithm moves down to the leaf nodes.

3. **Leaf node:** If the working set of the node is empty, then it is a leaf node and stop training for the leaf nodes.

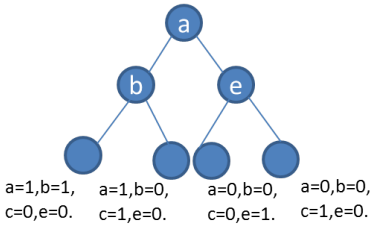

Figure 3: Schematic illustration of AT. We use the same example, which is aforementioned in Figure 2, to illustrate our annotation tree. Following Algorithm 4, we build a BAC for label a in the root node. For internal nodes, we build two BAC for label b and e in the left and right child nodes of the root, respectively. The working set in leaf nodes is empty, so we do not train any classifiers for the leaf nodes.

We predict the multi-label output for a new testing instance from the root to leaves and assign the labels of the leaf node to this testing instance. The schematic illustration of our tree is shown in Figure 3 and the details of algorithm is presented as follows:

6.3 Testing Time Complexity Analysis and Generalization Error Bound

In this section, we study the testing time complexity and generalization error bound for both label powerset and multi-label annotations. We denote logarithms to base 2 by log. Let $\mathbf{T}$ and $\mathbb{T}$ represent PT and AT, respectively.

6.3.1 Testing Time Complexity Analysis

As the annotation efficiency critically depends on the number of annotation times, we first study the average number of annotations for the both cases.

We first introduce the noiseless coding theorem in (Roman, 1992). Let $C = \{c_1, \cdots, c_n\}$ be the symbol set of size n. $p(c_i)$ is the probability that symbol c_i occurs. After encoding of symbols in C, $l(c_i)$ denotes the length of code c_i and the average codeword length is defined as $AveLen(c_1, \cdots, c_n) = \sum_{i=1}^n p(c_i) l(c_i)$. The entropy of $\{p(c_1), \cdots, p(c_n)\}$ is de-

Algorithm 4 Annotation Tree (AT) for Multi-label Annotation

Input: Given node g and its corresponding G_g, T_g and L_g.
Output: Annotation Tree

Compute $Zero_g$, One_g and W_g
while $W_g \neq \emptyset$ **do**
  select label $l_g \in W_g$ with the highest frequency
  build a BAC for l_g
  set the label set of left and right child as $W_g \backslash l_g$
  split the training instances of node g into left child g_1 if the values of label l_g of these instances are 1 and call Algorithm 4 with input ($W_g \backslash l_g$, T_{g_1})
  split the rest of training instances of node g into right child g_0 and call Algorithm 4 with input ($W_g \backslash l_g$, T_{g_0})
end while
The tree is complete

fined as $H(p(c_1), \cdots, p(c_n)) = \sum_{i=1}^{n} p(c_i) \log(1/p(c_i))$. We get the following noiseless coding theorem:

Theorem 11 *(The Noiseless Coding Theorem) Given $\{p(c_1), \cdots, p(c_n)\}$, we have*

$$H(p(c_1), \cdots, p(c_n)) \leq AveLen(c_1, \cdots, c_n) < H(p(c_1), \cdots, p(c_n)) + 1$$

Label powerset annotation: We define $H(P_{lp}) = \sum_{i=1}^{\varpi} p(s_i) \log(1/p(s_i))$. $l(s_i)$ denotes the number of annotations for class s_i and the average number of annotations is defined as $mean(S) = \sum_{i=1}^{\varpi} p(s_i) l(s_i)$. Following Theorem 11, we obtain the bound of the average number of annotations for the label powerset annotation problem using Algorithm 3.

Theorem 12 *Assume we transform a random n multi-labeled sample to a multi-class sample which has ϖ classes. We obtain the bound of the average number of annotations for the transformed multi-class annotation problem based on* **T***:*

$$H(P_{lp}) \leq mean(S) < H(P_{lp}) + 1$$

Multi-label annotation: Assume there are Φ leaf nodes in a AT. These leaf nodes denoted by $S' = \{s'_1, \cdots, s'_\Phi\}$. Assume the frequency p'_i of each unique label set can be associated with leaf node s'_i. We define $H(P_l) = \sum_{i=1}^{\Phi} p(s'_i) \log(1/p(s'_i))$. Similar to label powerset annotation problem, we use $mean(S')$ to represent the average number of annotations of Algorithm 4. We obtain the bound of $mean(S')$ for multi-label annotation.

Theorem 13 *Given a random n multi-labeled sample which has Φ unique label set. We obtain the bound of the average number of annotations for multi-label annotation problem based on $\mathbb{T}$:*

$$H(P_l) \leq mean(S') < H(P_l) + 1$$

Table 2: Testing time complexity comparison between the main methods used in this paper. $\Upsilon, \Psi, \iota, \mathfrak{D}$: # clusters, the average # instances in each cluster, # learners and the dimension of the embedding space used in SLEEC. κ_w denotes the average number of non-zero weights of PD-Sparse.

Method	**Worst Testing Time**	**Average Testing Time**
BR	$\mathcal{O}(mq)$	$\mathcal{O}(mq)$
LP	$\mathcal{O}(m\vartheta)$	-
Homer	-	$\mathcal{O}(m \log_k(q))$
FastXML	-	$\mathcal{O}(\mathcal{T} m \log(q))$
SLEEC	-	$\mathcal{O}(\mathfrak{D}\Upsilon\iota + \mathfrak{D}\Psi\iota + m\mathfrak{D})$
PD-Sparse	-	$\mathcal{O}(\kappa_w q)$
PT	$\mathcal{O}(\varsigma B \log(\vartheta))$	$\mathcal{O}(\varsigma B H(P_{lp}))$
AT	$\mathcal{O}(\varsigma B q)$	$\mathcal{O}(\varsigma B H(P_l))$

Proof Assume there are n multi-labeled samples which have Φ unique label set. We build a hierarchical tree based on n sample according to Algorithm 4. Each node is associated with one label, so the labels associated with nodes in each path of the tree are one of the unique label set, so there are Φ number of paths and leaf nodes. The frequency of each unique label set can be associated with each leaf node. After this transformation, we apply Theorem 12 to obtain the above bounds. ■

Therefore, in the label powerset and multi-label annotation algorithms, we can expect that the number of annotations for each instance are around $H(P_{lp})$ and $H(P_l)$, which are much fewer than $\min(n, 2^q)$ and q, respectively.

Algorithm 4 and Algorithm 3 are denoted as AT and PT, respectively. We provide the testing time complexity analysis for each testing instance. The number of annotations for BR are equal to the number of labels. Each time Homer divides the problem into k sub-problems. Following (Tsoumakas et al., 2008), it takes $\mathcal{O}(m \log_k(q))$ on testing time. According to (Prabhu and Varma, 2014), the average cost of prediction for FastXML is $\mathcal{O}(\mathcal{T} m \log(q))$, where $\mathcal{T}$ is the number of trees in the FastXML ensemble. In the worst case, LP requires $\min(n, 2^q)$ times of annotations respectively. The number of annotations for PT and AT are $\log(\min(n, 2^q))$ and q, respectively. As shown in our theoretical analysis, on average, the number of annotations can be further reduced to $H(P_{lp})$ and $H(P_l)$. The testing time complexity for the main methods used in this paper is presented in Table 2, where $\vartheta = \min(n, 2^q)$. From Table 2, we can see that the average testing time cost of our proposed PT and AT is lower than other methods.

6.3.2 Generalization Error Bound

Label powerset annotation: This subsection aims to bound the generalization error for a specific transformed class k in terms of the nodes in which instances in class k are

used to train the classifiers. We define the probability of error for transformed class k as $\epsilon_k(\mathbf{T}) = P\{x : x \in \mathbb{R}^m, x \text{ in class } k \text{ and } x \text{ is misclassified by } \mathbf{T} \text{ or } x \text{ is misclassified as class } k \text{ by } \mathbf{T}\}$. We first state some important definition, lemma and theorem.

We begin with the definition of the fat shattering dimension.

Definition 14 (Kearns and Schapire (1990)) *Let $\mathcal{H}$ be a set of real valued functions. We say that a set of points $\mathfrak{P}$ is γ-shattered by $\mathcal{H}$ relative to $r = (r_p)_{p\in\mathfrak{P}}$ if there are real numbers r_p indexed by $p \in \mathfrak{P}$ such that for all binary vectors b indexed by $\mathfrak{P}$, there is a function $f_b \in \mathcal{H}$ satisfying*

$$f_b(p) = \begin{cases} \geq r_p + \gamma & \text{if } b_p = 1 \\ \leq r_p - \gamma & \text{otherwise} \end{cases}$$

The fat shattering dimension $fat(\gamma)$ of the set $\mathcal{H}$ is a function from the positive real numbers to the integers which maps a value γ to the size of the largest γ-shattered set, if this is finite, or infinity otherwise.

Then, we provide the following lemma and theorem:

Lemma 15 *Given a specified $\mathbf{T}$ model with K decision nodes with margins $\gamma^1, \gamma^2, \cdots, \gamma^K$ at the decision nodes satisfying $k_i = fat(\gamma^i/8)$, where fat is continuous from the right. If $\mathbf{T}$ has correctly classified n multi-labeled examples $\boldsymbol{s}$ generated independently according to the unknown (but fixed) distribution D and $\bar{\boldsymbol{s}}$ is a set of another n multi-labeled examples, then we can bound the following probability to be less than δ: $P\{\boldsymbol{s}\bar{\boldsymbol{s}} : \exists\, \mathbf{T}$, it correctly classifies $\boldsymbol{s}$, fraction of $\bar{\boldsymbol{s}}$ misclassified $> \epsilon(n, K, \delta)\} < \delta$, where $\epsilon(n, K, \delta) = \frac{1}{n}(\mathfrak{Q}\log(8n) + \log\frac{2^K}{\delta})$ and $\mathfrak{Q} = \sum_{i=1}^{K} k_i \log(\frac{4en}{k_i})$.*

The proof can be adapted from Shawe-Taylor and Cristianini (1997).

Theorem 16 (Bartlett and Shawe-Taylor (1998)) *Let $\mathcal{H}$ be restricted to points in a ball of $\mathbf{M}$ dimensions of radius R about the origin, then*

$$fat_{\mathcal{H}}(\gamma) \leq \min\left\{\frac{R^2}{\gamma^2}, \mathbf{M} + 1\right\} \tag{12}$$

Based on Lemma 15 and Theorem 16, we derive the following theorem:

Theorem 17 *Assume we transform a random n multi-labeled sample to multi-class sample which has ϖ classes. Suppose transformed class k can be correctly classified by a $\mathbf{T}$, where the internal nodes are K decision nodes with margins γ^i at node i. In addition, suppose the number of nodes in which instances in class k are used to train the classifiers is $\mathbf{N}(k)$. Then with probability greater than $1 - \delta$,*

$$\epsilon_k(\mathbf{T}) \leq \frac{130R^2}{n}(D'_k \log(4en)\log(4n) + \mathbf{N}(k)\log(2n) + \log\frac{2}{\delta})$$

where $D'_k = \sum_{i\in k-nodes} \frac{1}{(\gamma^i)^2}$ (k-nodes are the set of nodes in which instances in class k are used to train the classifiers) and R is the radius of a ball containing the distributions support.

The proof can be adapted from Platt et al. (1999).

We discuss the implications of Theorem 17. Theorem 17 reveals one important factors to reduce generalization error bound for a specific transformed class k: it is to control the complexity of the model by reducing the average number of decision nodes. We build a $\mathbf{T}$ for the transformed multi-class classification problem. So, we obtain shorter path for higher frequency classes than that for less frequent classes. Based on Theorem 12, we can see that the average number of annotations of Algorithm 3 is around $H(P_{lp})$. Thus, PT is able to reduce the generalization error.

Multi-label annotation: This subsection analyzes the generalization error bound of multi-label annotation problem using Algorithm 4. Let $Path_{k-nodes}$ be the set of decision nodes along k-th path in $\mathbb{T}$. Assume $\epsilon_k(\mathbb{T})$ is the probability that any of node in $Path_{k-nodes}$ makes mistake. We provide the following generalization error bound for $\epsilon_k(\mathbb{T})$:

Theorem 18 *Given random n multi-labeled sample, suppose there is no mistake made by any node in $Path_{k-nodes}$ of $\mathbb{T}$, where the internal nodes are K decision nodes with margins γ^i at node i. Denote $\mathbb{N}(k) = |Path_{k-nodes}|$, that is the number of decision nodes along k-th path in $\mathbb{T}$. Then with probability greater than $1 - \delta$,*

$$\epsilon_k(\mathbb{T}) \leq \frac{130R^2}{n}(D'_k \log(4en)\log(4n) + \mathbb{N}(k)\log(2n) + \log\frac{2}{\delta})$$

where $D'_k = \sum_{i\in Path_{k-nodes}} \frac{1}{(\gamma^i)^2}$ and R is the radius of a ball containing the distributions support.

The proof can be adapted from Bennett et al. (2000).

We discuss the implications of Theorem 18. Theorem 18 reveals one important factors to reduce generalization error bound for some decision nodes along a specific path in $\mathbb{T}$: it is to control the complexity of the model by reducing the average number of decision nodes. Based on Theorem 13, we can see that the average number of annotations of Algorithm 4 is around $H(P_l)$. Thus, our proposed AT is able to tighten the generalization error bound.

7. Practical Issues

Accessing features in sparse format is very expensive for high dimensional data sets. This paper proposes two efficient auxiliary data structures to reduce the computation cost of indexing and accessing features. We first propose a modified direct indexing method for small and medium-sized data sets.

Let ε be the selected feature set of the tree and $\mathcal{Q}_{|\varepsilon|}$ represent the natural number set which contains $|\varepsilon|$ numbers from 0 to $|\varepsilon|-1$. Then, we build an injection table: $\mathcal{I} : \varepsilon \mapsto \mathcal{Q}_{|\varepsilon|}$ to compress the whole selected feature set to a continuous index set. To support direct indexing for every instance, we maintain an array with size $|\varepsilon|$. For each feature that belongs to ε, we use $\mathcal{I}$ to find out the index number, and store the feature value at that index in the array.

To handle very high dimensional data sets, in which the data is usually stored in sparse format, we maintain a hash table to store the feature ID as the key and the feature value for each instance. The method takes $\mathcal{O}(1)$ time to access the features.

Table 3: Data sets used for SBT

Data Set	# Features	# Training	# Testing
colon	2,000	32	30
pcmac	3,289	1,555	388
gisette	5,000	6,000	1,000
epsilon	2,000	21,767	14,511
rcv	47,236	12,146	8,096
news20	1,355,191	15,997	3,999
webspam	16,609,143	28,000	7,000

8. Experiment

In this section, we conduct some experiments to evaluate the performance of our proposed methods.

8.1 Evaluation on SBT

In this subsection, we conduct comprehensive experiments to evaluate the proposed method on both synthetic and high dimensional real-world data sets. Most data sets are collected from LIBSVM website[2]. pcmac data set is from (Xu et al., 2014). The training/testing partition is either predefined or the data is randomly split into 80% training and 20% testing. The statistics of these data sets are described in Table 3.

We compare SBT with a number of baseline methods: standard SVM (l_2-SVM)[3], CART-LC (Breiman et al., 1984), OC1 (Murthy et al., 1994), LDKL (Jose et al., 2013), GBFS (Xu et al., 2014), CSTC (Xu et al., 2013) and FGM (Tan et al., 2014). We use the linear classification/regression package LIBLINEAR (Fan et al., 2008) with L2-regularized square hinge loss (primal) to implement standard SVM. LDKL uses composite non-linear kernels, and achieves significantly better classification accuracies as compared to localized multiple kernel learning (Gönen and Alpaydin, 2008) (which is competitive with RBF-SVM) and other state-of-the-art non-linear methods. Therefore, we do not compare with other non-linear SVMs. The codes of other baseline methods are provided by their authors.

We use 5-fold cross validation to prune SBT. Following the parameter settings in (Tan et al., 2014), B is chosen in a range of $\{2, 5, 10, 20, 50, 100, 150, 200, 250, 400\}$ for rcv, news20 and webspam data sets, and $\{0.01m, 0.02m, \cdots, 0.09m\}$ for other data sets. C is selected using 5-fold cross validation over the range $\{0.001, 0.01, 0.1, 5, 10\}$ for the first three data sets and we fix $C = 5$ for other data sets. Following the settings in (Oiwa and Fujimaki, 2014), the tree-depth is fixed to 3 in LDKL.

8.1.1 Experiments on Synthetic Data

We compare the performance of different methods on the XOR synthetic data with different numbers of noisy features, which is non-linearly separable. Following the strategy in (Tan et al., 2014), we generate the synthetic data as follows: At first, we generate 10,000 training instances, 2,000 testing instances and 200 features. The first two dimensions are informative features, which are independently sampled from Gaussian distribution $\mathcal{N}(0, 1)$. The remaining dimension are noisy features, which are independently sampled from Uniform distribution $\mathcal{U}(0, 1)$. The output y is decided by these two informative features. For instance, if the first two features have the same sign, then y is 1 and -1 otherwise. Then, we gradually increase the noisy features to the data set and test whether the considered methods can successfully identify the former two informative features and have stable and accurate classification performance. B is chosen in a range of $\{1, 3, 5, 10\}$ using cross validation for SBT. Figure 4 (left panel) shows two informative features.

2. https://www.csie.ntu.edu.tw/∼cjlin/libsvmtools/datasets/
3. https://www.csie.ntu.edu.tw/∼cjlin/liblinear/

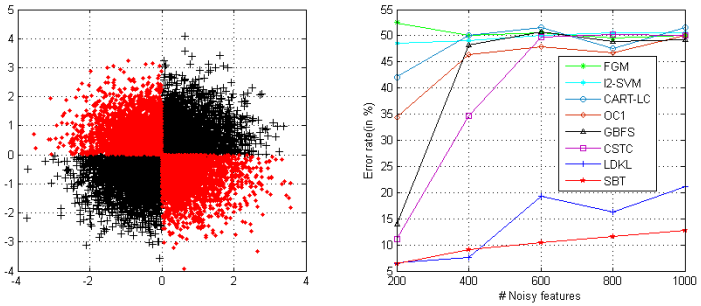

Figure 4: Testing error rates (in %) on the XOR synthetic data with different # noisy features.

Figure 4 (right panel) shows that: 1) l_2-SVM cannot work on the XOR data set. 2) FGM has shown impressive results in (Tan et al., 2014), but it cannot work on the XOR data set as well. 3) When the number of noisy features equals 200, CART-LC and OC1 are a bit better than l_2-SVM; GBFS and CSTC are much better than other baselines. However, CART-LC, OC1, GBFS and CSTC are sensitive to the number of noisy features. 4) LDKL and SBT are most successful, while our model generates more stable and accurate results.

8.1.2 Pruning Performance

To evaluate the pruning performance, this subsection compares the classification performance of our method with pruning and without pruning on epsilon and rcv data sets. The results are shown in Table 4. From this table, we can see that our proposed pruning strategy significantly improves the generalization performance, which corroborates our theoretical findings.

Table 4: Testing error rates (in %) for our method with pruning and without pruning. The best results are in bold.

Data set	SBT without pruning	SBT with pruning
epsilon	17.23	**12.45**
rcv	6.19	**3.85**

Table 5: Testing error rates (in %) for different methods. Numbers in parentheses indicate the depth of tree. The best results are in bold.

Data set	l_2-SVM	CART-LC	OC1	LDKL	SBT
colon	20.00	40.91(2)	33.33(2)	16.67	**13.33**(1)
pcmac	7.47	16.22(2)	9.68(6)	7.99	**7.22**(2)
gisette	2.30	48.17(5)	18.83(6)	2.80	**2.20**(2)
epsilon	13.24	49.40(2)	47.66(4)	15.36	**12.45**(8)
rcv	4.05	17.13(6)	48.68(3)	3.90	**3.85**(5)

8.1.3 Classification Performance

To verify the effectiveness of conducting feature selection in the decision tree, we evaluate the classification performance of SBT on real-world data sets compared with l_2-SVM, CART-LC, OC1 and LDKL. The results are shown in Table 5.

The results of Table 5 show that: 1) CART-LC and OC1 generally underperform on all data sets. The results support the argument of this paper: DT models usually suffer from the curse of dimensionality and achieve degenerated performance on high dimensional data sets, which boosts our approach. 2) SBT gets a lower error rate than l_2-SVM and LDKL. It is important to generate different hyperplanes with maximum-margin based on different sets of features. Thus, the results verify the effectiveness of conducting feature selection in the DT. 3) SBT has the best performance compared with baselines, while generating a small tree.

8.1.4 Feature Selection Performance

We evaluate the feature selection performance of SBT on pcmac, gisette, epsilon and rcv data sets compared with sparse classifier models, such as GBFS, CSTC and FGM. CSTC runs out of memory on rcv. The results of Figure 5 show that: 1) FGM and SBT clearly outperform GBFS and CSTC in terms of feature selection performance, which verifies that the sparse models with an explicit budget constraint on the weights are more effective than l_1-SVM based approaches. 2) SBT outperforms FGM. Thus, it is imperative to use the tree-structure to conduct feature selection.

Table 6: Training time (in second) for GBFS and our method on rcv data set. The faster results are in bold.

# Selected features	GBFS	SBT
100	874.2s	**5.9**s
500	5214.8s	**12.0**s
900	8523.3s	**41.9**s

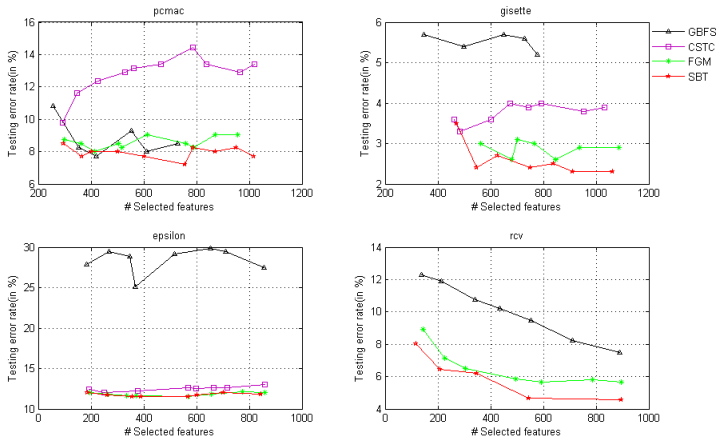

Figure 5: Testing error rates (in %) vs. # selected features for different methods on pcmac, gisette, epsilon and rcv data sets.

We next use rcv data set for training time comparison. The results are shown in Table 6. Since CART-LC, OC1 and CSTC are very slow on this data set, we do not report their training time here. From Table 6, we can see that, the training of our method is much faster than that of GBFS, and it is also much faster than LDKL, which takes 8019.3 seconds(s).

8.1.5 Results on Very High Dimensional Data Sets

We evaluate our method on news20 and webspam data sets with millions of dimensions. As CART-LC, OC1, LDKL, GBFS and CSTC are very slow on these data sets, we compare our method with l_2-SVM and FGM only on these data sets. The results are reported in

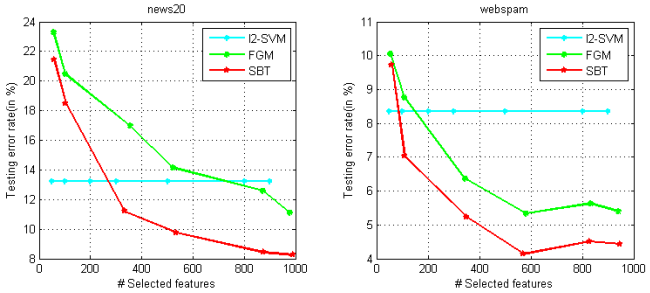

Figure 6: Testing error rates (in %) vs. # selected features for l_2-SVM, FGM and our method on news20 and webspam data sets. l_2-SVM uses all features.

Figure 6. From Figure 6, we can see that SBT consistently outperforms FGM and l_2-SVM on very high dimensional data sets.

The representation of SBT ($B = 2$) on webspam data set with 16,609,143 features is shown in Figure 7. In each decision node of Figure 7, we can see that our BAC can identify more informative and compact features. Thus, our SBT is easy to understand and interpret in ultrahigh dimensions.

8.2 Evaluation on PT and AT

In this subsection, we evaluate the performance of our proposed algorithms for multi-label annotation on a variety of real-world data sets from different application domains, which are collected from website[4][5]. The data sets fall into two categories. The first category contains five small and medium-sized data sets. The second category contains three large-scale data sets with very high label and feature dimensions. The details of data sets are shown in Table 7.

We compare our algorithms with several state-of-the-art multi-label annotation methods: 1) Flat methods: BR and LP; 2) Tree-based methods: Homer and FastXML; 3) Embedding-based method: Sparse local embedding for extreme classification (SLEEC) (Bhatia et al., 2015) is one of the most advanced embedding based method. 4) Sparse model: PD-Sparse (Yen et al., 2016) is a very recently proposed multiclass and multi-label approach which uses L1 regularization. The codes are provided by the respective authors. According to (Tsoumakas et al., 2008), k is chosen in a range of $\{2, 3, \cdots, 8\}$ using cross validation for Homer. Following (Prabhu and Varma, 2014), $\mathcal{T}$ is fixed to 50 for FastXML. We use the linear classification/regression package LIBLINEAR (Fan et al., 2008) with L2-regularized square hinge loss (primal) to train the classifier for both BR and LP. We use the default parameter in LIBLINEAR. According to the original setting in (Bhatia et al., 2015), we set

the number of the clusters as $\lfloor n/6000 \rfloor$, the number of learners as 15 and the dimension of the embedding space as 50 for small and medium-sized data sets, and 100 for very high dimensional data sets. We set B according to parameter settings in Section 8.1.

To measure the annotation performance of our methods and baseline methods fairly, this paper considers the standard F1 evaluation measurement (Du et al., 2017), which computes the F1 score for all the labels of each testing sample and takes the average over these samples. We use the publicly available split of the training and testing sets for very high dimensional data sets and perform 10-fold cross-validations on small and medium-sized data sets and report the mean and standard error of the F1 measure.

8.2.1 Results on Small and Medium-Sized Data Sets

This subsection studies the performance of various methods on mediamill, cal500, corel5k, Eur-Lex (dc) and Eur-Lex (ed) data sets. In our experiment, we cannot get the results of LP and Homer on Eur-Lex (ed) data set within one week. The F1 results of various methods on small and medium-sized data sets are listed in Table 8. From this table, we observe that: 1) Tree-based methods, such as Homer and FastXML, generally underperforms on all data sets.

Table 8: F1 Results of various methods on small and medium-sized data sets (mean ± standard deviation). The best results are in bold. Numbers in square brackets indicate the rank. "-" indicates that we cannot get the results of baselines within one week.

Data Set	BR	LP	Homer	FastXML	SLEEC	PD-Sparse	PT	AT

EUR-Lex(ed)	0.268±0.01[5]	-	-	0.254±0.01[6]	0.281±0.01[3]	0.302±0.01[2]	0.274±0.01[4]	**0.341**±0.01[1]
Ave. Rank	5.0	4.5	5.0	7.4	4.8	3.8	3.2	1.0

Table 9: F1 results of various methods on very high dimensional data sets. The best results are in bold.

Data Set	FastXML	SLEEC	PD-Sparse	PT	AT
wiki	0.1272	0.1364	0.1395	0.1422	**0.1657**
delicious	0.0077	0.0095	0.0086	0.0111	**0.0157**
amazon	0.0023	0.0148	0.0151	0.0166	**0.0348**

2) SLEEC, which is one of the most advanced embedding method, generally underperforms on small data sets, while it obtains competitive results on medium-sized data sets, such as Eur-Lex (dc) and Eur-Lex (ed). 3) PT and AT are two most successful methods, which significantly outperform tree-based algorithms, such as Homer and FastXML. The results verify our theoretical analysis.

Figure 8 shows the testing time of various methods spent on all testing instances per data set. From Figure 8.(a), we observe that: 1) SLEEC is slower than other baselines on all data sets. 2) Tree-based method, such as FastXML, is faster than BR, LP and SLEEC on medium-sized data sets. 3) PT and AT are faster than other baselines on all small and medium-sized data sets. For example, PT obtains around sixty times speedup over BR and LP, and about ten times speedup over FastXML on medium-sized data sets, such as Eur-Lex (dc). The results verify our testing time complexity analysis.

We next use Eur-Lex (ed) data set for training time comparison. BR, FastXML, SLEEC and PD-Sparse take 37652.1s, 269.9s, 5230.8s and 451.3s, respectively, while PT and AT take 839.8s and 1088.6s, respectively. Because BR and SLEEC require an expensive training process for each label and time-consuming embedding procedure, respectively, our proposed tree-based algorithms are able to achieve faster training than BR and SLEEC.

8.2.2 Results on Very High Dimensional Data Sets

In this subsection, we evaluate the performance of various methods on three very high dimensional data sets: wiki, delicious and amazon. In our experiment, we cannot get the

Table 10: F1@5 results of FastXML, SLEEC, PT and AT on wiki, delicious and amazon data sets. The best results are in bold.

Data Set	FastXML	SLEEC	PT	AT
wiki	0.5487	0.6067	0.6211	**0.6284**
delicious	0.4442	0.4631	0.4695	**0.4711**
amazon	0.4906	0.5077	0.5143	**0.5296**

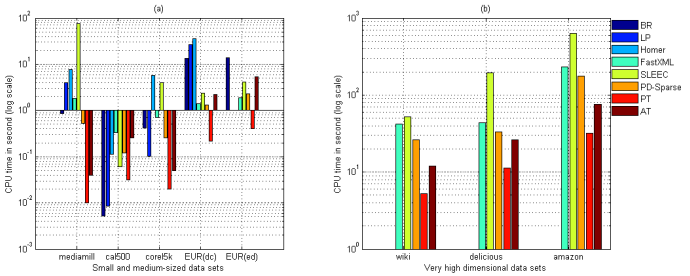

Figure 8: Testing time of various methods on all data sets (EUR-Lex is abbreviated to EUR).

results of BR, LP and Homer on these data sets within one week. The F1 results of various methods on three very high dimensional data sets are listed in Table 9. From Table 9 and Figure 8.(b), we can see that: 1) SLEEC outperforms FastXML, while FastXML is faster than SLEEC. 2) PD-Sparse is faster and more accurate than SLEEC and FastXML, which is consistent with the empirical studies in (Yen et al., 2016). 3) PT and AT are several times faster than FastXML, SLEEC and PD-Sparse. Moreover, PT and AT are much more accurate than FastXML, SLEEC and PD-Sparse on the data sets with millions of labels and features. Finally, we conclude that our proposed PT and AT are effective and efficient in ultrahigh label and feature dimensions.

Using Precision@5 and Recall@5, Table 10 shows the F1@5 results of FastXML, SLEEC, PT and AT on wiki, delicious and amazon data sets. From this table, we can see that our methods also outperform FastXML and SLEEC in terms of F1@5 measurement.

9. Conclusion

In this paper, we first develop a novel data-dependent generalization error bound for the PDT, where the data dependency of the bound comes from the training error loss, the

margin, the capacity of the kernel matrix defined on the training data, and the complexity of the tree. It provides the theoretical justification to learn a sparse linear hyperplane in each decision node and to prune the SBT. Our analysis reveals a new insight for the design of decision tree algorithms. Based on BAC and three important phenomena of real-world data sets from a variety of application domains, we develop the sparse coding tree framework for multi-label annotation with ultrahigh label and feature dimensions and provide generalized performance guarantee for our proposed PT and AT. Compared with state-of-the-art baselines, the results on the synthetic data set show that SBT is more resilient to noisy features, and empirical studies on real-world data sets demonstrate that SBT is easier to understand and interpret in ultrahigh dimensions and can identify more informative features than state-of-the-art feature selection methods. Moreover, our proposed PT and AT algorithms are able to annotate as well as possible, without performing unnecessary annotations in ultrahigh label and feature dimensions.

Abstract

Many applications in speech, robotics, finance, and biology deal with sequential data, where ordering matters and recurrent structures are common. However, this structure cannot be easily captured by standard kernel functions. To model such structure, we propose expressive closed-form kernel functions for Gaussian processes. The resulting model, GP-LSTM, fully encapsulates the inductive biases of long short-term memory (LSTM) recurrent networks, while retaining the non-parametric probabilistic advantages of Gaussian processes. We learn the properties of the proposed kernels by optimizing the Gaussian process marginal likelihood using a new provably convergent semi-stochastic gradient procedure, and exploit the structure of these kernels for scalable training and prediction. This approach provides a practical representation for Bayesian LSTMs. We demonstrate state-of-the-art performance on several benchmarks, and thoroughly investigate a consequential autonomous driving application, where the predictive uncertainties provided by GP-LSTM are uniquely valuable.

1. Introduction

There exists a vast array of machine learning applications where the underlying datasets are sequential. Applications range from the entirety of robotics, to speech, audio and video processing. While neural network based approaches have dealt with the issue of *representation learning* for sequential data, the important question of modeling and propagating uncertainty across time has rarely been addressed by these models. For a robotics application such as a self-driving car, however, it is not just desirable, but essential to have complete predictive densities for variables of interest. When trying to stay in lane and keep a safe following distance from the vehicle front, knowing the uncertainty associated with lanes and lead vehicles is as important as the point estimates.

Recurrent models with long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) have recently emerged as the leading approach to modeling sequential structure. The LSTM is an efficient gradient-based method for training recurrent networks. LSTMs use a memory cell inside each hidden unit and a special gating mechanism that stabilizes the flow of the back-propagated errors, improving the learning process of the model. While the LSTM provides state-of-the-art results on speech and text data (Graves et al., 2013; Sutskever et al., 2014), quantifying uncertainty or extracting full predictive distributions from deep models is still an area of active research (Gal and Ghahramani, 2016a).

In this paper, we quantify the predictive uncertainty of deep models by following a Bayesian nonparametric approach. In particular, we propose kernel functions which fully encapsulate the structural properties of LSTMs, for use with Gaussian processes. The resulting model enables Gaussian processes to achieve state-of-the-art performance on *sequential regression tasks*, while also allowing for a principled representation of uncertainty and non-parametric flexibility. Further, we develop a provably convergent semi-stochastic optimization algorithm that allows mini-batch updates of the recurrent kernels. We empirically demonstrate that this semi-stochastic approach significantly improves upon the standard non-stochastic first-order methods in runtime and in the quality of the converged solution. For additional scalability, we exploit the algebraic structure of these kernels, decomposing the relevant covariance matrices into Kronecker products of circulant matrices, for $\mathcal{O}(n)$ training time and $\mathcal{O}(1)$ test predictions (Wilson et al., 2015; Wilson and Nickisch, 2015). Our model not only can be interpreted as a Gaussian process with a recurrent kernel, but also as a deep recurrent network with probabilistic outputs, infinitely many hidden units, and a utility function robust to overfitting.

Throughout this paper, we assume basic familiarity with Gaussian processes (GPs). We provide a brief introduction to GPs in the background section; for a comprehensive reference, see, e.g., Rasmussen and Williams (2006). In the following sections, we formalize the problem of learning from sequential data, provide background on recurrent networks and the LSTM, and present an extensive empirical evaluation of our model. Specifically, we apply our model to a number of tasks, including system identification, energy forecasting, and self-driving car applications. Quantitatively, the model is assessed on the data ranging in size from hundreds of points to almost a million with various signal-to-noise ratios demonstrating state-of-the-art performance and linear scaling of our approach. Qualitatively, the model is tested on consequential self-driving applications: lane estimation and lead vehicle position prediction. Indeed, the main focus of this paper is on achieving state-of-the-art performance on consequential applications involving sequential data, following straightforward and scalable approaches to building highly flexible Gaussian process.

We release our code as a library at: `http://github.com/alshedivat/keras-gp`. This library implements the ideas in this paper as well as deep kernel learning (Wilson et al., 2016a) via a Gaussian process layer that can be added to *arbitrary* deep architectures and deep learning frameworks, following the Keras API specification. More tutorials and resources can be found at `https://people.orie.cornell.edu/andrew/code`.

2. Background

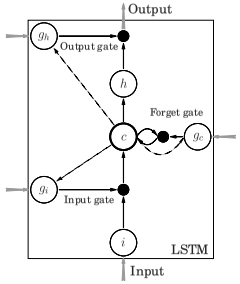
We consider the problem of learning a regression function that maps sequences to real-valued target vectors. Formally, let $\overline{\mathbf{X}} = \{\overline{\mathbf{x}_i}\}_{i=1}^n$ be a collection of sequences, $\overline{\mathbf{x}_i} = [\mathbf{x}_i^1, \mathbf{x}_i^2, \cdots, \mathbf{x}^{l_i}]$, each with corresponding length, l_i, where $\mathbf{x}_i^j \in \mathcal{X}$, and $\mathcal{X}$ is an arbitrary domain. Let $\mathbf{y} = \{\mathbf{y}_i\}_{i=1}^n$, $\mathbf{y}_i \in \mathbb{R}^d$, be a collection of the corresponding real-valued target vectors. Assuming that only the most recent L steps of a sequence are predictive of the targets, the goal is to learn a function, $f : \mathcal{X}^L \mapsto \mathbb{R}^d$, from some family, $\mathcal{F}$, based on the available data.

As a working example, consider the problem of estimating position of the lead vehicle at the next time step from LIDAR, GPS, and gyroscopic measurements of a self-driving car available for a number of previous steps. This task is a classical instance of the *sequence-to-reals regression*, where a temporal sequence of measurements is regressed to the future position estimates. In our notation, the sequences of inputs are vectors of measurements, $\overline{\mathbf{x}_1} = [\mathbf{x}^1]$, $\overline{\mathbf{x}_2} = [\mathbf{x}^1, \mathbf{x}^2]$, $\ldots$, $\overline{\mathbf{x}_n} = [\mathbf{x}^1, \mathbf{x}^2, \cdots \mathbf{x}^n]$, are indexed by time and would be of growing lengths. Typically, input sequences are considered up to a finite-time horizon, L, that is assumed to be predictive for the future targets of interest. The targets, $\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_n$, are two-dimensional vectors that encode positions of the lead vehicle in the ego-centric coordinate system of the self-driving car.

Note that the problem of learning a mapping, $f : \mathcal{X}^L \mapsto \mathbb{R}^d$, is challenging. While considering whole sequences of observations as input features is necessary for capturing long-term temporal correlations, it virtually blows up the dimensionality of the problem. If we assume that each measurement is p-dimensional, i.e., $\mathcal{X} \subseteq \mathbb{R}^p$, and consider L previous steps as distinct features, the regression problem will become $(L \times p)$-dimensional. Therefore, to avoid overfitting and be able to extract meaningful signal from a finite amount of data, it is crucial to exploit the sequential nature of observations.

Recurrent models. One of the most successful ways to exploit sequential structure of the data is by using a class of recurrent models. In the sequence-to-reals regression scenario, such a model expresses the mapping $f : \mathcal{X}^L \mapsto \mathbb{R}^d$ in the following general recurrent form:

$$\mathbf{y} = \boldsymbol{\psi}(\mathbf{h}^L) + \boldsymbol{\epsilon}^t,\ \mathbf{h}^t = \boldsymbol{\phi}(\mathbf{h}^{t-1}, \mathbf{x}^t) + \boldsymbol{\delta}^t,\ t = 1, \ldots, L, \tag{1}$$



where $\mathbf{x}^t$ is an input observation at time t, $\mathbf{h}^t$ is a corresponding latent representation, and $\mathbf{y}$ is a target vector. Functions $\boldsymbol{\phi}(\cdot)$ and $\boldsymbol{\psi}(\cdot)$ specify model transitions and emissions, respectively, and $\boldsymbol{\delta}^t$ and $\boldsymbol{\epsilon}^t$ are additive noises. While $\boldsymbol{\phi}(\cdot)$ and $\boldsymbol{\psi}(\cdot)$ can be arbitrary, they are typically time-invariant. This strong but realistic assumption incorporated into the structure of the recurrent mapping significantly reduces the complexity of the family of functions, $\mathcal{F}$, regularizes the problem, and helps to avoid severe overfitting.

Recurrent models can account for various patterns in sequences by *memorizing* internal representations of their dynamics via adjusting $\boldsymbol{\phi}$ and $\boldsymbol{\psi}$. Recurrent neural networks (RNNs) model recurrent processes by using linear parametric maps followed by nonlinear activations:

$$\mathbf{y} = \boldsymbol{\psi}(W_{hy}^\top \mathbf{h}^{t-1}),\ \mathbf{h}^t = \boldsymbol{\phi}(W_{hh}^\top \mathbf{h}^{t-1}, W_{xh}^\top \mathbf{x}^{t-1}),\ t = 1, \ldots, L, \tag{2}$$

where W_{hy}, W_{hh}, W_{xh} are weight matrices to be learned[1] and $\boldsymbol{\phi}(\cdot)$ and $\boldsymbol{\psi}(\cdot)$ here are some fixed element-wise functions. Importantly and contrary to the standard hidden Markov models (HMMs), *the state* of an RNN at any time t is *distributed* and effectively represented by an entire hidden sequence, $[\mathbf{h}^1, \cdots, \mathbf{h}^{t-1}, \mathbf{h}^t]$. A major disadvantage of the vanilla RNNs is that their training is nontrivial due to the so-called *vanishing gradient* problem (Bengio et al., 1994): the error back-propagated through t time steps diminishes exponentially which makes learning long-term relationships nearly impossible.

LSTM. To overcome vanishing gradients, Hochreiter and Schmidhuber (1997) proposed a long short-term memory (LSTM) mechanism that places a *memory cell* into each hidden unit and uses differentiable gating variables. The update rules for the hidden representation at time t have the following form (here $\sigma(\cdot)$ and $\tanh(\cdot)$ are element-wise sigmoid and hyperbolic tangent functions, respectively):

$$\begin{aligned}
\mathbf{i}^t &= \tanh\left(W_{xc}^\top \mathbf{x}^t + W_{hc}^\top \mathbf{h}^{t-1} + \mathbf{b}_c\right),\\
\mathbf{g}_i^t &= \sigma\left(W_{xi}^\top \mathbf{x}^t + W_{hi}^\top \mathbf{h}^{t-1} + W_{ci}^\top \mathbf{c}^{t-1} + \mathbf{b}_i\right),\\
\mathbf{c}^t &= \mathbf{g}_c^t\ \mathbf{c}^{t-1} + \mathbf{g}_i^t\ \mathbf{i}^t,\\
\mathbf{g}_c^t &= \sigma\left(W_{xf}^\top \mathbf{x}^t + W_{hf}^\top \mathbf{h}^{t-1} + W_{cf}^\top \mathbf{c}^{t-1} + \mathbf{b}_f\right),\\
\mathbf{o}^t &= \tanh\left(\mathbf{c}^t\right),\\
\mathbf{g}_o^t &= \sigma\left(W_{xo}^\top \mathbf{x}^t + W_{ho}^\top \mathbf{h}^{t-1} + W_{co}^\top \mathbf{c}^t + \mathbf{b}_o\right),\\
\mathbf{h}^t &= \mathbf{g}_o^t\ \mathbf{o}^t.
\end{aligned} \tag{3}$$

As illustrated above, $\mathbf{g}_i^t$, $\mathbf{g}_c^t$, and $\mathbf{g}_o^t$ correspond to the input, forget, and output gates, respectively. These variables take their values in $[0, 1]$ and when combined with the internal states, $\mathbf{c}^t$, and inputs, $\mathbf{x}^t$, in a multiplicative fashion, they play the role of soft gating. The gating mechanism not only improves the flow of errors through time, but also, allows the the network to decide whether to keep, erase, or overwrite certain memorized information based on the forward flow of inputs and the backward flow of errors. This mechanism adds stability to the network's memory.

Gaussian processes. The Gaussian process (GP) is a Bayesian nonparametric model that generalizes the Gaussian distributions to functions. We say that a random function f is drawn from a GP with a mean function μ and a covariance kernel k, $f \sim \mathcal{GP}(\mu, k)$, if for any vector of inputs, $[\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n]$, the corresponding vector of function values is Gaussian:

$$[f(\mathbf{x}_1), f(\mathbf{x}_2), \ldots, f(\mathbf{x}_n)] \sim \mathcal{N}(\boldsymbol{\mu}, K_{X,X}),$$

with mean $\boldsymbol{\mu}$, such that $\boldsymbol{\mu}_i = \mu(\mathbf{x}_i)$, and covariance matrix $K_{X,X}$ that satisfies $(K_{X,X})_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$. GPs can be seen as distributions over the reproducing kernel Hilbert space (RKHS) of functions which is uniquely defined by the kernel function, k (Schölkopf and Smola, 2002).

1. The bias terms are omitted for clarity of presentation.

GPs with RBF kernels are known to be universal approximators with prior support to within an arbitrarily small epsilon band of any continuous function (Micchelli et al., 2006).

Assuming additive Gaussian noise, $y \mid \mathbf{x} \sim \mathcal{N}\left(f(\mathbf{x}), \sigma^2\right)$, and a GP prior on $f(\mathbf{x})$, given training inputs $\mathbf{x}$ and training targets $\mathbf{y}$, the predictive distribution of the GP evaluated at an arbitrary test point $\mathbf{x}_*$ is:

$$\mathbf{f}_* \mid \mathbf{x}_*, \mathbf{x}, \mathbf{y}, \sigma^2 \sim \mathcal{N}\left(\mathbb{E}[\mathbf{f}_*], \mathrm{Cov}[\mathbf{f}_*]\right), \tag{4}$$

where

$$\begin{aligned} \mathbb{E}[\mathbf{f}_*] &= \boldsymbol{\mu}_{X_*} + K_{X_*,X}[K_{X,X} + \sigma^2 I]^{-1}\mathbf{y}, \\ \mathrm{Cov}[\mathbf{f}_*] &= K_{X_*,X_*} - K_{X_*,X}[K_{X,X} + \sigma^2 I]^{-1}K_{X,X_*}. \end{aligned} \tag{5}$$

Here, $K_{X_*,X}$, K_{X,X_*}, $K_{X,X}$, and K_{X_*,X_*} are matrices that consist of the covariance function, k, evaluated at the corresponding points, $\mathbf{x} \in \mathbf{X}$ and $\mathbf{x}_* \in \mathbf{X}_*$, and $\boldsymbol{\mu}_{X_*}$ is the mean function evaluated at $\mathbf{x}_* \in \mathbf{X}_*$. GPs are fit to the data by optimizing *the evidence*—the marginal probability of the data given the model—with respect to kernel hyperparameters. The evidence has the form:

$$\log \mathbb{P}\left(\mathbf{y} \mid \mathbf{x}\right) = -\left[\mathbf{y}^\top (K + \sigma^2 I)^{-1}\mathbf{y} + \log\det(K + \sigma^2 I)\right] + \text{const}, \tag{6}$$

where we use a shorthand K for $K_{X,X}$, and K implicitly depends on the kernel hyperparameters. This objective function consists of a *model fit* and a *complexity penalty* term that results in an automatic Occam's razor for realizable functions (Rasmussen and Ghahramani, 2001). By optimizing the evidence with respect to the kernel hyperparameters, we effectively learn the the structure of the space of functional relationships between the inputs and the targets. For further details on Gaussian processes and relevant literature we refer interested readers to the classical book by Rasmussen and Williams (2006).

Turning back to the problem of learning from sequential data, it seems natural to apply the powerful GP machinery to modeling complicated relationships. However, GPs are limited to learning only pairwise correlations between the inputs and are unable to account for long-term dependencies, often dismissing complex temporal structures. Combining GPs with recurrent models has potential to addresses this issue.

3. Related work

The problem of learning from sequential data, especially from temporal sequences, is well known in the control and dynamical systems literature. Stochastic temporal processes are usually described either with generative *autoregressive models* (AM) or with *state-space models* (SSM) (Van Overschee and De Moor, 2012). The former approach includes nonlinear auto-regressive models with exogenous inputs (NARX) that are constructed by using, *e.g.*, neural networks (Lin et al., 1996) or Gaussian processes (Kocijan et al., 2005). The latter approach additionally introduces unobservable variables, *the state*, and constructs

autoregressive dynamics in the latent space. This construction allows to represent and propagate uncertainty through time by explicitly modeling the signal (via the state evolution) and the noise. Generative SSMs can be also used in conjunction with discriminative models via the Fisher kernel (Jaakkola and Haussler, 1999).

Modeling time series with GPs is equivalent to using *linear-Gaussian* autoregressive or SSM models (Box et al., 1994). Learning and inference are efficient in such models, but they are not designed to capture long-term dependencies or correlations beyond pairwise. Wang et al. (2005) introduced GP-based state-space models (GP-SSM) that use GPs for transition and/or observation functions. These models appear to be more general and flexible as they account for uncertainty in the state dynamics, though require complicated approximate training and inference, which are hard to scale (Turner et al., 2010; Frigola et al., 2014).

Perhaps the most recent relevant work to our approach is *recurrent Gaussian processes* (RGP) (Mattos et al., 2015). RGP extends the GP-SSM framework to regression on sequences by using a recurrent architecture with GP-based activation functions. The structure of the RGP model mimics the standard RNN, where every parametric layer is substituted with a Gaussian process. This procedure allows one to propagate uncertainty throughout the network for an additional cost. Inference is intractable in RGP, and efficient training requires a sophisticated *approximation* procedure, the so-called *recurrent variational Bayes*. In addition, the authors have to turn to RNN-based approximation of the variational mean functions to battle the growth of the number of variational parameters with the size of data. While technically promising, RGP seems problematic from the application perspective, especially in its implementation and scalability aspects.

Our model has several distinctions with prior work aiming to regress sequences to reals. Firstly, one of our goals is to keep the model as simple as possible while being able to represent and quantify *predictive uncertainty*. We maintain an analytical objective function and refrain from complicated and difficult-to-diagnose inference schemes. This simplicity is achieved by giving up the idea of propagating signal through a chain GPs connected in a recurrent fashion. Instead, we propose to directly *learn kernels* with recurrent structure via joint optimization of a simple functional composition of a standard GP with a recurrent model (*e.g.*, LSTM), as described in detail in the following section. Similar approaches have recently been explored and proved to be fruitful for non-recurrent deep networks (Wilson et al., 2016a,b; Calandra et al., 2016). We remark that combinations of GPs with nonlinear functions have also been considered in the past in a slightly different setting of warped regression targets (Snelson et al., 2003; Wilson and Ghahramani, 2010; Lázaro-Gredilla, 2012). Additionally, uncertainty over the recurrent parts of our model is represented via dropout, which is computationally cheap and turns out to be equivalent to approximate Bayesian inference in a deep Gaussian process (Damianou and Lawrence, 2013) with particular intermediate kernels (Gal and Ghahramani, 2016a,b). Finally, one can also view our model as a standalone flexible Gaussian process, which leverages learning techniques that scale to massive datasets (Wilson and Nickisch, 2015; Wilson et al., 2015).

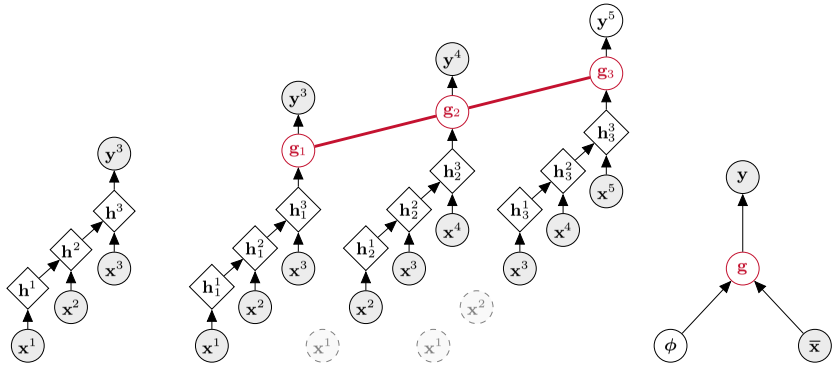


Figure 1: (a) Graphical representation of a recurrent model (RNN/LSTM) that maps an input sequence to a target value in one-step-ahead prediction manner. Shaded variables are observable, diamond variables denote deterministic dependence on the inputs. (b) Graphical model for GP-LSTM with a time lag, $L = 3$, two training time points, $t = 3$ and $t = 4$, and a testing time point, $t = 5$. Latent representations are mapped to the outputs through a Gaussian field (denoted in red) that globally correlates predictions. Dashed variables represent data instances unused at the given time step. (c) Graphical representation of a GP with a kernel structured with a parametric map, $\boldsymbol{\phi}$.

4. Learning recurrent kernels

Gaussian processes with different kernel functions correspond to different structured probabilistic models. For example, some special cases of the Matérn class of kernels induce models with Markovian structure (Stein, 1999). To construct deep kernels with recurrent structure we transform the original input space with an LSTM network and build a kernel directly in the transformed space, as shown in Figure 1b.

In particular, let L $\boldsymbol{\phi} : \mathcal{X}^L \mapsto \mathcal{H}$ be an arbitrary deterministic transformation of the input sequences into some latent space, $\mathcal{H}$. Next, let $k : \mathcal{H}^2 \mapsto \mathbb{R}$ be a real-valued kernel defined on $\mathcal{H}$. The decomposition of the kernel and the transformation, $\tilde{k} = k \circ \boldsymbol{\phi}$, is defined as

$$\tilde{k}(\overline{\mathbf{x}}, \overline{\mathbf{x}}') = k(\boldsymbol{\phi}(\overline{\mathbf{x}}), \boldsymbol{\phi}(\overline{\mathbf{x}}')), \text{ where } \overline{\mathbf{x}}, \overline{\mathbf{x}}' \in \mathcal{X}^L, \text{ and } \tilde{k} : \left(\mathcal{X}^L\right)^2 \mapsto \mathbb{R}. \tag{7}$$

It is trivial to show that $\tilde{k}(\overline{\mathbf{x}}, \overline{\mathbf{x}}')$ is a valid kernel defined on $\mathcal{X}^L$ (MacKay, 1998, Ch. 5.4.3). In addition, if $\boldsymbol{\phi}(\cdot)$ is represented by a neural network, the resulting model can be viewed as the same network, but with an additional GP-layer and the negative log marginal likelihood (NLML) objective function used instead of the standard mean squared error (MSE).

Input embedding is well-known in the Gaussian process literature (e.g. MacKay, 1998; Hinton and Salakhutdinov, 2008). Recently, Wilson et al. (2016a,b) have successfully scaled the approach and demonstrated strong results in regression and classification tasks for kernels based on feedforward and convolutional architectures. In this paper, we apply the same technique to learn kernels with recurrent structure by transforming input sequences with a recurrent neural network that acts as $\boldsymbol{\phi}(\cdot)$. In particular, a (multi-layer) LSTM architecture is used to embed L steps of the input time series into a single vector in the hidden space, $\mathcal{H}$. For the embedding, as common, we use the last hidden vector produced by the recurrent network. Note that however, any variations to the embedding (e.g., using other types of recurrent units, adding 1-dimensional pooling layers, or attention mechanisms) are all fairly straightforward[2]. More generally, the recurrent transformation can be random itself (Figure 1), which would enable direct modeling of uncertainty *within* the recurrent dynamics, but would also require inference for $\boldsymbol{\phi}$ (e.g., as in Mattos et al., 2015). In this study, we limit our consideration of random recurrent maps to only those induced by dropout.

Unfortunately, once the the MSE objective is substituted with NLML, it no longer factorizes over the data. This prevents us from using the well-established stochastic optimization techniques for training our recurrent model. In the case of feedforward and convolutional networks, Wilson et al. (2016a) proposed to pre-train the input transformations and then fine-tune them by jointly optimizing the GP marginal likelihood with respect to hyperparameters and the network weights using *full-batch* algorithms. When the transformation is recurrent, stochastic updates play a key role. Therefore, we propose a semi-stochastic block-gradient optimization procedure which allows mini-batching weight updates and fully joint training of the model from scratch.

4.1 Optimization

The negative log marginal likelihood of the Gaussian process has the following form:

$$\mathcal{L}(K) = \mathbf{y}^\top (K_y + \sigma^2 I)^{-1} \mathbf{y} + \log\det(K_y + \sigma^2 I) + \text{const}, \tag{8}$$

where $K_y + \sigma^2 I$ ($\triangleq K$) is the Gram kernel matrix, K_y, is computed on $\{\boldsymbol{\phi}(\overline{\mathbf{x}}_i)\}_{i=1}^N$ and implicitly depends on the base kernel hyperparameters, $\boldsymbol{\theta}$, and the parameters of the recurrent neural transformation, $\boldsymbol{\phi}(\cdot)$, denoted W and further referred as the *transformation hyperparameters*. Our goal is to optimize $\mathcal{L}$ with respect to both $\boldsymbol{\theta}$ and W.

The derivative of the NLML objective with respect to $\boldsymbol{\theta}$ is standard and takes the following form (Rasmussen and Williams, 2006):

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\theta}} = \frac{1}{2} \mathbf{tr}\left(\left[K^{-1} \mathbf{y}\mathbf{y}^\top K^{-1} - K^{-1} \right] \frac{\partial K}{\partial \boldsymbol{\theta}} \right), \tag{9}$$

2. Details on the particular architectures used in our empirical study are discussed in the next section.

where $\partial K/\partial \boldsymbol{\theta}$ is depends on the kernel function, $k(\cdot,\cdot)$, and usually has an analytic form. The derivative with respect to the l-th transformation hyperparameter, W_l, is as follows:[3]

$$\frac{\partial \mathcal{L}}{\partial W_l} = \frac{1}{2}\sum_{i,j}\left(K^{-1}\mathbf{y}\mathbf{y}^\top K^{-1} - K^{-1}\right)_{ij}\left\{\left(\frac{\partial k(\mathbf{h}_i,\mathbf{h}_j)}{\partial \mathbf{h}_i}\right)^\top \frac{\partial \mathbf{h}_i}{\partial W_l} + \left(\frac{\partial k(\mathbf{h}_i,\mathbf{h}_j)}{\partial \mathbf{h}_j}\right)^\top \frac{\partial \mathbf{h}_j}{\partial W_l}\right\}, \tag{10}$$

where $\mathbf{h}_i = \boldsymbol{\phi}(\overline{\mathbf{x}}_i)$ corresponds to the latent representation of the the i-th data instance. Once the derivatives are computed, the model can be trained with any first-order or quasi-Newton optimization routine. However, application of the stochastic gradient method—the *de facto* standard optimization routine for deep recurrent networks—is not straightforward: neither the objective, nor its derivatives factorize over the data[4] due to the kernel matrix inverses, and hence convergence is not guaranteed.

Semi-stochastic alternating gradient descent. Observe that once the kernel matrix, K, is *fixed*, the expression, $\left(K^{-1}\mathbf{y}\mathbf{y}^\top K^{-1} - K^{-1}\right)$, can be precomputed on the full data and fixed. Subsequently, Eq. (10) turns into a weighted sum of independent functions of each data point. This observation suggests that, given a *fixed kernel matrix*, one could compute a stochastic update for W on a mini-batch of training points by only using the corresponding sub-matrix of K. Hence, we propose to optimize GPs with recurrent kernels in a semi-stochastic fashion, alternating between updating the kernel hyperparameters, $\boldsymbol{\theta}$, on the full data first, and then updating the weights of the recurrent network, W, using stochastic steps. The procedure is given in Algorithm 1.

Semi-stochastic alternating gradient descent is a special case of block-stochastic gradient iteration (Xu and Yin, 2015). While the latter splits the variables into arbitrary blocks and applies Gauss–Seidel type stochastic gradient updates to each of them, our procedure alternates between applying deterministic updates to $\boldsymbol{\theta}$ and stochastic updates to W of the form $\boldsymbol{\theta}^{(t+1)} \leftarrow \boldsymbol{\theta}^{(t)} + \lambda_{\boldsymbol{\theta}}^{(t)}\mathbf{g}_{\boldsymbol{\theta}}^{(t)}$ and $W^{(t+1)} \leftarrow W^{(t)} + \lambda_W^{(t)}\mathbf{g}_W^{(t)}$[5]. The corresponding Algorithm 1 is provably convergent for convex and non-convex problems under certain conditions. The following theorem adapts results of Xu and Yin (2015) to our optimization scheme.

Theorem 1 (informal) *Semi-stochastic alternating gradient descent converges to a fixed point when the learning rate, λ_t, decays as $\Theta(1/t^{\frac{1+\delta}{2}})$ for any $\delta \in (0,1]$.*

Applying alternating gradient to our case has a catch: the kernel matrix (and its inverse) has to be updated each time W and $\boldsymbol{\theta}$ are changed, *i.e.*, on every mini-batch iteration (marked red in Algorithm 1). Computationally, this updating strategy defeats the purpose of stochastic gradients because we have to use the entire data on each step. To deal with the issue of computational efficiency, we use ideas from asynchronous optimization.

3. Step-by-step derivations are given in Appendix B.
4. Cannot be represented as sums of independent functions of each data point.
5. In principle, stochastic updates of $\boldsymbol{\theta}$ are also possible. As we will see next, we choose in practice to keep the kernel matrix fixed while performing stochastic updates. Due to sensitivity of the kernel to even small changes in $\boldsymbol{\theta}$, convergence of the fully stochastic scheme is fragile.

Algorithm 1 Semi-stochastic alternating gradient descent.

input Data – $(X, \mathbf{y})$, kernel – $k_{\boldsymbol{\theta}}(\cdot,\cdot)$, recurrent transformation – $\phi_{\mathbf{w}}(\cdot)$.
1: Initialize $\boldsymbol{\theta}$ and $\mathbf{w}$; compute initial K.
2: **repeat**
3: **for all** mini-batches X_b in X **do**
4: $\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} + \texttt{update}_{\boldsymbol{\theta}}(X, \boldsymbol{\theta}, K)$. and $\mathbf{w} \leftarrow \mathbf{w} + \texttt{update}_{\mathbf{w}}(X_b, \mathbf{w}, K)$.
5: Update the kernel matrix, K.
6: **end for**
7: **until** Convergence
output Optimal $\boldsymbol{\theta}^*$ and $\mathbf{w}^*$

Algorithm 2 Semi-stochastic asynchronous gradient descent.

input Data – $(X, \mathbf{y})$, kernel – $k_{\boldsymbol{\theta}}(\cdot,\cdot)$, recurrent transformation – $\phi_{\mathbf{w}}(\cdot)$.
1: Initialize $\boldsymbol{\theta}$ and $\mathbf{w}$; compute initial K.
2: **repeat**
3: $\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} + \texttt{update}_{\boldsymbol{\theta}}(X, \mathbf{w}, K)$.
4: **for all** mini-batches X_b in X **do**
5: $\mathbf{w} \leftarrow \mathbf{w} + \texttt{update}_{\mathbf{w}}(X_b, \mathbf{w}, K^{\text{stale}})$.
6: **end for**
7: Update the kernel matrix, K.
8: **until** Convergence
output Optimal $\boldsymbol{\theta}^*$ and $\mathbf{w}^*$

Asynchronous techniques. One of the recent trends in parallel and distributed optimization is applying updates in an asynchronous fashion (Agarwal and Duchi, 2011). Such strategies naturally require some tolerance to delays in parameter updates (Langford et al., 2009). In our case, we modify Algorithm 1 to allow *delayed kernel matrix updates*.

The key observation is very intuitive: when the stochastic updates of W are small enough, K does not change much between mini-batches, and hence we can perform multiple stochastic steps for W before re-computing the kernel matrix, K, and still converge. For example, K may be updated once at the end of each pass through the entire data (see Algorithm 2). To ensure convergence of the algorithm, it is important to strike the balance between (a) the learning rate for W and (b) the frequency of the kernel matrix updates. The following theorem provides convergence results under certain conditions.

Theorem 2 (informal) *Semi-stochastic gradient descent with τ-delayed kernel updates converges to a fixed point when the learning rate, λ_t, decays as $\Theta(1/\tau t^{\frac{1+\delta}{2}})$ for any $\delta \in (0,1]$.*

Formal statements, conditions, and proofs for Theorems 1 and 2 are given in Appendix C.2.

Why stochastic optimization? GPs with recurrent kernels can be also trained with full-batch gradient descent, as proposed by Wilson et al. (2016a). However, stochastic gradient methods have been proved to attain better generalization (Hardt et al., 2016) and often demonstrate superior performance in deep and recurrent architectures (Wilson and Martinez, 2003). Moreover, stochastic methods are 'online', i.e., they update model parameters based on subsets of an incoming data stream, and hence can scale to very large datasets. In our experiments, we demonstrate that GPs with recurrent kernels trained with Algorithm 2 converge faster (i.e., require fewer passes through the data) and attain better performance than if trained with full-batch techniques.

Stochastic variational inference. Stochastic variational inference (SVI) in Gaussian processes (Hensman et al., 2013) is another viable approach to enabling stochastic optimization for GPs with recurrent kernels. Such method would optimize a variational lower bound on the original objective that factorizes over the data by construction. Recently, Wilson et al. (2016b) developed such a stochastic variational approach in the context of deep kernel learning. Note that unlike all previous existing work, our proposed approach does not require a variational approximation to the marginal likelihood to perform mini-batch training of Gaussian processes.

4.2 Scalability

Learning and inference with Gaussian processes requires solving a linear system involving an $n \times n$ kernel matrix, $K^{-1}y$, and computing a log determinant over K. These operations typically require $\mathcal{O}(n^3)$ computations for n training data points, and $\mathcal{O}(n^2)$ storage. In our approach, scalability is achieved through semi-stochastic training and structure-exploiting inference. In particular, asynchronous semi-stochastic gradient descent reduces both the total number of passes through the data required for the model to converge and the number of calls to the linear system solver; exploiting the structure of the kernels significantly reduces the time and memory complexities of the linear algebraic operations.

More precisely, we replace all instances of the covariance matrix $K_{\mathbf{y}}$ with $WK_{U,U}W^{\top}$, where W is a sparse interpolation matrix, and $K_{U,U}$ is the covariance matrix evaluated over m latent inducing points, which decomposes into a Kronecker product of circulant matrices (Wilson and Nickisch, 2015; Wilson et al., 2015). This construction makes inference and learning scale as $\mathcal{O}(n)$ and test predictions be $\mathcal{O}(1)$, while preserving model structure. For the sake of completeness, we provide an overview of the underlying algebraic machinery in Appendix A.

At a high level, because W is sparse and $K_{U,U}$ is structured it is possible to take extremely fast matrix vector multiplications (MVMs) with the approximate covariance matrix $K_{X,X}$. One can then use methods such as linear conjugate gradients, which only use MVMs, to efficiently solve linear systems. MVM or scaled eigenvalue approaches (Wilson and Nickisch, 2015; Wilson et al., 2015) can also be used to efficiently compute the log determinant and its derivatives. Kernel interpolation (Wilson et al., 2015) also enables fast predictions, as we describe further in the Appendix.

5. Experiments

We compare the proposed Gaussian processes with recurrent kernels based on RNN and LSTM architectures (GP-RNN/LSTM) with a number of baselines on datasets of various complexity and ranging in size from hundreds to almost a million of time points. For the datasets with more than a few thousand points, we use a massively scalable version of GPs (see Section 4.2) and demonstrate its scalability during inference and learning. We carry

Table 1: Statistics for the data used in experiments. SNR was determined by assuming a certain degree of smoothness of the signal, fitting kernel ridge regression with RBF kernel to predict the targets from the input time series, and regarding the residuals as the noise. Tasks with low average correlation between inputs and targets and lower SNR are harder prediction problems.

Dataset	Task	# time steps	# dim	# outputs	Abs. corr.	SNR

	lanes		26	16	0.0816	—
	lead vehicle		9	2	0.1099	—

out a number of experiments that help to gain empirical insights about the convergence properties of the proposed optimization procedure with delayed kernel updates. Additionally, we analyze the regularization properties of GP-RNN/LSTM and compare them with other techniques, such as dropout. Finally, we apply the model to the problem of lane estimation and lead vehicle position prediction, both critical in autonomous driving applications.

5.1 Data and the setup

Below, we describe each dataset we used in our experiments and the associated prediction tasks. The essential statistics for the datasets are summarized in Table 1.

System identification. In the first set of experiments, we used publicly available nonlinear system identification datasets: *Actuator*[6] (Sjöberg et al., 1995) and *Drives*[7] (Wigren, 2010). Both datasets had one dimensional input and output time series. *Actuator* had the size of the valve opening as the input and the resulting change in oil pressure as the output. *Drives* was from a system with motors that drive a pulley using a flexible belt; the input was the sum of voltages applied to the motors and the output was the speed of the belt.

Smart grid data[8]. We considered the problem of forecasting for the smart grid that consisted of two tasks (Figure 2). The first task was to predict power load from the historical temperature data. The data had 11 input time series coming from hourly measurements of temperature on 11 zones and an output time series that represented the cumulative hourly power load on a U.S. utility. The second task was to predict power generated by wind farms from the wind forecasts. The data consisted of 4 different hourly forecasts of the wind and hourly values of the generated power by a wind farm. Each wind forecast was a

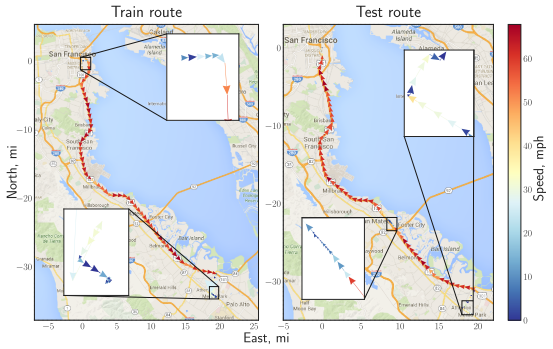
Cumulative power load is generally negatively correlated with the temperature measurements on all the zones. **Right:** Visualization of the *GEF-wind* time series with the time resolution of 1 day.



4-element vector that corresponded to *zonal component*, *meridional component*, *wind speed* and *wind angle*. In our experiments, we concatenated the 4 different 4-element forecasts, which resulted in a 16-dimensional input time series.

Self-driving car dataset[9]**.** One of the main target applications of the proposed model is prediction for autonomous driving. We considered a large dataset coming from sensors of a self-driving car that was recorded on two car trips with discretization of 10 *ms*. The data featured two sets of GPS ECEF locations, ECEF velocities, measurements from a fiber-optic gyro compass, LIDAR, and a few more time series from a variety of IMU sensors. Additionally, locations of the left and right lanes were extracted from a video stream for each time step as well as the position of the lead vehicle from the LIDAR measurements. We considered the data from the first trip for training and from the second trip for validation and testing. A visualization of the car routes with 25 second discretization in the ENU coordinates are given in Figure 3. We consider four tasks, the first two of which are more of proof-of-concept type variety, while the final two are fundamental to good performance for a self-driving car:

1. Speed prediction from noisy GPS velocity estimates and gyroscopic inputs.
2. Prediction of the angular acceleration of the car from the estimates of its speed and steering angle.
3. Point-wise prediction of the lanes from the estimates at the previous time steps, and estimates of speed, gyroscopic and compass measurements.
4. Prediction of the lead vehicle location from its location at the previous time steps, and estimates of speed, gyroscopic and compass measurements.

We provide more specific details on the smart grid data and self-driving data in Appendix D.

9. The dataset is proprietary. It was released in part for public use under the Creative Commons Attribution 3.0 license: http://archive.org/details/comma-dataset. More about the self-driving car: http://www.bloomberg.com/features/2015-george-hotz-self-driving-car/.

Models and metrics. We used a number of classical baselines: NARX (Lin et al., 1996), GP-NARX models (Kocijan et al., 2005), and classical RNN and LSTM architectures. The kernels of our models, GP-NARX/RNN/LSTM, used the ARD base kernel function and were structured by the corresponding baselines.[10] As the primary metric, we used root mean squared error (RMSE) on a held out set and additionally negative log marginal likelihood (NLML) on the training set for the GP-based models.

We train all the models to perform one-step-ahead prediction in an autoregressive setting, where targets at the future time steps are predicted from the input and target values at a fixed number of past time steps. For the system identification task, we additionally consider the non-autoregressive scenario (i.e., mapping only input sequences to the future targets), where we are performing prediction in the *free simulation mode*, and included recurrent Gaussian processes (Mattos et al., 2015) in our comparison. In this case, none of the future targets are available and the models have to re-use their own past predictions to produce future forecasts).

A note on implementation. Recurrent parts of each model were implemented using *Keras*[11] library. We extended *Keras* with the GP layer and developed a backed engine based on the *GPML* library[12]. Our approach allows us to take full advantage of the functionality available in *Keras* and *GPML*, *e.g.*, use automatic differentiation for the recurrent part of the model. Our code is available at http://github.com/alshedivat/keras-gp/.

10. GP-NARX is a special instance of our more general framework and we trained it using the proposed semi-stochastic algorithm.

5.2 Analysis

This section discusses quantitative and qualitative experimental results. We only briefly introduce the model architectures and the training schemes used in each of the experiments. We provide a comprehensive summary of these details in Appendix E.

5.2.1 Convergence of the optimization

To address the question of whether stochastic optimization of recurrent kernels is necessary and to assess the behavior of the proposed optimization scheme with delayed kernel updates, we conducted a number of experiments on the Actuator dataset (Figure 4).

First, we constructed two GP-LSTM models with 1 recurrent hidden layer and 16 or 64 hidden units and trained them with (non-stochastic) full-batch iterative procedure (similar to the proposal of Wilson et al. (2016a)) and with our semi-stochastic optimizer with delayed kernel updates (Algorithm 2). The convergence results are given on the first two charts. Both in terms of the error on a held out set and the NLML on the training set, the models trained with mini-batches converged faster and demonstrated better final performance.

Next, we compared the two optimization schemes on the same GP-LSTM architecture with different sizes of the hidden layer ranging from 2 to 32. It is clear from the third chart that, even though full-batch approach seemed to find a better optimum when the number of hidden units was small, the stochastic approach was clearly superior for larger hidden layers.

Finally, we compared the behavior of Algorithm 2 with different number of mini-batches used for each epoch (equivalently, the number of steps between the kernel matrix updates) and different learning rates. The results are give on the last chart. As expected, there is a fine balance between the number of mini-batches and the learning rate: if the number of mini-batches is large (*i.e.*, the delay between the kernel updates becomes too long) while the learning rate is high enough, optimization does not converge; at the same time, an appropriate combination of the learning rate and the mini-batch size leads better generalization than the default batch approach of Wilson et al. (2016a).

Table 3: Average performance of the models in terms of RMSE on the system identification tasks. The averages were computed over 5 runs; the standard deviation is given in the parenthesis. Results for the RGP model are as reported by Mattos et al. (2015), available only for the free simulation.

RGP	—	—	**0.249**	—	—	**0.368**

5.2.2 Regression, Auto-regression, and Free Simulation

In this set of experiments, our main goal is to provide a comparison between three different modes of one-step-ahead prediction, referred to as (i) regression, (ii) autoregression, and (iii) free simulation, and compare performance of our models with RGP—a classical RNN with every parametric layer substituted with a Gaussian process (Mattos et al., 2015)—on the Actuator and Drives datasets. The difference between the prediction modes consists in whether and how the information about the past targets is used. In the regression scenario, inputs and targets are separate time series and the model learns to map input values at a number of past time points to a target value at a future point in time. Autoregression, additionally, uses the *true* past target values as inputs; in the free simulation mode, the model learns to map past inputs and its own past predictions to a future target.

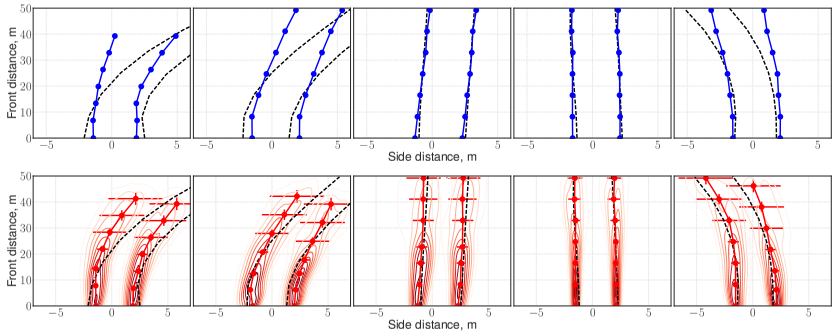
In the experiments in autoregression and free simulation modes, we used short time lags, $L = 10$, as suggested by Mattos et al. (2015). In the regression mode, since the model does not build the recurrent relationships based on the information about the targets (or their estimates), it generally requires larger time lags that can capture the state of the dynamics. Hence we increased the time lag to 32 in the regression mode. More details are given in Appendix E.

We present the results in Table 3. We note that GP-based architectures consistently yielded improved predictive performance compared to their vanilla deep learning counterparts on both of the datasets, in each mode. Given the small size of the datasets, we attribute such behavior to better regularization properties of the negative log marginal likelihood loss function. We also found out that when GP-based models were initialized with weights of pre-trained neural networks, they tended to overfit and give overly confident predictions on these tasks. The best performance was achieved when the models were trained from a random initialization (contrary to the findings of Wilson et al., 2016a). In free simulation mode RGP performs best of the compared models. This result is expected—RGP was particularly designed to represent and propagate uncertainty through a recurrent process.

Table 4: Average performance of the best models in terms of RMSE on the GEF and Car tasks. The averages were computed over 5 runs; the standard deviation is given in the parenthesis.

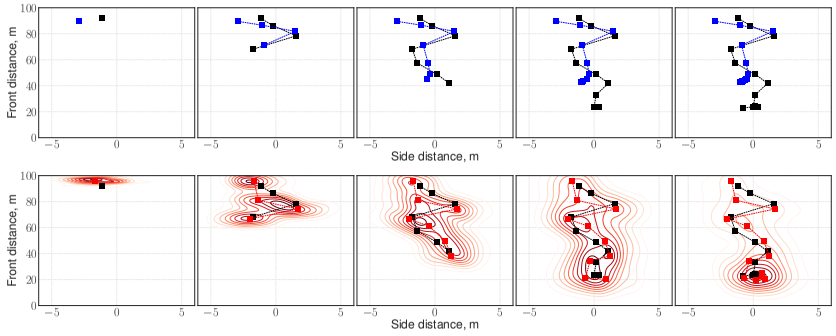
	GEF		Car			
	power load	wind power	speed	gyro yaw	lanes	lead vehicle
NARX	0.54 (0.02)	0.84 (0.01)	0.114 (0.010)	0.19 (0.01)	0.13 (0.01)	0.41 (0.02)
RNN	0.61 (0.02)	0.81 (0.01)	0.152 (0.012)	0.22 (0.01)	0.33 (0.02)	0.44 (0.03)
LSTM	0.45 (0.01)	**0.77** (0.01)	0.027 (0.008)	0.13 (0.01)	0.08 (0.01)	0.40 (0.01)
GP-NARX	0.78 (0.03)	0.83 (0.02)	0.125 (0.015)	0.23 (0.02)	0.10 (0.01)	0.34 (0.02)
GP-RNN	0.24 (0.02)	0.79 (0.01)	0.089 (0.013)	0.24 (0.01)	0.46 (0.08)	0.41 (0.02)
GP-LSTM	**0.17** (0.02)	**0.76** (0.01)	**0.019** (0.006)	**0.08** (0.01)	**0.06** (0.01)	**0.32** (0.02)

Our framework focuses on using recurrence to build expressive kernels for regression on sequences.



The suitability of each prediction mode depends on the task at hand. In many applications where the future targets become readily available as the time passes (e.g., power estimation or stock market prediction), the autoregression mode is preferable. We particularly consider autoregressive prediction in the further experiments.

5.2.3 Prediction for smart grid and self-driving car applications



For both smart grid prediction tasks we used LSTM and GP-LSTM models with 48 hour time lags and were predicting the target values one hour ahead. LSTM and GP-LSTM were trained with one or two layers and 32 to 256 hidden units. The best models were selected on 25% of the training data used for validation. For autonomous driving prediction tasks, we used the same architectures but with 128 time steps of lag (1.28 s). All models were regularized with dropout (Srivastava et al., 2014; Gal and Ghahramani, 2016b). On both GEF and self-driving car datasets, we used the scalable version of Gaussian process (MSGP) (Wilson et al., 2015). Given the scale of the data and the challenge of nonlinear optimization of the recurrent models, we initialized the recurrent parts of GP-RNN and GP-LSTM with pre-trained weights of the corresponding neural networks. Fine-tuning of the models was performed with Algorithm 2. The quantitative results are provided in Table 4 and demonstrate that GPs with recurrent kernels attain the state-of-the-art performance.

Additionally, we investigated convergence and regularization properties of LSTM and GP-LSTM models on the GEF-power dataset. The first two charts of Figure 6 demonstrate that GP-based models are less prone to overfitting, even when the data is not enough. The third panel shows that architectures with a particular number of hidden units per layer attain the best performance on the power prediction task. An additional advantage of the GP-layers over the standard recurrent networks is that the best architecture could be identified based on the negative log likelihood of the model as shown on the last chart.

Finally, Figure 5 qualitatively demonstrates the difference between the predictions given by LSTM vs. GP-LSTM on point-wise lane estimation (Figure 5a) and the front vehicle

(a) Point-wise predictions of the lanes made by LSTM (upper) and by GP-LSTM (lower). Dashed lines correspond to the ground truth extracted from video sequences and used for training.

(b) LSTM (upper) and by GP-LSTM (lower) position predictions of the lead vehicle. Black markers and dashed lines are the ground truth; blue and red markers with solid lines correspond to predictions.

Figure 5: Qualitative comparison of the LSTM and GP-LSTM predictions on self-driving tasks. Predictive uncertainty of the GP-LSTM model is showed by contour plots and error-bars; the latter denote one standard deviation of the predictive distributions.

tracking (Figure 5b) tasks. We note that GP-LSTM not only provides a more robust fit, but also estimates the uncertainty of its predictions. Such information can be further used in downstream prediction-based decision making, *e.g.*, such as whether a self-driving car should slow down and switch to a more cautious driving style when the uncertainty is high.

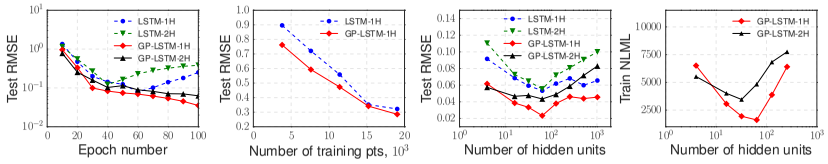


Figure 6: *Left to right*: RMSE vs. the number of training points; RMSE vs. the number model parameters per layer; NLML vs. the number model parameters per layer for GP-based models. All metrics are averages over 5 runs with different random initializations, computed on a held-out set.

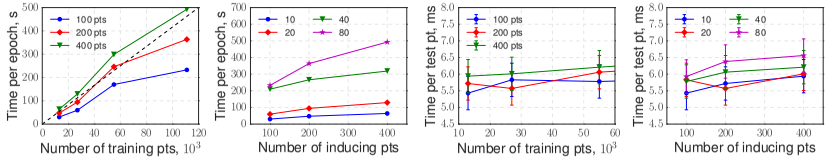

Figure 7: The charts demonstrate scalability of learning and inference of MSGP with an LSTM-based recurrent kernel. Legends with points denote the number of inducing points used. Legends with percentages denote the percentage of the training dataset used learning the model.

5.2.4 Scalability of the model

Following Wilson et al. (2015), we performed a generic scalability analysis of the MSGP-LSTM model on the car sensors data. The LSTM architecture was the same as described in the previous section: it was transforming multi-dimensional sequences of inputs to a two-dimensional representation. We trained the model for 10 epochs on 10%, 20%, 40%, and 80% of the training set with 100, 200, and 400 inducing points per dimension and measured the average training time per epoch and the average prediction time per testing point. The measured time was the total time spent on both LSTM optimization and MSGP computations. The results are presented in Figure 7.

The training time per epoch (one full pass through the entire training data) grows linearly with the number of training examples and depends linearly on the number of inducing points (Figure 7, two left charts). Thus, given a fixed number of inducing points per dimension, the time complexity of MSGP-LSTM learning and inference procedures is linear in the number of training examples. The prediction time per testing data point is virtually constant and does not depend on neither on the number of training points, nor on the number of inducing points (Figure 7, two right charts).

6. Discussion

We proposed a method for learning kernels with recurrent long short-term memory structure on sequences. Gaussian processes with such kernels, termed the GP-LSTM, have the structure and learning biases of LSTMs, while retaining a probabilistic Bayesian nonparametric representation. The GP-LSTM outperforms a range of alternatives on several sequence-to-reals regression tasks. The GP-LSTM also works on data with low and high signal-to-noise ratios, and can be scaled to very large datasets, all with a straightforward, practical, and generally applicable model specification. Moreover, the semi-stochastic scheme proposed in our paper is provably convergent and efficient in practical settings, in conjunction with structure exploiting algebra. In short, the GP-LSTM provides a natural mechanism for Bayesian LSTMs, quantifying predictive uncertainty while harmonizing with the standard deep learning toolbox. Predictive uncertainty is of high value in robotics applications, such as autonomous driving, and could also be applied to other areas such as financial modeling and computational biology.

There are several exciting directions for future research. The GP-LSTM quantifies predictive uncertainty but does not model the propagation of uncertainty in the inputs through a recurrent structure. Treating free simulation as a structured prediction problem and using online corrective algorithms, e.g., DAGGER (Ross et al., 2011), are likely to improve performance of GP-LSTM in the free prediction mode. This approach would not require explicitly modeling and propagating uncertainty through the recurrence and would maintain the high computational efficiency of our method.

Alternatively, it would be exciting to have a probabilistic treatment of all parameters of the GP-LSTM kernel, including all LSTM weights. Such an extension could be combined with stochastic variational inference, to enable both classification and non-Gaussian likelihoods as in Wilson et al. (2016b), but also open the doors to stochastic gradient Hamiltonian Monte Carlo (Chen et al., 2014) (SG-HMC) for efficient inference over kernel parameters. Indeed, SG-HMC has recently been used for efficient inference over network parameters in the Bayesian GAN (Saatchi and Wilson, 2017). A Bayesian approach to marginalizing the weights of the GP-LSTM kernel would also provide a principled probabilistic mechanism for learning model hyperparameters.

One could relax several additional assumptions. We modeled each output dimension with independent GPs that shared a recurrent transformation. To capture the correlations between output dimensions, it would be promising to move to a multi-task formulation. In the future, one could also learn the time horizon in the recurrent transformation, which could lead to major additional performance gains.

Finally, the semi-stochastic learning procedure naturally complements research in asynchronous optimization (e.g., Deisenroth and Ng, 2015). In combination with stochastic variational inference, the semi-stochastic approach could be used for parallel kernel learning, side-stepping the independence assumptions in prior work. We envision that such efforts for Gaussian processes will harmonize with current progress in Bayesian deep learning.

7. Acknowledgements

Appendix A. Massively scalable Gaussian processes

Massively scalable Gaussian processes (MSGP) (Wilson et al., 2015) is a significant extension of the kernel interpolation framework originally proposed by Wilson and Nickisch (2015). The core idea of the framework is to improve scalability of the inducing point methods (Quinonero-Candela and Rasmussen, 2005) by (1) placing the virtual points on a regular grid, (2) exploiting the resulting Kronecker and Toeplitz structures of the relevant covariance matrices, and (3) do local cubic interpolation to go back to the kernel evaluated at the original points. This combination of techniques brings the complexity down to $\mathcal{O}(n)$ for training and $\mathcal{O}(1)$ for each test prediction. Below, we overview the methodology. We remark that a major difference in philosophy between MSGP and many classical inducing point methods is that the points are *selected and fixed* rather than optimized over. This allows to use significantly more virtual points which typically results in a better approximation of the true kernel.

A.1 Structured kernel interpolation

Given a set of m inducing points, the $n \times m$ cross-covariance matrix, $K_{X,U}$, between the training inputs, X, and the inducing points, $\mathbf{U}$, can be approximated as $\tilde{K}_{X,U} = W_X K_{U,U}$ using a (potentially sparse) $n \times m$ matrix of interpolation weights, W_X. This allows to approximate $K_{\mathbf{X},\mathbf{Z}}$ for an arbitrary set of inputs $\mathbf{Z}$ as $K_{\mathbf{X},\mathbf{Z}} \approx \tilde{K}_{X,U} W_{\mathbf{Z}}^\top$. For any given kernel function, K, and a set of inducing points, $\mathbf{U}$, *structured kernel interpolation* (SKI) procedure (Wilson and Nickisch, 2015) gives rise to the following approximate kernel:

$$K_{\text{SKI}}(\mathbf{x}, \mathbf{z}) = W_X K_{U,U} W_z^\top, \tag{A.1}$$

which allows to approximate $K_{X,X} \approx W_X K_{U,U} W_X^\top$. Wilson and Nickisch (2015) note that standard inducing point approaches, such as subset of regression (SoR) or fully independent training conditional (FITC), can be reinterpreted from the SKI perspective. Importantly, the efficiency of SKI-based MSGP methods comes from, first, a clever choice of a set of inducing points that allows to exploit algebraic structure of $K_{U,U}$, and second, from using very sparse local interpolation matrices. In practice, local cubic interpolation is used (Keys, 1981).

A.2 Kernel approximations

If inducing points, U, form a regularly spaced P-dimensional grid, and we use a stationary product kernel (e.g., the RBF kernel), then $K_{U,U}$ decomposes as a Kronecker product of Toeplitz matrices:

$$K_{U,U} = \mathbf{T}_1 \otimes \mathbf{T}_2 \otimes \cdots \otimes \mathbf{T}_P. \tag{A.2}$$

The Kronecker structure allows to compute the eigendecomposition of $K_{U,U}$ by separately decomposing $\mathbf{T}_1, \ldots, \mathbf{T}_P$, each of which is much smaller than $K_{U,U}$. Further, to efficiently

eigendecompose a Toeplitz matrix, it can be approximated by a circulant matrix[13] which eigendecomposes by simply applying discrete Fourier transform (DFT) to its first column. Therefore, an approximate eigendecomposition of each $\mathbf{T}_1, \ldots, \mathbf{T}_P$ is computed via the fast Fourier transform (FFT) and requires only $\mathcal{O}(m \log m)$ time.

A.3 Structure exploiting inference

To perform inference, we need to solve $(K_{\text{SKI}} + \sigma^2\mathbf{I})^{-1}\mathbf{y}$; kernel learning requires evaluating $\log\det(K_{\text{SKI}} + \sigma^2\mathbf{I})$. The first task can be accomplished by using an iterative scheme—linear conjugate gradients—which depends only on matrix vector multiplications with $(K_{\text{SKI}} + \sigma^2\mathbf{I})$. The second is done by exploiting the Kronecker and Toeplitz structure of $K_{U,U}$ for computing an approximate eigendecomposition, as described above.

A.4 Fast Test Predictions

To achieve constant time prediction, we approximate the latent mean and variance of $\mathbf{f}_*$ by applying the same SKI technique. In particular, for a set of n_* testing points, X_*, we have

$$\begin{aligned} \mathbb{E}[\mathbf{f}_*] &= \boldsymbol{\mu}_{X_*} + K_{\mathbf{X}_*,\mathbf{X}}\left[K_{X,X} + \sigma^2 I\right]^{-1}\mathbf{y} \\ &\approx \boldsymbol{\mu}_{X_*} + \tilde{K}_{\mathbf{X}_*,\mathbf{X}}\left[\tilde{K}_{X,X} + \sigma^2 I\right]^{-1}\mathbf{y}, \end{aligned} \tag{A.3}$$

where $\tilde{K}_{X,X} = W K_{U,U} W^\top$ and $\tilde{K}_{\mathbf{X}_*,\mathbf{X}} = W_* K_{U,U} W^\top$, and W and W_* are $n \times m$ and $n_* \times m$ sparse interpolation matrices, respectively. Since $K_{U,U}W^\top[\tilde{K}_{X,X} + \sigma^2\mathbf{I}]^{-1}\mathbf{y}$ is precomputed at training time, at test time, we only multiply the latter with W_* matrix which results which costs $\mathcal{O}(n_*)$ operations leading to $\mathcal{O}(1)$ operations per test point. Similarly, approximate predictive variance can be also estimated in $\mathcal{O}(1)$ operations (Wilson et al., 2015).

Note that the fast prediction methodology can be readily applied to any trained Gaussian process model as it is agnostic to the way inference and learning were performed.

Appendix B. Gradients for GPs with recurrent kernels

GPs with deep recurrent kernels are trained by minimizing the negative log marginal likelihood objective function. Below we derive the update rules.

By applying the chain rule, we get the following first order derivatives:

$$\frac{\partial\mathcal{L}}{\partial\gamma} = \frac{\partial\mathcal{L}}{\partial K}\cdot\frac{\partial K}{\partial\boldsymbol{\gamma}}, \quad \frac{\partial\mathcal{L}}{\partial W} = \frac{\partial\mathcal{L}}{\partial K}\cdot\frac{\partial K}{\partial\boldsymbol{\phi}}\cdot\frac{\partial\boldsymbol{\phi}}{\partial W}. \tag{B.4}$$

The derivative of the log marginal likelihood w.r.t. to the kernel hyperparameters, $\boldsymbol{\theta}$, and the parameters of the recurrent map, W, are generic and take the following form (Rasmussen and Williams, 2006, Ch. 5, Eq. 5.9):

$$\frac{\partial\mathcal{L}}{\partial\boldsymbol{\theta}} = \tfrac{1}{2}\mathbf{tr}\left(\left[K^{-1}\mathbf{y}\mathbf{y}^\top K^{-1} - K^{-1}\right]\tfrac{\partial K}{\partial\boldsymbol{\theta}}\right), \tag{B.5}$$

$$\frac{\partial\mathcal{L}}{\partial W} = \tfrac{1}{2}\mathbf{tr}\left(\left[K^{-1}\mathbf{y}\mathbf{y}^\top K^{-1} - K^{-1}\right]\tfrac{\partial K}{\partial W}\right). \tag{B.6}$$

The derivative $\partial K/\partial\boldsymbol{\theta}$ is also standard and depends on the form of a particular chosen kernel function, $k(\cdot,\cdot)$. However, computing each part of $\partial\mathcal{L}/\partial W$ is a bit subtle, and hence we elaborate these derivations below.

Consider the ij-th entry of the kernel matrix, K_{ij}. We can think of K as a matrix-valued function of all the data vectors in d-dimensional transformed space which we denote by $H \in \mathbb{R}^{N\times d}$. Then K_{ij} is a scalar-valued function of H and its derivative w.r.t. the l-th parameter of the recurrent map, W_l, can be written as follows:

$$\frac{\partial K_{ij}}{\partial W_l} = \mathbf{tr}\left(\left(\frac{\partial K_{ij}}{\partial H}\right)^\top\frac{\partial H}{\partial W_l}\right). \tag{B.7}$$

Notice that $\partial K_{ij}/\partial H$ is a derivative of a scalar w.r.t. to a matrix and hence is a matrix; $\partial H/\partial W_l$ is a derivative of a matrix w.r.t. to a scalar which is taken element-wise and also gives a matrix. Also notice that K_{ij} is a function of H, but it only depends the i-th and j-th elements for which the kernel is being computed. This means that $\partial K_{ij}/\partial H$ will have only non-zero i-th row and j-th column and allows us to re-write (B.7) as follows:

$$\begin{aligned} \frac{\partial K_{ij}}{\partial W_l} &= \left(\frac{\partial K_{ij}}{\partial\mathbf{h}_i}\right)^\top\frac{\partial\mathbf{h}_i}{\partial W_l} + \left(\frac{\partial K_{ij}}{\partial\mathbf{h}_j}\right)^\top\frac{\partial\mathbf{h}_j}{\partial W_l} \\ &= \left(\frac{\partial K(\mathbf{h}_i,\mathbf{h}_j)}{\partial\mathbf{h}_i}\right)^\top\frac{\partial\mathbf{h}_i}{\partial W_l} + \left(\frac{\partial K(\mathbf{h}_i,\mathbf{h}_j)}{\partial\mathbf{h}_j}\right)^\top\frac{\partial\mathbf{h}_j}{\partial W_l}. \end{aligned} \tag{B.8}$$

Since the kernel function has two arguments, the derivatives must be taken with respect of each of them and evaluated at the corresponding points in the hidden space, $\mathbf{h}_i = \boldsymbol{\phi}(\mathbf{x}_i)$ and $\mathbf{h}_j = \boldsymbol{\phi}(\mathbf{x}_j)$. When we plug this into (B.6), we arrive at the following expression:

$$\frac{\partial\mathcal{L}}{\partial W_l} = \frac{1}{2}\sum_{i,j}\left(K^{-1}\mathbf{y}\mathbf{y}^\top K^{-1} - K^{-1}\right)_{ij}\left\{\left(\frac{\partial K(\mathbf{h}_i,\mathbf{h}_j)}{\partial\mathbf{h}_i}\right)^\top\frac{\partial\mathbf{h}_i}{\partial W_l} + \left(\frac{\partial K(\mathbf{h}_i,\mathbf{h}_j)}{\partial\mathbf{h}_j}\right)^\top\frac{\partial\mathbf{h}_j}{\partial W_l}\right\}. \tag{B.9}$$

The same expression can be written in a more compact form using the *Einstein notation*:

$$\frac{\partial\mathcal{L}}{\partial W_l} = \frac{1}{2}\left(K^{-1}\mathbf{y}\mathbf{y}^\top K^{-1} - K^{-1}\right)_i^j\left(\left[\frac{\partial K}{\partial\mathbf{h}}\right]_i^{jd} + \left[\frac{\partial K}{\partial\mathbf{h}}\right]_j^{id}\right)\left[\frac{\partial\mathbf{h}}{\partial W}\right]_i^{dl} \tag{B.10}$$

where d indexes the dimensions of the $\mathbf{h}$ and l indexes the dimensions of W.

13. Wilson et al. (2015) explored 5 different approximation methods known in the numerical analysis literature.

In practice, deriving a computationally efficient analytical form of $\partial K/\partial \mathbf{h}$ might be too complicated for some kernels (*e.g.*, the spectral mixture kernels (Wilson and Adams, 2013)), especially if the grid-based approximations of the kernel are enabled. In such cases, we can simply use a finite difference approximation of this derivative. As we remark in the following section, numerical errors that result from this approximation do not affect convergence of the algorithm.

Appendix C. Convergence results

Convergence results for the semi-stochastic alternating gradient schemes with and without delayed kernel matrix updates are based on (Xu and Yin, 2015). There are a few notable differences between the original setting and the one considered in this paper:

1. Xu and Yin (2015) consider a stochastic program that minimizes the expectation of the objective w.r.t. some distribution underlying the data:

$$\min_{x\in\mathcal{X}} f(x) := \mathbb{E}_\xi F(x;\xi), \tag{C.11}$$

   where every iteration a new ξ is sampled from the underlying distribution. In our case, the goal is to minimize the negative log marginal likelihood on a particular given dataset. This is equivalent to the original formulation (C.11), but with the expectation taken w.r.t. the empirical distribution that corresponds to the given dataset.

2. The optimization procedure of Xu and Yin (2015) has access to only a single random point generated from the data distribution at each step. Our algorithm requires having access to the entire training data each time the kernel matrix is computed.

3. For a given sample, Xu and Yin (2015) propose to loop over a number of coordinate blocks and apply Gauss–Seidel type gradient updates to each block. Our semi-stochastic scheme has only two parameter blocks, $\boldsymbol{\theta}$ and W, where $\boldsymbol{\theta}$ is updated deterministically on the entire dataset while W is updated with stochastic gradient on samples from the empirical distribution.

Noting these differences, we first adapt convergence results for the smooth non-convex case (Xu and Yin, 2015, Theorem 2.10) to our scenario, and then consider the variant with delaying kernel matrix updates.

C.1 Semi-stochastic alternating gradient

As shown in Algorithm 1, we alternate between updating $\boldsymbol{\theta}$ and W. At step t, we get a mini-batch of size N_t, $\mathbf{x}_t \equiv \{\bar{\mathbf{x}}_i\}_{i\in\mathcal{I}_t}$, which is just a selection of points from the full set, $\mathbf{x}$. Define the gradient errors for $\boldsymbol{\theta}$ and W at step t as follows:

$$\delta^t_{\boldsymbol{\theta}} := \tilde{\mathbf{g}}^t_{\boldsymbol{\theta}} - \mathbf{g}^t_{\boldsymbol{\theta}}, \quad \delta^t_W := \tilde{\mathbf{g}}^t_W - \mathbf{g}^t_W, \tag{C.12}$$

where $\mathbf{g}^{\mathbf{T}}_{\boldsymbol{\theta}}$ and $\mathbf{g}^{\mathbf{T}}_W$ are the true gradients and $\tilde{\mathbf{g}}^{\mathbf{T}}_{\boldsymbol{\theta}}$ and $\tilde{\mathbf{g}}^{\mathbf{T}}_W$ are estimates[14]. We first update $\boldsymbol{\theta}$ and then W, and hence the expressions for the gradients take the following form:

$$\tilde{\mathbf{g}}^t_{\boldsymbol{\theta}} \equiv \mathbf{g}^t_{\boldsymbol{\theta}} = \frac{1}{N}\nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\theta}^t, W^t) = \frac{1}{2N}\sum_{i,j}\left(K_t^{-1}\mathbf{y}\mathbf{y}^\top K_t^{-1} - K_t^{-1}\right)_{ij}\left(\frac{\partial K_t}{\partial \boldsymbol{\theta}}\right)_{ij} \tag{C.13}$$

$$\mathbf{g}^t_W = \frac{1}{N}\nabla_W\mathcal{L}(\boldsymbol{\theta}^{t+1}, W^t) = \frac{1}{2N}\sum_{i,j}\left(K_{t+1}^{-1}\mathbf{y}\mathbf{y}^\top K_{t+1}^{-1} - K_{t+1}^{-1}\right)_{ij}\left(\frac{\partial K_{t+1}}{\partial W}\right)_{ij} \tag{C.14}$$

$$\tilde{\mathbf{g}}^t_W = \frac{1}{2N_t}\sum_{i,j\in\mathcal{I}_t}\left(K_{t+1}^{-1}\mathbf{y}\mathbf{y}^\top K_{t+1}^{-1} - K_{t+1}^{-1}\right)_{ij}\left(\frac{\partial K_{t+1}}{\partial W}\right)_{ij} \tag{C.15}$$

Note that as we have shown in Appendix B, when the kernel matrix is fixed, $\mathbf{g}_W$ and $\tilde{\mathbf{g}}_W$ factorize over $\mathbf{x}$ and $\mathbf{x}_t$, respectively. Further, we denote all the mini-batches sampled before t as $\mathbf{x}_{[t-1]}$.

Lemma 1 *For any step t, $\mathbb{E}[\delta^t_W \mid \mathbf{x}_{[t-1]}] = \mathbb{E}[\delta^t_{\boldsymbol{\theta}} \mid \mathbf{x}_{[t-1]}] = 0$.*

Proof First, $\delta^t_{\boldsymbol{\theta}} \equiv 0$, and hence $\mathbb{E}[\delta^t_{\boldsymbol{\theta}} \mid \mathbf{x}_{[t-1]}] = 0$ is trivial. Next, by definition of δ^t_W, we have $\mathbb{E}[\delta^t_W \mid \mathbf{x}_{[t-1]}] = \mathbb{E}[\tilde{\mathbf{g}}^t_W - \mathbf{g}^t_W \mid \mathbf{x}_{[t-1]}]$. Consider the following:

- Consider $\mathbb{E}[\mathbf{g}^t_W \mid \mathbf{x}_{[t-1]}]$: $\mathbf{g}^t_W$ is a deterministic function of $\boldsymbol{\theta}^{t+1}$ and W^t. $\boldsymbol{\theta}^{t+1}$ is being updated deterministically using $\mathbf{g}^{t-1}_{\boldsymbol{\theta}}$, and hence only depends on W^t and $\boldsymbol{\theta}^t$. Therefore, it is independent of $\mathbf{x}_t$, which means that $\mathbb{E}[\mathbf{g}^t_W \mid \mathbf{x}_{[t-1]}] \equiv \mathbf{g}^t_W$.

- Now, consider $\mathbb{E}[\tilde{\mathbf{g}}^t_W \mid \mathbf{x}_{[t-1]}]$: Noting that the expectation is taken w.r.t. the empirical distribution and K_{t+1} does not depend on the current mini-batch, we can write:

$$\begin{aligned}\mathbb{E}[\tilde{\mathbf{g}}^t_W \mid \mathbf{x}_{[t-1]}] &= \mathbb{E}\left[\frac{1}{2N_t}\sum_{i,j\in\mathcal{I}_t}\left(K_{t+1}^{-1}\mathbf{y}\mathbf{y}^\top K_{t+1}^{-1} - K_{t+1}^{-1}\right)_{ij}\left(\frac{\partial K_{t+1}}{\partial W}\right)_{ij}\right] \\ &= \frac{N_t}{2NN_t}\sum_{i,j}\left(K_{t+1}^{-1}\mathbf{y}\mathbf{y}^\top K_{t+1}^{-1} - K_{t+1}^{-1}\right)_{ij}\left(\frac{\partial K_{t+1}}{\partial W}\right)_{ij} \\ &\equiv \mathbf{g}^t_W.\end{aligned} \tag{C.16}$$

Finally, $\mathbb{E}[\delta^t_W \mid \mathbf{x}_{[t-1]}] = \mathbf{g}^t_W - \mathbf{g}^t_W = 0$. ■

In other words, semi-stochastic gradient descent that alternates between updating $\boldsymbol{\theta}$ and W computes unbiased estimates of the gradients on each step.

14. Here, we consider the gradients and their estimates scaled by the number of full data points, N, and the mini-batch size, N_t, respectively. These constant scaling is introduced for sake of having cleaner proofs.

Remark 1 *Note that in case if $(\partial K_{t+1}/\partial W)$ is computed approximately, Lemma 1 still holds since both $\mathbf{g}_W^t$ and $\mathbb{E}[\tilde{\mathbf{g}}_W^t \mid \mathbf{x}_{[t-1]}]$ will contain exactly the same numerical errors.*

Assumption 1 *For any step t, $\mathbb{E}\|\delta_{\boldsymbol{\theta}}^t\|^2 \leq \sigma_t^2$ and $\mathbb{E}\|\delta_W^t\|^2 \leq \sigma_t^2$.*

Lemma 1 and Assumption 1 result into a stronger condition than the original assumption given by Xu and Yin (2015). This is due to the semi-stochastic nature of the algorithm, it simplifies the analysis, though it is not critical. Assumptions 2 and 3 are straightforwardly adapted from the original paper.

Assumption 2 *The objective function, $\mathcal{L}$, is lower bounded and its partial derivatives w.r.t. $\boldsymbol{\theta}$ and W are uniformly Lipschitz with constant $L > 0$:*

$$\|\nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\theta}, W) - \nabla_{\boldsymbol{\theta}}\mathcal{L}(\tilde{\boldsymbol{\theta}}, W)\| \leq L\|\boldsymbol{\theta} - \tilde{\boldsymbol{\theta}}\|, \quad \|\nabla_W\mathcal{L}(\boldsymbol{\theta}, W) - \nabla_W\mathcal{L}(\boldsymbol{\theta}, \tilde{W})\| \leq L\|W - \tilde{W}\|. \tag{C.17}$$

Assumption 3 *There exists a constant ρ such that $\|\boldsymbol{\theta}^t\|^2 + \mathbb{E}\|W^t\|^2 \leq \rho^2$ for all t.*

Lemma 2 *Under Assumptions 2 and 3,*

$$\mathbb{E}\|W^t\|^2 \leq \rho^2, \quad \mathbb{E}\|\boldsymbol{\theta}^t\|^2 \leq \rho^2, \quad \mathbb{E}\|\mathbf{g}_W^t\|^2 \leq M_\rho^2, \quad \mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2 \leq M_\rho^2 \quad \forall t,$$

where $M_\rho^2 = 4L^2\rho^2 + 2\max\{\nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\theta}^0, W^0), \nabla_W\mathcal{L}(\boldsymbol{\theta}^0, W^0)\}$.

Proof The inequalities for $\mathbb{E}\|\boldsymbol{\theta}\|^2$ and $\mathbb{E}\|W\|^2$ are trivial, and the ones for $\mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2$ and $\mathbb{E}\|\mathbf{g}_W^t\|^2$ are merely corollaries from Assumption 2. ■

Negative log marginal likelihood of a Gaussian process with a structured kernel is a nonconvex function of its arguments. Therefore, we can only show that the algorithm converges to a stationary point, *i.e.*, a point at which the gradient of the objective is zero.

Theorem 1 *Let $\{(\boldsymbol{\theta}^t, W^t)\}$ be a sequence generated from Algorithm 1 with learning rates for $\boldsymbol{\theta}$ and W being $\lambda_{\boldsymbol{\theta}}^t = c_{\boldsymbol{\theta}}^t\alpha_t$ and $\lambda_W^t = c_W^t\alpha_t$, respectively, where $c_{\boldsymbol{\theta}}^t, c_W^t, \alpha_t$ are positive scalars, such that*

$$0 < \inf_t c_{\{\boldsymbol{\theta},W\}}^t \leq \sup_t c_{\{\boldsymbol{\theta},W\}}^t < \infty, \quad \alpha_t \geq \alpha_{t+1}, \quad \sum_{t=1}^{\infty}\alpha_t = +\infty, \quad \sum_{t=1}^{\infty}\alpha_t^2 < +\infty, \quad \forall t. \tag{C.18}$$

Then, under Assumptions 1 through 3 and if $\sigma = \sup_t \sigma_t < \infty$, we have

$$\lim_{t\to\infty}\mathbb{E}\|\nabla\mathcal{L}(\boldsymbol{\theta}^t, W^t)\| = 0. \tag{C.19}$$

Proof The proof is an adaptation of the one given by Xu and Yin (2015) with the following three adjustments: (1) we have only two blocks of coordinates and (2) updates for $\boldsymbol{\theta}$ are deterministic which zeros out their variance terms, (3) the stochastic gradients are unbiased.

- From the Lipschitz continuity of $\nabla_W\mathcal{L}$ and $\nabla_{\boldsymbol{\theta}}\mathcal{L}$ (Assumption 2), we have:

$$\begin{aligned}
&\mathcal{L}(\boldsymbol{\theta}^{t+1}, W^{t+1}) - \mathcal{L}(\boldsymbol{\theta}^{t+1}, W^t) \\
\leq\ & \langle \mathbf{g}_W^t, W^{t+1} - W^t\rangle + \frac{L}{2}\|W^{t+1} - W^t\|^2 \\
=\ & -\lambda_W^t\langle \mathbf{g}_W^t, \tilde{\mathbf{g}}_W^t\rangle + \frac{L}{2}(\lambda_W^t)^2\|\tilde{\mathbf{g}}_W^t\|^2 \\
=\ & -\left(\lambda_W^t - \frac{L}{2}(\lambda_W^t)^2\right)\|\mathbf{g}_W^t\|^2 + \frac{L}{2}(\lambda_W^t)^2\|\delta_W^t\|^2 - \left(\lambda_W^t - L(\lambda_W^t)^2\right)\langle \mathbf{g}_W^t, \delta_W^t\rangle \\
=\ & -\left(\lambda_W^t - \frac{L}{2}(\lambda_W^t)^2\right)\|\mathbf{g}_W^t\|^2 + \frac{L}{2}(\lambda_W^t)^2\|\delta_W^t\|^2 \\
& -\left(\lambda_W^t - L(\lambda_W^t)^2\right)\left(\langle \mathbf{g}_W^t - \nabla_W\mathcal{L}(\boldsymbol{\theta}^t, W^t), \delta_W^t\rangle + \langle \nabla_W\mathcal{L}(\boldsymbol{\theta}^t, W^t), \delta_W^t\rangle\right) \\
\leq\ & -\left(\lambda_W^t - \frac{L}{2}(\lambda_W^t)^2\right)\|\mathbf{g}_W^t\|^2 + \frac{L}{2}(\lambda_W^t)^2\|\delta_W^t\|^2 - \left(\lambda_W^t - L(\lambda_W^t)^2\right)\langle \nabla_W\mathcal{L}(\boldsymbol{\theta}^t, W^t), \delta_W^t\rangle \\
& +\frac{L}{2}\lambda_{\boldsymbol{\theta}}^t\left(\lambda_W^t + L(\lambda_W^t)^2\right)\left(\|\delta_W^t\|^2 + \|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2\right),
\end{aligned}$$

  where the last inequality comes from the following (note that $\mathbf{g}_W^t := \nabla_W\mathcal{L}(\boldsymbol{\theta}^{t+1}, W^t)$):

$$\begin{aligned}
& -\left(\lambda_W^t - L(\lambda_W^t)^2\right)\langle \nabla_W\mathcal{L}(\boldsymbol{\theta}^{t+1}, W^t) - \nabla_W\mathcal{L}(\boldsymbol{\theta}^t, W^t), \delta_W^t\rangle \\
\leq\ & \left|\lambda_W^t - L(\lambda_W^t)^2\right|\|\delta_W^t\|\|\nabla_W\mathcal{L}(\boldsymbol{\theta}^{t+1}, W^t) - \nabla_W\mathcal{L}(\boldsymbol{\theta}^t, W^t)\| \\
\leq\ & L\lambda_{\boldsymbol{\theta}}^t\left|\lambda_W^t - L(\lambda_W^t)^2\right|\|\delta_W^t\|\|\mathbf{g}_{\boldsymbol{\theta}}^t\| \\
\leq\ & \frac{L}{2}\lambda_{\boldsymbol{\theta}}^t\left(\lambda_W^t + L(\lambda_W^t)^2\right)\left(\|\delta_W^t\|^2 + \|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2\right).
\end{aligned}$$

  Analogously, we derive a bound on $\mathcal{L}(\boldsymbol{\theta}^{t+1}, W^t) - \mathcal{L}(\boldsymbol{\theta}^t, W^t)$:

$$\begin{aligned}
&\mathcal{L}(\boldsymbol{\theta}^{t+1}, W^t) - \mathcal{L}(\boldsymbol{\theta}^t, W^t) \\
\leq\ & -\left(\lambda_{\boldsymbol{\theta}}^t - \frac{L}{2}(\lambda_{\boldsymbol{\theta}}^t)^2\right)\|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2 + \frac{L}{2}(\lambda_{\boldsymbol{\theta}}^t)^2\|\delta_{\boldsymbol{\theta}}^t\|^2 - \left(\lambda_{\boldsymbol{\theta}}^t - L(\lambda_{\boldsymbol{\theta}}^t)^2\right)\langle \nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\theta}^t, W^t), \delta_{\boldsymbol{\theta}}^t\rangle
\end{aligned}$$

- Since $(\boldsymbol{\theta}^t, W^t)$ is independent from the current mini-batch, $\mathbf{x}_t$, using Lemma 1, we have that $\mathbb{E}\langle \nabla_{\boldsymbol{\theta}}\mathcal{L}(\boldsymbol{\theta}^t, W^t), \delta_{\boldsymbol{\theta}}^t\rangle = 0$ and $\mathbb{E}\langle \nabla_W\mathcal{L}(\boldsymbol{\theta}^t, W^t), \delta_W^t\rangle = 0$.

Summing the two obtained inequalities and applying Assumption 1, we get:

$$\begin{aligned}
&\mathbb{E}[\mathcal{L}(\boldsymbol{\theta}^{t+1}, W^{t+1}) - \mathcal{L}(\boldsymbol{\theta}^t, W^t)] \\
\leq\ & -\left(\lambda_W^t - \frac{L}{2}(\lambda_W^t)^2\right)\mathbb{E}\|\mathbf{g}_W^t\|^2 + \frac{L}{2}(\lambda_W^t)^2\sigma + \frac{L}{2}\lambda_{\boldsymbol{\theta}}^t\left(\lambda_W^t + L(\lambda_W^t)^2\right)(\sigma + \mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2) \\
& -\left(\lambda_{\boldsymbol{\theta}}^t - \frac{L}{2}(\lambda_{\boldsymbol{\theta}}^t)^2\right)\mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2 + \frac{L}{2}(\lambda_{\boldsymbol{\theta}}^t)^2\sigma \\
\leq\ & -\left(c\alpha_t - \frac{L}{2}C^2\alpha_t^2\right)\mathbb{E}\|\mathbf{g}_W^t\|^2 + LC^2\sigma\alpha_t + \frac{L}{2}C^2\alpha_t^2(1 + LC\alpha_t)(\sigma + \mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2) \\
& -\left(c\alpha_t - \frac{L}{2}C^2\alpha_t^2\right)\mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2 + \frac{L}{2}C^2\alpha_t^2\sigma,
\end{aligned}$$

where we denoted $c = \min\{\inf_t c_W^t, \inf_t c_{\boldsymbol{\theta}}^t\}$, $C = \max\{\sup_t c_W^t, \sup_t c_{\boldsymbol{\theta}}^t\}$. Note that from Lemma 2, we also have $\mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2 \leq M_\rho^2$ and $\mathbb{E}\|\mathbf{g}_W^t\|^2 \leq M_\rho^2$. Therefore, summing the right hand side of the final inequality over t and using (C.18), we have:

$$\lim_{t\to\infty}\mathbb{E}\mathcal{L}(\boldsymbol{\theta}^{t+1}, W^{t+1}) - \mathbb{E}\mathcal{L}(\boldsymbol{\theta}^0, W^0) \leq -c\sum_{t=1}^{\infty}\alpha_t\left(\mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2 + \mathbb{E}\|\mathbf{g}_W^t\|^2\right). \tag{C.20}$$

Since the objective function is lower bounded, this effectively means:

$$\sum_{t=1}^{\infty}\alpha_t\mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2 < \infty, \quad \sum_{t=1}^{\infty}\alpha_t\mathbb{E}\|\mathbf{g}_W^t\|^2 < \infty.$$

- Finally, using Lemma 2, our assumptions and Jensen's inequality, it follows that

$$\left|\mathbb{E}\|\mathbf{g}_W^{t+1}\|^2 - \mathbb{E}\|\mathbf{g}_W^t\|^2\right| \leq 2LM_\rho C\alpha_t\sqrt{2(M_\rho^2 + \sigma^2)}.$$

According to Proposition 1.2.4 of (Bertsekas, 1999), we have $\mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\|^2 \to 0$ and $\mathbb{E}\|\mathbf{g}_W^t\|^2 \to 0$ as $t \to \infty$, and hence

$$\begin{aligned}
\mathbb{E}\|\nabla\mathcal{L}(\boldsymbol{\theta}^t, W^t)\| &\leq \mathbb{E}\|\nabla_W\mathcal{L}(\boldsymbol{\theta}^t, W^t) - \mathbf{g}_{\boldsymbol{\theta}}^t\| + \mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\| + \mathbb{E}\|\nabla_W\mathcal{L}(\boldsymbol{\theta}^t, W^t) - \mathbf{g}_{\boldsymbol{\theta}}^t\| + \mathbb{E}\|\mathbf{g}_W^t\| \\
&\leq 2LC\sqrt{2(M_\rho^2 + \sigma^2)}\alpha + \mathbb{E}\|\mathbf{g}_{\boldsymbol{\theta}}^t\| + \mathbb{E}\|\mathbf{g}_W^t\| \to 0 \text{ as } t \to \infty,
\end{aligned}$$

where the first term of the last inequality follows from Lemma 2 and Jensen's inequality. ■

C.2 Semi-stochastic gradient with delayed kernel matrix updates

We show that given a bounded delay on the kernel matrix updates, the algorithm is still convergent. Our analysis is based on computing the change in $\delta_{\boldsymbol{\theta}}^t$ and δ_W^t and applying the same argument as in Theorem 1. The only difference is that we need to take into account the perturbations of the kernel matrix due to the introduced delays, and hence we have to impose certain assumptions on its spectrum.

Assumption 4 *Recurrent transformations, $\boldsymbol{\phi}_W(\bar{\mathbf{x}})$, is L-Lipschitz w.r.t. W for all $\bar{\mathbf{x}} \in \mathcal{X}^L$:*

$$\|\boldsymbol{\phi}_{\tilde{W}}(\bar{\mathbf{x}}) - \boldsymbol{\phi}_W(\bar{\mathbf{x}})\| \leq L\|\tilde{W} - W\|.$$

Assumption 5 *The kernel function, $k(\cdot,\cdot)$, is uniformly G-Lipschitz and its first partial derivatives are uniformly J-Lipschitz:*

$$\left\|k(\tilde{\mathbf{h}}_1, \mathbf{h}_2) - k(\mathbf{h}_1, \mathbf{h}_2)\right\| \leq G\|\tilde{\mathbf{h}}_1 - \mathbf{h}_1\|, \ \left\|k(\mathbf{h}_1, \tilde{\mathbf{h}}_2) - k(\mathbf{h}_1, \mathbf{h}_2)\right\| \leq G\|\tilde{\mathbf{h}}_2 - \mathbf{h}_2\|,$$
$$\left\|\partial_1 k(\mathbf{h}_1, \mathbf{h}_2) - \partial_1 k(\tilde{\mathbf{h}}_1, \mathbf{h}_2)\right\| \leq J\|\tilde{\mathbf{h}}_1 - \mathbf{h}_1\|, \ \left\|\partial_2 k(\mathbf{h}_1, \mathbf{h}_2) - \partial_2 k(\mathbf{h}_1, \tilde{\mathbf{h}}_2)\right\| \leq J\|\tilde{\mathbf{h}}_2 - \mathbf{h}_2\|.$$

Assumption 6 *For any collection of data representations, $\{\mathbf{h}_i\}_{i=1}^N$, the smallest eigenvalue of the corresponding kernel matrix, K, is lower bounded by a positive constant $\gamma > 0$.*

Note that not only the assumptions are relevant to practice, Assumptions 5 and 6 can be also controlled by choosing the class of kernel functions used in the model. For example, the smallest eigenvalue of the kernel matrix, K, can be controlled by the smoothing properties of the kernel (Rasmussen and Williams, 2006).

Consider a particular stochastic step of Algorithm 2 at time t for a given mini-batch, $\mathbf{x}_t$, assuming that the kernel was last updated τ steps ago. The stochastic gradient will take the following form:

$$\hat{\mathbf{g}}_W^t = \frac{1}{N_t}\nabla_W\mathcal{L}(\boldsymbol{\theta}^{t+1}, W^t, K_{t-\tau}) = \frac{1}{2N_t}\sum_{i,j\in\mathcal{I}_t}\left(K_{t-\tau}^{-1}\mathbf{y}\mathbf{y}^\top K_{t-\tau}^{-1} - K_{t-\tau}^{-1}\right)_{ij}\left(\frac{\partial K_{t-\tau}}{\partial W}\right)_{ij}. \tag{C.21}$$

We can define $\hat{\delta}_W^t = \hat{\mathbf{g}}_W^t - \mathbf{g}_W^t$ and uniformly bound $\|\hat{\delta}_W^t - \delta_W^t\|$ in order to enable the same argument as in Theorem 1. To do that, we simply need to understand effect of perturbation of the kernel matrix on $\tilde{\mathbf{g}}_W^t$.

Lemma 3 *Under the given assumptions, the following bound holds for all $i, j = 1, \ldots, N$:*

$$\left|\left(K_{t-\tau}^{-1}\mathbf{y}\mathbf{y}^\top K_{t-\tau}^{-1} - K_{t-\tau}^{-1}\right)_{ij} - \left(K_t^{-1}\mathbf{y}\mathbf{y}^\top K_t^{-1} - K_t^{-1}\right)_{ij}\right| \leq D^2\|y\|^2 + D, \tag{C.22}$$

where $D = \gamma^{-1} + \left(\gamma - 2GL\tau\lambda\sigma\sqrt{N}\right)^{-1}$.

Proof The difference between $K_{t-\tau}^{-1}$ and K_t^{-1} is simply due to that the former has been computed for $W^{t-\tau}$ and the latter for W^t. To prove the bound, we need multiple steps.

- First, we need to bound the element-wise difference between $K_{t-\tau}$ and K_t. This is done by using Assumptions 4 and 5 and the triangular inequality:

$$\begin{aligned} |(K_t)_{ij} - (K_{t-\tau})_{ij}| &\leq G\left(\|\boldsymbol{\phi}_{W^t}(\bar{\mathbf{x}}_i) - \boldsymbol{\phi}_{W^{t-\tau}}(\bar{\mathbf{x}}_i)\| + \|\boldsymbol{\phi}_{W^t}(\bar{\mathbf{x}}_j) - \boldsymbol{\phi}_{W^{t-\tau}}(\bar{\mathbf{x}}_j)\|\right) \\ &\leq 2GL\|W^t - W^{t-\tau}\| \\ &= 2GL\|\sum_{s=1}^{\tau} \lambda_W^{t-\tau+s} \hat{\mathbf{g}}_W^{t-\tau+s}\| \\ &\leq 2GL\tau\lambda\sigma \end{aligned}$$

- Next, since each element of the perturbed matrix is bounded by $2GL\tau\lambda\sigma$, we can bound its spectral norm as follows:

$$\|K_t - K_{t-\tau}\| \leq \|K_t - K_{t-\tau}\|_F \leq 2GL\tau\lambda\sigma\sqrt{N},$$

  which means that the minimal singular value of the perturbed matrix is at least $\sigma_1 = \gamma - 2GL\tau\lambda\sigma\sqrt{N}$ due to Assumption 6.

- The spectral norm of the expression of interest can be bounded (quite pessimistically!) by summing up together the largest eigenvalues of the matrix inverses:

$$\begin{aligned} &\left|\left(K_{t-\tau}^{-1}\mathbf{y}\mathbf{y}^\top K_{t-\tau}^{-1} - K_{t-\tau}^{-1}\right)_{ij} - \left(K_t^{-1}\mathbf{y}\mathbf{y}^\top K_t^{-1} - K_t^{-1}\right)_{ij}\right| \\ \leq &\left\|\left(K_{t-\tau}^{-1} - K_t^{-1}\right)\mathbf{y}\mathbf{y}^\top\left(K_{t-\tau}^{-1} - K_t^{-1}\right) - \left(K_{t-\tau}^{-1} - K_t^{-1}\right)\right\| \\ \leq &\left(\gamma^{-1} + \left(\gamma - 2GL\tau\lambda\sigma\sqrt{N}\right)^{-1}\right)^2 \|\mathbf{y}\|^2 + \gamma^{-1} + \left(\gamma - 2GL\tau\lambda\sigma\sqrt{N}\right)^{-1}. \end{aligned}$$

Each element of a matrix is bounded by the largest eigenvalue. ■

Using Lemma 3, it is straightforward to extend Theorem 1 to Algorithm 2.

Theorem 2 *Let $\{(\boldsymbol{\theta}^t, W^t)\}$ be a sequence generated from Algorithm 2 with learning rates for $\boldsymbol{\theta}$ and W being $\lambda_{\boldsymbol{\theta}}^t = c_{\boldsymbol{\theta}}^t\alpha_t$ and $\lambda_W^t = c_W^t\alpha_t$, respectively, where $c_{\boldsymbol{\theta}}^t, c_W^t, \alpha_t$ are positive scalars, such that*

$$0 < \inf_t c_{\{\boldsymbol{\theta},W\}}^t \leq \sup_t c_{\{\boldsymbol{\theta},W\}}^t < \infty, \quad \alpha_t \geq \alpha_{t+1}, \quad \sum_{t=1}^{\infty}\alpha_t = +\infty, \quad \sum_{t=1}^{\infty}\alpha_t^2 < +\infty, \quad \forall t. \tag{C.23}$$

Then, under Assumptions 1 through 6 and if $\sigma = \sup_t \sigma_t < \infty$, we have

$$\lim_{t\to\infty} \mathbb{E}\|\nabla\mathcal{L}(\boldsymbol{\theta}^t, W^t)\| = 0. \tag{C.24}$$

Proof The proof is identical to the proof of Theorem 1. The only difference is in the following upper bound on the expected gradient error: $\mathbb{E}\|\delta_W^t\| \leq \sigma + 2ND(D\|y\|^2 + 1)J\rho$, where D is as given in Lemma 3. ■

Remark 1 *Even though the provided bounds are crude due to pessimistic estimates of the perturbed kernel matrix spectrum*[15]*, we still see a fine balance between the delay, τ, and the learning rate, λ, as given in the expression for the D constant.*

Appendix D. Details on the datasets

The datasets varied in the number of time steps (from hundreds to a million), input and output dimensionality, and the nature of the estimation tasks.

D.1 Self-driving car

The following is description of the input and target time series used in each of the autonomous driving tasks (dimensionality is given in parenthesis).

- **Car speed estimation:**
  - *Features:* GPS velocity (3), fiber gyroscope (3).
  - *Targets:* speed measurements from the car speedometer.
- **Car yaw estimation:**
  - *Features:* acceleration (3), compass measurements (3).
  - *Targets:* yaw in the car-centric frame.
- **Lane sequence prediction:** Each lane was represented by 8 cubic polynomial coefficients [4 coefficients for x (front) and 4 coefficients for y (left) axes in the car-centric frame]. Instead of predicting the coefficients (which turned out to lead to overall less stable results), we discretized the lane curves using 7 points (initial, final and 5 equidistant intermediate points).
  - *Features:* lanes at a previous time point (16), GPS velocity (3), fiber gyroscope (3), compass (3), steering angle (1).
  - *Targets:* coordinates of the lane discretization points (7 points per lane resulting in 28 total output dimensions).

15. Tighter bounds can be derived by inspecting the effects of perturbations on specific kernels as well as using more specific assumptions about the data distribution.

Table 5: Summary of the feedforward and recurrent neural architectures and the corresponding hyperparameters used in the experiments. GP-based models used the same architectures as their non-GP counterparts. Activations are given for the hidden units; vanilla neural nets used linear output activations.

Name	Data	Time lag	Layers	Units*	Type	Regularizer**	Optimizer
NARX	Actuator	32	1	256	ReLU	dropout(0.5)	Adam(0.01)
	Drives	16	1	128			
	GEF-power	48	1	256

Abstract

Convolutional neural networks (CNN) have led to many state-of-the-art results spanning through various fields. However, a clear and profound theoretical understanding of the forward pass, the core algorithm of CNN, is still lacking. In parallel, within the wide field of sparse approximation, Convolutional Sparse Coding (CSC) has gained increasing attention in recent years. A theoretical study of this model was recently conducted, establishing it as a reliable and stable alternative to the commonly practiced patch-based processing. Herein, we propose a novel multi-layer model, ML-CSC, in which signals are assumed to emerge from a cascade of CSC layers. This is shown to be tightly connected to CNN, so much so that the forward pass of the CNN is in fact the thresholding pursuit serving the ML-CSC model. This connection brings a fresh view to CNN, as we are able to attribute to this architecture theoretical claims such as uniqueness of the representations throughout the network, and their stable estimation, all guaranteed under simple local sparsity conditions. Lastly, identifying the weaknesses in the above pursuit scheme, we propose an alternative to the forward pass, which is connected to deconvolutional and recurrent networks, and also has better theoretical guarantees.

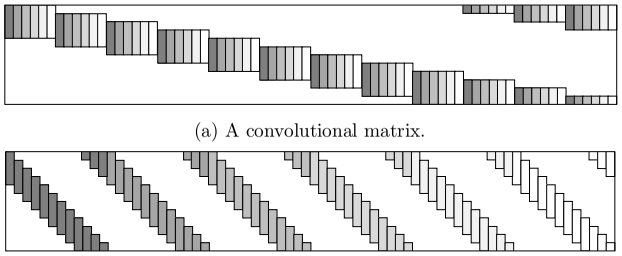
1. Introduction

Deep learning (LeCun et al., 2015), and in particular CNN (LeCun et al., 1990, 1998; Krizhevsky et al., 2012), has gained a copious amount of attention in recent years as it has led to many state-of-the-art results spanning through many fields – including speech recognition (Bengio et al., 2003; Hinton et al., 2012; Mikolov et al., 2013), computer vision (Farabet et al., 2013; Simonyan and Zisserman, 2014; He et al., 2015), signal and image processing (Gatys et al., 2015; Ulyanov et al., 2016; Johnson et al., 2016; Dong et al., 2016), to name a few. In the context of CNN, the forward pass is a multi-layer scheme that provides an end-to-end mapping, from an input signal to some desired output. Each layer of this algorithm consists of three steps. The first convolves the input with a set of learned filters, resulting in a set of feature (or kernel) maps. These then undergo a point wise non-linear function, in a second step, often resulting in a sparse outcome (Glorot et al., 2011). A third (and optional) down-sampling step, termed *pooling*, is then applied on the result in order to reduce its dimensions. The output of this layer is then fed into another one, thus forming the multi-layer structure, often termed *forward pass*.

Despite its marvelous empirical success, a clear and profound theoretical understanding of this scheme is still lacking. A few preliminary theoretical results were recently suggested. In (Mallat, 2012; Bruna and Mallat, 2013) the Scattering Transform was proposed, suggesting to replace the learned filters in the CNN with predefined Wavelet functions. Interestingly, the features obtained from this network were shown to be invariant to various transformations such as translations and rotations. Other works have studied the properties of deep and fully connected networks under the assumption of independent identically distributed random weights (Giryes et al., 2015; Saxe et al., 2013; Arora et al., 2014; Dauphin et al., 2014; Choromanska et al., 2015). In particular, in (Giryes et al., 2015) deep neural networks were proven to preserve the metric structure of the input data as it propagates through the layers of the network. This, in turn, was shown to allow a stable recovery of the data from the features obtained from the network.



Another prominent paradigm in data processing is the sparse representation concept, being one of the most popular choices for a prior in the signal and image processing communities, and leading to exceptional results in various applications (Elad and Aharon, 2006; Dong et al., 2011; Zhang and Li, 2010; Jiang et al., 2011; Mairal et al., 2014). In this framework, one assumes that a signal can be represented as a linear combination of a few columns (called atoms) from a matrix termed a dictionary. Put differently, the signal is equal to a multiplication of a dictionary by a sparse vector. The task of retrieving the sparsest representation of a signal over a dictionary is called sparse coding or pursuit. Over the years, various algorithms were proposed to tackle this problem, among of which we mention the thresholding algorithm (Elad, 2010) and its iterative variant (Daubechies et al., 2004). When handling natural signals, this model has been commonly used for modeling local patches extracted from the global data mainly due to the computational difficulties related to the task of learning the dictionary (Elad and Aharon, 2006; Dong et al., 2011; Mairal et al., 2014; Romano and Elad, 2015; Sulam and Elad, 2015). However, in recent years an alternative to this patch-based processing has emerged in the form of the Convolutional Sparse Coding (CSC) model (Bristow et al., 2013; Kong and Fowlkes, 2014; Wohlberg, 2014; Gu et al., 2015; Heide et al., 2015; Papyan et al., 2016a,b). This circumvents the afore-

mentioned limitations by imposing a special structure – a union of banded and Circulant matrices – on the dictionary involved. The traditional sparse model has been extensively studied over the past two decades (Elad, 2010; Foucart and Rauhut, 2013). More recently, the convolutional extension was extensively analyzed in (Papyan et al., 2016a,b), shedding light on its theoretical aspects and prospects of success.

In this work, by leveraging the recent study of CSC, we aim to provide a new perspective on CNN, leading to a clear and profound theoretical understanding of this scheme, along with new insights. Embarking from the classic CSC, our approach builds upon the observation that similar to the original signal, the representation vector itself also admits a convolutional sparse representation. As such, it can be modeled as a superposition of atoms, taken from a different convolutional dictionary. This rationale can be extended to several layers, leading to the definition of our proposed ML-CSC model. Building on the recent analysis of the CSC, we provide a theoretical study of this novel model and its associated pursuits, namely the layered thresholding algorithm and the layered basis pursuit (BP).

Our analysis reveals the relation between the CNN and the ML-CSC model, showing that *the forward pass of the CNN is in fact identical to our proposed pursuit – the layered thresholding algorithm*. This connection is of significant importance since it gives a clear mathematical meaning, objective and model to the CNN architecture, which in turn can be accompanied by guarantees for the success of the forward pass, studied via the layered thresholding algorithm. Specifically, we show that the forward pass is guaranteed to recover an estimate of the underlying representations of an input signal, assuming these are sparse in a local sense. Moreover, considering a setting where a norm-bounded noise is added to the signal, we show that such a mild corruption in the input results in a bounded perturbation in the output – indicating the stability of the CNN in recovering the underlying representations. Lastly, we exploit the answers to the above questions in order to propose an alternative to the commonly used forward pass algorithm, which is tightly connected to both deconvolutional (Zeiler et al., 2010; Pu et al., 2016) and recurrent networks (Bengio et al., 1994). The proposed alternative scheme is accompanied by a thorough theoretical study. Although this and the analysis presented throughout this work focus on CNN, we will show that they also hold for fully connected networks.

This paper is organized as follows. In Section 2 we review the basics of both the CNN and the Sparse-Land model. We then define the proposed ML-CSC model in Section 3, together with its corresponding deep sparse coding problem. In Section 4, we aim to solve this using the layered thresholding algorithm, which is shown to be equivalent to the forward pass of the CNN. Next, having established the relevance of our model to CNN, we proceed to its analysis in Section 5. Standing on these theoretical grounds, we then propose in Section 6 a provably improved pursuit, termed the layered BP, accompanied by its theoretical analysis. We revisit the assumptions of our model in Section 7. First, in Section 7.1 we link the double sparsity model to ours by assuming the dictionaries throughout the layers are sparse. Then, in Section 7.2 we consider an idea typically employed in CNN, termed spatial-stride, showing its benefits from a simple theoretical perspective. Combining our insights from Section 7.1 and 7.2, we move to an experimental phase by constructing a family of signals satisfying the assumptions of our model, which are then used in order to verify our theoretical results. Finally, in Section 9 we conclude the contributions of this paper and present several future directions.

(a) A convolutional matrix.

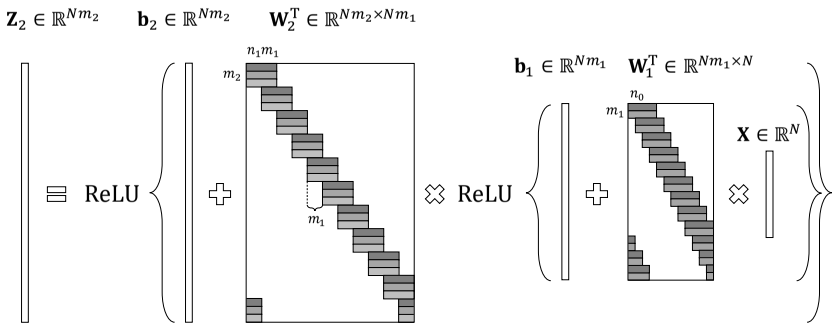
(b) A concatenation of banded and Circulant matrices.

Figure 1: The two facets of the convolutional structure.

2. Background

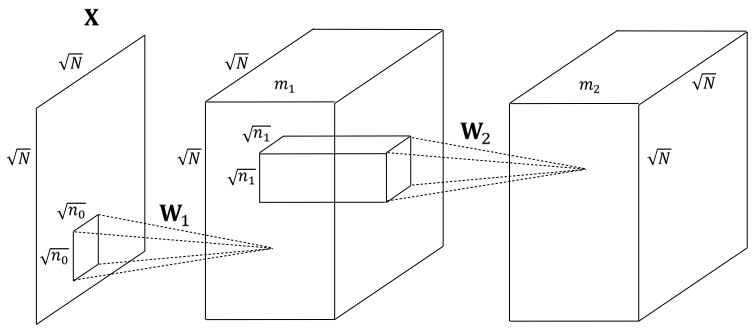
This section is divided into two parts: The first is dedicated to providing a simple mathematical formulation of the CNN and the forward pass, while the second reviews the Sparse-Land model and its various extensions. Readers familiar with these two topics can skip directly to Section 3, which moves to serve the main contribution of this work.

2.1 Deep Learning - Convolutional Neural Networks



The fundamental algorithm of deep learning is the *forward pass*, employed both in the training and the inference stages. The first step of this algorithm convolves an input (one dimensional) signal $\mathbf{X} \in \mathbb{R}^N$ with a set of m_1 learned filters of length n_0, creating m_1 feature (or kernel) maps. Equally, this convolution can be written as a matrix-vector multiplication, $\mathbf{W}_1^T\mathbf{X} \in \mathbb{R}^{Nm_1}$, where $\mathbf{W}_1 \in \mathbb{R}^{N\times Nm_1}$ is a matrix containing in its columns the m_1 filters with all of their shifts. This structure, also known as a convolutional matrix, is depicted in Figure 1a. A pointwise nonlinear function is then applied on the sum of the obtained feature maps $\mathbf{W}_1^T\mathbf{X}$ and a bias term denoted by $\mathbf{b}_1 \in \mathbb{R}^{Nm_1}$. Many possible functions were proposed over the years, the most popular one being the Rectifier Linear Unit (ReLU) (Glorot et al., 2011; Krizhevsky et al., 2012), formally defined as $\text{ReLU}(z) = \max(z, 0)$. By cascading the basic block of convolutions followed by a nonlinear function, $\mathbf{Z}_1 = \text{ReLU}(\mathbf{W}_1^T\mathbf{X} + \mathbf{b}_1)$, a multi-layer structure of depth K is constructed. Formally, for two layers this is given by

$$f(\mathbf{X}, \{\mathbf{W}_i\}_{i=1}^2, \{\mathbf{b}_i\}_{i=1}^2) = \mathbf{Z}_2 = \text{ReLU}\Big(\mathbf{W}_2^T \ \text{ReLU}\ (\ \mathbf{W}_1^T\mathbf{X} + \mathbf{b}_1\ ) + \mathbf{b}_2 \Big), \qquad (1)$$



where $\mathbf{W}_2 \in \mathbb{R}^{Nm_1\times Nm_2}$ is a convolutional matrix (up to a small modification discussed below) constructed from m_2 filters of length n_1m_1 and $\mathbf{b}_2 \in \mathbb{R}^{Nm_2}$ is its corresponding bias. Although the two layers considered here can be readily extended to a much deeper configuration, we defer this to a later stage.

By changing the order of the columns in the convolutional matrix, one can observe that it can be equally viewed as a concatenation of banded and Circulant[1] matrices, as depicted

1. We shall assume throughout this paper that boundaries are treated by a periodic continuation, which gives rise to the cyclic structure.

(a) An illustration of Equation (1) for a one dimensional signal $\mathbf{X}$.

(b) The evolution of an image $\mathbf{X}$ throughout the CNN. Notice that the number of channels in $\mathbf{X}$ is equal to one and as such $m_0 = 1$.

Figure 2: The forward pass algorithm for a one dimensional signal (a) and an image (b).

in Figure 1b. Using this observation, the above description for one dimensional signals can be extended to images, with the exception that now every Circulant matrix is replaced by a block Circulant with Circulant blocks one.

An illustration of the forward pass algorithm is presented in Figure 2a and 2b. In Figure 2a one can observe that $\mathbf{W}_2$ is not a regular convolutional matrix but a stride one, since it shifts local filters by skipping m_1 entries at a time. The reason for this becomes apparent once we look at Figure 2b; the convolutions of the second layer are computed by shifting the filters of $\mathbf{W}_2$ that are of size $\sqrt{n_1} \times \sqrt{n_1} \times m_1$ across N places, skipping m_1 indices at a time from the $\sqrt{N} \times \sqrt{N} \times m_1$-sized array. A matrix obeying this structure is called a *stride convolutional matrix*.

Thus far, we have presented the basic structure of CNN. However, oftentimes an additional non-linear function, termed *pooling*, is employed on the resulting feature map obtained from the ReLU operator. In essence, this step summarizes each w_i-dimensional spatial neighborhood from the i-th kernel map $\mathbf{Z}_i$ by replacing it with a single value. If the neighborhoods are non-overlapping, for example, this results in the down-sampling of the feature map by a factor of w_i. The most widely used variant of the above is the max pooling (Krizhevsky et al., 2012; Simonyan and Zisserman, 2014), which picks the maximal value of each neighborhood. In (Springenberg et al., 2014) it was shown that this operator can be replaced by a convolutional layer with increased stride without loss in performance in several image classification tasks. Moreover, the current state-of-the-art in image recognition is obtained by the residual network (He et al., 2015), which does not employ any pooling steps (except for a single layer). As such, we defer the analysis of this operator to a follow-up work.

In the context of classification, for example, the output of the last layer is fed into a simple classifier that attempts to predict the label of the input signal $\mathbf{X}$, denoted by $h(\mathbf{X})$. Given a set of signals $\{\mathbf{X}_j\}_j$, the task of learning the parameters of the CNN – including the filters $\{\mathbf{W}_i\}_{i=1}^K$, the biases $\{\mathbf{b}_i\}_{i=1}^K$ and the parameters of the classifier $\mathbf{U}$ – can be formulated as the following minimization problem

$$\min_{\{\mathbf{W}_i\}_{i=1}^K, \{\mathbf{b}_i\}_{i=1}^K, \mathbf{U}} \sum_j \ell\Big(h(\mathbf{X}_j), \mathbf{U}, f\left(\mathbf{X}_j, \{\mathbf{W}_i\}_{i=1}^K, \{\mathbf{b}_i\}_{i=1}^K\right)\Big). \tag{2}$$

This optimization task seeks for the set of parameters that minimize the mean of the loss function ℓ, representing the price incurred when classifying the signal $\mathbf{X}$ incorrectly. The input for ℓ is the true label $h(\mathbf{X})$ and the one estimated by employing the classifier defined by $\mathbf{U}$ on the final layer of the CNN given by $f\left(\mathbf{X}, \{\mathbf{W}_i\}_{i=1}^K, \{\mathbf{b}_i\}_{i=1}^K\right)$. Similarly one can tackle various other problems, e.g. regression or prediction.

In the remainder of this work we shall focus on the feature extraction process and assume that the parameters of the CNN model are pre-trained and fixed. These, for example, could have been obtained by minimizing the above objective via the backpropagation algorithm and the stochastic gradient descent, as in the VGG network (Simonyan and Zisserman, 2014).

2.2 Sparse-Land

This section presents an overview of the Sparse-Land model and its many extensions. We start with the traditional sparse representation and the core problem it aims to solve, and then proceed to its nonnegative variant. Next, we continue to the dictionary learning task both in the unsupervised and supervised cases. Finally, we describe the recent CSC model, which will lead us in the next section to the proposal of the ML-CSC model. This, in turn, will naturally connect the realm of sparsity to that of the CNN.

2.2.1 Sparse Representation

In the sparse representation model one assumes a signal $\mathbf{X} \in \mathbb{R}^N$ can be described as a multiplication of a matrix $\mathbf{D} \in \mathbb{R}^{N \times M}$, also called a dictionary, by a sparse vector $\mathbf{\Gamma} \in \mathbb{R}^M$.

Equally, the signal $\mathbf{X}$ can be seen as a linear combination of a few columns from the dictionary $\mathbf{D}$, coined atoms.

For a fixed dictionary, given a signal $\mathbf{X}$, the task of recovering its sparsest representation $\mathbf{\Gamma}$ is called sparse coding, or simply pursuit, and it attempts to solve the following problem (Donoho and Elad, 2003; Tropp, 2004; Elad, 2010):

$$(\mathrm{P}_0): \ \min_{\mathbf{\Gamma}} \|\mathbf{\Gamma}\|_0 \ \text{ s.t. } \ \mathbf{D}\mathbf{\Gamma} = \mathbf{X}, \tag{3}$$

where we have denoted by $\|\mathbf{\Gamma}\|_0$ the number of non-zeros in $\mathbf{\Gamma}$. The above has a convex relaxation in the form of the Basis-Pursuit (BP) problem (Chen et al., 2001; Donoho and Elad, 2003; Tropp, 2006), formally defined as

$$(\mathrm{P}_1): \ \min_{\mathbf{\Gamma}} \|\mathbf{\Gamma}\|_1 \ \text{ s.t. } \ \mathbf{D}\mathbf{\Gamma} = \mathbf{X}. \tag{4}$$

Many questions arise from the above two defined problems. For instance, given a signal $\mathbf{X}$, is its sparsest representation unique? Assuming that such a unique solution exists, can it be recovered using practical algorithms such as the Orthogonal Matching Pursuit (OMP) (Chen et al., 1989; Pati et al., 1993) and the BP (Chen et al., 2001; Daubechies et al., 2004)? The answers to these questions were shown to be positive under the assumption that the number of non-zeros in the underlying representation is not too high and in particular less than $\frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D})}\right)$ (Donoho and Elad, 2003; Tropp, 2004; Donoho et al., 2006). The quantity $\mu(\mathbf{D})$ is the mutual coherence of the dictionary $\mathbf{D}$, being the maximal inner product of two atoms extracted from it[2]. Formally, we can write

$$\mu(\mathbf{D}) = \max_{i \neq j} |\mathbf{d}_i^T \mathbf{d}_j|.$$

Tighter conditions, relying on sharper characterizations of the dictionary, were also suggested in the literature (Candes et al., 2006; Schnass and Vandergheynst, 2007; Candes et al., 2006; Candes and Tao, 2007). However, at this point, we shall not dwell on these.

One of the simplest approaches for tackling the P_0 and P_1 problems is via the hard and soft thresholding algorithms, respectively. These operate by computing the inner products between the signal $\mathbf{X}$ and all the atoms in $\mathbf{D}$ and then choosing the atoms corresponding to the highest responses. This can be described as solving, for some scalar β, the following problems:

$$\min_{\mathbf{\Gamma}} \frac{1}{2}\|\mathbf{\Gamma} - \mathbf{D}^T\mathbf{X}\|_2^2 + \beta\|\mathbf{\Gamma}\|_0$$

for the P_0, or

$$\min_{\mathbf{\Gamma}} \frac{1}{2}\|\mathbf{\Gamma} - \mathbf{D}^T\mathbf{X}\|_2^2 + \beta\|\mathbf{\Gamma}\|_1, \tag{5}$$

for the P_1. The above are simple projection problems that admit a closed-form solution in the form[3] of $\mathcal{H}_\beta(\mathbf{D}^T\mathbf{X})$ or $\mathcal{S}_\beta(\mathbf{D}^T\mathbf{X})$, where we have defined the hard thresholding operator

2. Hereafter, we assume that the atoms are normalized to a unit ℓ_2 norm.
3. The curious reader may identify the relation between the notations used here and the ones in the previous subsection, which starts to reveal the relation between CNN and sparsity-inspired models. This connection will be made clearer as we proceed to CSC.

$\mathcal{H}_\beta(\cdot)$ by

$$\mathcal{H}_\beta(z) = \begin{cases} z, & z < -\beta \\ 0, & -\beta \leq z \leq \beta \\ z, & \beta < z, \end{cases}$$

and the soft thresholding operator $\mathcal{S}_\beta(\cdot)$ by

$$\mathcal{S}_\beta(z) = \begin{cases} z+\beta, & z < -\beta \\ 0, & -\beta \leq z \leq \beta \\ z-\beta, & \beta < z. \end{cases}$$

Both of the above, depicted in Figure 3, nullify small entries and thus promote a sparse solution. However, while the hard thresholding operator does not modify large coefficients (in absolute value), the soft thresholding does, by contracting these to zero. This inherent limitation of the soft version will appear later on in our theoretical analysis.

As for the theoretical guarantees for the success of the simple thresholding algorithms; these depend on the properties of $\mathbf{D}$ and on the ratio between the minimal and maximal coefficients in absolute value in $\mathbf{\Gamma}$, and thus are weaker when compared to those found for OMP and BP (Donoho and Elad, 2003; Tropp, 2004; Donoho et al., 2006). Still, under some conditions, both algorithms are guaranteed to find the true support of $\mathbf{\Gamma}$ along with an approximation of its true coefficients. Moreover, a better estimation of these can be obtained by projecting the input signal onto the atoms corresponding to the found support (indices of the non-zero entries) by solving a Least-Squares problem. This step, termed debiasing (Elad, 2010), results in a more accurate identification of the non-zero values.

2.2.2 Nonnegative Sparse Coding

The nonnegative sparse representation model assumes a signal can be decomposed into a multiplication of a dictionary and a *nonnegative* sparse vector. A natural question arising from this is whether such a modification to the original Sparse-Land model affects its expressiveness. To address this, we hereby provide a simple reduction from the original sparse representation to the nonnegative one.

Consider a signal $\mathbf{X} = \mathbf{D}\mathbf{\Gamma}$, where the signs of the entries in $\mathbf{\Gamma}$ are unrestricted. Notice that this can be equally written as

$$\mathbf{X} = \mathbf{D}\mathbf{\Gamma}_P + (-\mathbf{D})(-\mathbf{\Gamma}_N),$$

where we have split the vector $\mathbf{\Gamma}$ to its positive coefficients, $\mathbf{\Gamma}_P$, and its negative ones, $\mathbf{\Gamma}_N$. Since the coefficients in $\mathbf{\Gamma}_P$ and $-\mathbf{\Gamma}_N$ are all positive, one can thus assume the signal $\mathbf{X}$ admits a non-negative sparse representation over the dictionary $[\mathbf{D}, -\mathbf{D}]$ with the vector $[\mathbf{\Gamma}_P, -\mathbf{\Gamma}_N]^T$. Thus, restricting the coefficients in the sparsity inspired model to be nonnegative does not change its expressiveness.

Similar to the original model, in the nonnegative case, one could solve the associated pursuit problem by employing a soft thresholding algorithm. However, in this case a constraint must be added to the optimization problem in Equation (5), forcing the outcome to be positive, i.e.,

$$\min_{\mathbf{\Gamma}} \frac{1}{2}\|\mathbf{\Gamma} - \mathbf{D}^T\mathbf{X}\|_2^2 + \beta\|\mathbf{\Gamma}\|_1 \quad \text{s.t.} \quad \mathbf{\Gamma} \geq \mathbf{0}.$$

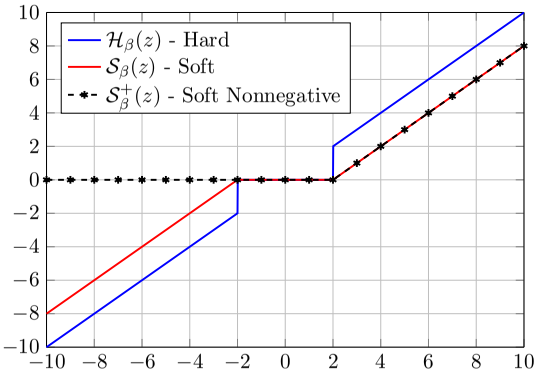


Figure 3: The thresholding operators for a constant $\beta = 2$.

Since the above is a simple projection problem (onto the ℓ_1 ball constrained to positive entries), it admits a closed-form solution $\mathcal{S}_\beta^+(\mathbf{D}^T\mathbf{X})$, where we have defined the soft nonnegative thresholding operator $\mathcal{S}_\beta^+(\cdot)$ as

$$\mathcal{S}_\beta^+(z) = \begin{cases} 0, & z \leq \beta \\ z - \beta, & \beta < z. \end{cases}$$

Remarkably, the above function satisfies

$$\mathcal{S}_\beta^+(z) = \max(z - \beta, 0) = \text{ReLU}(z - \beta).$$

In other words, the ReLU and the soft nonnegative thresholding operator are equal, a fact that will prove to be important later in our work. We should note that a similar conclusion was reached in (Fawzi et al., 2015). To summarize this discussion, we depict in Figure 3 the hard, soft, and nonnegative soft thresholding operators.

2.2.3 Unsupervised and Task Driven Dictionary Learning

At first, the dictionaries employed in conjunction with the sparsity inspired model were analytically defined matrices, such as the Wavelet and the Fourier (Daubechies et al., 1992; Mallat and Zhang, 1993; Elad and Bruckstein, 2002; Mallat, 2008). Although the sparse coding problem under these can be done very efficiently, over the years many have shifted to a data driven approach – adapting the dictionary $\mathbf{D}$ to a set of training signals at hand via some learning procedure. This was empirically shown to lead to sparser representations and better overall performance, at the cost of complicating the involved pursuit, since the dictionary was usually chosen to be redundant (having more columns than rows).

The task of learning a dictionary for representing a set of signals $\{\mathbf{X}_j\}_j$ can be formulated as follows

$$\min_{\mathbf{D},\{\mathbf{\Gamma}^j\}_j} \sum_j \|\mathbf{X}_j - \mathbf{D}\mathbf{\Gamma}^j\|_2^2 + \xi\|\mathbf{\Gamma}^j\|_0.$$

The above formulation is an unsupervised learning procedure, and it was later extended to a supervised setting. In this context, given a set of signals $\{\mathbf{X}_j\}_j$, one attempts to predict their corresponding labels $\{h(\mathbf{X}_j)\}_j$. A common approach for tackling this is first solving a pursuit problem for each signal $\mathbf{X}_j$ over a dictionary $\mathbf{D}$, resulting in

$$\mathbf{\Gamma}^\star(\mathbf{X}_j, \mathbf{D}) = \arg\min_{\mathbf{\Gamma}} \|\mathbf{\Gamma}\|_0 \quad \text{s.t.} \quad \mathbf{D}\mathbf{\Gamma} = \mathbf{X}_j,$$

and then feeding these sparse representations into a simple classifier, defined by the parameters $\mathbf{U}$. The task of learning jointly the dictionary $\mathbf{D}$ and the classifier $\mathbf{U}$ was addressed in (Mairal et al., 2012), where the following optimization problem was proposed

$$\min_{\mathbf{D},\mathbf{U}} \sum_j \ell\Big(h(\mathbf{X}_j), \mathbf{U}, \mathbf{\Gamma}^\star(\mathbf{X}_j, \mathbf{D})\Big).$$

The loss function ℓ in the above objective penalizes the estimated label if it is different from the true $h(\mathbf{X}_j)$, similar to what we have seen in Section 2.1. The above formulation contains in it the unsupervised option as a special case, in which $\mathbf{U}$ is of no importance, and the loss function is the representation error $\sum_j \|\mathbf{X}_j - \mathbf{D}\mathbf{\Gamma}_j^\star\|_2^2$.

Double sparsity – first proposed in (Rubinstein et al., 2010) and later employed in (Sulam et al., 2016) – attempts to benefit from both the computational efficiency of analytically defined matrices, and the adaptability of data driven dictionaries. In this model, one assumes the dictionary $\mathbf{D}$ can be factorized into a multiplication of two matrices, $\mathbf{D}_1$ and $\mathbf{D}_2$, where $\mathbf{D}_1$ is an analytic dictionary with fast implementation, and $\mathbf{D}_2$ is a trained sparse one. As a result, the signal $\mathbf{X}$ can be represented as

$$\mathbf{X} = \mathbf{D}\mathbf{\Gamma}_2 = \mathbf{D}_1\mathbf{D}_2\mathbf{\Gamma}_2,$$

where $\mathbf{\Gamma}_2$ is sparse.

We propose a different interpretation for the above, which is unrelated to practical aspects. Since both the matrix $\mathbf{D}_2$ and the vector $\mathbf{\Gamma}_2$ are sparse, one would expect their multiplication $\mathbf{\Gamma}_1 = \mathbf{D}_2\mathbf{\Gamma}_2$ to be sparse as well. As such, the double sparsity model implicitly assumes that the signal $\mathbf{X}$ can be decomposed into a multiplication of a dictionary $\mathbf{D}_1$ and sparse vector $\mathbf{\Gamma}_1$, which in turn can also be decomposed similarly via $\mathbf{\Gamma}_1 = \mathbf{D}_2\mathbf{\Gamma}_2$.

2.2.4 Convolutional Sparse Coding Model

Due to the computational constraints entailed when deploying trained dictionaries, this approach seems valid only for treatment of low-dimensional signals. Indeed, the sparse representation model is traditionally used for modeling local patches extracted from a global signal. An alternative, which was recently proposed, is the CSC model that attempts to represent the whole signal $\mathbf{X} \in \mathbb{R}^N$ as a multiplication of a global convolutional dictionary $\mathbf{D} \in \mathbb{R}^{N \times Nm}$ and a sparse vector $\mathbf{\Gamma} \in \mathbb{R}^{Nm}$. Interestingly, the former is constructed by

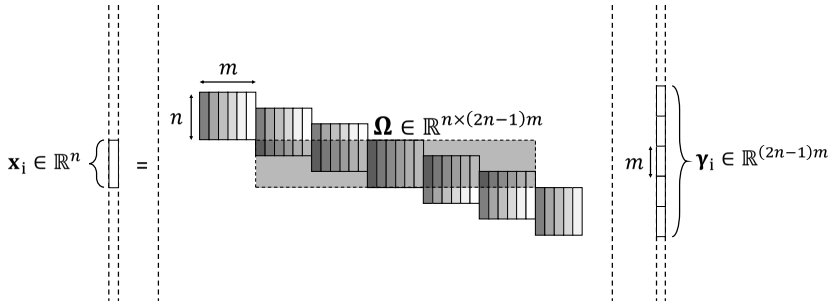

Figure 4: The i-th patch $\mathbf{x}_i$ of the global system $\mathbf{X} = \mathbf{D}\mathbf{\Gamma}$, given by $\mathbf{x}_i = \mathbf{\Omega}\boldsymbol{\gamma}_i$.

shifting a local matrix of size $n \times m$ in all possible positions, resulting in the same structure as the one shown in Figure 1a.

In the convolutional model, the classical theoretical guarantees (we are referring to results reported in (Chen et al., 2001; Donoho and Elad, 2003; Tropp, 2006)) for the P_0 problem, defined in Equation (3), are very pessimistic. In particular, the condition for the uniqueness of the underlying solution and the requirement for the success of the sparse coding algorithms depend on the global number of non-zeros being less than $\frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D})}\right)$. Following the Welch bound (Welch, 1974), this expression was shown in (Papyan et al., 2016a) to be impractical, allowing the global number of non-zeros in $\mathbf{\Gamma}$ to be extremely low.

In order to provide a better theoretical understanding of this model, which exploits the inherent structure of the convolutional dictionary, a recent work (Papyan et al., 2016a) suggested to measure the sparsity of $\mathbf{\Gamma}$ in a localized manner. More concretely, consider the i-th n-dimensional patch of the global system $\mathbf{X} = \mathbf{D}\mathbf{\Gamma}$, given by $\mathbf{x}_i = \mathbf{\Omega}\boldsymbol{\gamma}_i$. The stripe-dictionary $\mathbf{\Omega}$, which is of size $n \times (2n-1)m$, is obtained by extracting the i-th patch from the global dictionary $\mathbf{D}$ and discarding all the zero columns from it. The stripe vector $\boldsymbol{\gamma}_i$ is the corresponding sparse representation of length $(2n-1)m$, containing all coefficients of atoms contributing to $\mathbf{x}_i$. This relation is illustrated in Figure 4. Notably, the choice of a convolutional dictionary results in signals such that every patch of length n extracted from them can be sparsely represented using a single shift-invariant local dictionary $\mathbf{\Omega}$ – a common assumption usually employed in signal and image processing.

Following the above construction, the $\ell_{0,\infty}$ norm of the global sparse vector $\mathbf{\Gamma}$ is defined to be the maximal number of non-zeros in a stripe of length $(2n-1)m$ extracted from it. Formally,

$$\|\mathbf{\Gamma}\|_{0,\infty}^{\mathbf{s}} = \max_i \|\boldsymbol{\gamma}_i\|_0,$$

where the letter $\mathbf{s}$ emphasizes that the $\ell_{0,\infty}$ norm is computed by sweeping over all stripes. Given a signal $\mathbf{X}$, finding its sparest representation $\mathbf{\Gamma}$ in the $\ell_{0,\infty}$ sense is equal to the following optimization problem:

$$(\mathrm{P}_{0,\infty}): \quad \min_{\mathbf{\Gamma}} \quad \|\mathbf{\Gamma}\|_{0,\infty}^{\mathbf{s}} \quad \text{s.t.} \quad \mathbf{D}\mathbf{\Gamma} = \mathbf{X}. \tag{6}$$

Intuitively, this seeks for a global vector $\mathbf{\Gamma}$ that can represent sparsely every patch in the signal $\mathbf{X}$ using the dictionary $\mathbf{\Omega}$. The advantage of the above problem over the traditional P_0 becomes apparent as we move to consider its theoretical aspects. Assuming that the **number of non-zeros per stripe** (and not globally) in $\mathbf{\Gamma}$ is less than $\frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D})}\right)$, in (Papyan et al., 2016a) it was proven that the solution for the $\mathrm{P}_{0,\infty}$ problem is unique. Furthermore, classical pursuit methods, originally tackling the P_0 problem, are guaranteed to find this representation.

When modeling natural signals, due to measurement noise as well as model deviations, one can not impose a perfect reconstruction such as $\mathbf{X} = \mathbf{D}\mathbf{\Gamma}$ on the signal $\mathbf{X}$. Instead, one assumes $\mathbf{Y} = \mathbf{X} + \mathbf{E} = \mathbf{D}\mathbf{\Gamma} + \mathbf{E}$, where $\mathbf{E}$ is, for example, an ℓ_2-bounded error vector. To address this, the work reported in (Papyan et al., 2016b) considered the extension of the $\mathrm{P}_{0,\infty}$ problem to the $\mathrm{P}_{0,\infty}^{\boldsymbol{\mathcal{E}}}$ one, formally defined as

$$(\mathrm{P}_{0,\infty}^{\boldsymbol{\mathcal{E}}}): \quad \min_{\mathbf{\Gamma}} \|\mathbf{\Gamma}\|_{0,\infty}^{\mathbf{s}} \quad \text{s.t.} \quad \|\mathbf{Y} - \mathbf{D}\mathbf{\Gamma}\|_2^2 \leq \boldsymbol{\mathcal{E}}^2.$$

Similar to the $\mathrm{P}_{0,\infty}$ problem, this was also analyzed theoretically, shedding light on the theoretical aspects of the convolutional model in the presence of noise. In particular, a stability claim for the $\mathrm{P}_{0,\infty}^{\boldsymbol{\mathcal{E}}}$ problem and guarantees for the success of both the OMP and the BP were provided. Similar to the noiseless case, these assumed that the number of non-zeros per stripe is low.

3. From Atoms to Molecules: Multi-Layer Convolutional Sparse Model

Convolutional sparsity assumes an inherent structure for natural signals. Similarly, the representations themselves could also be assumed to have such a structure. In what follows, we propose a novel layered model that relies on this rationale.

The convolutional sparse model assumes a global signal $\mathbf{X} \in \mathbb{R}^N$ can be decomposed into a multiplication of a convolutional dictionary $\mathbf{D}_1 \in \mathbb{R}^{N\times Nm_1}$, composed of m_1 local filters of length n_0, and a sparse vector $\mathbf{\Gamma}_1 \in \mathbb{R}^{Nm_1}$. Herein, we extend this by proposing a similar factorization of the vector $\mathbf{\Gamma}_1$, which can be perceived as an N-dimensional global signal with m_1 channels. In particular, we assume $\mathbf{\Gamma}_1 = \mathbf{D}_2\mathbf{\Gamma}_2$, where $\mathbf{D}_2 \in \mathbb{R}^{Nm_1\times Nm_2}$ is a stride convolutional dictionary (skipping m_1 entries at a time) and $\mathbf{\Gamma}_2 \in \mathbb{R}^{Nm_2}$ is a sparse representation. We denote the number of unique filters constructing $\mathbf{D}_2$ by m_2 and their corresponding length by n_1m_1. Due to the multi-layer nature of this model and the imposed convolutional structure, we name this the ML-CSC model.

Intuitively, $\mathbf{X} = \mathbf{D}_1\mathbf{\Gamma}_1$ assumes that the signal $\mathbf{X}$ is a superposition of **atoms** taken from $\mathbf{D}_1$. While equation $\mathbf{X} = \mathbf{D}_1\mathbf{D}_2\mathbf{\Gamma}_2$ views the signal as a superposition of more complex entities taken from the dictionary $\mathbf{D}_1\mathbf{D}_2$, which we coin **molecules**.

While this proposal can be interpreted as a straightforward fusion between the double sparsity model (Rubinstein et al., 2010) and the convolutional one, it is in fact substantially different. The double sparsity model assumes that $\mathbf{D}_2$ is sparse, and forces **only** the deepest representation $\mathbf{\Gamma}_2$ to be sparse as well. Here, on the other hand, we replace this constraint by forcing $\mathbf{D}_2$ to have a stride convolution structure, putting emphasis on the sparsity of both the representations $\mathbf{\Gamma}_1$ and $\mathbf{\Gamma}_2$. In Section 7.1 we will revisit the double sparsity work and its ties to ours by showing the benefits of injecting the assumption on the sparsity of $\mathbf{D}_2$ into our proposed model.

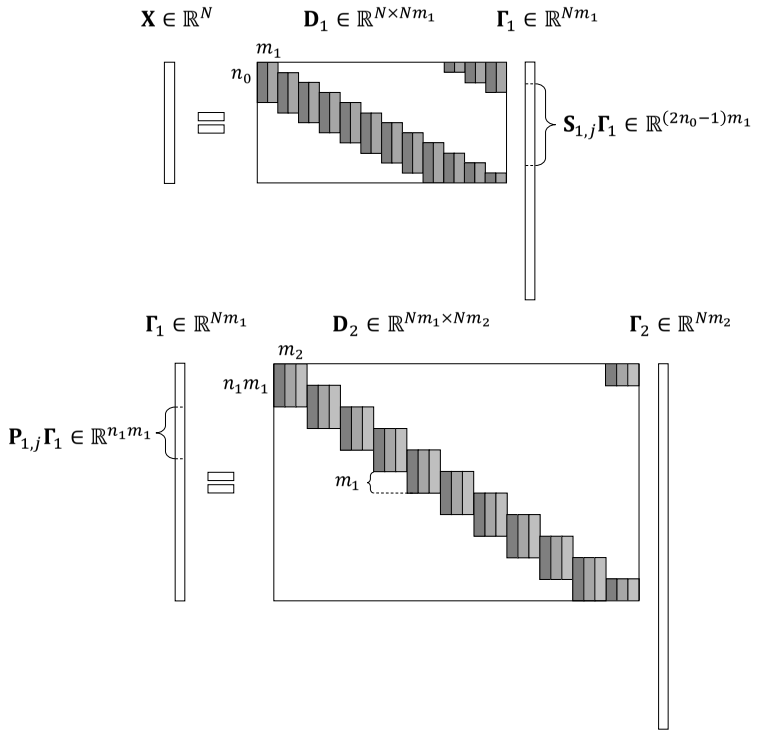

Figure 5: An instance $\mathbf{X} = \mathbf{D}_1\mathbf{\Gamma}_1 = \mathbf{D}_1\mathbf{D}_2\mathbf{\Gamma}_2$ of the ML-CSC model. Notice that $\mathbf{\Gamma}_1$ is built of both stripes $\mathbf{S}_{1,j}\mathbf{\Gamma}_1$ and patches $\mathbf{P}_{1,j}\mathbf{\Gamma}_1$.

Under the above construction the sparse vector $\mathbf{\Gamma}_1$ has two roles. In the context of the system of equations $\mathbf{X} = \mathbf{D}_1\mathbf{\Gamma}_1$, it is the convolutional sparse representation of the signal $\mathbf{X}$ over the dictionary $\mathbf{D}_1$. As such, the vector $\mathbf{\Gamma}_1$ is composed from $(2n_0 - 1)m_1$-dimensional stripes, $\mathbf{S}_{1,j}\mathbf{\Gamma}_1$, where $\mathbf{S}_{i,j}$ is the operator that extracts the j-th stripe from $\mathbf{\Gamma}_i$. From another point of view, $\mathbf{\Gamma}_1$ is in itself a signal that admits a sparse representation $\mathbf{\Gamma}_1 = \mathbf{D}_2\mathbf{\Gamma}_2$. Denoting by $\mathbf{P}_{i,j}$ the operator that extracts the j-th patch from $\mathbf{\Gamma}_i$, the signal $\mathbf{\Gamma}_1$ is composed of patches $\mathbf{P}_{1,j}\mathbf{\Gamma}_1$ of length $n_1 m_1$. The above model is depicted in Figure 5, presenting both roles of $\mathbf{\Gamma}_1$ and their corresponding constituents – stripes and patches. Clearly, the above construction can be extended to more than two layers, leading to the following definition:

Definition 1 *For a global signal $\mathbf{X}$, a set of convolutional dictionaries $\{\mathbf{D}_i\}_{i=1}^K$, and a vector $\boldsymbol{\lambda}$, define the deep coding problem $DCP_{\boldsymbol{\lambda}}$ as:*

$$(DCP_{\boldsymbol{\lambda}}): \quad \text{find} \quad \{\mathbf{\Gamma}_i\}_{i=1}^K \quad \text{s.t.} \quad \begin{aligned} \mathbf{X} &= \mathbf{D}_1\mathbf{\Gamma}_1, & \|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}} &\le \lambda_1 \\ \mathbf{\Gamma}_1 &= \mathbf{D}_2\mathbf{\Gamma}_2, & \|\mathbf{\Gamma}_2\|_{0,\infty}^{\mathbf{s}} &\le \lambda_2 \\ &\vdots & &\vdots \\ \mathbf{\Gamma}_{K-1} &= \mathbf{D}_K\mathbf{\Gamma}_K, & \|\mathbf{\Gamma}_K\|_{0,\infty}^{\mathbf{s}} &\le \lambda_K, \end{aligned}$$

where the scalar λ_i is the i-th entry of $\boldsymbol{\lambda}$.

Denoting $\mathbf{\Gamma}_0$ to be the signal $\mathbf{X}$, the $\text{DCP}_{\boldsymbol{\lambda}}$ can be rewritten compactly as

$$(\text{DCP}_{\boldsymbol{\lambda}}): \quad \text{find} \quad \{\mathbf{\Gamma}_i\}_{i=1}^K \quad \text{s.t.} \quad \mathbf{\Gamma}_{i-1} = \mathbf{D}_i\mathbf{\Gamma}_i, \quad \|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{s}} \le \lambda_i, \quad \forall 1 \le i \le K.$$

Intuitively, given a signal $\mathbf{X}$, this problem seeks for a set of representations, $\{\mathbf{\Gamma}_i\}_{i=1}^K$, such that each one is locally sparse. As we shall see next, the above can be easily solved using simple algorithms that also enjoy from theoretical justifications. Next, we extend the $\text{DCP}_{\boldsymbol{\lambda}}$ problem to a noisy regime.

Definition 2 *For a global signal $\mathbf{Y}$, a set of convolutional dictionaries $\{\mathbf{D}_i\}_{i=1}^K$, and vectors $\boldsymbol{\lambda}$ and $\boldsymbol{\mathcal{E}}$, define the deep coding problem $DCP_{\boldsymbol{\lambda}}^{\boldsymbol{\mathcal{E}}}$ as:*

$$(DCP_{\boldsymbol{\lambda}}^{\boldsymbol{\mathcal{E}}}): \quad \text{find} \quad \{\mathbf{\Gamma}_i\}_{i=1}^K \quad \text{s.t.} \quad \begin{aligned} \|\mathbf{Y} - \mathbf{D}_1\mathbf{\Gamma}_1\|_2 &\le \mathcal{E}_0, & \|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}} &\le \lambda_1 \\ \|\mathbf{\Gamma}_1 - \mathbf{D}_2\mathbf{\Gamma}_2\|_2 &\le \mathcal{E}_1, & \|\mathbf{\Gamma}_2\|_{0,\infty}^{\mathbf{s}} &\le \lambda_2 \\ &\vdots & &\vdots \\ \|\mathbf{\Gamma}_{K-1} - \mathbf{D}_K\mathbf{\Gamma}_K\|_2 &\le \mathcal{E}_{K-1}, & \|\mathbf{\Gamma}_K\|_{0,\infty}^{\mathbf{s}} &\le \lambda_K, \end{aligned}$$

where the scalars λ_i and $\mathcal{E}_i$ are the i-th entry of $\boldsymbol{\lambda}$ and $\boldsymbol{\mathcal{E}}$, respectively.

We now move to the task of learning the model parameters. Denote by $\text{DCP}_{\boldsymbol{\lambda}}^{\star}(\mathbf{X}, \{\mathbf{D}_i\}_{i=1}^K)$ the representation $\mathbf{\Gamma}_K$ obtained by solving the DCP problem (Definition 1, i.e., noiseless) for the signal $\mathbf{X}$ and the set of dictionaries $\{\mathbf{D}_i\}_{i=1}^K$. Relying on this, we now extend the dictionary learning problem, as presented in Section 2.2.3, to the multi-layer convolutional sparse representation setting.

Definition 3 *For a set of global signals $\{\mathbf{X}_j\}_j$, their corresponding labels $\{h(\mathbf{X}_j)\}_j$, a loss function ℓ, and a vector $\boldsymbol{\lambda}$, define the deep learning problem $DLP_{\boldsymbol{\lambda}}$ as:*

$$(DLP_{\boldsymbol{\lambda}}): \quad \min_{\{\mathbf{D}_i\}_{i=1}^K, \mathbf{U}} \sum_j \ell\Big(h(\mathbf{X}_j), \mathbf{U}, DCP_{\boldsymbol{\lambda}}^{\star}(\mathbf{X}_j, \{\mathbf{D}_i\}_{i=1}^K)\Big).$$

A clarification for the chosen name, deep learning problem, will be provided shortly. The solution for the above results in an end-to-end mapping, from a set of input signals to their corresponding labels. Similarly, we can define the $\text{DLP}_{\boldsymbol{\lambda}}^{\boldsymbol{\mathcal{E}}}$ problem. However, this is omitted for the sake of brevity. We conclude this section by summarizing, for the convenience of the reader, all notations used throughout this work in Table 1.

$\mathbf{X} = \mathbf{\Gamma}_0$	:	a global signal of length N.
$\mathbf{E}$, $\mathbf{Y} = \hat{\mathbf{\Gamma}}_0$	:	a global error vector and its corresponding noisy signal, where generally $\mathbf{Y} = \mathbf{X} + \mathbf{E}$.
K	:	the number of layers.
m_i	:	the number of local filters in $\mathbf{D}_i$, and also the number of channels in $\mathbf{\Gamma}_i$. Notice that $m_0 = 1$.
n_0	:	the size of a local patch in $\mathbf{X} = \mathbf{\Gamma}_0$.
$n_i,\ i \geq 1$	:	the size of a local patch (not including channels) in $\mathbf{\Gamma}_i$.
$n_i m_i$	:	the size of a local patch (including channels) in $\mathbf{\Gamma}_i$.
$\mathbf{D}_1$	:	a (full) convolutional dictionary of size $N \times Nm_1$ with filters of length n_0.
$\mathbf{D}_i,\ i \geq 2$	:	a convolutional dictionary of size $Nm_{i-1} \times Nm_i$ with filters of length $n_{i-1}m_{i-1}$ and a stride equal to m_{i-1}.
$\mathbf{\Gamma}_i$	:	a sparse vector of length Nm_i that is the representation of $\mathbf{\Gamma}_{i-1}$ over the dictionary $\mathbf{D}_i$, i.e. $\mathbf{\Gamma}_{i-1} = \mathbf{D}_i\mathbf{\Gamma}_i$.
$\mathbf{S}_{i,j}$	:	an operator that extracts the j-th stripe of length $(2n_{i-1}-1)m_i$ from $\mathbf{\Gamma}_i$.
$\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{S}}$	:	the maximal number of non-zeros in a stripe from $\mathbf{\Gamma}_i$.
$\mathbf{P}_{i,j}$	:	an operator that extracts the j-th $n_i m_i$-dimensional patch from $\mathbf{\Gamma}_i$.
$\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{P}}$	:	the maximal number of non-zeros in a patch from $\mathbf{\Gamma}_i$ (Definition 6).
$\mathbf{R}_{i,j}$	:	an operator that extracts the filter of length $n_{i-1}m_{i-1}$ from the j-th atom in $\mathbf{D}_i$.
$\|\mathbf{V}\|_{2,\infty}^{\mathbf{P}}$	:	the maximal ℓ_2 norm of a patch extracted from a vector $\mathbf{V}$ (Definition 6).

Table 1: Summary of notations used throughout the paper.

4. Layered Thresholding: The Crux of the Matter

Consider the ML-CSC model defined by the set of dictionaries $\{\mathbf{D}_i\}_{i=1}^K$. Assume we are given a signal

$$\begin{aligned}\mathbf{X} &= \mathbf{D}_1\mathbf{\Gamma}_1 \\ \mathbf{\Gamma}_1 &= \mathbf{D}_2\mathbf{\Gamma}_2 \\ &\vdots \\ \mathbf{\Gamma}_{K-1} &= \mathbf{D}_K\mathbf{\Gamma}_K,\end{aligned}$$

and our goal is to find its underlying representations, $\{\mathbf{\Gamma}_i\}_{i=1}^K$. Tackling this problem by recovering all the vectors at once might be computationally and conceptually challenging; therefore, we propose the *layered thresholding algorithm* that gradually computes the sparse vectors one at a time across the different layers. Denoting by $\mathcal{P}_\beta(\cdot)$ a sparsifying operator that is equal to $\mathcal{H}_\beta(\cdot)$ in the hard thresholding case and $\mathcal{S}_\beta(\cdot)$ in the soft one; we commence by computing $\hat{\mathbf{\Gamma}}_1 = \mathcal{P}_{\beta_1}(\mathbf{D}_1^T\mathbf{X})$, which is an approximation of $\mathbf{\Gamma}_1$. Next, by applying another thresholding algorithm, however this time on $\hat{\mathbf{\Gamma}}_1$, an approximation of $\mathbf{\Gamma}_2$ is obtained, $\hat{\mathbf{\Gamma}}_2 = \mathcal{P}_{\beta_2}(\mathbf{D}_2^T\hat{\mathbf{\Gamma}}_1)$. This process, which is iterated until the last representation $\hat{\mathbf{\Gamma}}_K$ is acquired, is summarized in Algorithm 1.

One might ponder as to why does the application of the thresholding algorithm on the signal $\mathbf{X}$ not result in the true representation $\mathbf{\Gamma}_1$, but instead an approximation of it. As

Algorithm 1 The layered thresholding algorithm.

Input:

$\mathbf{X}$ – a signal.
$\{\mathbf{D}_i\}_{i=1}^K$ – convolutional dictionaries.
$\mathcal{P} \in \{\mathcal{H}, \mathcal{S}, \mathcal{S}^+\}$ – a thresholding operator.
$\{\beta_i\}_{i=1}^K$ – thresholds.

Output:

A set of representations $\{\hat{\mathbf{\Gamma}}_i\}_{i=1}^K$.

Process:

$\hat{\mathbf{\Gamma}}_0 \leftarrow \mathbf{X}$
for $i = 1 : K$ **do**
  $\hat{\mathbf{\Gamma}}_i \leftarrow \mathcal{P}_{\beta_i}(\mathbf{D}_i^T\hat{\mathbf{\Gamma}}_{i-1})$
end for

previously described in Section 2.2.1, assuming some conditions are met, the result of the thresholding algorithm, $\hat{\mathbf{\Gamma}}_1$, is guaranteed to have the correct support. In order to obtain the vector $\mathbf{\Gamma}_1$ itself, one should project the signal $\mathbf{X}$ onto this obtained support, by solving a Least-Squares problem. For reasons that will become clear shortly, we choose not to employ this step in the layered thresholding algorithm. Despite this algorithm failing in recovering the exact representations in the noiseless setting, as we shall see in Section 5, the estimated sparse vectors and the true ones are close – indicating the stability of this simple algorithm.

Thus far, we have assumed a noiseless setting. However, the same layered thresholding algorithm could be employed for the recovery of the representations of a noisy signal $\mathbf{Y} = \mathbf{X} + \mathbf{E}$, with the exception that the threshold constants, $\{\beta_i\}_{i=1}^K$, would be different and proportional to the noise level.

Assuming two layers for simplicity, Algorithm 1 can be summarized in the following equation

$$\hat{\mathbf{\Gamma}}_2 = \mathcal{P}_{\beta_2}\Big(\ \mathbf{D}_2^T\mathcal{P}_{\beta_1}\left(\ \mathbf{D}_1^T\mathbf{X}\ \right)\ \Big).$$

Comparing the above with Equation (1), given by

$$f(\mathbf{X}, \{\mathbf{W}_i\}_{i=1}^2, \{\mathbf{b}_i\}_{i=1}^2) = \text{ReLU}\Big(\ \mathbf{W}_2^T\ \text{ReLU}\left(\ \mathbf{W}_1^T\mathbf{X} + \mathbf{b}_1\ \right) + \mathbf{b}_2\ \Big),$$

one can notice a striking similarity between the two. Moreover, by replacing $\mathcal{P}_\beta(\cdot)$ with the soft nonnegative thresholding, $\mathcal{S}_\beta^+(\cdot)$, we obtain that *the aforementioned pursuit and the forward pass of the CNN are equal*! Notice that we are relying here on the discussion of Section 2.2.2, where we have shown that the ReLU and the soft nonnegative thresholding are equal[4].

4. A slight difference does exist between the soft nonnegative layered thresholding algorithm and the forward pass of the CNN. While in the former a constant threshold β is employed for all entries, the latter uses a bias vector, $\mathbf{b}$, that might not be constant in all of its entries. This is of little significance, however, since a similar approach of an entry-based constant could be used in the layered thresholding algorithm as well.

Recall the optimization problem of the training stage of the CNN as shown in Equation (2), given by

$$\min_{\{\mathbf{W}_i\}_{i=1}^K,\{\mathbf{b}_i\}_{i=1}^K,\mathbf{U}} \sum_j \ell\Big(h(\mathbf{X}_j),\mathbf{U},f\left(\mathbf{X}_j,\{\mathbf{W}_i\}_{i=1}^K,\{\mathbf{b}_i\}_{i=1}^K\right)\Big),$$

and its parallel in the ML-CSC model, the DLP$_{\boldsymbol{\lambda}}$ problem, defined by

$$\min_{\{\mathbf{D}_i\}_{i=1}^K,\mathbf{U}} \sum_j \ell\Big(h(\mathbf{X}_j),\mathbf{U},\mathrm{DCP}^\star_{\boldsymbol{\lambda}}(\mathbf{X}_j,\{\mathbf{D}_i\}_{i=1}^K)\Big).$$

Notice the remarkable similarity between both objectives, the only difference being in the feature vector on which the classification is done; in the CNN this is the output of the forward pass algorithm, given by $f\left(\mathbf{X}_j,\{\mathbf{W}_i\}_{i=1}^K,\{\mathbf{b}_i\}_{i=1}^K\right)$, while in the sparsity case this is the result of the DCP$_{\boldsymbol{\lambda}}$ problem. In light of the discussion above, the solution for the DCP$_{\boldsymbol{\lambda}}$ problem can be approximated using the layered thresholding algorithm, which is in turn equal to the forward pass of the CNN. We can therefore conclude that the problems solved by the training stage of the CNN and the DLP$_{\boldsymbol{\lambda}}$ are tightly connected, and in fact are equal once the solution for the DLP$_{\boldsymbol{\lambda}}$ is approximated via the layered thresholding algorithm (hence the name DLP$_{\boldsymbol{\lambda}}$).

5. Theoretical Study

Thus far, we have defined the ML-CSC model and its corresponding pursuits – the DCP$_{\boldsymbol{\lambda}}$ and DCP$^{\boldsymbol{\mathcal{E}}}_{\boldsymbol{\lambda}}$ problems. We have proposed a method to tackle them, coined the layered thresholding algorithm, which was shown to be equivalent to the forward pass of the CNN. Relying on this, we conclude that the proposed ML-CSC is the global Bayesian model implicitly imposed on the signal $\mathbf{X}$ when deploying the forward pass algorithm. Put differently, the ML-CSC answers the question of who are the signals belonging to the model behind the CNN. Having established the importance of our model, we now proceed to its theoretical analysis.

We should emphasize that the following study does not assume any specific form on the network's parameters, apart from a broad coherence property (as will be shown hereafter). This is in contrast to the work of (Bruna and Mallat, 2013) that assumes that the filters are Wavelets, or the analysis in (Giryes et al., 2015) that considers random weights.

5.1 Uniqueness of the DCP$_{\boldsymbol{\lambda}}$ Problem

Consider a signal $\mathbf{X}$ admitting a multi-layer convolutional sparse representation defined by the sets $\{\mathbf{D}_i\}_{i=1}^K$ and $\{\lambda_i\}_{i=1}^K$. Can another set of sparse vectors represent the signal $\mathbf{X}$? In other words, can we guarantee that, under some conditions, the set $\{\boldsymbol{\Gamma}_i\}_{i=1}^K$ is a unique solution to the DCP$_{\boldsymbol{\lambda}}$ problem? In the following theorem we provide an answer to this question.

Theorem 4 *(Uniqueness via the mutual coherence): Consider a signal* $\mathbf{X}$ *satisfying the DCP*$_{\boldsymbol{\lambda}}$ *model,*

$$\begin{aligned}\mathbf{X}&=\mathbf{D}_1\boldsymbol{\Gamma}_1\\ \boldsymbol{\Gamma}_1&=\mathbf{D}_2\boldsymbol{\Gamma}_2\\ &\vdots\\ \boldsymbol{\Gamma}_{K-1}&=\mathbf{D}_K\boldsymbol{\Gamma}_K,\end{aligned}$$

where $\{\mathbf{D}_i\}_{i=1}^K$ *is a set of convolutional dictionaries and* $\{\mu(\mathbf{D}_i)\}_{i=1}^K$ *are their corresponding mutual coherences. If*

$$\forall\ 1\le i\le K \qquad \|\boldsymbol{\Gamma}_i\|^{\mathbf{s}}_{0,\infty}<\frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_i)}\right),$$

then the set $\{\boldsymbol{\Gamma}_i\}_{i=1}^K$ *is the unique solution to the DCP*$_{\boldsymbol{\lambda}}$ *problem, assuming that the thresholds* $\{\lambda_i\}_{i=1}^K$ *are chosen to satisfy*

$$\forall\ 1\le i\le K \qquad \|\boldsymbol{\Gamma}_i\|^{\mathbf{s}}_{0,\infty}\le\lambda_i<\frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_i)}\right).$$

The proof for the above theorem is given in Appendix A. In what follows, we present its importance in the context of CNN. Assume a signal $\mathbf{X}$ is fed into a network, resulting in a set of activation values across the different layers. These, in the realm of sparsity, correspond to the set of sparse representations $\{\boldsymbol{\Gamma}_i\}_{i=1}^K$, which according to the above theorem are in fact unique representations of the signal $\mathbf{X}$.

One might ponder at this point whether there exists an algorithm for obtaining the unique solution guaranteed in this subsection for the DCP$_{\boldsymbol{\lambda}}$ problem. As previously mentioned, the layered thresholding algorithm is incapable of finding the exact representations, $\{\boldsymbol{\Gamma}_i\}_{i=1}^K$, due to the lack of a Least-Squares step after each layer. One should not despair, however, as we shall see in a following section an alternative algorithm, which manages to overcome this hurdle.

5.2 Global Stability of the DCP$^{\boldsymbol{\mathcal{E}}}_{\boldsymbol{\lambda}}$ Problem

Consider an instance signal $\mathbf{X}$ belonging to the ML-CSC model, defined by the sets $\{\mathbf{D}_i\}_{i=1}^K$ and $\{\lambda_i\}_{i=1}^K$. Assume $\mathbf{X}$ is contaminated by a noise vector $\mathbf{E}$, generating the perturbed signal $\mathbf{Y}=\mathbf{X}+\mathbf{E}$. Suppose we solve the DCP$^{\boldsymbol{\mathcal{E}}}_{\boldsymbol{\lambda}}$ problem and obtain a set of solutions $\{\hat{\boldsymbol{\Gamma}}_i\}_{i=1}^K$. How close is every solution in this set, $\hat{\boldsymbol{\Gamma}}_i$, to its corresponding true representation, $\boldsymbol{\Gamma}_i$? In what follows, we provide a theorem addressing this question of stability, the proof of which is deferred to Appendix B.

Theorem 5 *(Stability of the solution to the DCP*$^{\boldsymbol{\mathcal{E}}}_{\boldsymbol{\lambda}}$ *problem): Suppose a signal* $\mathbf{X}$ *that has a decomposition*

$$\begin{aligned}\mathbf{X}&=\mathbf{D}_1\boldsymbol{\Gamma}_1\\ \boldsymbol{\Gamma}_1&=\mathbf{D}_2\boldsymbol{\Gamma}_2\\ &\vdots\\ \boldsymbol{\Gamma}_{K-1}&=\mathbf{D}_K\boldsymbol{\Gamma}_K\end{aligned}$$

is contaminated with noise $\mathbf{E}$*, resulting in* $\mathbf{Y}=\mathbf{X}+\mathbf{E}$*. Assume we solve the DCP*$^{\boldsymbol{\mathcal{E}}}_{\boldsymbol{\lambda}}$ *problem for* $\mathcal{E}_0=\|\mathbf{E}\|_2$ *and* $\mathcal{E}_i=0 \quad \forall 1\leq i\leq K$*, obtaining a set of solutions* $\{\hat{\mathbf{\Gamma}}_i\}_{i=1}^K$*. If for all* $1\leq i\leq K$

$$\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{s}} \leq \lambda_i < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_i)}\right),$$

then

$$\|\mathbf{\Gamma}_i-\hat{\mathbf{\Gamma}}_i\|_2^2 \leq 4\|\mathbf{E}\|_2^2 \prod_{j=1}^{i}\frac{1}{1-(2\lambda_j-1)\mu(\mathbf{D}_j)}.$$

Intuitively, the above claims that as long as all the feature vectors $\{\mathbf{\Gamma}_i\}_{i=1}^K$ are $\ell_{0,\infty}$-sparse, then the representations obtained by solving the DCP$^{\boldsymbol{\mathcal{E}}}_{\boldsymbol{\lambda}}$ problem must be close to the true ones. Interestingly, the obtained bound increases as a function of the depth of the layer.

Is this necessarily the true behavior of a deep network? Perhaps the answer to this resides in the choice we made above of considering the noise as adversary. A similar, yet somewhat more involved, analysis with a random noise assumption should be done, with the hope to see a better controlled noise propagation in this system. We leave this for our future work.

Another important remark is that the above bounds the *absolute error* between the estimated and the true representation. In practice, however, the *relative error* is of more importance. This is measured in terms of the signal to noise ratio (SNR), which we shall define in Section 8.

Having established the stability of the DCP$^{\boldsymbol{\mathcal{E}}}_{\boldsymbol{\lambda}}$ problem, we now turn to the stability of the algorithms attempting to solve it, the chief one being the forward pass of CNN.

5.3 Stability of the Layered Hard Thresholding

Consider a signal $\mathbf{X}$ that admits a multi-layer convolutional sparse representation, which is defined by the sets $\{\mathbf{D}_i\}_{i=1}^K$ and $\{\lambda_i\}_{i=1}^K$. Assume we run the layered hard thresholding algorithm on $\mathbf{X}$, obtaining the sparse vectors $\{\hat{\mathbf{\Gamma}}_i\}_{i=1}^K$. Under certain conditions, can we guarantee that the estimate $\hat{\mathbf{\Gamma}}_i$ recovers the true support of $\mathbf{\Gamma}_i$? or that the norm of the difference between the two is bounded? Assume $\mathbf{X}$ is contaminated with a noise vector $\mathbf{E}$, resulting in the measurement $\mathbf{Y}=\mathbf{X}+\mathbf{E}$. Assume further that this signal is then fed to the layered thresholding algorithm, resulting in another set of representations. How do the answers to the above questions change? To tackle these, we commence by presenting a stability claim for the simple hard thresholding algorithm, relying on the $\ell_{0,\infty}$ norm. We should note that the analysis conducted in this subsection is for the noisy scenario, and the results for the noiseless case are simply obtained by setting the noise level to zero.

Next, we present a localized ℓ_2 and ℓ_0 measure of a global vector that will prove to be useful in the following analysis.

Definition 6 *Define the* $\|\cdot\|_{2,\infty}^{\mathbf{p}}$ *and* $\|\cdot\|_{0,\infty}^{\mathbf{p}}$ *norm of* $\mathbf{\Gamma}_i$ *to be*

$$\|\mathbf{\Gamma}_i\|_{2,\infty}^{\mathbf{p}} = \max_j \|\mathbf{P}_{i,j}\mathbf{\Gamma}_i\|_2$$

and

$$\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{p}} = \max_j \|\mathbf{P}_{i,j}\mathbf{\Gamma}_i\|_0,$$

respectively. The operator $\mathbf{P}_{i,j}$ *extracts the* j*-th patch of length* $n_i m_i$ *from the* i*-th sparse vector* $\mathbf{\Gamma}_i$*.*

In the above definition, the letter $\mathbf{p}$ emphasizes that the norms are computed by sweeping over all patches, rather than stripes. Recall that we have defined $m_0=1$, since the number of channels in the input signal $\mathbf{X}=\mathbf{\Gamma}_0$ is equal to one.

Given $\mathbf{Y}=\mathbf{X}+\mathbf{E}=\mathbf{D}_1\mathbf{\Gamma}_1+\mathbf{E}$, the first stage of the layered hard thresholding algorithm attempts to recover the representation $\mathbf{\Gamma}_1$. Intuitively, assuming that the underlying representation $\mathbf{\Gamma}_1$ is $\ell_{0,\infty}$-sparse, and that the energy of the noise $\mathbf{E}$ is $\ell_{2,\infty}$-bounded; we would expect that the simple hard thresholding algorithm would succeed in recovering a solution $\hat{\mathbf{\Gamma}}_1$, which is both close to $\mathbf{\Gamma}_1$ and has its support. We now present such a claim, the proof of which is found in Appendix C.

Lemma 7 *(Stable recovery of hard thresholding in the presence of noise): Suppose a clean signal* $\mathbf{X}$ *has a convolutional sparse representation* $\mathbf{D}_1\mathbf{\Gamma}_1$*, and that it is contaminated with noise* $\mathbf{E}$ *to create the signal* $\mathbf{Y}=\mathbf{X}+\mathbf{E}$*, such that* $\|\mathbf{E}\|_{2,\infty}^{\mathbf{p}}\leq\epsilon_0$*. Denote by* $|\Gamma_1^{min}|$ *and* $|\Gamma_1^{max}|$ *the lowest and highest entries in absolute value in* $\mathbf{\Gamma}_1$*, respectively. Denote further by* $\hat{\mathbf{\Gamma}}_1$ *the solution obtained by running the hard thresholding algorithm on* $\mathbf{Y}$ *with a constant* β_1*, i.e.* $\hat{\mathbf{\Gamma}}_1=\mathcal{H}_{\beta_1}(\mathbf{D}_1^T\mathbf{Y})$*. Assuming that*

a) $\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_1)}\frac{|\Gamma_1^{min}|}{|\Gamma_1^{max}|}\right)-\frac{1}{\mu(\mathbf{D}_1)}\frac{\epsilon_0}{|\Gamma_1^{max}|}$*; and*

b) The threshold β_1 *is chosen according to Equation* (14) *(see below),*

then the following must hold:

1. *The support of the solution* $\hat{\mathbf{\Gamma}}_1$ *is equal to that of* $\mathbf{\Gamma}_1$*; and*
2. $\|\mathbf{\Gamma}_1-\hat{\mathbf{\Gamma}}_1\|_{2,\infty}^{\mathbf{p}} \leq \sqrt{\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{p}}}\Big(\epsilon_0+\mu(\mathbf{D}_1)\left(\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}-1\right)|\Gamma_1^{max}|\Big)$.

Notice that by plugging $\epsilon_0=0$ the above theorem covers the noiseless scenario. Notably, even in such a case, we obtain a deviation from the true representation due to the lack of a Least-Squares step.

We suspect that, both in the noiseless and the noisy case, the obtained bound might be improved, based on the following observation. Given an $\ell_{2,\infty}$-norm bounded noise, the above proof first quantifies the deviation between the true representation and the estimated one in terms of the ℓ_∞ norm, and only then translates the latter into the $\ell_{2,\infty}$ sense. A direct analysis going from an $\ell_{2,\infty}$ input error to an $\ell_{2,\infty}$ output deviation (bypassing the ℓ_∞ norm) might lead to smaller deviations. We leave this for future work.

We now proceed to the next layer. Given $\hat{\mathbf{\Gamma}}_1$, which can be considered as a perturbed version of $\mathbf{\Gamma}_1$, the second stage of the layered hard thresholding algorithm attempts to recover the representation $\mathbf{\Gamma}_2$. Using the stability of the first layer – guaranteeing that $\mathbf{\Gamma}_1$ and $\hat{\mathbf{\Gamma}}_1$ are close in terms of the $\ell_{2,\infty}$ norm – and relying on the $\ell_{0,\infty}$-sparsity of $\mathbf{\Gamma}_2$, we show next that the second stage of the layered hard thresholding algorithm is stable as well. Applying the same rationale to all the remaining layers, we obtain the theorem below guaranteeing the stability of the complete layered hard thresholding algorithm.

Theorem 8 *(Stability of layered hard thresholding in the presence of noise): Suppose a clean signal* $\mathbf{X}$ *has a decomposition*

$$\begin{aligned}\mathbf{X} &= \mathbf{D}_1\mathbf{\Gamma}_1\\ \mathbf{\Gamma}_1 &= \mathbf{D}_2\mathbf{\Gamma}_2\\ &\vdots\\ \mathbf{\Gamma}_{K-1} &= \mathbf{D}_K\mathbf{\Gamma}_K,\end{aligned}$$

and that it is contaminated with noise $\mathbf{E}$ *to create the signal* $\mathbf{Y} = \mathbf{X}+\mathbf{E}$*, such that* $\|\mathbf{E}\|_{2,\infty}^{\mathbf{p}} \leq \epsilon_0$*. Denote by* $|\Gamma_i^{min}|$ *and* $|\Gamma_i^{max}|$ *the lowest and highest entries in absolute value in the vector* $\mathbf{\Gamma}_i$*, respectively. Let* $\{\hat{\mathbf{\Gamma}}_i\}_{i=1}^K$ *be the set of solutions obtained by running the layered hard thresholding algorithm with thresholds* $\{\beta_i\}_{i=1}^K$*, i.e.* $\hat{\mathbf{\Gamma}}_i = \mathcal{H}_{\beta_i}(\mathbf{D}_i^T\hat{\mathbf{\Gamma}}_{i-1})$ *where* $\hat{\mathbf{\Gamma}}_0 = \mathbf{Y}$*. Assuming that* $\forall\ 1 \leq i \leq K$

a) $\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1 + \frac{1}{\mu(\mathbf{D}_i)}\frac{|\Gamma_i^{min}|}{|\Gamma_i^{max}|}\right) - \frac{1}{\mu(\mathbf{D}_i)}\frac{\epsilon_{i-1}}{|\Gamma_i^{max}|}$*; and*

b) The threshold β_i *is chosen according to Equation* (19)*,*

then[5]

1. *The support of the solution* $\hat{\mathbf{\Gamma}}_i$ *is equal to that of* $\mathbf{\Gamma}_i$*; and*
2. $\|\mathbf{\Gamma}_i - \hat{\mathbf{\Gamma}}_i\|_{2,\infty}^{\mathbf{p}} \leq \epsilon_i$*,*

where $\epsilon_i = \sqrt{\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{p}}}\left(\epsilon_{i-1} + \mu(\mathbf{D}_i)\left(\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{s}} - 1\right)|\Gamma_i^{max}|\right)$*.*

The proof for the above is given in Appendix D. We now turn to an analogous theorem for the forward pass of the CNN, prior to discussing the surprising implications of these theorems.

5.4 Stability of the Forward Pass (Layered Soft Thresholding)

In light of the discussion in Section 4, the equivalence between the layered thresholding algorithm and the forward pass of the CNN is achieved assuming that the operator employed is the nonnegative soft thresholding $\mathcal{S}_\beta^+(\cdot)$. However, thus far, we have analyzed the closely related hard version $\mathcal{H}_\beta(\cdot)$ instead. In what follows, we show how the stability theorem presented in the previous subsection can be modified to the soft version, $\mathcal{S}_\beta(\cdot)$. For simplicity, and in order to stay in line with the vast sparse representation theory, herein we choose not to assume the nonnegative assumption. This implies that we are proposing a slightly different CNN architecture in which the ReLU function is two sided (Kavukcuoglu et al., 2010). We now move to the stable recovery of the soft thresholding algorithm.

5. Recall that $\|\mathbf{\Gamma}_i\|_{2,\infty}^{\mathbf{p}}$ is defined to be the maximal ℓ_2 norm of a patch extract from $\mathbf{\Gamma}_i$. The size of this patch is defined according to the dictionary $\mathbf{D}_{i+1}$. However, the last sparse vector $\mathbf{\Gamma}_K$ does not have a corresponding dictionary $\mathbf{D}_{K+1}$. As such, the size of a patch in $\mathbf{\Gamma}_K$ can be chosen arbitrarily. Where the choice of the size directly affects the bound on the difference, ϵ_i, due to the term $\sqrt{\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{p}}}$.

Lemma 9 *(Stable recovery of soft thresholding in the presence of noise): Suppose a clean signal* $\mathbf{X}$ *has a convolutional sparse representation* $\mathbf{D}_1\mathbf{\Gamma}_1$*, and that it is contaminated with noise* $\mathbf{E}$ *to create the signal* $\mathbf{Y} = \mathbf{X} + \mathbf{E}$*, such that* $\|\mathbf{E}\|_{2,\infty}^{\mathbf{p}} \leq \epsilon_0$*. Denote by* $|\Gamma_1^{min}|$ *and* $|\Gamma_1^{max}|$ *the lowest and highest entries in absolute value in* $\mathbf{\Gamma}_1$*, respectively. Denote further by* $\hat{\mathbf{\Gamma}}_1$ *the solution obtained by running the soft thresholding algorithm on* $\mathbf{Y}$ *with a constant* β_1*, i.e.* $\hat{\mathbf{\Gamma}}_1 = \mathcal{S}_{\beta_1}(\mathbf{D}_1^T\mathbf{Y})$*. Assuming that*

a) $\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1 + \frac{1}{\mu(\mathbf{D}_1)}\frac{|\Gamma_1^{min}|}{|\Gamma_1^{max}|}\right) - \frac{1}{\mu(\mathbf{D}_1)}\frac{\epsilon_0}{|\Gamma_1^{max}|}$*; and*

b) The threshold β_1 *is chosen according to Equation* (14)*,*

then the following must hold:

1. *The support of the solution* $\hat{\mathbf{\Gamma}}_1$ *is equal to that of* $\mathbf{\Gamma}_1$*; and*
2. $\|\mathbf{\Gamma}_1 - \hat{\mathbf{\Gamma}}_1\|_{2,\infty}^{\mathbf{p}} \leq \sqrt{\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{p}}}\left(\epsilon_0 + \mu(\mathbf{D}_1)\left(\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}} - 1\right)|\Gamma_1^{max}| + \beta_1\right)$*.*

Armed with the above lemma, which is proven in Appendix E, we now proceed to the stability of the forward pass of the CNN.

Theorem 10 *(Stability of the forward pass (layered soft thresholding algorithm) in the presence of noise): Suppose a clean signal* $\mathbf{X}$ *has a decomposition*

$$\begin{aligned}\mathbf{X} &= \mathbf{D}_1\mathbf{\Gamma}_1\\ \mathbf{\Gamma}_1 &= \mathbf{D}_2\mathbf{\Gamma}_2\\ &\vdots\\ \mathbf{\Gamma}_{K-1} &= \mathbf{D}_K\mathbf{\Gamma}_K,\end{aligned}$$

and that it is contaminated with noise $\mathbf{E}$ *to create the signal* $\mathbf{Y} = \mathbf{X}+\mathbf{E}$*, such that* $\|\mathbf{E}\|_{2,\infty}^{\mathbf{p}} \leq \epsilon_0$*. Denote by* $|\Gamma_i^{min}|$ *and* $|\Gamma_i^{max}|$ *the lowest and highest entries in absolute value in the vector* $\mathbf{\Gamma}_i$*, respectively. Let* $\{\hat{\mathbf{\Gamma}}_i\}_{i=1}^K$ *be the set of solutions obtained by running the layered soft thresholding algorithm with thresholds* $\{\beta_i\}_{i=1}^K$*, i.e.* $\hat{\mathbf{\Gamma}}_i = \mathcal{S}_{\beta_i}(\mathbf{D}_i^T\hat{\mathbf{\Gamma}}_{i-1})$ *where* $\hat{\mathbf{\Gamma}}_0 = \mathbf{Y}$*. Assuming that* $\forall\ 1 \leq i \leq K$

a) $\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1 + \frac{1}{\mu(\mathbf{D}_i)}\frac{|\Gamma_i^{min}|}{|\Gamma_i^{max}|}\right) - \frac{1}{\mu(\mathbf{D}_i)}\frac{\epsilon_{i-1}}{|\Gamma_i^{max}|}$*; and*

b) The threshold β_i *is chosen according to Equation* (19) *(with the* ϵ_i *defined below),*

then

1. *The support of the solution* $\hat{\mathbf{\Gamma}}_i$ *is equal to that of* $\mathbf{\Gamma}_i$*; and*
2. $\|\mathbf{\Gamma}_i - \hat{\mathbf{\Gamma}}_i\|_{2,\infty}^{\mathbf{p}} \leq \epsilon_i$*,*

where $\epsilon_i = \sqrt{\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{p}}}\left(\epsilon_{i-1} + \mu(\mathbf{D}_i)\left(\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{s}} - 1\right)|\Gamma_i^{max}| + \beta_i\right)$*.*

The proof for the above is omitted since it is tantamount to that of Theorem 8. As one can see, the layered soft thresholding algorithm is in fact inferior to its hard variant due to the added constant of β_i in the local error level, ϵ_i. This results in a more strict assumption on the $\ell_{0,\infty}$ norm of the various representations and also augments the bound on the distance between the true sparse vector and the one recovered. Following this observation, a natural question arises; why does the deep learning community employ the ReLU, which corresponds to a soft nonnegative thresholding operator instead of another nonlinearity that is more similar to its hard counterpart? One possible explanation could be that the filter training stage of the CNN becomes harder when the ReLU is replaced with a non-convex alternative, which also has discontinuities, such as the hard thresholding operator.

The above theorem guarantees that the distances between the original representations and the ones obtained from the CNN are bounded. Even if we set $\epsilon_0 = 0$, the recovered activations deviate from the true ones, simply because the layered thresholding algorithm does not do a perfect job, even on a noiseless signal. When the signal is noisy, these deviations are strengthened, but still in a controlled way.

This, by itself, might not be surprising. After all, the CNN is a deterministic system of linear operations (convolutions), followed by simple non-linearities that are non-expanding. If we feed a slightly perturbed signal to such a system, it is clear that the activations all along the network will be perturbed as well with a bounded effect. However, the above theorem shows far more than that. There are, in fact, two types of stabilities, the trivial one that considers the sensitivity of the whole feed-forward network to perturbations in its input, and the more intricate one that shows that this system enables a rather accurate recovery of the **generating representations**. The second option is the stability we prove here.

5.5 Guarantees for Fully Connected Networks

One should note that the convolutional structure imposed on the dictionaries in our model could be removed, and the theoretical guarantees we have provided above would still hold. The reason being is that the unconstrained dictionary can be regarded as a convolutional one, constructed from a single shift of a local matrix with no circular boundary. In the context of CNN, this is analogous to a fully connected layer. As such, the theoretical analysis provided here sheds light on both convolutional and fully connected networks. A different point of view on the same matter can also be proposed; fully connected layers can be viewed as convolutional ones with filters that cover their entire input (Long et al., 2015).

5.6 Worst-Case Analysis

The proposed analysis takes a worst-case point of view, where the noise is adversary (rather than random), the number of nonzeros in each stripe is maximal and the characteristics of the dictionaries are simple. Specifically, the success and stability guarantees are given in terms of the mutual coherences of the dictionaries. In classic sparse theory it is known that this measure is pessimistic. Still, it is widely used in proving guarantees for sparse representations, perhaps because it is simple and intuitive to grasp.

Sharper bounds, relying on stronger characterizations of the dictionary, result in significantly harder analysis. One example for a different characterization is that of the average mutual coherence – defined to be the average correlation in absolute value between two distinct atoms taken from the dictionary (instead of the highest correlation, as measured by the original mutual coherence). From a theoretical point of view, this measure was shown to lead to better theoretical guarantees in classic sparse theory (Bajwa et al., 2012). In addition, from a practical point of view, it was proven beneficial penalizing over this quantity in compressed sensing applications (Elad, 2007).

Our analysis did not rely on the average mutual coherence, but rather on the maximal coherence. Still, the two are closely related, and following the discussion above we believe that this might predict better the performance of CNN in practice. Interestingly, the work of (Shang, 2015) measured the average mutual coherences of the different layers in the "all-conv" network, which was trained on the ImageNet dataset (Springenberg et al., 2014). The authors found that most layers have a low average mutual coherence.

6. Layered Basis Pursuit

The stability analysis presented above unveils two significant limitations of the forward pass of the CNN. First, this algorithm is incapable of recovering the unique solution for the $\text{DCP}_{\boldsymbol{\lambda}}$ problem, the existence of which is guaranteed from Theorem 4. This acts against our expectations, since in the traditional sparsity inspired model it is a well known fact that such a unique representation can be retrieved, assuming certain conditions are met.

The second issue is with the condition for the successful recovery of the true support. The $\ell_{0,\infty}$ norm of the true solution, $\boldsymbol{\Gamma}_i$, is required to be less than an expression that depends on the term $|\Gamma_i^{\min}|/|\Gamma_i^{\max}|$. The dependence on this ratio is a direct consequence of the forward pass algorithm relying on the simple thresholding operator that is known for having such a theoretical limitation[6]. However, alternative pursuits whose success would not depend on this ratio could be proposed, as indeed was done in the Sparse-Land model; resulting in both theoretical and practical benefits.

A solution for the first problem, already presented throughout this work, is a two-stage approach. First, run the thresholding operator in order to recover the correct support. Then, once the atoms are chosen, their corresponding coefficients can be obtained by solving a linear system of equations. In addition to retrieving the true representation in the noiseless case, this step can also be beneficial in the noisy scenario, resulting in a solution closer to the underlying one. However, since no such step exists in current CNN architectures, we refrain from further analyzing its theoretical implications.

Next, we present an alternative to the layered soft thresholding algorithm, which will tackle both of the aforementioned problems. Recall that the result of the soft thresholding is a simple approximation of the solution for the P_1 problem, previously defined in Equation (4). In every layer, instead of applying a simple thresholding operator that estimates the sparse vector by computing $\hat{\boldsymbol{\Gamma}}_i = \mathcal{S}_{\beta_i}(\mathbf{D}_i^T \hat{\boldsymbol{\Gamma}}_{i-1})$; we propose to tackle the full pursuit, i.e. to

6. The dependence on the ratio is also a direct consequence of assuming a worst-case analysis. Perhaps in reality this ratio does not play such a critical role.

minimize

$$\hat{\mathbf{\Gamma}}_i = \arg\min_{\mathbf{\Gamma}_i} \|\mathbf{\Gamma}_i\|_1 \quad \text{s.t.} \quad \hat{\mathbf{\Gamma}}_{i-1} = \mathbf{D}_i\mathbf{\Gamma}_i. \tag{7}$$

Notice that one could readily obtain the nonnegative sparse coding problem by simply adding an extra constraint in the above equation, forcing the coefficients in $\mathbf{\Gamma}_i$ to be nonnegative. More generally, Equation (7) can be written in its Lagrangian formulation

$$\hat{\mathbf{\Gamma}}_i = \arg\min_{\mathbf{\Gamma}_i} \xi_i\|\mathbf{\Gamma}_i\|_1 + \frac{1}{2}\|\mathbf{D}_i\mathbf{\Gamma}_i - \hat{\mathbf{\Gamma}}_{i-1}\|_2^2, \tag{8}$$

where the constant ξ_i is proportional to the noise level and should tend to zero in the noiseless scenario. We name the above the *layered basis pursuit* (BP) algorithm. In practice, one possible method for solving it is the iterative soft thresholding (IST). Formally, this obtains the minimizer of Equation (8) by repeating the following recursive formula

$$\hat{\mathbf{\Gamma}}_i^t = \mathcal{S}_{\xi_i/c_i}\left(\hat{\mathbf{\Gamma}}_i^{t-1} + \frac{1}{c_i}\mathbf{D}_i^T\left(\hat{\mathbf{\Gamma}}_{i-1} - \mathbf{D}_i\hat{\mathbf{\Gamma}}_i^{t-1}\right)\right), \tag{9}$$

where $\hat{\mathbf{\Gamma}}_i^t$ is the estimate of $\mathbf{\Gamma}_i$ at iteration t. The above can be interpreted as a simple projected gradient descent algorithm, where the constant c_i is inversely proportional to its step size. As a result, if c_i is chosen to be large enough[7], the above algorithm is guaranteed to converge to its global minimum that is the solution of (8), as was shown in (Daubechies et al., 2004). The method obtained by gradually computing the set of sparse representations, $\{\mathbf{\Gamma}_i\}_{i=1}^K$, via the IST is summarized in Algorithm 2 and named *layered iterative soft thresholding*. Notice that this algorithm coincides with the simple layered soft thresholding if it is run for a single iteration with $c_i = 1$ and initialized with $\hat{\mathbf{\Gamma}}_i^0 = \mathbf{0}$. This implies that the above algorithm is a natural extension to the forward pass of the CNN. Moreover, the above is similar to the approach taken in the work of deconvolutional networks (Zeiler et al., 2010), where the authors suggested to solve a sequence of BP problems across different layers of abstraction.

With respect to the computational aspects of the IST algorithm, the work of (Gregor and LeCun, 2010) proposed the LISTA method, showing how the number of iterations required by the IST to convergence can be reduced using neural networks. Later, (Giryes et al., 2016) proved the theoretical justification for this algorithm, and (Sprechmann et al., 2015) extended LISTA to other sparse and low-rank problems. Analogously, the work of (Xin et al., 2016) presented a generalization for the iterative hard thresholding (IHT), which was shown to be both theoretically and empirically superior to the original IHT.

The original motivation for the layered IST was its theoretical superiority over the forward pass algorithm – one that will be explored in detail in the next subsection. Yet more can be said about this algorithm and the CNN architecture it induces. In (Gregor and LeCun, 2010) it was shown that the IST algorithm can be formulated as a simple recurrent neural network. As such, the same can be said regarding the layered IST algorithm proposed here, with the exception that the induced recurrent network is much deeper. The reader can

7. The constant c_i should satisfy $c_i > 0.5\lambda_{\max}\left(\mathbf{D}_i^T\mathbf{D}_i\right)$, where $\lambda_{\max}\left(\mathbf{D}_i^T\mathbf{D}_i\right)$ is the maximal eigenvalue of the gram matrix $\mathbf{D}_i^T\mathbf{D}_i$ (Combettes and Wajs, 2005).

Algorithm 2 The layered iterative soft thresholding algorithm.

Input:

$\mathbf{X}$ – a signal.
$\{\mathbf{D}_i\}_{i=1}^K$ – convolutional dictionaries.
$\mathcal{P} \in \{\mathcal{S}, \mathcal{S}^+\}$ – a soft thresholding operator.
$\{\xi_i\}_{i=1}^K$ – Lagrangian parameters.
$\{1/c_i\}_{i=1}^K$ – step sizes.
$\{T_i\}_{i=1}^K$ – number of iterations.

Output:

A set of representations $\{\hat{\mathbf{\Gamma}}_i\}_{i=1}^K$.

Process:

$\hat{\mathbf{\Gamma}}_0 \leftarrow \mathbf{X}$
for $i = 1 : K$ **do**
  $\hat{\mathbf{\Gamma}}_i^0 \leftarrow \mathbf{0}$
  for $t = 1 : T_i$ **do**
    $\hat{\mathbf{\Gamma}}_i^t \leftarrow \mathcal{P}_{\xi_i/c_i}\left(\hat{\mathbf{\Gamma}}_i^{t-1} + \frac{1}{c_i}\mathbf{D}_i^T\left(\hat{\mathbf{\Gamma}}_{i-1} - \mathbf{D}_i\hat{\mathbf{\Gamma}}_i^{t-1}\right)\right)$
  end for
  $\hat{\mathbf{\Gamma}}_i \leftarrow \hat{\mathbf{\Gamma}}_i^{T_i}$
end for

therefore interpret this part of the work as a theoretical study of a special case of recurrent neural networks.

From another perspective, the underlying architecture of the layered IST algorithm is a cascade of K blocks. Each of these corresponds to a fixed number of unfolded iterations, T_i, of a single IST algorithm. These unfolded iterations attempt to estimate better the representation after the initial thresholding operator. Practically, this can be implemented using several convolutional layers with shared weights, as well as skip connections in order to compute the residual, $\hat{\mathbf{\Gamma}}_{i-1} - \mathbf{D}_i\hat{\mathbf{\Gamma}}_i^{t-1}$, as defined in Equation (9). Interestingly, the above description is reminiscent of residual networks (He et al., 2015), which have recently led to state-of-the-art results in image recognition. The authors of (Greff et al., 2016) propose a similar viewpoint of residual networks, based on unrolled iterative estimation. Similar to the above discussion, they claim that a group of successive layers iteratively refine estimates of the same features instead of computing an entirely new representation.

Since the submission of our work, the authors of (Sun et al., 2017) suggested an algorithm similar to the layered IST, showing promising results for the task of image recognition when compared to other conventional architectures.

6.1 Noiseless Case: Success of Layered BP Algorithm

In Section 5.1, we established the uniqueness of the solution for the DCP$_{\boldsymbol{\lambda}}$ problem, assuming that certain conditions on the $\ell_{0,\infty}$ norm of the underlying representations are met. However, as we have seen in the theoretical analysis of the previous section, the forward pass of the CNN is incapable of finding this unique solution; instead, it is guaranteed to

be close to it in terms of the $\ell_{2,\infty}$ norm. Herein, we address the question of whether the layered BP algorithm can prevail in a task where the forward pass did not.

Theorem 11 *(Layered BP recovery guarantee using the $\ell_{0,\infty}$ norm): Consider a signal $\mathbf{X}$,*

$$\begin{aligned}\mathbf{X} &= \mathbf{D}_1\mathbf{\Gamma}_1\\ \mathbf{\Gamma}_1 &= \mathbf{D}_2\mathbf{\Gamma}_2\\ &\vdots\\ \mathbf{\Gamma}_{K-1} &= \mathbf{D}_K\mathbf{\Gamma}_K,\end{aligned}$$

where $\{\mathbf{D}_i\}_{i=1}^K$ is a set of convolutional dictionaries and $\{\mu(\mathbf{D}_i)\}_{i=1}^K$ are their corresponding mutual coherences. Assuming that $\forall\ 1 \le i \le K$

$$\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_i)}\right)$$

then the layered BP algorithm is guaranteed to recover the set $\{\mathbf{\Gamma}_i\}_{i=1}^K$.

The proof for the above can be directly derived from the recovery condition of the BP using the $\ell_{0,\infty}$ norm, as presented in (Papyan et al., 2016a). The implications of this theorem are that the layered BP algorithm can indeed recover the unique solution to the $\text{DCP}_{\boldsymbol{\lambda}}$ problem.

6.2 Noisy Case: Stability of Layered BP Algorithm

Having established the guarantee for the success of the layered BP algorithm, we now move to its stability analysis. In particular, in a noisy scenario where obtaining the true underlying representations is impossible, does this algorithm remain stable? If so, how do its guarantees compare to those of the layered thresholding algorithm? The following theorem, which we prove in Appendix F, aims to answer these questions.

Theorem 12 *(Stability of the layered BP algorithm in the presence of noise): Suppose a clean signal $\mathbf{X}$ has a decomposition*

$$\begin{aligned}\mathbf{X} &= \mathbf{D}_1\mathbf{\Gamma}_1\\ \mathbf{\Gamma}_1 &= \mathbf{D}_2\mathbf{\Gamma}_2\\ &\vdots\\ \mathbf{\Gamma}_{K-1} &= \mathbf{D}_K\mathbf{\Gamma}_K,\end{aligned}$$

and that it is contaminated with noise $\mathbf{E}$ to create the signal $\mathbf{Y} = \mathbf{X}+\mathbf{E}$, such that $\|\mathbf{E}\|_{2,\infty}^{\mathbf{p}} \le \epsilon_0$. Let $\{\hat{\mathbf{\Gamma}}_i\}_{i=1}^K$ be the set of solutions obtained by running the layered BP algorithm with parameters $\{\xi_i\}_{i=1}^K$. Assuming that $\forall\ 1 \le i \le K$

a) $\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{s}} \le \frac{1}{3}\left(1+\frac{1}{\mu(\mathbf{D}_i)}\right)$*; and*

b) $\xi_i = 4\epsilon_{i-1}$,

then

1. *The support of the solution $\hat{\mathbf{\Gamma}}_i$ is contained in that of $\mathbf{\Gamma}_i$;*
2. *$\|\mathbf{\Gamma}_i - \hat{\mathbf{\Gamma}}_i\|_{2,\infty}^{\mathbf{p}} \le \epsilon_i$;*
3. *In particular, every entry of $\mathbf{\Gamma}_i$ greater in absolute value than $\frac{\epsilon_i}{\sqrt{\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{p}}}}$ is guaranteed to be recovered; and*
4. *The solution $\hat{\mathbf{\Gamma}}_i$ is the unique minimizer of the Lagrangian BP problem (Equation (8)),*

where $\epsilon_i = \|\mathbf{E}\|_{2,\infty}^{\mathbf{p}}\ 7.5^i\ \prod_{j=1}^i \sqrt{\|\mathbf{\Gamma}_j\|_{0,\infty}^{\mathbf{p}}}$.

Several remarks are due at this point. The condition for the stability of the layered thresholding algorithm, given by

$$\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_i)}\frac{|\Gamma_i^{\min}|}{|\Gamma_i^{\max}|}\right) - \frac{1}{\mu(\mathbf{D}_i)}\frac{\epsilon_{i-1}}{|\Gamma_i^{\max}|},$$

is expected to be more strict than that of the theorem presented above, which is

$$\|\mathbf{\Gamma}_i\|_{0,\infty}^{\mathbf{s}} < \frac{1}{3}\left(1+\frac{1}{\mu(\mathbf{D}_i)}\right).$$

In the case of the layered BP algorithm, the bound on the $\ell_{0,\infty}$ norm of the underlying sparse vectors does no longer depend on the ratio $|\Gamma_i^{\min}|/|\Gamma_i^{\max}|$ – a term present in all the theoretical results of the thresholding algorithm. Moreover, the $\ell_{0,\infty}$ norm becomes independent of the local noise level of the previous layers, thus allowing more non-zeros per stripe.

In addition, similar to the stability analysis presented in Section 5.2, the above shows the growth (as a function of the depth) of the distance between the recovered representations and the true ones.

7. A Closer Look at the Proposed Model

In this section, we revisit the assumptions of our model by imposing additional constraints on the dictionaries involved and showing their theoretical benefits. These additional assumptions originate from the current common practice of both CNN and sparsity.

7.1 When a Patch Becomes a Stripe

Throughout the analysis presented in this work, we have assumed that the representations in the different layers, $\{\mathbf{\Gamma}_i\}_{i=1}^K$, are $\ell_{0,\infty}$-sparse. Herein, we study the propagation of the $\ell_{0,\infty}$ norm throughout the layers of the network, showing how an assumption on the sparsity of the deepest representation $\mathbf{\Gamma}_K$ reflects on that of the remaining layers. The exact connection between the sparsities will be given in terms of a simple characterization of the dictionaries $\{\mathbf{D}_i\}_{i=1}^K$.

Consider the representation $\mathbf{\Gamma}_{K-1}$, given by

$$\mathbf{\Gamma}_{K-1} = \mathbf{D}_K \mathbf{\Gamma}_K,$$

where $\mathbf{\Gamma}_K$ is $\ell_{0,\infty}$-sparse. Following Figure 4, the i-th patch in $\mathbf{\Gamma}_{K-1}$ can be expressed as

$$\mathbf{P}_{K-1,i}\mathbf{\Gamma}_{K-1} = \mathbf{\Omega}_K \boldsymbol{\gamma}_{K,i},$$

where $\mathbf{\Omega}_K$ is the stripe-dictionary of $\mathbf{D}_K$, the vector $\mathbf{P}_{K-1,i}\mathbf{\Gamma}_{K-1}$ is the i-th patch in $\mathbf{\Gamma}_{K-1}$ and $\boldsymbol{\gamma}_{K,i}$ is its corresponding stripe. Recalling the definition of the $\|\cdot\|^{\mathbf{P}}_{0,\infty}$ norm (Definition 6 in Section 5.3), we have that

$$\|\mathbf{\Gamma}_{K-1}\|^{\mathbf{P}}_{0,\infty} = \max_i \|\mathbf{\Omega}_K \boldsymbol{\gamma}_{K,i}\|_0.$$

Consider the following definition.

Definition 13 *Define the induced ℓ_0 pseudo-norm of a dictionary $\mathbf{D}$, denoted by $\|\mathbf{D}\|_0$, to be the maximal number of non-zeros in any of its atoms*[8].

The multiplication $\mathbf{\Omega}_K \boldsymbol{\gamma}_{K,i}$ can be seen as a linear combination of at most $\|\boldsymbol{\gamma}_{K,i}\|_0$ atoms, each contributing no more than $\|\mathbf{\Omega}_K\|_0$ non-zeros. As such

$$\|\mathbf{\Gamma}_{K-1}\|^{\mathbf{P}}_{0,\infty} \leq \max_i \|\mathbf{\Omega}_K\|_0 \, \|\boldsymbol{\gamma}_{K,i}\|_0.$$

Noticing that $\|\mathbf{\Omega}_K\|_0 = \|\mathbf{D}_K\|_0$ (as can be seen in Figure 4), and using the definition of the $\|\cdot\|^{\mathbf{s}}_{0,\infty}$ norm, we conclude that

$$\|\mathbf{\Gamma}_{K-1}\|^{\mathbf{P}}_{0,\infty} \leq \|\mathbf{D}_K\|_0 \, \|\mathbf{\Gamma}_K\|^{\mathbf{s}}_{0,\infty}. \tag{10}$$

In other words, given $\|\mathbf{\Gamma}_K\|^{\mathbf{s}}_{0,\infty}$ and $\|\mathbf{D}_K\|_0$, we can bound the maximal number of non-zeros in a patch from $\mathbf{\Gamma}_{K-1}$.

The claims in Section 5 and 6 are given in terms of not only $\|\mathbf{\Gamma}_{K-1}\|^{\mathbf{P}}_{0,\infty}$, but also $\|\mathbf{\Gamma}_{K-1}\|^{\mathbf{s}}_{0,\infty}$. According to Table 1, the length of a patch in $\mathbf{\Gamma}_{K-1}$ is $n_{K-1}m_{K-1}$, while the size of a stripe is $(2n_{K-2}-1)m_{K-1}$. As such, we can fit $(2n_{K-2}-1)/n_{K-1}$ patches in a stripe. Assume for simplicity that this ratio is equal to one. As a result, we obtain that a patch in the *signal* $\mathbf{\Gamma}_{K-1}$ extracted from the system

$$\mathbf{\Gamma}_{K-1} = \mathbf{D}_K \mathbf{\Gamma}_K,$$

is also a stripe in the *representation* $\mathbf{\Gamma}_{K-1}$ when considering

$$\mathbf{\Gamma}_{K-2} = \mathbf{D}_{K-1}\mathbf{\Gamma}_{K-1},$$

hence the name of this subsection. Leveraging this assumption, we return to Equation (10) and obtain that

$$\|\mathbf{\Gamma}_{K-1}\|^{\mathbf{s}}_{0,\infty} = \|\mathbf{\Gamma}_{K-1}\|^{\mathbf{P}}_{0,\infty} \leq \|\mathbf{D}_K\|_0 \, \|\mathbf{\Gamma}_K\|^{\mathbf{s}}_{0,\infty}.$$

8. According to the definition of the induced norm $\|\mathbf{D}\|_0 = \max_{\mathbf{v}} \|\mathbf{D}\mathbf{v}\|_0$ s.t. $\|\mathbf{v}\|_0 = 1$. Since $\|\mathbf{v}\|_0 = 1$, the multiplication $\mathbf{D}\mathbf{v}$ is simply equal to one of the atoms in $\mathbf{D}$ times a scalar, and $\|\mathbf{D}\mathbf{v}\|_0$ counts the number of non-zeros in this atom. As a result, $\|\mathbf{D}\|_0$ is equal to the maximal number of non-zeros in any atom from $\mathbf{D}$.

Using the same rationale for the remaining layers, and assuming that once again the patches become stripes, we conclude that

$$\|\mathbf{\Gamma}_i\|^{\mathbf{s}}_{0,\infty} = \|\mathbf{\Gamma}_i\|^{\mathbf{P}}_{0,\infty} \leq \|\mathbf{\Gamma}_K\|^{\mathbf{s}}_{0,\infty} \prod_{j=i+1}^{K} \|\mathbf{D}_j\|_0. \tag{11}$$

We note that our assumption here of having sparse dictionaries is reasonable, since at the training stage of the CNN an ℓ_1 penalty is often imposed on the filters as a regularization, promoting their sparsity. The conclusion thus is that the $\ell_{0,\infty}$ norm is expected to decrease as a function of the depth of the representation. This aligns with the intuition that the higher the depth, the more abstraction one obtains in the filters, and thus the less non-zeros are required to represent the data. Taking this to the extreme, if every input signal could be represented via a single coefficient at the deepest layer, we would obtain that its $\ell_{0,\infty}$ norm is equal to one.

7.2 On the Role of the Spatial-Stride

A common step among practitioners of CNN (Krizhevsky et al., 2012; Simonyan and Zisserman, 2014; He et al., 2015) is to convolve the input to each layer with a set of filters, skipping a fixed number of spatial locations in a regular pattern. One of the primary motivations for this is to reduce the dimensions of the kernel maps throughout the layers, leading to **computational benefits**. In this subsection we unveil some **theoretical benefits** of this common practice, which we coin *spatial-stride*.

Following Figure 5, recall that $\mathbf{D}_i$ is a stride convolutional dictionary that skips m_{i-1} shifts at a time, which correspond to the number of channels in $\mathbf{\Gamma}_{i-1}$. Translating the spatial-stride to our language, the above mentioned works do not consider all spatial shifts of the filters in $\mathbf{D}_i$. Instead, a stride of $m_{i-1}s_{i-1}$ is employed, where m_{i-1} corresponds to the *channel-stride*, while s_{i-1} is due to the *spatial-stride*. The addition of the latter implies that instead of assuming that the i-th sparse vector satisfies $\mathbf{\Gamma}_{i-1} = \mathbf{D}_i\mathbf{\Gamma}_i$, we have that $\mathbf{Q}_{i-1}\mathbf{\Gamma}_{i-1} = \mathbf{D}_i\mathbf{Q}_i^T\mathbf{Q}_i\mathbf{\Gamma}_i$. We denote $\mathbf{Q}_i^T \in \mathbb{R}^{Nm_i \times Nm_i/s_{i-1}}$ as a columns' selection operator that chooses the atoms from $\mathbf{D}_i$ that align with the spatial-stride. The coefficients corresponding to these atoms are extracted from $\mathbf{\Gamma}_i$ (resulting in its subsampled version) via the $\mathbf{Q}_i$ matrix. In light of the above discussion, we modify the $\text{DCP}_{\boldsymbol{\lambda}}$ problem, as defined in Definition 1, into the following

$$\begin{aligned}
\text{find} \quad \{\mathbf{\Gamma}_i\}_{i=1}^K \qquad \text{s.t.} \qquad & \mathbf{X} = \mathbf{D}_1\mathbf{Q}_1^T\mathbf{Q}_1\mathbf{\Gamma}_1, && \|\mathbf{Q}_1\mathbf{\Gamma}_1\|^{\mathbf{s}}_{0,\infty} \leq \lambda_1 \\
& \mathbf{Q}_1\mathbf{\Gamma}_1 = \mathbf{D}_2\mathbf{Q}_2^T\mathbf{Q}_2\mathbf{\Gamma}_2, && \|\mathbf{Q}_2\mathbf{\Gamma}_2\|^{\mathbf{s}}_{0,\infty} \leq \lambda_2 \\
& \qquad\vdots && \qquad\vdots \\
& \mathbf{Q}_{K-1}\mathbf{\Gamma}_{K-1} = \mathbf{D}_K\mathbf{Q}_K^T\mathbf{Q}_K\mathbf{\Gamma}_K, && \|\mathbf{Q}_K\mathbf{\Gamma}_K\|^{\mathbf{s}}_{0,\infty} \leq \lambda_K.
\end{aligned}$$

Note that while the original $\|\mathbf{\Gamma}_i\|^{\mathbf{s}}_{0,\infty}$ is equal to the maximal number of non-zeros in a stripe of length $(2n_{i-1}-1)m_i$ in $\mathbf{\Gamma}_i$, the term $\|\mathbf{Q}_i\mathbf{\Gamma}_i\|^{\mathbf{s}}_{0,\infty}$ counts the same quantity but for stripes of length $(2\lceil n_{i-1}/s_{i-1}\rceil - 1)m_i$ in $\mathbf{Q}_i\mathbf{\Gamma}_i$.

According to the study in Section 5 and 6, the theoretical advantage of the spatial-stride is twofold. First, consider the mutual coherence of the stride convolutional dictionary $\mathbf{D}_i$.

Due to the locality of the filters and their restriction to certain spatial shifts, the mutual coherence of $\mathbf{D}_i\mathbf{Q}_i^T$ is expected to be lower than that of $\mathbf{D}_i$, thus leading to more non-zeros allowed per stripe. Second, the length of a stripe in $\mathbf{Q}_i\mathbf{\Gamma}_i$ is equal to $(2\lceil n_{i-1}/s_{i-1}\rceil - 1)m_i$, while that of $\mathbf{\Gamma}_i$ is $(2n_{i-1}-1)m_i$. As such, our analysis allows a larger number of non-zeros per a smaller-sized stripe. From another perspective, notice that imposing a spatial-stride on the dictionary $\mathbf{D}_i$ is equivalent to forcing a portion of the entries in $\mathbf{\Gamma}_i$ to be zero. As such, the spatial-stride encourages sparser solutions.

8. Experiments: The Generator Behind the CNN

Consider the following question: can we synthesize signals obeying the ML-CSC model? Throughout this work we have posited that the answer to this question is positive; we have assumed the existence of a set of signals $\mathbf{X}$, which satisfy $\forall i\ \mathbf{\Gamma}_i = \mathbf{D}_{i+1}\mathbf{\Gamma}_{i+1}$ where $\{\mathbf{\Gamma}_i\}_{i=1}^K$ are all $\ell_{0,\infty}$ bounded. However, a natural question arises as to whether we can give a simple example of set of dictionaries $\{\mathbf{D}_i\}_{i=1}^K$ and their corresponding signals $\mathbf{X}$ that indeed satisfy our model assumptions.

A naïve attempt would be to choose an arbitrary set of dictionaries, $\{\mathbf{D}_i\}_{i=1}^K$, and a random deepest representation, $\mathbf{\Gamma}_K$, and compute the remaining sparse vectors (and the signal itself) using the set of relations $\mathbf{\Gamma}_i = \mathbf{D}_{i+1}\mathbf{\Gamma}_{i+1}$. However, without further restrictions, this would lead to a set of representations $\{\mathbf{\Gamma}_i\}_{i=1}^K$ with growing $\ell_{0,\infty}$ norm as we propagate towards $\mathbf{\Gamma}_0$. A somewhat better approach would be to impose sparsity on the dictionaries involved, as suggested in Section 7.1, thus leading to sparser representations. However, besides the obvious drawback of forcing a limiting structure on the dictionaries, as can be seen in Equation (11), in the worst case this would also lead to growth in the density of the representations, even if it is more controlled. The spatial-stride – at first glance unrelated to this discussion – is another solution that addresses the same problem. In particular, in Section 7.2 this idea was shown to encourage sparser vectors by forcing zeros in a regular pattern in the set of representations $\{\mathbf{\Gamma}_i\}_{i=1}^K$.

In this section we combine the above notions in order to achieve our goal – generate a set of signals that will satisfy the ML-CSC assumptions. These will then serve as a playground for several experiments, which will compare both theoretically and practically the different pursuits presented in this paper.

8.1 Designing the Dictionaries

We commence by describing the design of the dictionaries, and in the next subsection continue to the actual generation of the signals. In our experiments, the signal is one dimensional and therefore $m_0 = 1$. Moreover, for simplicity, the dictionary in every layer contains a single atom with its shifts and thus $m_i = 1\ \forall 1 \le i \le K$. We should note that the choice of a single atom simplifies the involved pursuit problem, but as we will see, even in such a case the suggested layered pursuits (including the forward pass) may fail. This is because the mutual coherence and the amount of non-zeros are still non-trivial.

In the first layer we choose this filter to be the analytically defined discrete Meyer Wavelet of length $n_0 = 29$. In order to obtain sparser representations and improve the coherence of the global dictionary $\mathbf{D}_1$, we employ a stride of $s_0 = 6$, resulting in $\mu(\mathbf{D}_1) = 2.44 \times 10^{-4}$. As a consequence of our choice of $\mathbf{D}_1$, the signals resulting from our model

are a superposition of shifted versions of discrete Meyer Wavelets, multiplied by different coefficients.

Recall that in the context of the layered thresholding algorithm, our theoretical study has shown that the stability of the pursuit depends on the ratio $|\Gamma_i^{\min}|/|\Gamma_i^{\max}|$. As such, in addition to requiring $\mu(\mathbf{D}_i)$ to be small, we would also like the ratio $|\Gamma_i^{\min}|/|\Gamma_i^{\max}|$ to be as close as possible to one. Since the sparse vectors satisfy $\mathbf{\Gamma}_i = \mathbf{D}_{i+1}\mathbf{\Gamma}_{i+1}\ \forall 1 \le i \le K-1$, one can control this ratio by forcing the entries in the dictionaries $\{\mathbf{D}_i\}_{i=2}^K$ to be[9] discrete[10]. Following this observation, and motivated by the benefits of a sparse dictionary, we generate a filter of length 20 with 7 non-zero entries belonging to the set $\{-8,-7,...,7,8\}$ (these are the entries before the atom is normalized to a unit ℓ_2 norm). In practice, this is done by sampling random vectors satisfying these constraints and choosing one resulting in a good mutual coherence. For simplicity, all $\{\mathbf{D}_i\}_{i=2}^K$ are created from the very same local atom, i.e. $n_i = 20\ \forall 1 \le i \le K-1$. Moreover, in all the dictionaries this atom is shifted by a stride of $s_i = 6$, leading to $\mu(\mathbf{D}_i) = 4.33 \times 10^{-3}$. Note that in the above description the specific number of layers K was purposely omitted, as this number will vary in the following experiments.

8.2 Noiseless Experiments

We now move to the task of sampling a signal when the number of layers is $K = 3$. First, we draw a random $\mathbf{\Gamma}_3$ of length 100 with an ℓ_0 norm in the range $[20, 66]$ and set each non-zero coefficient in it to ± 1, with equal probability. Given the dictionaries and the sampled sparse vector $\mathbf{\Gamma}_3$, we then compute the representations $\mathbf{\Gamma}_2$, $\mathbf{\Gamma}_1$ and the signal $\mathbf{X}$, which are of length 600, 3,600 and $N = 21{,}600$, respectively. The obtained sparse vectors satisfy $\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}} = 8$, $5 \le \|\mathbf{\Gamma}_2\|_{0,\infty}^{\mathbf{s}} \le 6$ and $3 \le \|\mathbf{\Gamma}_3\|_{0,\infty}^{\mathbf{s}} \le 7$.

Given the signals, we attempt to retrieve their underlying representations using the layered pursuits presented in this work. Recall that our analysis in Section 5 and 6 indicates that the layered hard thresholding is superior to its soft counterpart, which is equivalent to the forward pass, and that the layered BP is even better than both of these algorithms. We now turn to asserting this claim empirically. While doing so, we aim to study the gap between the theoretical guarantees presented throughout our paper and the empirical performance obtained in practice.

For every signal $\mathbf{X}$ (termed *realization* below), we employ the layered hard thresholding algorithm. The thresholds are set to be the ones presented in Theorem 8, since the $\ell_{0,\infty}$ norms of the representations of each $\mathbf{X}$ satisfy the assumptions of this theorem. Given the estimated sparse vectors $\{\hat{\mathbf{\Gamma}}_i\}_{i=1}^3$, we then compute the errors $\|\hat{\mathbf{\Gamma}}_i - \mathbf{\Gamma}_i\|_{2,\infty}^{\mathbf{p}}$ and compare these to the theoretical bounds. While doing so, we also verify that the correct support is indeed retrieved, as our theorem guarantees. Next, the same process is repeated for the

9. Note that we do not force the entries in $\mathbf{D}_1$ to be discrete since $\mathbf{X} = \mathbf{D}_1\mathbf{\Gamma}_1$ and the ratio of the entries in $\mathbf{X}$ is of no significance to the success of the layered thresholding algorithms.

10. In our experiments, the non-zero entries in the deepest representation $\mathbf{\Gamma}_K$ are chosen to be ± 1. As such, the sparse vector $\mathbf{\Gamma}_{K-1} = \mathbf{D}_K\mathbf{\Gamma}_K$ is a superposition of filters (or their negative) taken from the dictionary $\mathbf{D}_K$. If the entries in $\mathbf{D}_K$ are non-discrete then the summation of two filters can result in extremely small values in $\mathbf{\Gamma}_{K-1}$, which in turn would lead to a very small $|\Gamma_{K-1}^{\min}|$ and a bad ratio. On the other hand, if the atoms are chosen to be discrete, this would not happen since the entries would simply cancel each other.

layered soft thresholding algorithm, with the exception that the thresholds and the bound on the distance are computed according to Theorem 10. We note that the assumptions of this hold as well for every signal $\mathbf{X}$. The results for both algorithms are depicted in Figure 6 in terms of the local signal to noise ratio (SNR), defined as $20\log 10\Big(\frac{\|\mathbf{\Gamma}_i\|_{2,\infty}^{\mathbf{P}}}{\|\hat{\mathbf{\Gamma}}_i-\mathbf{\Gamma}_i\|_{2,\infty}^{\mathbf{P}}}\Big)$. Due to the locality of the analysis, we choose to deviate from the classical definition of the (global) SNR, given by $20\log 10\left(\frac{\|\mathbf{\Gamma}_i\|_2}{\|\hat{\mathbf{\Gamma}}_i-\mathbf{\Gamma}_i\|_2}\right)$.

Several remarks are due here. First and foremost, the theoretical bounds indeed hold, since the blue points are above their corresponding green ones and the correct supports are always recovered. Second, our analysis predicts that the distance between the estimated sparse representation, $\hat{\mathbf{\Gamma}}_i$, and the true ones, $\mathbf{\Gamma}_i$, should increase with the layer. This is evident by the decrease in the values of the green points with the layers. The empirical results presented here (blue dots) corroborate this prognosis, as the error in both algorithms is lowest in the first layer and highest in the last[11]. Third, our analysis suggests that the layered hard thresholding algorithm should be superior to its soft counterpart. Once again, this can be deduced from the figure by comparing the values of the green points in both of the algorithms. The empirical results presented in Figure 6 confirm this behavior, as can be clearly seen by comparing the errors (blue points) obtained by both algorithms in the i-th layer. One should note that the performance gap exhibited here is due to the constant β_i being subtracted from every entry in the soft thresholding algorithm.

The implications of the above discussion might be troubling in the context of CNN, as what this experiment shows is a deterioration of the **empirical** SNR throughout the layers of the network. Is this truly the behavior of CNN? Recall that in practice the biases of the different layers (thresholds) are learned in order to achieve the best possible performance in solving a certain task. As such, it might be possible that the decline in SNR presented here is alleviated when better thresholds are employed in lieu of the theoretical ones used thus far. We demonstrate this by running the layered soft thresholding algorithm with an oracle parameter, chosen to be the minimal threshold that leads to $\|\mathbf{\Gamma}_i\|_0$ non-zeros being chosen in the estimated sparse representation $\hat{\mathbf{\Gamma}}_i$. The results for this are presented in Figure 6 and colored in red. Indeed, we observe that this better choice of parameters improves the empirical performance of the layered soft thresholding algorithm and leads to a slower decline in SNR. Still, the performance of the layered soft thresholding is inferior to that of its hard variant[12], as can be seen by comparing the red points with the blue ones in the subplots below.

Next, we proceed our experiments by running the layered BP algorithm, as defined in Section 6, on the same set of signals. Recall that one of the prime motivations for proposing this algorithm was its ability to retrieve the exact underlying representations, as justified theoretically in Theorem 11. In our experiments, we validate this claim by checking that its conditions hold for each signal and that the underlying representations are indeed retrieved. We omit showing a plot for this and comparing it to the layered thresholding algorithms since the errors obtained are simply zeros.

11. Interestingly, the error in the layered hard thresholding algorithm is approximately equal in the second and third layers.
12. Note that in the layered hard thresholding, as long as the correct support is chosen, the threshold does not affect the error and as such the oracle version for it is meaningless.

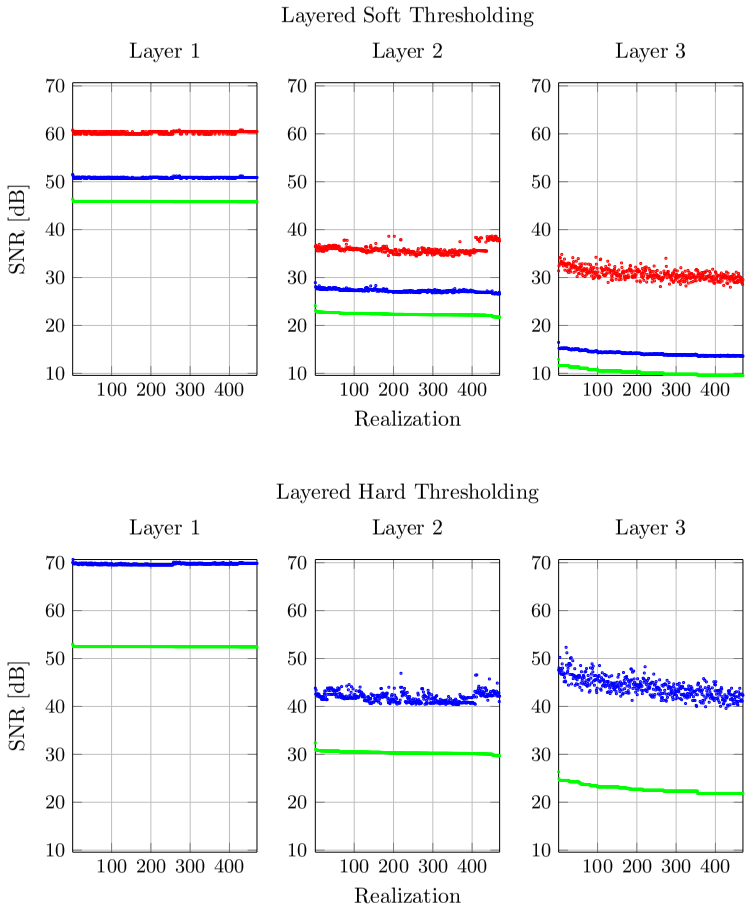

Figure 6: Comparison between the performance of the layered thresholding algorithms in a noiseless setting. All the signals presented here satisfy the assumptions of Theorem 8 and 10 and indeed the correct support of all the representations are recovered. The horizontal axis plots the realization number, while the vertical axis shows the SNR (the higher the better). Blue: layered thresholding algorithm with the theoretically justifiable thresholds. Green: the theoretical bound on the error. Red: layered soft thresholding algorithm with oracle thresholds. Note that the points are sorted according to the theoretical bound.

8.3 Noisy Experiments

Having established the stability of our proposed algorithms in a perfect scenario, where $\epsilon_0 = 0$, we now turn to a noisy setting. Naturally, the estimation task becomes now even more challenging – not only does the SNR drop with each layer, as demonstrated previously, but also the input SNR is no longer infinity. In order to facilitate the success of our algorithms, in this section we demonstrate the empirical performance and theoretical bounds on $K = 2$ layers and a small noise level.

Similar to the previous subsection, we begin by sampling a signal $\mathbf{X}$. To this end, we draw a random $\mathbf{\Gamma}_2$ of length 100 where $20 \leq \|\mathbf{\Gamma}_2\|_0 \leq 66$. Each non-zero coefficient in it is then set to ± 1, with equal probability. Given the dictionaries and the sampled sparse vector $\mathbf{\Gamma}_2$, we then compute the representation $\mathbf{\Gamma}_1$ and the signal $\mathbf{X}$, which are of length 600 and 3,600, respectively. The $\ell_{0,\infty}$ norm of the obtained sparse vectors satisfies $7 \leq \|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}} \leq 8$ and $3 \leq \|\mathbf{\Gamma}_2\|_{0,\infty}^{\mathbf{s}} \leq 7$.

Next, we contaminate each signal $\mathbf{X}$ with a zero-mean white additive Gaussian noise $\mathbf{E}$, creating a signal $\mathbf{Y} = \mathbf{X} + \mathbf{E}$. The average SNR of the obtained noisy signals is 68.53 dB. These are then fed into the layered pursuits, resulting in a set of estimated sparse representations, $\hat{\mathbf{\Gamma}}_i$. We note that the $\ell_{0,\infty}$ norms of the representations of each $\mathbf{X}$ satisfy the assumptions of Theorem 8, 10 and 12. As such, the parameters for every algorithm are chosen according to our theoretical study. For each estimated representation we compute the error $\|\hat{\mathbf{\Gamma}}_i - \mathbf{\Gamma}_i\|_{2,\infty}^{\mathbf{p}}$ and its corresponding theoretical bound obtained from the aforementioned theorems. Since the underlying representations satisfy the assumptions of the stability theorem for the layered thresholding algorithms, for each signal we verify that indeed the correct support is found. As for the layered BP, our stability analysis guarantees that the support retrieved should be contained in the true one and coefficients that are large enough in $\mathbf{\Gamma}_i$ should be retrieved. In practice, the layered BP always finds the full support.

We present the obtained results in terms of the local SNR in Figure 7, showing the stability of the different algorithms that is in accordance with our theoretical bounds. Similar to the noiseless experiment, we observe that for all the algorithms the error increases both theoretically (green points) and empirically (blue points) with the layer depth. As previously discussed, a performance gap exists between the soft and hard layered thresholding algorithms. To mitigate this, we run the layered soft thresholding with an oracle parameter and compare the obtained errors (red points) to those of the other algorithms. The results, depicted in the same figure, show a clear improvement in the performance.

Interestingly, although theoretically superior, the layered BP leads to similar performance to that of the layered soft thresholding and worse performance than that of the layered hard thresholding (when comparing the blue points). We attribute this phenomenon to the suboptimal choice of the parameter ξ_i, which was chosen thus far according to our theoretical analysis. To validate this suspicion, we run the layered BP with hand-picked ξ_i and plot the obtained SNR in red in Figure 7. Not only are the correct supports retrieved for all the signals, but we can also see a clear improvement in terms of the SNR. In the first layer, the layered BP outperforms the layered soft thresholding and leads to similar results to those of the layered hard thresholding, while in the second, the layered BP significantly outperforms both of the other pursuit algorithms.

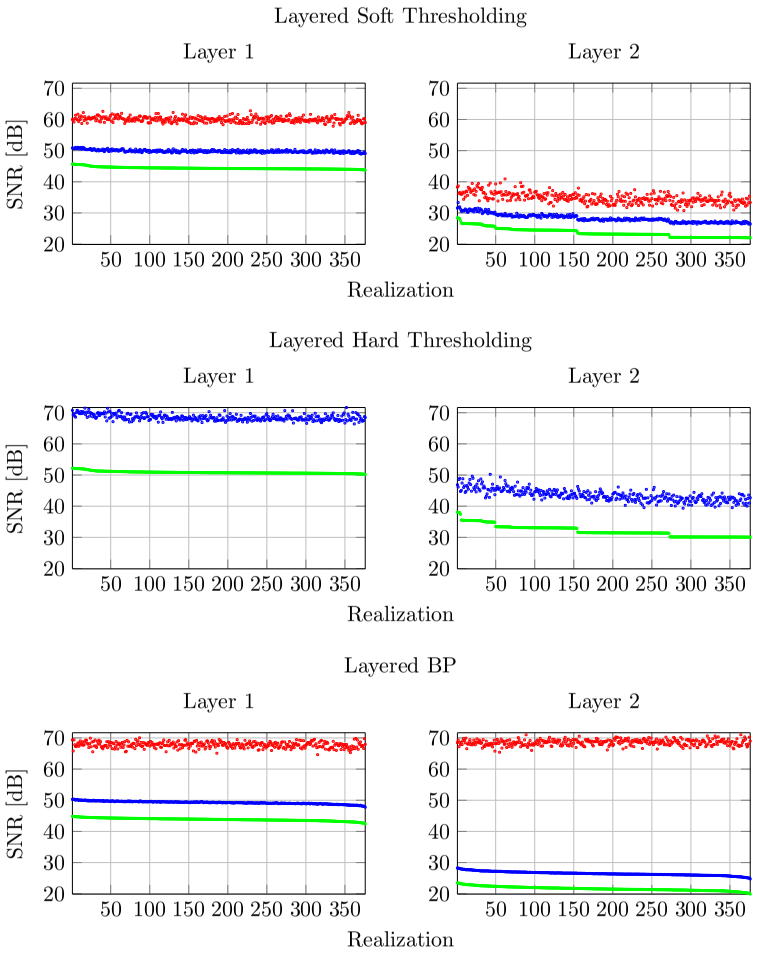

Figure 7: Comparison between the performance of the layered pursuit algorithms in a noisy setting. All the signals presented here satisfy the assumptions of Theorem 8, 10 and 12 and the correct support of all the representations are indeed recovered. The horizontal axis plots the realization number, while the vertical axis shows the SNR (the higher the better). Blue: layered pursuits with the theoretically justifiable thresholds. Green: the theoretical bound on the error. Red: layered soft thresholding with oracle thresholds and layered BP with hand-picked parameters. Note that the points are sorted according to the theoretical bound.

Thus far, our experiments focused on a setting where the ratio of the coefficients in $\mathbf{\Gamma}_i$ is reasonable. One should note, however, that the superiority of the layered BP becomes conspicuous once this ratio is spoiled. In this case, the layered thresholding algorithms will fail, while the layered BP will still succeed. To illustrate this, we create a signal using the dictionaries delineated in subsection 8.1, where the number of layers is $K = 5$. We first draw a random $\mathbf{\Gamma}_5$ of length 100 where its ℓ_0 norm is in the range $20 \leq \|\mathbf{\Gamma}_5\|_0 \leq 66$, and then set the non-zero coefficients in $\mathbf{\Gamma}_5$, similar to how it was done in the previous experiments. Given the dictionaries and the sampled sparse vector $\mathbf{\Gamma}_5$, we compute the representation $\{\mathbf{\Gamma}_i\}_{i=1}^4$ and the signal $\mathbf{X}$, which is of length $N = 777,600$. The $\ell_{0,\infty}$ norms of the obtained sparse vectors are $\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}} = 8$, $\|\mathbf{\Gamma}_2\|_{0,\infty}^{\mathbf{s}} = 6$, $\|\mathbf{\Gamma}_3\|_{0,\infty}^{\mathbf{s}} = 6$, $\|\mathbf{\Gamma}_4\|_{0,\infty}^{\mathbf{s}} = 6$ and $4 \leq \|\mathbf{\Gamma}_5\|_{0,\infty}^{\mathbf{s}} \leq 7$. Besides the depth of the network, the main difference between this experiment and the previous ones is the coefficient ratio. While the ratio of the deepest representation $\mathbf{\Gamma}_5$ is equal to 1, due to the coefficients in it being equal to ± 1, the ratio of $\mathbf{\Gamma}_1$ is equal to 2.44×10^{-4}. As a consequence, the theoretical results we have presented for the layered thresholding algorithms do not hold, while those of the layered BP still do.

Next, each signal $\mathbf{X}$ is contaminated with a zero-mean white additive Gaussian noise $\mathbf{E}$, resulting in a noisy signal $\mathbf{Y} = \mathbf{X} + \mathbf{E}$. The average SNR of the noisy signals obtained is 124.43 dB. Note that this is a weak noise, chosen due to the deterioration of the SNR throughout the layers (one that is worsened when the theoretical parameters are employed). The signals are then fed into the layered BP algorithm, resulting in a set of estimated sparse representations, $\hat{\mathbf{\Gamma}}_i$. The parameters ξ_i employed are the theoretically justified ones, $\xi_i = 4\epsilon_{i-1}$. We should note that in our experiments we attempted to run the layered thresholding algorithms, however, as our theory predicts these failed in recovering the correct supports.

Given the estimated representations, we compute the errors $\|\hat{\mathbf{\Gamma}}_i - \mathbf{\Gamma}_i\|_{2,\infty}^{\mathbf{p}}$ and compare these to their corresponding theoretical bounds, obtained from Theorem 12. In addition, we verify that the retrieved supports are contained in the true one, as the theorem guarantees. In practice, we obtain that the layered BP always finds the full support. The obtained results are depicted in Figure 8 in terms of the local SNR. For comparison, we run the layered BP with hand-picked ξ_i and present the obtained results in the same figure. We conclude that the layered BP remains stable despite the poor coefficient ratio, unlike the layered thresholding algorithms. Moreover, tuning the ξ_i results in a much better performance, similar to what we have seen in the previous experiment.

At this point, one might ponder as to whether the hurdle of poor coefficient ratio is one that the layered soft thresholding (forward pass) can not overcome. We believe that several ideas currently used in CNN, such as Batch Normalization (Ioffe and Szegedy, 2015) or Local Response Normalization (Krizhevsky et al., 2012), are tightly connected to this problem. However, their exact relation to this issue and its theoretical analysis is a matter of future work.

9. Conclusion

Definition: "A guiding question is the fundamental query that directs the search for understanding" (Traver, 1998). In this work our guiding question was who are the signals that the CNN architecture is designed for? To answer this we have defined the ML-CSC model, for which the thresholding pursuit is nothing but the forward pass of the CNN.

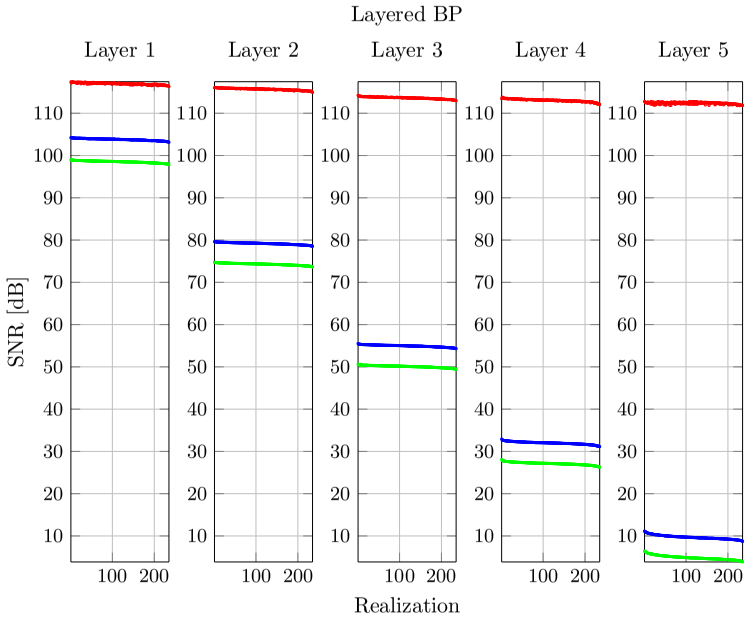

Figure 8: The performance of the layered BP algorithm in a noisy setting. All the signals presented here satisfy the assumptions of Theorem 12 and the correct support of all the representations are recovered. The horizontal axis plots the realization number, while the vertical axis shows the SNR (the higher the better). Blue: layered BP with the theoretically justifiable thresholds. Green: the theoretical bound on the error. Red: layered BP with hand-picked parameters. Note that the points are sorted according to the theoretical bound.

Although nothing promises that the forward pass will lead to the original representation of a signal emerging from the ML-CSC model, we have shown this is indeed the case. Having established the relevance of our model to CNN, we then turned to its theoretical analysis. In particular, we provided guarantees for the uniqueness of the feature maps CNN aims to recover, and the stability of the problem CNN aims to solve.

Inspired by the evolution of the pursuit methods in the theory of Sparse-Land, we continued our work by proposing the layered BP algorithm. In the noiseless case, this was theoretically shown to be capable of finding the unique solution of the deep coding problem, the existence of which has been also guaranteed; while in the noisy setting, we have proved the stability of this algorithm.

We analyzed the theoretical benefits of two popular ideas employed in the CNN community, namely the use of sparse filters and the spatial-stride. Leveraging those, we then

generated signals satisfying the ML-CSC assumptions and demonstrated the performance of the pursuits presented throughout this work.

We conclude this work by presenting our ongoing research directions:

1. Through this paper we have assumed the worst – an adversary noise. Can our theoretical analysis be extended to a setting where the noise is random?

2. Thus far in tackling the deep coding problem, we have restricted ourself to existing methods, such as the forward pass of the CNN or deconvolutional networks (Zeiler et al., 2010). Can we suggest better approximations for the solution of this problem?

3. What is the role of common tricks currently employed in CNN in the context of the ML-CSC model? These include but are not limited to, Batch Normalization (Ioffe and Szegedy, 2015), Local Response Normalization (Krizhevsky et al., 2012), Dropout (Srivastava et al., 2014) and Pooling (LeCun et al., 1990; Krizhevsky et al., 2012; Simonyan and Zisserman, 2014).

Acknowledgments

The authors would like to thank Jeremias Sulam for the inspiring discussions and creative advice.

Appendix A.
Uniqueness via the Mutual Coherence (Proof of Theorem 4)

Proof In (Papyan et al., 2016a) a solution $\mathbf{\Gamma}$ to the $\mathrm{P}_{0,\infty}$ problem, as defined in Equation (6), was shown to be unique assuming that $\|\mathbf{\Gamma}\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D})}\right)$. In other words, if the true representation is sparse enough in the $\ell_{0,\infty}$ sense, no other solution is possible. Herein, we leverage this claim in order to prove the uniqueness of the $\mathrm{DCP}_{\boldsymbol{\lambda}}$ problem.

Let $\{\hat{\mathbf{\Gamma}}_i\}_{i=1}^K$ be a set of representations of the signal $\mathbf{X}$, obtained by solving the $\mathrm{DCP}_{\boldsymbol{\lambda}}$ problem. According to our assumptions, $\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_1)}\right)$. Moreover, since the set $\{\hat{\mathbf{\Gamma}}_i\}_{i=1}^K$ is a solution of the $\mathrm{DCP}_{\boldsymbol{\lambda}}$ problem, we also have that $\|\hat{\mathbf{\Gamma}}_1\|_{0,\infty}^{\mathbf{s}} \leq \lambda_1 < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_1)}\right)$. As such, in light of the aforementioned uniqueness theorem, both representations are equal. Once we have concluded that $\mathbf{\Gamma}_1 = \hat{\mathbf{\Gamma}}_1$, we would also like to show that the representations $\mathbf{\Gamma}_2$ and $\hat{\mathbf{\Gamma}}_2$ are identical. Similarly, the assumptions $\|\mathbf{\Gamma}_2\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_i)}\right)$ and $\|\hat{\mathbf{\Gamma}}_2\|_{0,\infty}^{\mathbf{s}} \leq \lambda_2 < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_2)}\right)$ guarantee that $\mathbf{\Gamma}_2 = \hat{\mathbf{\Gamma}}_2$. The same set of steps can be applied for all $1 \leq i \leq K$, leading to the fact that both sets of representations are identical. ■

Appendix B.
Global Stability of the $\mathrm{DCP}_{\boldsymbol{\lambda}}^{\boldsymbol{\mathcal{E}}}$ Problem (Proof of Theorem 5)

Proof In (Papyan et al., 2016b), for a signal $\mathbf{Y} = \mathbf{X} + \mathbf{E} = \mathbf{D}_1\mathbf{\Gamma}_1 + \mathbf{E}$, it was shown that if the following hold:

1. $\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}} \leq \lambda_1 < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_1)}\right)$ and $\|\mathbf{E}\|_2 = \|\mathbf{Y} - \mathbf{D}_1\mathbf{\Gamma}_1\|_2$,
2. $\|\hat{\mathbf{\Gamma}}_1\|_{0,\infty}^{\mathbf{s}} \leq \lambda_1 < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_1)}\right)$ and $\|\mathbf{Y} - \mathbf{D}_1\hat{\mathbf{\Gamma}}_1\|_2 \leq \|\mathbf{E}\|_2$,

then

$$\|\mathbf{\Gamma}_1 - \hat{\mathbf{\Gamma}}_1\|_2^2 \leq \frac{4\|\mathbf{E}\|_2^2}{1-(2\lambda_1-1)\mu(\mathbf{D}_1)}.$$

In item 2 we have used the fact that the solution for the $\mathrm{DCP}_{\boldsymbol{\lambda}}^{\boldsymbol{\mathcal{E}}}$ problem, $\hat{\mathbf{\Gamma}}_1$, must satisfy $\|\mathbf{Y} - \mathbf{D}_1\hat{\mathbf{\Gamma}}_1\|_2 \leq \|\mathbf{E}\|_2$ and $\|\hat{\mathbf{\Gamma}}_1\|_{0,\infty}^{\mathbf{s}} \leq \lambda_1$. Notice that the true solution satisfies $\mathbf{\Gamma}_1 = \mathbf{D}_2\mathbf{\Gamma}_2$ and also the solution of $\mathrm{DCP}_{\boldsymbol{\lambda}}^{\boldsymbol{\mathcal{E}}}$ satisfies $\hat{\mathbf{\Gamma}}_1 = \mathbf{D}_2\hat{\mathbf{\Gamma}}_2$. As such,

$$\|\mathbf{D}_2\mathbf{\Gamma}_2 - \mathbf{D}_2\hat{\mathbf{\Gamma}}_2\|_2^2 = \|\mathbf{\Gamma}_1 - \hat{\mathbf{\Gamma}}_1\|_2^2 \leq \frac{4\|\mathbf{E}\|_2^2}{1-(2\lambda_1-1)\mu(\mathbf{D}_1)}. \tag{12}$$

Using the definition of SRIP from (Papyan et al., 2016b) and the fact that

$$\|\mathbf{\Gamma}_2 - \hat{\mathbf{\Gamma}}_2\|_{0,\infty}^{\mathbf{s}} \leq 2\lambda_2$$

we have

$$(1-\delta_{2\lambda_2})\ \|\mathbf{\Gamma}_2 - \hat{\mathbf{\Gamma}}_2\|_2^2 \leq \|\mathbf{D}_2\mathbf{\Gamma}_2 - \mathbf{D}_2\hat{\mathbf{\Gamma}}_2\|_2^2,$$

where $\delta_{2\lambda_2}$ is the SRIP constant of $\mathbf{D}_2$ for an $\ell_{0,\infty}$ norm equal to $2\lambda_2$. Bounding the SRIP using the mutual coherence, as was done in (Papyan et al., 2016b), the above results in

$$\begin{aligned}(1-(2\lambda_2-1)\,\mu(\mathbf{D}_2))\ \|\mathbf{\Gamma}_2 - \hat{\mathbf{\Gamma}}_2\|_2^2 \leq &(1-\delta_{2\lambda_2})\ \|\mathbf{\Gamma}_2 - \hat{\mathbf{\Gamma}}_2\|_2^2 \\ \leq &\|\mathbf{D}_2\mathbf{\Gamma}_2 - \mathbf{D}_2\hat{\mathbf{\Gamma}}_2\|_2^2.\end{aligned}$$

Combining this together with Equation (12), we obtain

$$\|\mathbf{\Gamma}_2 - \hat{\mathbf{\Gamma}}_2\|_2^2 \leq \frac{4\|\mathbf{E}\|_2^2}{(1-(2\lambda_1-1)\mu(\mathbf{D}_1))\,(1-(2\lambda_2-1)\mu(\mathbf{D}_2))}.$$

Repeating the above set of steps for the deeper layers, we conclude that

$$\forall\ 1 \leq i \leq K \qquad \|\mathbf{\Gamma}_i - \hat{\mathbf{\Gamma}}_i\|_2^2 \leq 4\|\mathbf{E}\|_2^2 \prod_{j=1}^{i} \frac{1}{1-(2\lambda_j-1)\mu(\mathbf{D}_j)},$$

as claimed. ■

Appendix C.
Stable Recovery of Hard Thresholding in the Presence of Noise (Proof of Lemma 7)

Proof Denote by $\mathcal{T}_1$ the support of $\mathbf{\Gamma}_1$. Denote further the i-th atom from $\mathbf{D}_1$ by $\mathbf{d}_{1,i}$. The success of the hard thresholding algorithm with threshold β_1 in recovering the correct support is guaranteed if the following holds

$$\min_{i\in\mathcal{T}_1}\left|\mathbf{d}_{1,i}^T\mathbf{Y}\right| > \beta_1 > \max_{j\notin\mathcal{T}_1}\left|\mathbf{d}_{1,j}^T\mathbf{Y}\right|.$$

Using the same set of steps as those used in proving Theorem 4 in (Papyan et al., 2016b), we can lower bound the left-hand-side by

$$\min_{i\in\mathcal{T}_1}\left|\mathbf{d}_{1,i}^T\mathbf{Y}\right| \geq |\mathbf{\Gamma}_1^{\min}| - (\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}-1)\mu(\mathbf{D}_1)|\mathbf{\Gamma}_1^{\max}| - \epsilon_0$$

and upper bound the right-hand-side via

$$\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}\mu(\mathbf{D}_1)|\mathbf{\Gamma}_1^{\max}| + \epsilon_0 \geq \max_{j\notin\mathcal{T}_1}\left|\mathbf{d}_{1,j}^T\mathbf{Y}\right|.$$

Next, by requiring

$$\begin{aligned}\min_{i\in\mathcal{T}_1}\left|\mathbf{d}_{1,i}^T\mathbf{Y}\right| \geq& |\mathbf{\Gamma}_1^{\min}| - (\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}-1)\mu(\mathbf{D}_1)|\mathbf{\Gamma}_1^{\max}| - \epsilon_0 \\ >& \beta_1 \\ >& \|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}\mu(\mathbf{D}_1)|\mathbf{\Gamma}_1^{\max}| + \epsilon_0 \\ \geq& \max_{j\notin\mathcal{T}_1}\left|\mathbf{d}_{1,j}^T\mathbf{Y}\right|,\end{aligned} \tag{13}$$

we ensure the success of the thresholding algorithm. This condition can be equally written as

$$\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_1)}\frac{|\Gamma_1^{\min}|}{|\Gamma_1^{\max}|}\right) - \frac{1}{\mu(\mathbf{D}_1)}\frac{\epsilon_0}{|\Gamma_1^{\max}|}.$$

Equation (13) also implies that the threshold β_1 that should be employed must satisfy

$$|\mathbf{\Gamma}_1^{\min}| - (\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}-1)\mu(\mathbf{D}_1)|\mathbf{\Gamma}_1^{\max}| - \epsilon_0 > \beta_1 > \|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}\mu(\mathbf{D}_1)|\mathbf{\Gamma}_1^{\max}| + \epsilon_0. \tag{14}$$

Thus far, we have considered the successful recovery of the support of $\mathbf{\Gamma}_1$. Next, assuming this correct support was recovered, we shall dwell on the deviation of the thresholding result, $\hat{\mathbf{\Gamma}}_1$, from the true $\mathbf{\Gamma}_1$. Denote by $\mathbf{\Gamma}_{1,\mathcal{T}_1}$ and $\hat{\mathbf{\Gamma}}_{1,\mathcal{T}_1}$ the vectors $\mathbf{\Gamma}_1$ and $\hat{\mathbf{\Gamma}}_1$ restricted to the support $\mathcal{T}_1$, respectively. We have that

$$\begin{aligned}\|\mathbf{\Gamma}_1-\hat{\mathbf{\Gamma}}_1\|_\infty &= \|\mathbf{\Gamma}_{1,\mathcal{T}_1}-\hat{\mathbf{\Gamma}}_{1,\mathcal{T}_1}\|_\infty \\ &= \left\|\left(\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{D}_{1,\mathcal{T}_1}\right)^{-1}\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{X} - \mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{Y}\right\|_\infty \\ &= \left\|\left(\left(\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{D}_{1,\mathcal{T}_1}\right)^{-1}\mathbf{D}_{1,\mathcal{T}_1}^T - \mathbf{D}_{1,\mathcal{T}_1}^T\right)\mathbf{X} - \mathbf{D}_{1,\mathcal{T}_1}^T(\mathbf{Y}-\mathbf{X})\right\|_\infty,\end{aligned}$$

where the Gram $\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{D}_{1,\mathcal{T}_1}$ is invertible according to Lemma 1 in (Papyan et al., 2016a). Using the triangle inequality of the ℓ_∞ norm and the relation $\mathbf{X}=\mathbf{D}_{1,\mathcal{T}_1}\mathbf{\Gamma}_{1,\mathcal{T}_1}$, we obtain

$$\begin{aligned}\|\mathbf{\Gamma}_1-\hat{\mathbf{\Gamma}}_1\|_\infty &\leq \left\|\left(\left(\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{D}_{1,\mathcal{T}_1}\right)^{-1}\mathbf{D}_{1,\mathcal{T}_1}^T - \mathbf{D}_{1,\mathcal{T}_1}^T\right)\mathbf{D}_{1,\mathcal{T}_1}\mathbf{\Gamma}_{1,\mathcal{T}_1}\right\|_\infty + \left\|\mathbf{D}_{1,\mathcal{T}_1}^T(\mathbf{Y}-\mathbf{X})\right\|_\infty \\ &= \left\|\left(\mathbf{I}-\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{D}_{1,\mathcal{T}_1}\right)\mathbf{\Gamma}_{1,\mathcal{T}_1}\right\|_\infty + \left\|\mathbf{D}_{1,\mathcal{T}_1}^T(\mathbf{Y}-\mathbf{X})\right\|_\infty,\end{aligned}$$

where $\mathbf{I}$ is an identity matrix. Relying on the definition of the induced ℓ_∞ norm, the above is equal to

$$\|\mathbf{\Gamma}_1-\hat{\mathbf{\Gamma}}_1\|_\infty \leq \left\|\mathbf{I}-\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{D}_{1,\mathcal{T}_1}\right\|_\infty\cdot\|\mathbf{\Gamma}_{1,\mathcal{T}_1}\|_\infty + \left\|\mathbf{D}_{1,\mathcal{T}_1}^T(\mathbf{Y}-\mathbf{X})\right\|_\infty. \tag{15}$$

In what follows, we shall upper bound both of the expressions in the right hand side of the inequality.

Beginning with the first term in the above inequality, $\left\|\mathbf{I}-\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{D}_{1,\mathcal{T}_1}\right\|_\infty$, recall that the induced infinity norm of a matrix is equal to its maximum absolute row sum. The diagonal entries of $\mathbf{I}-\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{D}_{1,\mathcal{T}_1}$ are equal to zero, due to the normalization of the atoms, while the off diagonal entries can be bounded by relying on the locality of the atoms and the definition of the $\ell_{0,\infty}$ norm. As such, each row has at most $\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}-1$ non-zeros, where each is bounded by $\mu(\mathbf{D}_1)$ based on the definition of the mutual coherence. We conclude that the maximum absolute row sum can be bounded by

$$\|\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{D}_{1,\mathcal{T}_1}-\mathbf{I}\|_\infty \leq (\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}-1)\mu(\mathbf{D}_1). \tag{16}$$

Next, moving to the second expression, define $\mathbf{R}_{1,i}\in\mathbb{R}^{n_0\times N}$ to be the operator that extracts a filter of length n_0 from $\mathbf{d}_{1,i}$. Consequently, the operator $\mathbf{R}_{1,i}^T$ pads a local filter of length n_0 with zeros, resulting in a global atom of length N. Notice that, due to the locality of the atoms $\mathbf{R}_{1,i}^T\mathbf{R}_{1,i}\mathbf{d}_{1,i}=\mathbf{d}_{1,i}$. Using this together with the Cauchy-Schwarz inequality, the normalization of the atoms, and the local bound on the error $\|\mathbf{Y}-\mathbf{X}\|_{2,\infty}^{\mathbf{p}}\leq\epsilon_0$, we have that

$$\begin{aligned}\left\|\mathbf{D}_{1,\mathcal{T}_1}^T(\mathbf{Y}-\mathbf{X})\right\|_\infty &= \max_{i\in\mathcal{T}_1}\left|\mathbf{d}_{1,i}^T(\mathbf{Y}-\mathbf{X})\right| \\ &= \max_{i\in\mathcal{T}_1}\left|\left(\mathbf{R}_{1,i}\mathbf{d}_{1,i}\right)^T\mathbf{R}_{1,i}(\mathbf{Y}-\mathbf{X})\right| \\ &\leq \max_{i\in\mathcal{T}_1}\|\mathbf{R}_{1,i}\mathbf{d}_{1,i}\|_2\cdot\|\mathbf{R}_{1,i}(\mathbf{Y}-\mathbf{X})\|_2 \\ &\leq 1\cdot\|\mathbf{Y}-\mathbf{X}\|_{2,\infty}^{\mathbf{p}} \\ &\leq \epsilon_0.\end{aligned} \tag{17}$$

In the second to last inequality we have used Definition 6, denoting the maximal ℓ_2 norm of a *patch* extracted from $\mathbf{Y}-\mathbf{X}$ by $\|\mathbf{Y}-\mathbf{X}\|_{2,\infty}^{\mathbf{p}}$. Plugging (16) and (17) into Equation (15), and using the fact that $\|\mathbf{\Gamma}_{1,\mathcal{T}_1}\|_\infty=|\mathbf{\Gamma}_1^{\max}|$, we obtain that

$$\|\mathbf{\Gamma}_1-\hat{\mathbf{\Gamma}}_1\|_\infty \leq (\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}-1)\mu(\mathbf{D}_1)|\mathbf{\Gamma}_1^{\max}| + \epsilon_0. \tag{18}$$

In the remainder of this proof we will localize the above bound into one that is posed in terms of patch-errors. Note that $\|\mathbf{\Gamma}_1-\hat{\mathbf{\Gamma}}_1\|_{2,\infty}^{\mathbf{p}}$ is equal to the maximal energy of an n_1m_1-dimensional patch taken from it, where the i-th patch can be extracted using the operator

$\mathbf{P}_{1,i}$. Relying on this and the relation $\|\mathbf{V}\|_2 \leq \sqrt{\|\mathbf{V}\|_0}\,\|\mathbf{V}\|_\infty$, we have that

$$\begin{aligned}\|\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\|_{2,\infty}^{\mathbf{P}} &= \max_i \left\|\mathbf{P}_{1,i}\left(\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\right)\right\|_2 \\ &\leq \max_i \sqrt{\left\|\mathbf{P}_{1,i}\left(\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\right)\right\|_0}\ \left\|\mathbf{P}_{1,i}\left(\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\right)\right\|_\infty .\end{aligned}$$

Recalling that, based on Definition 6, $\|\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\|_{0,\infty}^{\mathbf{P}}$ denotes the maximal number of non-zeros in a patch of length n_1m_1 extracted from this vector, we obtain that

$$\begin{aligned}\|\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\|_{2,\infty}^{\mathbf{P}} &\leq \sqrt{\|\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\|_{0,\infty}^{\mathbf{P}}}\ \|\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\|_\infty \\ &\leq \sqrt{\|\boldsymbol{\Gamma}_1\|_{0,\infty}^{\mathbf{P}}}\ \|\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\|_\infty .\end{aligned}$$

In the last inequality we have used the success of the first stage in recovering the correct support, resulting in $\|\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\|_{0,\infty}^{\mathbf{P}} \leq \|\boldsymbol{\Gamma}_1\|_{0,\infty}^{\mathbf{P}}$. Plugging inequality (18) into the above equation, we conclude that

$$\|\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\|_{2,\infty}^{\mathbf{P}} \leq \sqrt{\|\boldsymbol{\Gamma}_1\|_{0,\infty}^{\mathbf{P}}}\Big(\epsilon_0+\mu(\mathbf{D}_1)\left(\|\boldsymbol{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}-1\right)|\Gamma_1^{\max}|\Big),$$

as claimed. ■

Appendix D. Stability of the Layered Hard Thresholding in the Presence of Noise (Proof of Theorem 8)

Proof The stability of the first stage of the layered hard thresholding algorithm is obtained from Lemma 7. Denoting by $\boldsymbol{\Delta}_1=\hat{\boldsymbol{\Gamma}}_1-\boldsymbol{\Gamma}_1$, notice that $\hat{\boldsymbol{\Gamma}}_1=\boldsymbol{\Gamma}_1+\boldsymbol{\Delta}_1=\mathbf{D}_2\boldsymbol{\Gamma}_2+\boldsymbol{\Delta}_1$. In other words, $\boldsymbol{\Gamma}_1$ is a signal that admits a convolutional sparse representation $\mathbf{D}_2\boldsymbol{\Gamma}_2$, which is contaminated with noise $\boldsymbol{\Delta}_1$, resulting in $\hat{\boldsymbol{\Gamma}}_1$. Next, we would like to employ Lemma 7 for the signal $\hat{\boldsymbol{\Gamma}}_1=\boldsymbol{\Gamma}_1+\boldsymbol{\Delta}_1=\mathbf{D}_2\boldsymbol{\Gamma}_2+\boldsymbol{\Delta}_1$, with the local noise level

$$\|\boldsymbol{\Delta}_1\|_{2,\infty}^{\mathbf{P}} \leq \sqrt{\|\boldsymbol{\Gamma}_1\|_{0,\infty}^{\mathbf{P}}}\Big(\epsilon_0+\mu(\mathbf{D}_1)\left(\|\boldsymbol{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}-1\right)|\Gamma_1^{\max}|\Big)=\epsilon_1,$$

to obtain the stability of the second stage. To this end, we require its conditions to hold; in particular, the $\ell_{0,\infty}$ norm of $\boldsymbol{\Gamma}_2$ to obey

$$\|\boldsymbol{\Gamma}_2\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_2)}\frac{|\Gamma_2^{\min}|}{|\Gamma_2^{\max}|}\right)-\frac{1}{\mu(\mathbf{D}_2)}\frac{\epsilon_1}{|\Gamma_2^{\max}|},$$

and the threshold β_2 to satisfy

$$|\boldsymbol{\Gamma}_2^{\min}|-(\|\boldsymbol{\Gamma}_2\|_{0,\infty}^{\mathbf{s}}-1)\mu(\mathbf{D}_2)|\boldsymbol{\Gamma}_2^{\max}|-\epsilon_1 > \ \beta_2 > \|\boldsymbol{\Gamma}_2\|_{0,\infty}^{\mathbf{s}}\mu(\mathbf{D}_2)|\boldsymbol{\Gamma}_2^{\max}|+\epsilon_1.$$

Assuming the above hold, Lemma 7 guarantees that the support of $\hat{\boldsymbol{\Gamma}}_2$ is equal to that of $\boldsymbol{\Gamma}_2$, and also that

$$\|\boldsymbol{\Gamma}_2-\hat{\boldsymbol{\Gamma}}_2\|_{2,\infty}^{\mathbf{P}} \leq \sqrt{\|\boldsymbol{\Gamma}_2\|_{0,\infty}^{\mathbf{P}}}\Big(\epsilon_1+\mu(\mathbf{D}_2)\left(\|\boldsymbol{\Gamma}_2\|_{0,\infty}^{\mathbf{s}}-1\right)|\Gamma_2^{\max}|\Big)=\epsilon_2.$$

Using the same steps as above, we obtain the desired claim for all the remaining layers, assuming that

$$\|\boldsymbol{\Gamma}_i\|_{0,\infty}^{\mathbf{s}} < \frac{1}{2}\left(1+\frac{1}{\mu(\mathbf{D}_i)}\frac{|\Gamma_i^{\min}|}{|\Gamma_i^{\max}|}\right)-\frac{1}{\mu(\mathbf{D}_i)}\frac{\epsilon_{i-1}}{|\Gamma_i^{\max}|}$$

and that the thresholds β_i are chosen to satisfy

$$|\boldsymbol{\Gamma}_i^{\min}|-(\|\boldsymbol{\Gamma}_i\|_{0,\infty}^{\mathbf{s}}-1)\mu(\mathbf{D}_i)|\boldsymbol{\Gamma}_i^{\max}|-\epsilon_{i-1} > \ \beta_i > \|\boldsymbol{\Gamma}_i\|_{0,\infty}^{\mathbf{s}}\mu(\mathbf{D}_i)|\boldsymbol{\Gamma}_i^{\max}|+\epsilon_{i-1}. \tag{19}$$

This completes our proof. ■

Appendix E. Stable Recovery of Soft Thresholding in the Presence of Noise (Proof of Lemma 9)

Proof The success of the soft thresholding algorithm with threshold β_1 in recovering the correct support is guaranteed if the following holds

$$\min_{i\in\mathcal{T}_1}\left|\mathbf{d}_{1,i}^T\mathbf{Y}\right| > \beta_1 > \max_{j\notin\mathcal{T}_1}\left|\mathbf{d}_{1,j}^T\mathbf{Y}\right|.$$

Since the soft thresholding operator chooses all atoms with correlations greater than β_1, the above implies that the true support $\mathcal{T}_1$ will be chosen. This condition is equal to that of the hard thresholding algorithm, and thus using the same steps as in Lemma 7, we are guaranteed that the correct support will be chosen under Assumptions (a) and (b).

The difference between the hard thresholding algorithm and its soft counterpart becomes apparent once we consider the estimated sparse vector. While the former estimates the non-zero entries in $\hat{\boldsymbol{\Gamma}}_1$ by computing $\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{Y}$, the latter subtracts or adds a constant β_1 from these, obtaining $\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{Y}-\beta_1\mathbf{B}$, where $\mathbf{B}$ is a vector of ±1. As a result, the distance between the true sparse vector and the estimated one is given by

$$\begin{aligned}\|\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\|_\infty &= \left\|\boldsymbol{\Gamma}_{1,\mathcal{T}_1}-\hat{\boldsymbol{\Gamma}}_{1,\mathcal{T}_1}\right\|_\infty \\ &= \left\|\left(\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{D}_{1,\mathcal{T}_1}\right)^{-1}\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{X}-\left(\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{Y}-\beta_1\mathbf{B}\right)\right\|_\infty \\ &\leq \left\|\left(\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{D}_{1,\mathcal{T}_1}\right)^{-1}\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{X}-\mathbf{D}_{1,\mathcal{T}_1}^T\mathbf{Y}\right\|_\infty+\|\beta_1\mathbf{B}\|_\infty ,\end{aligned}$$

where in the last step we have used the triangle inequality for the ℓ_∞ norm. Notice that $\|\beta_1\mathbf{B}\|_\infty=\beta_1$, since β_1 must be positive according to Equation (14). Combining this together with the same steps as those used in proving Lemma 7, the above can be bounded by

$$\|\boldsymbol{\Gamma}_1-\hat{\boldsymbol{\Gamma}}_1\|_{2,\infty}^{\mathbf{P}} \leq \sqrt{\|\boldsymbol{\Gamma}_1\|_{0,\infty}^{\mathbf{P}}}\Big(\epsilon_0+\mu(\mathbf{D}_1)\left(\|\boldsymbol{\Gamma}_1\|_{0,\infty}^{\mathbf{s}}-1\right)|\Gamma_1^{\max}|+\beta_1\Big),$$

resulting in the desired claim. ■

Appendix F.
Stability of the Layered BP Algorithm in the Presence of Noise (Proof of Theorem 12)

Proof In (Papyan et al., 2016b), for a signal $\mathbf{Y} = \mathbf{X} + \mathbf{E} = \mathbf{D}_1\mathbf{\Gamma}_1 + \mathbf{E}$, it was shown that if the following hold:

a) $\|\mathbf{Y} - \mathbf{X}\|_{2,\infty}^{\mathbf{P}} \leq \epsilon_0$; and

b) $\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{S}} \leq \frac{1}{3}\left(1 + \frac{1}{\mu(\mathbf{D}_1)}\right)$,

then the solution $\hat{\mathbf{\Gamma}}_1$ for the Lagrangian formulation of the BP problem with $\beta_1 = 4\epsilon_0$ (see Equation (8)) satisfies that

1. The support of the solution $\hat{\mathbf{\Gamma}}_1$ is contained in that of $\mathbf{\Gamma}_1$;
2. $\|\mathbf{\Delta}_1\|_\infty = \|\mathbf{\Gamma}_1 - \hat{\mathbf{\Gamma}}_1\|_\infty \leq 7.5\ \epsilon_0$;
3. In particular, every entry of $\mathbf{\Gamma}_1$ greater in absolute value than $7.5\ \epsilon_0$ is guaranteed to be recovered; and
4. The solution $\hat{\mathbf{\Gamma}}_1$ is the unique minimizer of the Lagrangian BP problem (Equation (8)).

Using similar steps to those employed in the proof of Theorem 8, we obtain that

$$\|\mathbf{\Delta}_1\|_{2,\infty}^{\mathbf{P}} \leq \sqrt{\|\mathbf{\Delta}_1\|_{0,\infty}^{\mathbf{P}}}\ \|\mathbf{\Delta}_1\|_\infty.$$

Plugging above the inequality $\|\mathbf{\Delta}_1\|_\infty \leq 7.5\ \epsilon_0$, we get

$$\|\mathbf{\Delta}_1\|_{2,\infty}^{\mathbf{P}} \leq \sqrt{\|\mathbf{\Delta}_1\|_{0,\infty}^{\mathbf{P}}}\ 7.5\ \epsilon_0.$$

Since the support of $\hat{\mathbf{\Gamma}}_1$ is contained in that of $\mathbf{\Gamma}_1$, we have that $\|\mathbf{\Delta}_1\|_{0,\infty}^{\mathbf{P}} = \|\mathbf{\Gamma}_1 - \hat{\mathbf{\Gamma}}_1\|_{0,\infty}^{\mathbf{P}} \leq \|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{P}}$, leading to

$$\|\mathbf{\Delta}_1\|_{2,\infty}^{\mathbf{P}} \leq \sqrt{\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{P}}}\ 7.5\ \epsilon_0 = \epsilon_1.$$

We conclude that the first stage of the layered BP is stable and the following must hold

1. The support of the solution $\hat{\mathbf{\Gamma}}_1$ is contained in that of $\mathbf{\Gamma}_1$;
2. $\|\mathbf{\Delta}_1\|_{2,\infty}^{\mathbf{P}} \leq\ \epsilon_1$;
3. In particular, every entry of $\mathbf{\Gamma}_1$ greater in absolute value than $\frac{\epsilon_1}{\sqrt{\|\mathbf{\Gamma}_1\|_{0,\infty}^{\mathbf{P}}}}$ is guaranteed to be recovered; and
4. The solution $\hat{\mathbf{\Gamma}}_1$ is the unique minimizer of the Lagrangian BP problem (Equation (8)).

Next, we turn to the stability of the second stage of the layered BP algorithm. Notice that $\hat{\mathbf{\Gamma}}_1 = \mathbf{\Gamma}_1 + \mathbf{\Delta}_1 = \mathbf{D}_2\mathbf{\Gamma}_2 + \mathbf{\Delta}_1$. Put differently, $\mathbf{\Gamma}_1$ is a signal that admits a convolutional sparse representation $\mathbf{D}_2\mathbf{\Gamma}_2$ that is perturbed by $\mathbf{\Delta}_1$, resulting in $\hat{\mathbf{\Gamma}}_1$. As such, we can invoke once again the same theorem from (Papyan et al., 2016b). Since we have that

a) $\|\mathbf{\Delta}_1\|_{2,\infty}^{\mathbf{P}} \leq \epsilon_1$; and

b) $\|\mathbf{\Gamma}_2\|_{0,\infty}^{\mathbf{S}} \leq \frac{1}{3}\left(1 + \frac{1}{\mu(\mathbf{D}_2)}\right)$,

we are guaranteed that the solution $\hat{\mathbf{\Gamma}}_2$ for the Lagrangian formulation of the BP problem with parameter $\beta_2 = 4\epsilon_1$ satisfies

1. The support of the solution $\hat{\mathbf{\Gamma}}_2$ is contained in that of $\mathbf{\Gamma}_2$;
2. $\|\mathbf{\Delta}_2\|_\infty = \|\mathbf{\Gamma}_2 - \hat{\mathbf{\Gamma}}_2\|_\infty \leq 7.5\ \epsilon_1$;
3. In particular, every entry of $\mathbf{\Gamma}_2$ greater in absolute value than $7.5\ \epsilon_1$ is guaranteed to be recovered; and
4. The solution $\hat{\mathbf{\Gamma}}_2$ is the unique minimizer of the Lagrangian BP problem (Equation (8)).

Using similar steps to those used above, the inequality that relies on the ℓ_∞ norm can be translated into another one that depends on the $\ell_{2,\infty}$. This results in

$$\|\mathbf{\Delta}_2\|_{2,\infty}^{\mathbf{P}} \leq \sqrt{\|\mathbf{\Gamma}_2\|_{0,\infty}^{\mathbf{P}}}\ 7.5\ \epsilon_1 = \epsilon_2.$$

We conclude that, similar to the first one, the second stage of the layered BP is stable and the following must hold

1. The support of the solution $\hat{\mathbf{\Gamma}}_2$ is contained in that of $\mathbf{\Gamma}_2$;
2. $\|\mathbf{\Delta}_2\|_{2,\infty}^{\mathbf{P}} \leq\ \epsilon_2$;
3. In particular, every entry of $\mathbf{\Gamma}_2$ greater in absolute value than $7.5\ \epsilon_1 = \frac{\epsilon_2}{\sqrt{\|\mathbf{\Gamma}_2\|_{0,\infty}^{\mathbf{P}}}}$ is guaranteed to be recovered; and
4. The solution $\hat{\mathbf{\Gamma}}_2$ is the unique minimizer of the Lagrangian BP problem (Equation (8)).

Using the same set of steps, we obtain similarly the stability of the remaining layers. ■

Abstract

We consider a generic convex optimization problem associated with regularized empirical risk minimization of linear predictors. The problem structure allows us to reformulate it as a convex-concave saddle point problem. We propose a stochastic primal-dual coordinate (SPDC) method, which alternates between maximizing over a randomly chosen dual variable and minimizing over the primal variables. An extrapolation step on the primal variables is performed to obtain accelerated convergence rate. We also develop a mini-batch version of the SPDC method which facilitates parallel computing, and an extension with weighted sampling probabilities on the dual variables, which has a better complexity than uniform sampling on unnormalized data. Both theoretically and empirically, we show that the SPDC method has comparable or better performance than several state-of-the-art optimization methods.

Keywords: empirical risk minimization, randomized algorithms, convex-concave saddle point problems, primal-dual algorithms, computational complexity

1. Introduction

We consider a generic convex optimization problem that arises often in machine learning: regularized empirical risk minimization (ERM) of linear predictors. More specifically, let $a_1, \ldots, a_n \in \mathbb{R}^d$ be the feature vectors of n data samples, $\phi_i : \mathbb{R} \to \mathbb{R}$ be a convex loss function associated with the linear prediction $a_i^T x$, for $i = 1, \ldots, n$, and $g : \mathbb{R}^d \to \mathbb{R}$ be a convex regularization function for the predictor $x \in \mathbb{R}^d$. Our goal is to solve the following optimization problem:

$$\underset{x\in\mathbb{R}^d}{\text{minimize}} \quad \Big\{ P(x) \stackrel{\text{def}}{=} \frac{1}{n}\sum_{i=1}^n \phi_i(a_i^T x) + g(x) \Big\}. \tag{1}$$

Examples of this formulation include many well-known classification and regression problems. For binary classification, each feature vector a_i is associated with a label $b_i \in \{\pm 1\}$. We obtain the linear SVM (support vector machine) by setting $\phi_i(z) = \max\{0, 1 - b_i z\}$ (the hinge loss) and $g(x) = (\lambda/2)\|x\|_2^2$, where $\lambda > 0$ is a regularization parameter. Regularized logistic regression is obtained by setting $\phi_i(z) = \log(1 + \exp(-b_i z))$. For linear regression problems, each feature vector a_i is associated with a dependent variable $b_i \in \mathbb{R}$, and $\phi_i(z) = (1/2)(z - b_i)^2$. Then we get ridge regression with $g(x) = (\lambda/2)\|x\|_2^2$, and the Lasso with $g(x) = \lambda\|x\|_1$. Further background on regularized ERM in machine learning and statistics can be found, e.g., in the book by Hastie et al. (2009).

We are especially interested in developing efficient algorithms for solving the problem (1) when the number of samples n is very large. In this case, evaluating the full gradient or subgradient of the function $P(x)$ is very expensive, thus incremental methods that operate on a single component function ϕ_i at each iteration can be very attractive. There has been extensive research on incremental gradient and subgradient methods (e.g., Tseng, 1998; Blatt et al., 2007; Nedić and Bertsekas, 2001; Bertsekas, 2011, 2012) as well as variants of the stochastic gradient method (e.g., Zhang, 2004; Bottou, 2010; Duchi and Singer, 2009; Langford et al., 2009; Xiao, 2010). While the computational cost per iteration of these methods is only a small fraction, say $1/n$, of that of the batch gradient methods, their iteration complexities are much higher (they need a lot more iterations to reach the same precision). In order to better quantify the complexities of various algorithms and position our contributions, we need to make some concrete assumptions and introduce the notion of *condition number* and *batch complexity*.

1.1 Condition Number and Batch Complexity

Let γ and λ be two positive real parameters. We make the following assumption:

Assumption A *Each ϕ_i is convex and differentiable, and its derivative is $(1/\gamma)$-Lipschitz continuous (same as ϕ_i being $(1/\gamma)$-smooth), i.e.,*

$$|\phi_i'(\alpha) - \phi_i'(\beta)| \le (1/\gamma)|\alpha - \beta|, \quad \forall\, \alpha, \beta \in \mathbb{R}, \quad i = 1, \ldots, n.$$

In addition, the regularization function g is λ-strongly convex, i.e.,

$$g(x) \ge g(y) + g'(y)^T(x - y) + \frac{\lambda}{2}\|x - y\|_2^2, \quad \forall\, g'(y) \in \partial g(y), \quad x, y \in \mathbb{R}^n.$$

For example, the logistic loss $\phi_i(z) = \log(1 + \exp(-b_i z))$ is $(1/4)$-smooth, the squared error $\phi_i(z) = (1/2)(z - b_i)^2$ is 1-smooth, and the squared ℓ_2-norm $g(x) = (\lambda/2)\|x\|_2^2$ is λ-strongly convex. The hinge loss $\phi_i(z) = \max\{0, 1 - b_i z\}$ and the ℓ_1-regularization $g(x) = \lambda\|x\|_1$ do not satisfy Assumption A. Nevertheless, we can treat them using smoothing and strongly convex perturbations, respectively, so that our algorithm and theoretical framework still apply (see Section 3).

Under Assumption A, the gradient of each component function, $\nabla\phi_i(a_i^T x)$, is also Lipschitz continuous, with Lipschitz constant $L_i = \|a_i\|_2^2/\gamma \le R^2/\gamma$, where $R = \max_i \|a_i\|_2$. In other words, each $\phi_i(a_i^T x)$ is (R^2/γ)-smooth. We define the *condition number*

$$\kappa = R^2/(\lambda\gamma), \tag{2}$$

and focus on ill-conditioned problems where $\kappa \gg 1$. In statistical learning, the regularization parameter λ is usually on the order of $1/\sqrt{n}$ or $1/n$ (e.g., Bousquet and Elisseeff, 2002),

*. A short paper based on a previous version of this manuscript (arXiv:1409.3257) appeared in the Proceedings of The 32nd International Conference on Machine Learning (ICML), Lille, France, July 2015.

thus the condition number κ is on the order of $\sqrt{n}$ or n. It can be much larger if the strong convexity in g is added purely for numerical regularization purposes (see Section 3). We note that the actual conditioning of problem (1) may be better than κ, if the empirical loss function $(1/n)\sum_{i=1}^n \phi_i(a_i^T x)$ by itself is strongly convex. In those cases, our complexity estimates in terms of κ can be loose (upper bounds), but they are still useful in comparing different algorithms for solving the same problem.

Let $P^\star$ be the optimal value of problem (1), i.e., $P^\star = \min_{x\in\mathbb{R}^d} P(x)$. In order to find an approximate solution $\hat{x}$ satisfying $P(\hat{x}) - P^\star \le \epsilon$, the classical full gradient method and its proximal variants require $\mathcal{O}((1+\kappa)\log(1/\epsilon))$ iterations (e.g., Nesterov, 2004, 2013). Accelerated full gradient methods enjoy the improved iteration complexity $\mathcal{O}((1+\sqrt{\kappa})\log(1/\epsilon))$ (Nesterov, 2004; Tseng, 2008; Beck and Teboulle, 2009; Nesterov, 2013)[1]. However, each iteration of these batch methods requires a full pass over the dataset, computing the gradient of each component function and forming their average, which cost $\mathcal{O}(nd)$ operations (assuming the features vectors $a_i \in \mathbb{R}^d$ are dense). In contrast, the stochastic gradient method and its proximal variants operate on one single component $\phi_i(a_i^T x)$ (chosen randomly) at each iteration, which only costs $\mathcal{O}(d)$. But their iteration complexities are far worse. Under Assumption A, it takes them $\mathcal{O}(\kappa/\epsilon)$ iterations to find an $\hat{x}$ such that $\mathbb{E}[P(\hat{x}) - P^\star] \le \epsilon$, where the expectation is with respect to the random choices made at all the iterations (e.g., Polyak and Juditsky, 1992; Nemirovski et al., 2009; Duchi and Singer, 2009; Langford et al., 2009; Xiao, 2010).

To make fair comparisons with batch methods, we measure the complexity of stochastic or incremental gradient methods in terms of the number of equivalent passes over the dataset required to reach an expected precision ϵ. We call this measure the *batch complexity*, which is usually obtained by dividing their iteration complexities by n. For example, the batch complexity of the stochastic gradient method is $\mathcal{O}(\kappa/(n\epsilon))$. The batch complexities of full gradient methods are the same as their iteration complexities.

By exploiting the finite average structure in (1), several recent work (e.g., Le Roux et al., 2012; Shalev-Shwartz and Zhang, 2013a; Johnson and Zhang, 2013; Xiao and Zhang, 2014; Defazio et al., 2014) proposed new variants of the stochastic gradient and dual coordinate ascent methods which achieve the iteration complexity $\mathcal{O}((n+\kappa)\log(1/\epsilon))$. Since their computational cost per iteration is $\mathcal{O}(d)$, the equivalent batch complexity is $1/n$ of their iteration complexity, i.e., $\mathcal{O}((1+\kappa/n)\log(1/\epsilon))$. This complexity has much weaker dependence on n than the full gradient methods, and also much weaker dependence on ϵ than the stochastic gradient methods.

In this paper, we propose a stochastic primal-dual coordinate (SPDC) method, which has the iteration complexity

$$\mathcal{O}\big((n+\sqrt{\kappa n})\log(1/\epsilon)\big),$$

or equivalently, the batch complexity

$$\mathcal{O}\big((1+\sqrt{\kappa/n})\log(1/\epsilon)\big). \tag{3}$$

When $\kappa > n$, this is lower than the $\mathcal{O}((1+\kappa/n)\log(1/\epsilon))$ batch complexity mentioned above. Indeed, it reaches a lower bound for minimizing finite sums established in Lan and Zhou (2015); see also Agarwal and Bottou (2015) and Woodworth and Srebro (2016). Several other recent work also achieved the same complexity bound, either with a dual or a primal accelerated randomized algorithm (Lin et al., 2015b; Lan and Zhou, 2015; Allen-Zhu, 2017) or through the proximal-point algorithm (Shalev-Shwartz and Zhang, 2015; Frostig et al., 2015; Lin et al., 2015a). We will discuss these related work in Section 5.

1. For the analysis of full gradient methods, we should use $(R^2/\gamma+\lambda)/\lambda = 1+\kappa$ as the condition number of problem (1); see Nesterov (2013, Section 5.1). Here we used the upper bound $\sqrt{1+\kappa} < 1+\sqrt{\kappa}$ for easy comparison. When $\kappa \gg 1$, the additive constant 1 can be dropped.

1.2 Outline of the Paper

Our approach is based on reformulating problem (1) as a convex-concave saddle point problem, and then devising a primal-dual algorithm to approximate the saddle point. More specifically, we replace each component function $\phi_i(a_i^T x)$ through convex conjugation, i.e.,

$$\phi_i(a_i^T x) = \sup_{y_i\in\mathbb{R}} \left\{ y_i \langle a_i, x\rangle - \phi_i^*(y_i) \right\},$$

where $\phi_i^*(y_i) = \sup_{\alpha\in\mathbb{R}}\{\alpha y_i - \phi_i(\alpha)\}$, and $\langle a_i, x\rangle$ denotes the inner product of a_i and x (which is the same as $a_i^T x$, but is more convenient for later presentation). This leads to a convex-concave saddle point problem

$$\min_{x\in\mathbb{R}^d} \max_{y\in\mathbb{R}^n} \left\{ f(x,y) \stackrel{\text{def}}{=} \frac{1}{n}\sum_{i=1}^n \big(y_i\langle a_i, x\rangle - \phi_i^*(y_i)\big) + g(x) \right\}. \tag{4}$$

Under Assumption A, each ϕ_i is $(1/\gamma)$-smooth, which implies that ϕ_i^* is γ-strongly convex (see, e.g., Hiriart-Urruty and Lemaréchal, 2001, Theorem 4.2.2). In addition, the regularization g is λ-strongly convex. As a consequence, the saddle point problem (4) has a unique solution, which we denote by $(x^\star, y^\star)$.

The above saddle-point formulation allows the regularized ERM problem to be solved by the primal-dual first-order algorithms developed in Chambolle and Pock (2011). Under Assumption A, Algorithm 3 in Chambolle and Pock (2011) have the complexity $\mathcal{O}(1+\sqrt{\kappa})\log(1/\epsilon)$, which is that same as that of the accelerated full gradient methods. Our SPDC method can be viewed as a randomized coordinate variant of the primal-dual algorithm in Chambolle and Pock (2011), which achieves a much better complexity by exploiting the finite-sum structure of the regularized ERM problem.

In Section 2, we present the SPDC method as well as its convergence analysis. It alternates between maximizing f over a randomly chosen dual coordinate y_i and minimizing f over the primal variable x. In order to accelerate the convergence, an extrapolation step is applied in updating the primal variable x. We also give a mini-batch SPDC algorithm which is well suited for parallel computing.

In Section 3 and Section 4, we present two extensions of the SPDC method. We first explain how to solve problem (1) when Assumption A does not hold. The idea is to apply small regularizations to the saddle point function so that SPDC can still be applied, which results in accelerated sublinear rates for solving the original problem. The second extension is a SPDC method with non-uniform sampling. The batch complexity of this algorithm has the same form as (3), but with $\kappa = \bar{R}/(\lambda\gamma)$, where $\bar{R} = \frac{1}{n}\sum_{i=1}^n \|a_i\|$, which can be much smaller than $R = \max_i \|a_i\|$ if there is considerable variation in the norms $\|a_i\|$.

In Section 5, we discuss related work. In particular, we explain the connection of SPDC with the primal-dual batch methods in Chambolle and Pock (2011), and several recent work that achieves the same complexity as SPDC.

In Section 6, we discuss efficient implementation of the SPDC method when the feature vectors a_i are sparse. We focus on two popular cases: when g is a squared ℓ_2-norm penalty and when g is an $\ell_1 + \ell_2$ penalty. We show that the computational cost per iteration of SPDC only depends on the number of non-zero elements in the feature vectors.

In Section 7, we present experiment results comparing SPDC with several state-of-the-art optimization methods, including both batch algorithms and randomized incremental and coordinate gradient methods. On all scenarios we tested, SPDC has comparable or better performance.

The SPDC method was first proposed and analyzed in Zhang and Xiao (2015). This manuscript is a significant expansion, which includes several major technical changes, as well as new experiment results. More specifically, the main theoretical result (Theorem 1) has been strengthened to include both iterate convergence and a new result on saddle-point function convergence. This required major changes in the technical proof in Appendix A. Moreover, the convergence rate analysis of the primal-dual gap in Zhang and Xiao (2015) required additional assumptions than those in Theorem 1. In this paper (Section 2.2), we present a new proof that do not require additional assumptions. The SPDC method with non-uniform sampling (Section 4) has been extended with a more general parametrized sampling probability, and we give the optimal parameterization based on the condition number. Additional numerical experiments are presented for both synthetic and real datasets, including new comparisons with the accelerated SDCA algorithm by Shalev-Shwartz and Zhang (2015), and also comparisons between uniform and weighted sampling.

2. The SPDC Method

In this section, we describe and analyze the Stochastic Primal-Dual Coordinate (SPDC) method. The basic idea of SPDC is quite simple: to approach the saddle point of $f(x, y)$ defined in (4), we alternatively maximize f with respect to y, and minimize f with respect to x. Since the dual vector y has n coordinates and each coordinate is associated with a feature vector $a_i \in \mathbb{R}^d$, maximizing f with respect to y takes $\mathcal{O}(nd)$ computation, which can be very expensive if n is large. We reduce the computational cost by randomly picking a single coordinate of y at a time, and maximizing f only with respect to this coordinate. Consequently, the computational cost of each iteration is $\mathcal{O}(d)$.

We give the details of the SPDC method in Algorithm 1. The dual coordinate update and primal vector update are given in equations (5) and (6) respectively. Instead of maximizing f over y_k and minimizing f over x directly, we add two quadratic regularization terms to penalize $y_k^{(t+1)}$ and $x^{(t+1)}$ from deviating from $y_k^{(t)}$ and $x^{(t)}$. The parameters σ and τ control their regularization strength, which we will specify in the convergence analysis (Theorem 1). Moreover, we introduce two auxiliary variables $u^{(t)}$ and $\overline{x}^{(t)}$. Combining the initialization $u^{(0)} = (1/n)\sum_{i=1}^n y_i^{(0)} a_i$ and the update rules (5) and (7), we have

$$u^{(t)} = \frac{1}{n}\sum_{i=1}^n y_i^{(t)} a_i, \qquad t = 0, \ldots, T.$$

Equation (8) obtains $\overline{x}^{(t+1)}$ based on an extrapolation from $x^{(t)}$ and $x^{(t+1)}$. This step is similar to Nesterov's acceleration technique (Nesterov, 2004, Section 2.2), and yields faster convergence rate.

Algorithm 1: The SPDC method

Input: parameters $\tau, \sigma, \theta \in \mathbb{R}_+$, number of iterations T, initial points $x^{(0)}$ and $y^{(0)}$.

Initialize: $\overline{x}^{(0)} = x^{(0)}$, $u^{(0)} = (1/n)\sum_{i=1}^n y_i^{(0)} a_i$.

for $t = 0, 1, 2, \ldots, T-1$ **do**

Pick $k \in \{1, 2, \ldots, n\}$ uniformly at random, and execute the following updates:

$$y_i^{(t+1)} = \begin{cases} \arg\max_{\beta \in \mathbb{R}} \left\{ \beta \langle a_i, \overline{x}^{(t)} \rangle - \phi_i^*(\beta) - \frac{1}{2\sigma}(\beta - y_i^{(t)})^2 \right\} & \text{if } i = k, \\ y_i^{(t)} & \text{if } i \neq k, \end{cases} \tag{5}$$

$$x^{(t+1)} = \arg\min_{x \in \mathbb{R}^d} \left\{ g(x) + \left\langle u^{(t)} + (y_k^{(t+1)} - y_k^{(t)}) a_k,\ x \right\rangle + \frac{\|x - x^{(t)}\|_2^2}{2\tau} \right\}, \tag{6}$$

$$u^{(t+1)} = u^{(t)} + \frac{1}{n}(y_k^{(t+1)} - y_k^{(t)}) a_k, \tag{7}$$

$$\overline{x}^{(t+1)} = x^{(t+1)} + \theta(x^{(t+1)} - x^{(t)}). \tag{8}$$

end

Output: $x^{(T)}$ and $y^{(T)}$

The mini-batch SPDC method in Algorithm 2 is a natural extension of Algorithm 1. The difference between these two algorithms is that, the mini-batch SPDC method may simultaneously select more than one dual coordinates to update. Let m be the mini-batch size. During each iteration, the mini-batch SPDC method randomly picks a subset of indices $K \subset \{1, \ldots, n\}$ of size m, such that the probability of each index being picked is equal to m/n. The following is a simple procedure to achieve this. First, partition the set of indices into m disjoint subsets, so that the cardinality of each subset is equal to n/m (assuming m divides n). Then, during each iteration, randomly select a single index from each subset and add it to K. Other approaches for mini-batch selection are also possible; see the discussions in Richtárik and Takáč (2016).

In Algorithm 2, we also switched the order of updating $x^{(t+1)}$ and $u^{(t+1)}$ (comparing with Algorithm 1), to better illustrate that $x^{(t+1)}$ is obtained based on an extrapolation from $u^{(t)}$ to $u^{(t+1)}$. However, this form is not recommended in implementation, because $u^{(t)}$ is usually a dense vector even if the feature vectors a_k are sparse. Details on efficient implementation of SPDC are given in Section 6. In the following discussion, we do not make sparseness assumptions.

With a single processor, each iteration of Algorithm 2 takes $\mathcal{O}(md)$ time to accomplish. Since the updates of each coordinate y_k are independent of each other, we can use parallel computing to accelerate the mini-batch SPDC method. Concretely, we can use m processors to update the m coordinates in the subset K in parallel, then aggregate them to update $x^{(t+1)}$. In terms of wall-clock time, each iteration takes $\mathcal{O}(d)$ time, which is the same as running one iteration of the basic SPDC algorithm. Not surprisingly, we will show that the mini-batch SPDC algorithm converges faster than SPDC in terms of the iteration complexity, because it processes multiple dual coordinates in a single iteration.

Algorithm 2: The mini-batch SPDC method

Input: mini-batch size m, parameters $\tau, \sigma, \theta \in \mathbb{R}_+$, number of iterations T, and the initial points $x^{(0)}$ and $y^{(0)}$.

Initialize: $\overline{x}^{(0)} = x^{(0)}$, $u^{(0)} = (1/n)\sum_{i=1}^n y_i^{(0)} a_i$.

for $t = 0, 1, 2, \ldots, T-1$ **do**

Randomly pick a subset $K \subset \{1, 2, \ldots, n\}$ of size m, such that the probability of each index being picked is equal to m/n. Execute the following updates:

$$y_i^{(t+1)} = \begin{cases} \arg\max_{\beta \in \mathbb{R}} \left\{ \beta \langle a_i, \overline{x}^{(t)} \rangle - \phi_i^*(\beta) - \frac{1}{2\sigma}(\beta - y_i^{(t)})^2 \right\} & \text{if } i \in K, \\ y_i^{(t)} & \text{if } i \notin K, \end{cases} \tag{9}$$

$$u^{(t+1)} = u^{(t)} + \frac{1}{n} \sum_{k \in K} (y_k^{(t+1)} - y_k^{(t)}) a_k,$$

$$x^{(t+1)} = \arg\min_{x \in \mathbb{R}^d} \left\{ g(x) + \left\langle u^{(t)} + \frac{n}{m}(u^{(t+1)} - u^{(t)}),\ x \right\rangle + \frac{\|x - x^{(t)}\|_2^2}{2\tau} \right\}, \tag{10}$$

$$\overline{x}^{(t+1)} = x^{(t+1)} + \theta(x^{(t+1)} - x^{(t)}).$$

end

Output: $x^{(T)}$ and $y^{(T)}$

2.1 Convergence Analysis

Since the basic SPDC algorithm is a special case of mini-batch SPDC with $m = 1$, we only present a convergence theorem for the mini-batch version. The expectations in the following results are taken with respect to the random variables $\{K^{(0)}, \ldots, K^{(T-1)}\}$, where $K^{(t)}$ denotes the random subset $K \subset \{1, \ldots, n\}$ picked at the t-th iteration of the mini-batch SPDC method.

Theorem 1 *Suppose Assumption A holds. Let $(x^\star, y^\star)$ be the unique saddle point of f defined in (4), $R = \max\{\|a_1\|_2, \ldots, \|a_n\|_2\}$, and define*

$$\Delta^{(t)} = \left(\frac{1}{2\tau} + \frac{\lambda}{2}\right)\|x^{(t)} - x^\star\|_2^2 + \left(\frac{1}{4\sigma} + \frac{\gamma}{2}\right)\frac{\|y^{(t)} - y^\star\|_2^2}{m} + f(x^{(t)}, y^\star) - f(x^\star, y^\star) + \frac{n}{m}\left(f(x^\star, y^\star) - f(x^\star, y^{(t)})\right). \tag{11}$$

If the parameters τ, σ and θ in Algorithm 2 are chosen such that

$$\tau = \frac{1}{2R}\sqrt{\frac{m\gamma}{n\lambda}}, \qquad \sigma = \frac{1}{2R}\sqrt{\frac{n\lambda}{m\gamma}}, \qquad \theta = 1 - \left(\frac{n}{m} + 2R\sqrt{\frac{n}{m\lambda\gamma}}\right)^{-1}, \tag{12}$$

then for each $t \geq 1$, the mini-batch SPDC algorithm achieves

$$\mathbb{E}[\Delta^{(t)}] \leq \theta^t \left(\Delta^{(0)} + \frac{\|y^{(0)} - y^\star\|_2^2}{4m\sigma}\right).$$

Comparing with Theorem 1 in Zhang and Xiao (2015), our definition of $\Delta^{(t)}$ in (11) includes the additional terms $f(x^{(t)}, y^\star) - f(x^\star, y^\star) + \frac{n}{m}\left(f(x^\star, y^\star) - f(x^\star, y^{(t)})\right)$. This is a weighted sum of the primal and dual gaps for the saddle-point problem. It will help us establish the convergence rate of the objective value for the ERM problem in Section 2.2, which is missing in Zhang and Xiao (2015).

The proof of Theorem 1 is given in Appendix A. The following corollary establishes the expected iteration complexity of mini-batch SPDC for obtaining an ϵ-accurate solution.

Corollary 2 *Suppose Assumption A holds and the parameters τ, σ and θ are set as in (12). In order for Algorithm 2 to obtain*

$$\mathbb{E}[\|x^{(T)} - x^\star\|_2^2] \leq \epsilon, \qquad \mathbb{E}[\|y^{(T)} - y^\star\|_2^2] \leq \epsilon, \tag{13}$$

it suffices to have the number of iterations T satisfy

$$T \geq \left(\frac{n}{m} + 2R\sqrt{\frac{n}{m\lambda\gamma}}\right)\log\left(\frac{C}{\epsilon}\right),$$

where

$$C = \frac{\Delta^{(0)} + \left\|y^{(t)} - y^\star\right\|_2^2/(4m\sigma)}{\min\left\{1/(2\tau) + \lambda/2,\ (1/(4\sigma) + \gamma/2)/m\right\}}.$$

Proof By Theorem 1, we have $\mathbb{E}[\|x^{(t)} - x^\star\|_2^2] \leq \theta^t C$ and $\mathbb{E}[\|y^{(t)} - y^\star\|_2^2] \leq \theta^t C$ for each $t > 0$. To obtain (13), it suffices to ensure that $\theta^T C \leq \epsilon$, which is equivalent to

$$T \geq \frac{\log(C/\epsilon)}{-\log(\theta)} = \frac{\log(C/\epsilon)}{-\log\left(1 - \left((n/m) + 2R\sqrt{(n/m)/(\lambda\gamma)}\right)^{-1}\right)}.$$

Applying the inequality $-\log(1-x) \geq x$ to the denominator above completes the proof. ■

Recall the definition of the condition number $\kappa = R^2/(\lambda\gamma)$ in (2). Corollary 2 establishes that the iteration complexity of the mini-batch SPDC method for achieving (13) is

$$\mathcal{O}\left(\left((n/m) + \sqrt{\kappa(n/m)}\right)\log(1/\epsilon)\right).$$

So a larger batch size m leads to less number of iterations. In the extreme case of $n = m$, we obtain a full batch algorithm, which has iteration or batch complexity $\mathcal{O}((1+\sqrt{\kappa})\log(1/\epsilon))$. This complexity is also shared by the accelerated gradient methods (Nesterov, 2004, 2013), as well as the batch primal-dual algorithm of Chambolle and Pock (2011); see discussions in Section 1.1 and related work in Section 5.

Since an equivalent pass over the dataset corresponds to n/m iterations, the batch complexity (the number of equivalent passes over the data) of mini-batch SPDC is

$$\mathcal{O}\left(\left(1 + \sqrt{\kappa(m/n)}\right)\log(1/\epsilon)\right).$$

The above expression implies that a smaller batch size m leads to less number of passes through the data. In this sense, the basic SPDC method with $m = 1$ is the most efficient one. However, if we prefer the least amount of wall-clock time, then the best choice is to choose a mini-batch size m that matches the number of parallel processors available.

2.2 Convergence Rate of Primal-Dual Gap

In the previous subsection, we established iteration complexity of the mini-batch SPDC method in terms of approximating the saddle point of the minimax problem (4), more specifically, to meet the requirement in (13). Next we show that it has the same order of complexity in reducing the primal-dual objective gap $P(x^{(t)}) - D(y^{(t)})$, where $P(x)$ is defined in (1) and

$$D(y) \stackrel{\text{def}}{=} \min_{x\in\mathbb{R}^d} f(x,y) = \frac{1}{n}\sum_{i=1}^n -\phi_i^*(y_i) - g^*\Big(-\frac{1}{n}\sum_{i=1}^n y_i a_i\Big). \tag{14}$$

where $g^*(u) = \sup_{x\in\mathbb{R}^d}\{x^T u - g(x)\}$ is the conjugate function of g.

Under Assumption A, the function $f(x,y)$ defined in (4) has a unique saddle point $(x^\star, y^\star)$, and

$$P(x^\star) = f(x^\star, y^\star) = D(y^\star).$$

However, in general, for any point $(x,y) \in \text{dom}(g)\times\text{dom}(\phi^*)$, we have

$$P(x) = \max_y f(x,y) \geq f(x,y^\star), \qquad D(y) = \min_x f(x,y) \leq f(x^\star, y).$$

Thus the result in Theorem 1 does not translate directly into a convergence bound on the primal-dual gap. We need to bound $P(x)$ and $D(y)$ by $f(x,y^\star)$ and $f(x^\star,y)$, respectively, in the opposite directions. For this purpose, we need the following result extracted from Yu et al. (2015). We provide the proof in Appendix B for completeness.

Lemma 3 *Suppose Assumption A holds. Let $(x^\star, y^\star)$ be the unique saddle-point of $f(x,y)$, and $R = \max_{1\leq i\leq n}\|a_i\|_2$. Then for any point $(x,y)\in\text{dom}(g)\times\text{dom}(\phi^*)$, we have*

$$P(x) \leq f(x,y^\star) + \frac{R^2}{2\gamma}\|x-x^\star\|_2^2, \qquad D(y) \geq f(x^\star,y) - \frac{R^2}{2\lambda n}\|y-y^\star\|_2^2.$$

Corollary 4 *Suppose Assumption A holds and the parameters τ, σ and θ are set as in (12). Let $\widetilde{\Delta}^{(0)} := \Delta^{(0)} + \frac{\|y^{(0)}-y^\star\|_2^2}{4m\sigma}$. Then for any $\epsilon \geq 0$, the iterates of Algorithm 2 satisfy*

$$\mathbb{E}[P(x^{(T)}) - D(y^{(T)})] \leq \epsilon$$

whenever

$$T \geq \left(\frac{n}{m} + 2R\sqrt{\frac{n}{m\lambda\gamma}}\right)\log\left(\left(1+\frac{R^2}{\lambda\gamma}\right)\frac{\widetilde{\Delta}^{(0)}}{\epsilon}\right).$$

Proof The function $f(x,y^\star)$ is strongly convex in x with parameter λ, and $x^\star$ is the minimizer. Similarly, $-f(x^\star,y)$ is strongly convex in y with parameter γ/n, and is minimized by $y^\star$. Therefore,

$$\frac{\lambda}{2}\|x^{(t)}-x^\star\|_2^2 \leq f(x^{(t)},y^\star) - f(x^\star,y^\star), \quad \frac{\gamma}{2n}\|y^{(t)}-y^\star\|_2^2 \leq f(x^\star,y^\star) - f(x^\star,y^{(t)}). \tag{15}$$

We bound the following weighted primal-dual gap

$$\begin{aligned}
& P(x^{(t)}) - P(x^\star) + \frac{n}{m}\Big(D(y^\star) - D(y^{(t)})\Big) \\
\leq\ & f(x^{(t)},y^\star) - f(x^\star,y^\star) + \frac{n}{m}\Big(f(x^\star,y^\star) - f(x^\star,y^{(t)})\Big) + \frac{R^2}{2\gamma}\|x^{(t)}-x^\star\|_2^2 + \frac{n}{m}\frac{R^2}{2n\lambda}\|y^{(t)}-y^\star\|_2^2 \\
\leq\ & \Delta^{(t)} + \frac{R^2}{\lambda\gamma}\left(\frac{\lambda}{2}\|x^{(t)}-x^\star\|_2^2 + \frac{n}{m}\frac{\gamma}{2n}\|y^{(t)}-y^\star\|_2^2\right) \\
\leq\ & \Delta^{(t)} + \frac{R^2}{\lambda\gamma}\left(f(x^{(t)},y^\star) - f(x^\star,y^\star) + \frac{n}{m}\Big(f(x^\star,y^\star) - f(x^\star,y^{(t)})\Big)\right) \\
\leq\ & \left(1+\frac{R^2}{\lambda\gamma}\right)\Delta^{(t)}.
\end{aligned}$$

The first inequality above is due to Lemma 3, the second and fourth inequalities are due to the definition of $\Delta^{(t)}$, and the third inequality is due to (15). Taking expectations on both sides of the above inequality, then applying Theorem 1, we obtain

$$\mathbb{E}\left[P(x^{(t)}) - P(x^\star) + \frac{n}{m}\Big(D(y^\star) - D(y^{(t)})\Big)\right] \ \leq\ \theta^t\left(1+\frac{R^2}{\lambda\gamma}\right)\widetilde{\Delta}^{(0)} = (1+\kappa)\widetilde{\Delta}^{(t)}.$$

Since $n \geq m$ and $D(y^\star) - D(y^{(t)})) \geq 0$, this implies the desired result. ■

3. Extensions to Non-Smooth or Non-Strongly Convex Functions

The complexity bounds established in Section 2 require each ϕ_i be $(1/\gamma)$-smooth, and the function g be λ-strongly convex. For general loss functions where either or both of these conditions fail (e.g., the hinge loss and ℓ_1-regularization), we can slightly perturb the saddle-point function $f(x,y)$ so that the SPDC method can still be applied.

To be concise, we only consider the case where neither ϕ_i is smooth nor g is strongly convex. Instead, we only assume that each ϕ_i and g are convex and Lipschitz continuous, and $f(x,y)$ has a saddle point $(x^\star,y^\star)$. We choose a scalar $\delta > 0$ and consider the modified saddle-point function:

$$f_\delta(x,y) \stackrel{\text{def}}{=} \frac{1}{n}\sum_{i=1}^n\left(y_i\langle a_i,x\rangle - \Big(\phi_i^*(y_i) + \frac{\delta y_i^2}{2}\Big)\right) + g(x) + \frac{\delta}{2}\|x\|_2^2. \tag{16}$$

Denote the saddle-point of f_δ by $(x_\delta^\star, y_\delta^\star)$. We employ the mini-batch SPDC method in Algorithm 2 to approximate $(x_\delta^\star, y_\delta^\star)$, treating $\phi_i^* + \frac{\delta}{2}(\cdot)^2$ as ϕ_i^* and $g + \frac{\delta}{2}\|\cdot\|_2^2$ as g, which are all δ-strongly convex. We note that adding strongly convex perturbation on ϕ_i^* is equivalent to smoothing ϕ_i, which becomes $(1/\delta)$-smooth (see, e.g., Nesterov, 2005). Letting $\gamma = \lambda = \delta$, the parameters τ, σ and θ in (12) become

$$\tau = \frac{1}{2R}\sqrt{\frac{m}{n}}, \qquad \sigma = \frac{1}{2R}\sqrt{\frac{n}{m}}, \qquad \text{and} \qquad \theta = 1 - \left(\frac{n}{m} + \frac{2R}{\delta}\sqrt{\frac{n}{m}}\right)^{-1}.$$

Although $(x_\delta^\star, y_\delta^\star)$ is not exactly the saddle point of f, the following corollary shows that applying SPDC to the perturbed function f_δ effectively minimizes the original loss function P. Similar results for the convergence of the primal-dual gap can also be established.

Corollary 5 *Assume that each ϕ_i is convex and G_ϕ-Lipschitz continuous, and g is convex and G_g-Lipschitz continuous. In addition, assume that f has a saddle point $(x^\star, y^\star)$ and let the unique saddle point of f_δ be $(x_\delta^\star, y_\delta^\star)$. Define two constants:*

$$C_1 = (\|x^\star\|_2^2 + G_\phi^2), \qquad C_2 = (G_\phi R + G_g)^2\Big(\frac{\Delta_\delta^{(0)} + \|y^{(0)} - y_\delta^\star\|_2^2 R/(4\sqrt{mn})}{1/(2\tau) + \lambda/2}\Big),$$

where $\Delta_\delta^{(0)}$ is evaluated as in (11) but in terms of the perturbed function f_δ. If we choose $\delta \le \epsilon/C_1$, then we have $\mathbb{E}[P(x^{(T)}) - P(x^\star)] \le \epsilon$ whenever

$$T \ge \left(\frac{n}{m} + \frac{2R}{\delta}\sqrt{\frac{n}{m}}\right)\log\left(\frac{4C_2}{\epsilon^2}\right).$$

Proof Let $\widetilde{y} = \arg\max_y f(x_\delta^\star, y)$ be a shorthand notation. We have

$$\begin{aligned} P(x_\delta^\star) &\overset{(i)}{=} f(x_\delta^\star, \widetilde{y}) \overset{(ii)}{\le} f_\delta(x_\delta^\star, \widetilde{y}) + \frac{\delta\|\widetilde{y}\|_2^2}{2n} \overset{(iii)}{\le} f_\delta(x_\delta^\star, y_\delta^\star) + \frac{\delta\|\widetilde{y}\|_2^2}{2n} \overset{(iv)}{\le} f_\delta(x^\star, y_\delta^\star) + \frac{\delta\|\widetilde{y}\|_2^2}{2n} \\ &\overset{(v)}{\le} f(x^\star, y_\delta^\star) + \frac{\delta\|x^\star\|_2^2}{2} + \frac{\delta\|\widetilde{y}\|_2^2}{2n} \overset{(vi)}{\le} f(x^\star, y^\star) + \frac{\delta\|x^\star\|_2^2}{2} + \frac{\delta\|\widetilde{y}\|_2^2}{2n} \\ &\overset{(vii)}{=} P(x^\star) + \frac{\delta\|x^\star\|_2^2}{2} + \frac{\delta\|\widetilde{y}\|_2^2}{2n}. \end{aligned}$$

Here, equations (i) and (vii) use the definition of the function f, inequalities (ii) and (v) use the definition of the function f_δ, inequalities (iii) and (iv) use the fact that $(x_\delta^\star, y_\delta^\star)$ is the saddle point of f_δ, and inequality (vi) is due to the fact that $(x^\star, y^\star)$ is the saddle point of f.

Since ϕ_i is G_ϕ-Lipschitz continuous, the domain of ϕ_i^* is in the interval $[-G_\phi, G_\phi]$, which implies $\|\widetilde{y}\|_2^2 \le nG_\phi^2$ (see, e.g., (Shalev-Shwartz and Zhang, 2015, Lemma 1)). Thus, we have

$$P(x_\delta^\star) - P(x^\star) \le \frac{\delta}{2}(\|x^\star\|_2^2 + G_\phi^2) = \frac{\delta}{2}C_1. \tag{17}$$

On the other hand, since P is $(G_\phi R + G_g)$-Lipschitz continuous, Theorem 1 implies

$$\begin{aligned} \mathbb{E}[P(x^{(T)}) - P(x_\delta^\star)] &\le (G_\phi R + G_g)\mathbb{E}[\|x^{(T)} - x_\delta^\star\|_2] \\ &\le \sqrt{C_2}\left(1 - \left(\frac{n}{m} + \frac{2R}{\delta}\sqrt{\frac{n}{m}}\right)^{-1}\right)^{T/2}. \end{aligned} \tag{18}$$

Combining (17) and (18), in order to obtain $\mathbb{E}[P(x^{(T)}) - P(x^\star)] \le \epsilon$, it suffices to have $C_1\delta \le \epsilon$ and

$$\sqrt{C_2}\left(1 - \left(\frac{n}{m} + \frac{2R}{\delta}\sqrt{\frac{n}{m}}\right)^{-1}\right)^{T/2} \le \frac{\epsilon}{2}. \tag{19}$$

ϕ_i	g	iteration complexity $\widetilde{\mathcal{O}}(\cdot)$
$(1/\gamma)$-smooth	λ-strongly convex	$n/m + \sqrt{(n/m)/(\lambda\gamma)}$
$(1/\gamma)$-smooth	non-strongly convex	$n/m + \sqrt{(n/m)/(\epsilon\gamma)}$
non-smooth	λ-strongly convex	$n/m + \sqrt{(n/m)/(\epsilon\lambda)}$
non-smooth	non-strongly convex	$n/m + \sqrt{n/m}/\epsilon$

Table 1: Iteration complexities of the SPDC method under different assumptions on the functions ϕ_i and g. For the last three cases, we solve the perturbed saddle-point problem with $\delta = \epsilon/C_1$.

The corollary is established by finding the smallest T that satisfies inequality (19). ■

There are two other cases that can be considered: when ϕ_i is not smooth but g is strongly convex, and when ϕ_i is smooth but g is not strongly convex. They can be handled with the same technique described above, and we omit the details here. Alternatively, it is possible to use the techniques described in Chambolle and Pock (2011, Section 5.1) to obtain accelerated sublinear convergence rates without using strongly convex perturbations. In Table 1, we list the complexities of the mini-batch SPDC method for finding an ϵ-optimal solution of problem (1) under various assumptions. Similar results are also obtained in Shalev-Shwartz and Zhang (2015).

4. SPDC with Non-Uniform Sampling

One potential drawback of the SPDC algorithm is that, its convergence rate depends on a problem-specific constant R, which is the largest ℓ_2-norm of the feature vectors a_i. As a consequence, the algorithm may perform badly on unnormalized data, especially if the ℓ_2-norms of some feature vectors are substantially larger than others. In this section, we propose an extension of the SPDC method to mitigate this problem, which is given in Algorithm 3.

The basic idea is to use non-uniform sampling in picking the dual coordinate to update at each iteration. In Algorithm 3, we pick coordinate k with the probability

$$p_k = (1-\alpha)\frac{1}{n} + \alpha\frac{\|a_k\|_2}{\sum_{i=1}^n \|a_i\|_2}, \qquad k = 1, \ldots, n, \tag{20}$$

where $\alpha \in (0,1)$ is a parameter. In other words, this distribution is a (strict) convex combination of the uniform distribution and the distribution that is proportional to the feature norms. Therefore, instances with large feature norms are sampled more frequently, controlled by α. Simultaneously, we adopt an adaptive regularization in step (21), imposing stronger regularization on such instances. In addition, we adjust the weight of a_k in (23) for updating the primal variable. As a consequence, the convergence rate of Algorithm 3 depends on the average norm of feature vectors, as well as the parameter α. This is summarized in the following theorem, whose proof is given in Appendix C.

Algorithm 3: SPDC method with weighted sampling

Input: parameters $\tau, \sigma, \theta \in \mathbb{R}_+$, number of iterations T, initial points $x^{(0)}$ and $y^{(0)}$.

Initialize: $\overline{x}^{(0)} = x^{(0)}$, $u^{(0)} = (1/n)\sum_{i=1}^n y_i^{(0)} a_i$.

for $t = 0, 1, 2, \ldots, T-1$ **do**

Randomly pick $k \in \{1, 2, \ldots, n\}$, with probability p_k given in (20).

Execute the following updates:

$$y_i^{(t+1)} = \begin{cases} \arg\max_{\beta\in\mathbb{R}} \left\{ \beta\langle a_i, \overline{x}^{(t)}\rangle - \phi_i^*(\beta) - \frac{p_i n}{2\sigma}(\beta - y_i^{(t)})^2 \right\} & i = k, \\ y_i^{(t)} & i \neq k, \end{cases} \tag{21}$$

$$u^{(t+1)} = u^{(t)} + \frac{1}{n}(y_k^{(t+1)} - y_k^{(t)}) a_k, \tag{22}$$

$$x^{(t+1)} = \arg\min_{x\in\mathbb{R}^d} \left\{ g(x) + \left\langle u^{(t)} + \frac{1}{p_k}(u^{(t+1)} - u^{(t)}),\ x \right\rangle + \frac{\|x - x^{(t)}\|_2^2}{2\tau} \right\}, \tag{23}$$

$$\overline{x}^{(t+1)} = x^{(t+1)} + \theta(x^{(t+1)} - x^{(t)}).$$

end

Output: $x^{(T)}$ and $y^{(T)}$.

Theorem 6 *Suppose Assumption A holds. Let* $R := \max_i \|a_i\|_2$, $\overline{R} := \frac{1}{n}\sum_{i=1}^n \|a_i\|_2$ *and* $R_\alpha := \big((1-\alpha)/R + \alpha/\overline{R}\big)^{-1}$. *If the parameters* τ, σ, θ *in Algorithm 3 are chosen such that*

$$\tau = \frac{1}{2R_\alpha}\sqrt{\frac{\gamma}{n\lambda}}, \qquad \sigma = \frac{1}{2R_\alpha}\sqrt{\frac{n\lambda}{\gamma}}, \qquad \theta = 1 - \left(\frac{n}{1-\alpha} + R_\alpha\sqrt{\frac{n}{\lambda\gamma}}\right)^{-1}, \tag{24}$$

then for each $t \geq 1$, *we have*

$$\begin{aligned} &\Big(\frac{1}{2\tau} + \lambda\Big)\mathbb{E}\big[\|x^{(t)} - x^\star\|_2^2\big] + \Big(\frac{1}{4\sigma} + \frac{\gamma}{n}\Big)\mathbb{E}\big[\|y^{(t)} - y^\star\|_2^2\big] \\ \leq\ & \theta^t\left(\Big(\frac{1}{2\tau} + \lambda\Big)\|x^{(0)} - x^\star\|_2^2 + \Big(\frac{1}{2\sigma} + \frac{\gamma}{1-\alpha}\Big)\|y^{(0)} - y^\star\|_2^2\right). \end{aligned}$$

Note that $R_\alpha \leq \overline{R}/\alpha$ always holds. If we choose $\alpha = 1/2$, then the contraction ratio θ is bounded by $1 - \left(\frac{n}{1-\alpha} + 2\overline{R}\sqrt{\frac{n}{\lambda\gamma}}\right)^{-1}$. Comparing this bound with Theorem 1 with $m = 1$, the convergence rate of Theorem 6 is determined by the average norm of the features, $\overline{R} = \frac{1}{n}\sum_{i=1}^n \|a_i\|_2$, instead of the largest one $R = \max_i \|a_i\|_2$. This difference makes Algorithm 3 more robust to unnormalized feature vectors. For example, if the a_i's are sampled i.i.d. from a multivariate normal distribution, then $\max_i\{\|a_i\|_2\}$ almost surely goes to infinity as $n \to \infty$, but the average norm $\frac{1}{n}\sum_{i=1}^n \|a_i\|_2$ converges to $\mathbb{E}[\|a_i\|_2]$.

Since θ is a bound on the convergence factor, we would like to make it as small as possible. Let $\rho := R/\overline{R} - 1$. The expression of θ in (24) can be minimized by choosing

$$\alpha^\star = \begin{cases} 0 & \text{if } \rho \leq \sqrt{n/\kappa}, \\ \frac{\rho^{1/2}(\kappa/n)^{1/4} - 1}{\rho^{1/2}(\kappa/n)^{1/4} + \rho} & \text{if } \rho > \sqrt{n/\kappa}. \end{cases} \tag{25}$$

where $\kappa = R^2/(\lambda\gamma)$ is the condition number. The value of $\alpha^\star$ will be equal to zero if the condition number is large enough, and increases slowly to one as the condition number increases. Thus, we choose a (more conservative) uniform distribution for ill-conditioned problems, but a more aggressively weighted distribution for well-conditioned problems.

For simplicity of presentation, we described in Algorithm 3 a weighted sampling SPDC method with single dual coordinate update, i.e., the case of $m = 1$. In fact, the non-uniform sampling scheme can also be extended to mini-batch SPDC. For mini-batch size $m > 1$, we randomly pick a subset of indices $K \subset \{1, 2, \ldots, n\}$ of size m. The probability of $i \in K$ is denoted by p_i and should satisfy the constraint:

$$\min\Big\{1, m\Big(\frac{1-\alpha}{n} + \frac{\alpha\|a_i\|_2}{n\overline{R}}\Big)\Big\} \ \leq\ p_i \ \leq\ 1 \tag{26}$$

for $i = 1, \ldots, n$, and

$$\sum_{i=1}^n p_i = m.$$

This constraint can be satisfied by first adding all indices $\{i : p_i = 1\}$ to the set K, then sampling without replacement from the remaining indices in order to make $|K| = m$. More concretely, there is an efficient sampling-without-replacement algorithm (Chao, 1982) which adds each remaining index i to the set K with probability proportional to $\frac{1-\alpha}{n} + \frac{\alpha\|a_i\|_2}{n\overline{R}}$. It can be verified that the lower bound in (26) holds with such a procedure.

For the mini-batch extension, we replace the updates (21)-(23) by the following updates:

$$y_i^{(t+1)} = \begin{cases} \arg\max_{\beta\in\mathbb{R}} \left\{ \beta\langle a_i, \overline{x}^{(t)}\rangle - \phi_i^*(\beta) - \frac{p_i n}{2\sigma m}(\beta - y_i^{(t)})^2 \right\} & i \in K, \\ y_i^{(t)} & i \notin K, \end{cases}$$

$$u^{(t+1)} = u^{(t)} + \frac{1}{n}\sum_{k\in K}(y_k^{(t+1)} - y_k^{(t)}) a_k,$$

$$x^{(t+1)} = \arg\min_{x\in\mathbb{R}^d} \left\{ g(x) + \left\langle u^{(t)} + \frac{1}{n}\sum_{k\in K}\frac{y_k^{(t+1)} - y_k^{(t)}}{p_k} a_k,\ x \right\rangle + \frac{\|x - x^{(t)}\|_2^2}{2\tau} \right\},$$

which resembles the updates of Algorithm 2. Similar to the mini-batch SPDC, we are able to show that by increasing the batch size m, the convergence rate of the algorithm will be improved. On the other hand, the lower bound on p_i given by constraint (26) implies that with a proper choice of α (e.g. $\alpha = 1/2$), the convergence rate will depend on

$$\max\left\{\overline{R},\ \frac{m}{n}R\right\},$$

instead of the maximum norm R. For $m = 1$, we have $\max\{\overline{R}, \frac{m}{n}R\} = \overline{R}$, so that it captures the theoretical guarantee for Algorithm 3 as a special case. We omit the proof details.

5. Related Work

Chambolle and Pock (2011) considered a class of convex optimization problems with the following saddle-point structure:

$$\min_{x\in\mathbb{R}^d}\max_{y\in\mathbb{R}^n} \big\{\langle Kx, y\rangle + G(x) - F^*(y)\big\}, \tag{27}$$

algorithm	τ	σ	θ	batch complexity
Chambolle-Pock	$\frac{\sqrt{n}}{\|A\|_2}\sqrt{\frac{\gamma}{\lambda}}$	$\frac{n\sqrt{n}}{\|A\|_2}\sqrt{\frac{\lambda}{\gamma}}$	$1-\frac{1}{1+\|A\|_2/(2\sqrt{n\lambda\gamma})}$	$\left(1+\frac{\|A\|_2}{2\sqrt{n\lambda\gamma}}\right)\log(1/\epsilon)$
SPDC with $m=n$	$\frac{1}{R}\sqrt{\frac{\gamma}{\lambda}}$	$\frac{1}{R}\sqrt{\frac{\lambda}{\gamma}}$	$1-\frac{1}{1+R/\sqrt{\lambda\gamma}}$	$\left(1+\frac{R}{\sqrt{\lambda\gamma}}\right)\log(1/\epsilon)$
SPDC with $m=1$	$\frac{1}{R}\sqrt{\frac{\gamma}{n\lambda}}$	$\frac{1}{R}\sqrt{\frac{n\lambda}{\gamma}}$	$1-\frac{1}{n+R\sqrt{n/\lambda\gamma}}$	$\left(1+\frac{R}{\sqrt{n\lambda\gamma}}\right)\log(1/\epsilon)$

Table 2: Comparing step sizes and complexity of SPDC with Chambolle and Pock (2011, Algorithm 3, Theorem 3). Here $A\in\mathbb{R}^{n\times d}$ and its spectral norm $\|A\|_2$ usually grows with n, but always bounded by $\sqrt{n}R$.

where $K\in\mathbb{R}^{m\times d}$, G and F^* are proper closed convex functions, with F^* itself being the conjugate of a convex function F. They developed the following first-order primal-dual algorithm:

$$y^{(t+1)}=\arg\max_{y\in\mathbb{R}^n}\left\{\langle K\overline{x}^{(t)},y\rangle-F^*(y)-\frac{1}{2\sigma}\|y-y^{(t)}\|_2^2\right\}, \tag{28}$$

$$x^{(t+1)}=\arg\min_{x\in\mathbb{R}^d}\left\{\langle K^Ty^{(t+1)},x\rangle+G(x)+\frac{1}{2\tau}\|x-x^{(t)}\|_2^2\right\}, \tag{29}$$

$$\overline{x}^{(t+1)}=x^{(t+1)}+\theta(x^{(t+1)}-x^{(t)}). \tag{30}$$

When both F^* and G are strongly convex and the parameters τ, σ and θ are chosen appropriately, this algorithm obtains accelerated linear convergence rate (Chambolle and Pock, 2011, Theorem 3).

We can map the saddle-point problem (4) into the form of (27) by letting $A=[a_1,\ldots,a_n]^T$ and

$$K=\frac{1}{n}A,\qquad G(x)=g(x),\qquad F^*(y)=\frac{1}{n}\sum_{i=1}^n\phi_i^*(y_i). \tag{31}$$

The SPDC method developed in this paper can be viewed as an extension of the batch method (28)-(30), where the dual update step (28) is replaced by a single coordinate update (5) or a mini-batch update (9). However, in order to obtain accelerated convergence rate, more subtle changes are necessary in the primal update step. More specifically, we introduced the auxiliary variable $u^{(t)}=\frac{1}{n}\sum_{i=1}^n y_i^{(t)}a_i=K^Ty^{(t)}$, and replaced the primal update step (29) by (6) and (10). The primal extrapolation step (30) stays the same.

To compare the batch complexity of SPDC with that of (28)-(30), we use the following facts implied by Assumption A and the relations in (31):

$$\|K\|_2=\frac{1}{n}\|A\|_2,\quad G(x)\text{ is }\lambda\text{-strongly convex},\quad\text{and }F^*(y)\text{ is }(\gamma/n)\text{-strongly convex}.$$

Based on these conditions, we list in Table 2 the equivalent parameters used by Algorithm 3 in Chambolle and Pock (2011) and the batch complexity obtained in Theorem 3 of that paper, and compare them with SPDC.

The batch complexity of the Chambolle-Pock algorithm is $\widetilde{\mathcal{O}}(1+\|A\|_2/(2\sqrt{n\lambda\gamma}))$, where the $\widetilde{\mathcal{O}}(\cdot)$ notation hides the $\log(1/\epsilon)$ factor. We can bound the spectral norm $\|A\|_2$ by the Frobenius norm $\|A\|_F$ and obtain

$$\|A\|_2\le\|A\|_F\le\sqrt{n}\max_i\{\|a_i\|_2\}=\sqrt{n}R.$$

(Note that the second inequality above would be an equality if the columns of A are normalized.) So in the worst case, the batch complexity of the Chambolle-Pock algorithm becomes

$$\widetilde{\mathcal{O}}\left(1+R/\sqrt{\lambda\gamma}\right)=\widetilde{\mathcal{O}}\left(1+\sqrt{\kappa}\right),\qquad\text{where }\kappa=R^2/(\lambda\gamma),$$

which matches the worst-case complexity of the accelerated gradient methods (Nesterov, 2004, 2013); see Section 1.1 and also the discussions in Lin et al. (2015b, Section 5). This is also of the same order as the complexity of SPDC with $m=n$ (see Section 2.1). When the condition number $\kappa\gg1$, they can be $\sqrt{n}$ worse than the batch complexity of SPDC with $m=1$, which is $\widetilde{\mathcal{O}}(1+\sqrt{\kappa/n})$.

If either $G(x)$ or $F^*(y)$ in (27) is not strongly convex, Chambolle and Pock (2011, Section 5.1) proposed variants of the primal-dual batch algorithm to achieve accelerated sublinear convergence rates. It is also possible to extend them to coordinate update methods for solving problem (1) when either ϕ_i^* or g is not strongly convex. Their complexities would be similar to those in Table 1.

Our algorithms and theory can be readily generalized to solve the problem of

$$\underset{x\in\mathbb{R}^d}{\text{minimize}}\quad\frac{1}{n}\sum_{i=1}^n\phi_i(A_i^Tx)+g(x),$$

where each A_i is an $d_i\times d$ matrix, and $\phi_i:\mathbb{R}^{d_i}\to\mathbb{R}$ is a smooth convex function. This more general formulation is used, e.g., in Shalev-Shwartz and Zhang (2015). Most recently, Lan and Zhou (2015) considered the case with $d_i=d$ and $A_i=I_d$, which corresponding to a general class of problems with the finite-sum (or finite-average) structure. He extended the primal-dual algorithm by replacing the quadratic penalty terms in (5) and (21) with the Bregman divergence associated with the loss functions themselves. This led to an algorithm that does not rely on computing the proximal mapping of the conjugate $\phi_i^\star$, but only requires computing the primal gradient $\nabla\phi_i$ at a particular sequence of the primal variables. As a result, the algorithm in Lan and Zhou (2015) can be considered as a (primal-only or dual-free) randomized incremental gradient algorithm, which share the same order of iteration complexity as SPDC.

5.1 Dual Coordinate Ascent Methods

We can also solve the primal problem (1) via its dual:

$$\underset{y\in\mathbb{R}^n}{\text{maximize}}\ \left\{D(y)\ \stackrel{\text{def}}{=}\ \frac{1}{n}\sum_{i=1}^n-\phi_i^*(y_i)-g^*\Big(-\frac{1}{n}\sum_{i=1}^n y_ia_i\Big)\right\}, \tag{32}$$

where $g^*(u)=\sup_{x\in\mathbb{R}^d}\{x^Tu-g(x)\}$ is the convex conjugate of g. Due to the problem structure, it is well-known that coordinate ascent methods can be more efficient than full

gradient methods for solving this problem (e.g., Platt, 1999; Chang et al., 2008; Hsieh et al., 2008; Shalev-Shwartz and Zhang, 2013a). In the stochastic dual coordinate ascent (SDCA) method a dual coordinate y_i is picked at random during each iteration and updated to increase the dual objective value. Shalev-Shwartz and Zhang (2013a) showed that the iteration complexity of SDCA is $O\left((n+\kappa)\log(1/\epsilon)\right)$, which corresponds to the batch complexity $\mathcal{O}\left((1+\kappa/n)\log(1/\epsilon)\right)$.

For more general convex optimization problems, there is a vast literature on coordinate descent methods; see, e.g., the recent overview by Wright (2015). In particular, the work of Nesterov (2012) on randomized coordinate descent sparked a lot of recent activities on this topic. Richtárik and Takáč (2014) extended the algorithm and analysis to composite convex optimization. When applied to the dual problem (32), it becomes one variant of the SDCA algorithm studied in Shalev-Shwartz and Zhang (2013a). Mini-batch and distributed versions of SDCA have been proposed and analyzed in Takáč et al. (2013) and Yang (2013) respectively. Non-uniform sampling schemes similar to the one used in Algorithm 3 have been studied for both stochastic gradient and dual coordinate ascent methods (e.g., Needell et al., 2016; Xiao and Zhang, 2014; Zhao and Zhang, 2015; Qu et al., 2015).

Shalev-Shwartz and Zhang (2013b) proposed an accelerated mini-batch SDCA method which incorporates additional primal updates than SDCA, and bears some similarity to our mini-batch SPDC method. They showed that its complexity interpolates between that of SDCA and accelerated gradient methods by varying the mini-batch size m. In particular, for $m = n$, it matches that of the accelerated gradient methods (as SPDC does). But for $m = 1$, the complexity of their method is the same as SDCA, which is worse than SPDC for ill-conditioned problems.

In addition, Shalev-Shwartz and Zhang (2015) developed an accelerated proximal SDCA method which achieves the same batch complexity $\widetilde{\mathcal{O}}\big(1+\sqrt{\kappa/n}\big)$ as SPDC. Their method is an inner-outer iteration procedure, where the outer loop is a full-dimensional accelerated gradient method in the primal space $x \in \mathbb{R}^d$. At each iteration of the outer loop, the SDCA method (Shalev-Shwartz and Zhang, 2013a) is called to solve the dual problem (32) with customized regularization parameter and precision. In contrast, SPDC is a straightforward single-loop coordinate optimization methods. Two recent works extended the inner-outer iteration method to derive more general accelerated proximal-point algorithms: Frostig et al. (2015) and Lin et al. (2015a). Basically, one can replace the inner-loop SDCA algorithm by other efficient algorithms such as Prox-SVRG (Xiao and Zhang, 2014) or SAGA (Defazio et al., 2014) to obtain the same overall complexity.

More recently, Lin et al. (2015b) developed an accelerated proximal coordinate gradient (APCG) method for solving a more general class of composite convex optimization problems. When applied to solve the dual problem (32), APCG enjoys the same batch complexity $\widetilde{\mathcal{O}}\big(1+\sqrt{\kappa/n}\big)$ for reducing the dual objective gap. In order to obtain the same complexity for the primal-dual gap, One needs an extra primal proximal-gradient step at the end after applying the APCG algorithm. The computational cost of this additional step is equivalent to one pass of the dataset, thus it does not affect the overall complexity.

5.2 Other Related Work

Another way to approach problem (1) is to reformulate it as a constrained optimization problem

$$\begin{aligned} \text{minimize} \quad & \frac{1}{n}\sum_{i=1}^{n}\phi_i(z_i) + g(x) \\ \text{subject to} \quad & a_i^T x = z_i, \quad i = 1,\dots,n, \end{aligned} \tag{33}$$

and solve it by ADMM type of operator-splitting methods (e.g., Lions and Mercier, 1979; Boyd et al., 2010). In fact, as shown in Chambolle and Pock (2011), the batch primal-dual algorithm (28)-(30) is equivalent to a pre-conditioned ADMM or an inexact Uzawa method (see, e.g., Zhang et al., 2011). Several authors (Wang and Banerjee, 2012; Ouyang et al., 2013; Suzuki, 2013; Zhong and Kwok, 2014) have considered a more general formulation than (33), where each ϕ_i is a function of the whole vector $z \in \mathbb{R}^n$. They proposed online or stochastic versions of ADMM which operate on only one ϕ_i in each iteration, and obtained sublinear convergence rates. However, their cost per iteration is $\mathcal{O}(nd)$ instead of $\mathcal{O}(d)$.

Suzuki (2014) considered a problem similar to (1), but with more complex regularization function g, meaning that g does not have a simple proximal mapping. Thus primal updates such as step (6) or (10) in SPDC and similar steps in SDCA cannot be computed efficiently. He proposed an algorithm that combines SDCA (Shalev-Shwartz and Zhang, 2013a) and ADMM, and showed that it has linear rate of convergence under similar conditions as Assumption A. It would be interesting to see if the SPDC method can be extended to their setting to obtain accelerated linear convergence rate.

6. Efficient Implementation with Sparse Data

During each iteration of the SPDC method, the update of primal variables (i.e., computing $x^{(t+1)}$) requires full d-dimensional vector operations; see the step (6) of Algorithm 1, the step (10) of Algorithm 2 and the step (23) of Algorithm 3. So the computational cost per iteration is $\mathcal{O}(d)$, and this can be too expensive if the dimension d is very high. In this section, we show how to exploit problem structure to avoid high-dimensional vector operations when the feature vectors a_i are sparse. We illustrate the efficient implementation for two popular cases: when g is an squared-ℓ_2 penalty and when g is an $\ell_1+\ell_2$ penalty. For both cases, we show that the computation cost per iteration only depends on the number of non-zero components of the feature vector.

6.1 Squared ℓ_2-Norm Penalty

Suppose that $g(x) = \frac{\lambda}{2}\|x\|_2^2$. For this case, the updates for each coordinate of x are independent of each other. More specifically, $x^{(t+1)}$ can be computed coordinate-wise in closed form:

$$x_j^{(t+1)} = \frac{1}{1+\lambda\tau}(x_j^{(t)} - \tau u_j^{(t)} - \tau\Delta u_j), \quad j = 1,\dots,n, \tag{34}$$

where Δu denotes $(y_k^{(t+1)} - y_k^{(t)})a_k$ in Algorithm 1, or $\frac{1}{m}\sum_{k\in K}(y_k^{(t+1)} - y_k^{(t)})a_k$ in Algorithm 2, or $(y_k^{(t+1)} - y_k^{(t)})a_k/(p_k n)$ in Algorithm 3, and Δu_j represents the j-th coordinate of Δu.

Although the dimension d can be very large, we assume that each feature vector a_k is sparse. We denote by $J^{(t)}$ the set of non-zero coordinates at iteration t, that is, if for some index $k \in K$ picked at iteration t we have $a_{kj} \neq 0$, then $j \in J^{(t)}$. If $j \notin J^{(t)}$, then the SPDC algorithm (and its variants) updates $y^{(t+1)}$ without using the value of $x_j^{(t)}$ or $\overline{x}_j^{(t)}$. This can be seen from the updates in (5), (9) and (21), where the value of the inner product $\langle a_k, \overline{x}^{(t)} \rangle$ does not depend on the value of $\overline{x}_j^{(t)}$. As a consequence, we can delay the updates on x_j and $\overline{x}_j$ whenever $j \notin J^{(t)}$ without affecting the updates on $y^{(t)}$, and process all the missing updates at the next time when $j \in J^{(t)}$.

Such a delayed update can be carried out very efficiently. We assume that t_0 is the last time when $j \in J^{(t)}$, and t_1 is the current iteration where we want to update x_j and $\overline{x}_j$. Since $j \notin J^{(t)}$ implies $\Delta u_j = 0$, we have

$$x_j^{t+1} = \frac{1}{1+\lambda\tau}(x_j^{(t)} - \tau u_j^{(t)}), \qquad t = t_0+1, t_0+2, \ldots, t_1-1. \tag{35}$$

Notice that $u_j^{(t)}$ is updated only at iterations where $j \in J^{(t)}$. The value of $u_j^{(t)}$ doesn't change during iterations $[t_0+1, t_1]$, so we have $u_j^{(t)} \equiv u_j^{(t_0+1)}$ for $t \in [t_0+1, t_1]$. Substituting this equation into the recursive formula (35), we obtain

$$x_j^{(t_1)} = \frac{1}{(1+\lambda\tau)^{t_1-t_0-1}} \left(x_j^{(t_0+1)} + \frac{u_j^{(t_0+1)}}{\lambda} \right) - \frac{u_j^{(t_0+1)}}{\lambda}. \tag{36}$$

The update (36) takes $\mathcal{O}(1)$ time to compute. Using the same formula, we can compute $x_j^{(t_1-1)}$ and subsequently compute $\overline{x}_j^{(t_1)} = x_j^{(t_1)} + \theta(x_j^{(t_1)} - x_j^{(t_1-1)})$. Thus, the computational complexity of a single iteration in SPDC is proportional to $|J^{(t)}|$, independent of the dimension d.

We note that similar tricks of delayed updates, or "just-in-time" updates, have been derived and used for the SAG algorithm (Schmidt et al., 2013). For SPDC, the delayed updates become more complex due to the full vector extrapolation required for Nesterov-type acceleration.

6.2 $(\ell_1 + \ell_2)$-Norm Penalty

Suppose that $g(x) = \lambda_1 \|x\|_1 + \frac{\lambda_2}{2}\|x\|_2^2$. Since both the ℓ_1-norm and the squared ℓ_2-norm are decomposable, the updates for each coordinate of $x^{(t+1)}$ are independent. More specifically,

$$x_j^{(t+1)} = \arg\min_{\alpha \in \mathbb{R}} \left\{ \lambda_1|\alpha| + \frac{\lambda_2\alpha^2}{2} + (u_j^{(t)} + \Delta u_j)\alpha + \frac{(\alpha - x_j^{(t)})^2}{2\tau} \right\}, \tag{37}$$

where Δu_j follows the definition in Section 6.1. If $j \notin J^{(t)}$, then $\Delta u_j = 0$ and equation (37) can be simplified as

$$x_j^{(t+1)} = \begin{cases} \frac{1}{1+\lambda_2\tau}(x_j^{(t)} - \tau u_j^{(t)} - \tau\lambda_1) & \text{if } x_j^{(t)} - \tau u_j^{(t)} > \tau\lambda_1, \\ \frac{1}{1+\lambda_2\tau}(x_j^{(t)} - \tau u_j^{(t)} + \tau\lambda_1) & \text{if } x_j^{(t)} - \tau u_j^{(t)} < -\tau\lambda_1, \\ 0 & \text{otherwise,} \end{cases} \qquad t \in [t_0+1, t_1]. \tag{38}$$

Similar to the approach of Section 6.1, we delay the update of x_j until $j \in J^{(t)}$. We assume t_0 to be the last iteration when $j \in J^{(t)}$, and let t_1 be the current iteration when we want to update x_j. During iterations $[t_0+1, t_1]$, the value of $u_j^{(t)}$ doesn't change, so we have $u_j^{(t)} \equiv u_j^{(t_0+1)}$ for $t \in [t_0+1, t_1]$. Using equation (38) and the invariance of $u_j^{(t)}$ for $t \in [t_0+1, t_1]$, we have an $\mathcal{O}(1)$ time algorithm to calculate $x_j^{(t_1)}$. More specifically, given $x_j^{(t_0+1)}$ at iteration t_0, we present an efficient algorithm for calculating $x_j^{(t_1)}$. We begin by examining the sign of $x_j^{(t_0+1)}$.

Case I ($x_j^{(t_0+1)} = 0$): If $-u_j^{(t_0+1)} > \lambda_1$, then equation (38) implies $x_j^{(t)} > 0$ for all $t > t_0+1$. Consequently, we have a closed-form formula for $x_j^{(t_1)}$:

$$x_j^{(t_1)} = \frac{1}{(1+\lambda_2\tau)^{t_1-t_0-1}} \left(x_j^{(t_0+1)} + \frac{u_j^{(t_0+1)} + \lambda_1}{\lambda_2} \right) - \frac{u_j^{(t_0+1)} + \lambda_1}{\lambda_2}. \tag{39}$$

If $-u_j^{(t_0+1)} < -\lambda_1$, then equation (38) implies $x_j^{(t)} < 0$ for all $t > t_0+1$. Therefore, we have the closed-form formula:

$$x_j^{(t_1)} = \frac{1}{(1+\lambda_2\tau)^{t_1-t_0-1}} \left(x_j^{(t_0+1)} + \frac{u_j^{(t_0+1)} - \lambda_1}{\lambda_2} \right) - \frac{u_j^{(t_0+1)} - \lambda_1}{\lambda_2}. \tag{40}$$

Finally, if $-u_j^{(t_0+1)} \in [-\lambda_1, \lambda_1]$, then equation (38) implies $x_j^{(t_1)} = 0$.

Case II ($x_j^{(t_0+1)} > 0$): If $-u_j^{(t_0+1)} \geq \lambda_1$, then it is easy to verify that $x_j^{(t_1)}$ is obtained by equation (39). Otherwise, We use the recursive formula (38) to derive the latest time $t^+ \in [t_0+1, t_1]$ such that $x_j^{t^+} > 0$ is true. Indeed, since $x_j^{(t)} > 0$ for all $t \in [t_0+1, t^+]$, we have a closed-form formula for $x_j^{t^+}$:

$$x_j^{t^+} = \frac{1}{(1+\lambda_2\tau)^{t^+-t_0-1}} \left(x_j^{(t_0+1)} + \frac{u_j^{(t_0+1)} + \lambda_1}{\lambda_2} \right) - \frac{u_j^{(t_0+1)} + \lambda_1}{\lambda_2}. \tag{41}$$

We look for the largest t^+ such that the right-hand side of equation (41) is positive, which is equivalent of

$$t^+ - t_0 - 1 < \log\left(1 + \frac{\lambda_2 x_j^{(t_0+1)}}{u_j^{(t_0+1)} + \lambda_1}\right) / \log(1+\lambda_2\tau). \tag{42}$$

Thus, t^+ is the largest integer in $[t_0+1, t_1]$ such that inequality (42) holds. If $t^+ = t_1$, then $x_j^{(t_1)}$ is obtained by (41). Otherwise, we can calculate $x_j^{t^++1}$ by formula (38), then resort to Case I or Case III, treating t^+ as t_0.

Case III ($x_j^{(t_0+1)} < 0$): If $-u_j^{(t_0+1)} \leq -\lambda_1$, then $x_j^{(t_1)}$ is obtained by equation (40). Otherwise, we calculate the largest integer $t^- \in [t_0+1, t_1]$ such that $x_j^{t^-} < 0$ is true. Using the same argument as for Case II, we have the closed-form expression

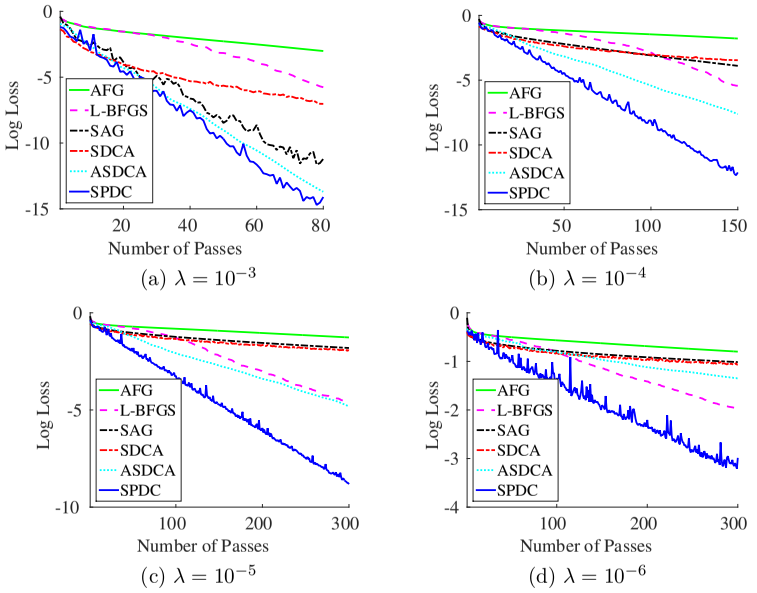
$$x_j^{t^-} = \frac{1}{(1+\lambda_2\tau)^{t^--t_0-1}} \left(x_j^{(t_0+1)} + \frac{u_j^{(t_0+1)} - \lambda_1}{\lambda_2} \right) - \frac{u_j^{(t_0+1)} - \lambda_1}{\lambda_2}. \tag{43}$$

where t^- is the largest integer in $[t_0+1, t_1]$ such that the following inequality holds:

$$t^- - t_0 - 1 < \log\left(1 + \frac{\lambda_2 x_j^{(t_0+1)}}{u_j^{(t_0+1)} - \lambda_1}\right) / \log(1+\lambda_2\tau). \tag{44}$$

If $t^- = t_1$, then $x_j^{(t_1)}$ is obtained by (43). Otherwise, we can calculate $x_j^{t^-+1}$ by formula (38), then resort to Case I or Case II, treating t^- as t_0.

Finally, we note that formula (38) implies the monotonicity of $x_j^{(t)}$ $(t = t_0+1, t_0+2, \dots)$. As a consequence, the procedure of either Case I, Case II or Case III is executed for at most once. Hence, the algorithm for calculating $x_j^{(t_1)}$ has $\mathcal{O}(1)$ time complexity.



The vector $\overline{x}_j^{(t_1)}$ can be updated by the same algorithm since it is a linear combination of $x_j^{(t_1)}$ and $x_j^{(t_1-1)}$. As a consequence, the computational complexity of each iteration in SPDC is proportional to $|J^{(t)}|$, independent of the dimension d.

7. Experiments

In this section, we compare the basic SPDC method (Algorithm 1) with several state-of-the-art algorithms for solving problem (1). They include two batch-update algorithms: the accelerated full gradient (AFG) method (Nesterov, 2004, Section 2.2), and the limited-memory quasi-Newton method L-BFGS (Nocedal and Wright, 2006, Section 7.2)). For the AFG method, we adopt an adaptive line search scheme (Nesterov, 2013) to improve its efficiency. For the L-BFGS method, we use the memory size 30 as suggested by Nocedal and Wright (2006, Section 7.2).

We also compare SPDC with three stochastic algorithms: the stochastic average gradient (SAG) method (Le Roux et al., 2012; Schmidt et al., 2013), the stochastic dual coordinate descent (SDCA) method (Shalev-Shwartz and Zhang, 2013a) and the accelerated stochastic dual coordinate descent (ASDCA) method(Shalev-Shwartz and Zhang, 2015). We conduct experiments on a synthetic dataset and three real datasets. The hyper-parameters τ, σ, θ of the SPDC algorithm are chosen by their theoretical values given in (12). For SDCA, we use their default parameter settings given in Shalev-Shwartz and Zhang (2013a), which can be determined from the Lipschitz constant $1/\gamma$ of the loss functions and the strongly convex regularization parameter λ. For SAG, we choose the learning rate $\alpha = \gamma/R$ as recommended by Schmidt et al. (2013).

We caution the readers that our numerical experiments in this section focus on comparing the *optimization* performance of various algorithms, i.e., how fast they can reduce the objective function to its minimum value. In order to illustrate their differences for very ill-conditioned problems, we often run the algorithms with hundreds of passes over the datasets in order to reach a small optimization error. Such large numbers of passes over datasets and the small optimization errors may not be appropriate for machine learning problems, especially from the point of view of *generalization* (reducing testing error). See Bottou and Bousquet (2008) for discussions on the fundamental tradeoffs of large scale learning problems.

(a) $\lambda = 10^{-3}$ (b) $\lambda = 10^{-4}$ (c) $\lambda = 10^{-5}$ (d) $\lambda = 10^{-6}$

Figure 1: Comparing SPDC with other methods for ridge regression on synthetic data, with the regularization coefficient $\lambda \in \{10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}\}$. The horizontal axis is the number of passes through the entire dataset, and the vertical axis is the logarithmic gap $\log(P(x^{(T)}) - P(x^\star))$.

7.1 Ridge Regression with Synthetic Data

We first compare SPDC with other algorithms on a simple quadratic problem using synthetic data. We generate $n = 500$ i.i.d. training examples $\{a_i, b_i\}_{i=1}^n$ according to the model

$$b = \langle a, x^* \rangle + \varepsilon, \quad a \sim \mathcal{N}(0, \Sigma), \quad \varepsilon \sim \mathcal{N}(0,1),$$

where $a \in \mathbb{R}^d$ and $d = 500$, and x^* is the all-ones vector. To make the problem ill-conditioned, the covariance matrix Σ is set to be diagonal with $\Sigma_{jj} = j^{-2}$, for $j = 1, \dots, d$. Given the set of examples $\{a_i, b_i\}_{i=1}^n$, we then solved a standard ridge regression problem

$$\underset{x \in \mathbb{R}^d}{\text{minimize}} \left\{ P(x) \stackrel{\text{def}}{=} \frac{1}{n}\sum_{i=1}^n \frac{1}{2}(a_i^T x - b_i)^2 + \frac{\lambda}{2}\|x\|_2^2 \right\}.$$

In the form of problem (1), we have $\phi_i(z) = z^2/2$ and $g(x) = (1/2)\|x\|_2^2$. As a consequence, the derivative of ϕ_i is 1-Lipschitz continuous and g is λ-strongly convex.

Dataset name	# of samples n	# of features d	sparsity	size
Covtype	581,012	54	22%	71 MB
RCV1	20,242	47,236	0.16%	37 MB
News20	19,996	1,355,191	0.04%	140 MB
RCV1-test	677,399	47,236	0.15%	1.2 GB
URL	2,396,130	3,231,961	0.004%	2.2 GB

Table 3: Characteristics of real datasets from LIBSVM data (Fan and Lin, 2011).

We evaluate the algorithms by the logarithmic optimality gap $\log(P(x^{(t)}) - P(x^\star))$, where $x^{(t)}$ is the output of the algorithms after t passes over the entire dataset, and $x^\star$ is the global minimum. When the regularization coefficient is relatively large, e.g., $\lambda = 10^{-1}$ or 10^{-2}, the problem is well-conditioned and we observe fast convergence of the stochastic algorithms SAG, SDCA, ASDCA and SPDC, which are substantially faster than the two batch methods AFG and L-BFGS.

Figure 1 shows the convergence of the five different algorithms when we varied λ from 10^{-3} to 10^{-6}. As the plot shows, when the condition number is greater than n, the SPDC algorithm also converges substantially faster than the other two stochastic methods SAG and SDCA. It is also notably faster than L-BFGS. These results support our theory that SPDC enjoys a faster convergence rate on ill-conditioned problems. In terms of their batch complexities, SPDC is up to $\sqrt{n}$ times faster than AFG, and $(\lambda n)^{-1/2}$ times faster than SAG and SDCA.

Theoretically, ASDCA enjoys the same batch complexity as SPDC up to a multiplicative constant factor. Figure 1 shows that the empirical performance of SPDC is substantially faster that of ASDCA for small λ. This may due to the fact that ASDCA follows an inner-outer iteration procedure, which requires careful selection of the regularization parameter and accuracy to reach for each call of SDCA. SPDC is a single-loop algorithm that needs less parameters to set up, thus it can be empirically more efficient.

7.2 Binary Classification with Real Data

Finally we show the results of solving the binary classification problem on real datasets. The datasets are obtained from the LIBSVM data collection (Fan and Lin, 2011) and summarized in Table 3. The first three datasets are selected to reflect different relations between the sample size n and the feature dimensionality d, which cover $n \gg d$ (Covtype), $n \approx d$ (RCV1) and $n \ll d$ (News20). The remaining two are relatively larger datasets (RCV1-test and URL) that we did not test in previous experiments conducted in Zhang and Xiao (2015). For all tasks, the data points take the form of (a_i, b_i), where $a_i \in \mathbb{R}^d$ is the feature vector, and $b_i \in \{-1, 1\}$ is the binary class label. As a preprocessing step, the feature vectors are normalized to the unit ℓ_2-norm (meaning $R = 1$).

Our goal is to minimize the regularized empirical risk:

$$P(x) = \frac{1}{n}\sum_{i=1}^{n} \phi_i(a_i^T x) + \frac{\lambda}{2}\|x\|_2^2, \quad \text{where} \quad \phi_i(z) = \begin{cases} 0 & \text{if } b_i z \geq 1 \\ \frac{1}{2} - b_i z & \text{if } b_i z \leq 0 \\ \frac{1}{2}(1 - b_i z)^2 & \text{otherwise.} \end{cases}$$

Here, ϕ_i is the smoothed hinge loss (see, e.g., Shalev-Shwartz and Zhang, 2013a). It is easy to verify that the conjugate function of ϕ_i is $\phi_i^*(\beta) = b_i\beta + \frac{1}{2}\beta^2$ for $b_i\beta \in [-1, 0]$ and ∞ otherwise.

The performance of the five algorithms on the three smaller datasets are plotted in Figure 2 and Figure 3. In Figure 2, we compare SPDC with the two batch methods: AFG and L-BFGS. The results show that SPDC is substantially faster than AFG and L-BFGS for relatively large λ, illustrating the advantage of stochastic methods over batch methods on well-conditioned problems. As λ decreases to 10^{-8}, the batch methods (especially L-BFGS) become comparable to SPDC.

In Figure 3, we compare SPDC with the three stochastic methods: SAG, SDCA and ASDCA. Note that the specification of ASDCA (Shalev-Shwartz and Zhang, 2015) requires the regularization coefficient λ satisfies $\lambda \leq \frac{R^2}{10n}$ where R is the maximum ℓ_2-norm of feature vectors. To satisfy this constraint, we run ASDCA with $\lambda \in \{10^{-6}, 10^{-7}, 10^{-8}\}$. In Figure 3, the observations are just the opposite to that of Figure 2. All stochastic algorithms have comparable performances on relatively large λ, but SPDC and ASDCA becomes substantially faster when λ gets closer to zero. In particular, ASDCA converges faster than SPDC on the Covtype dataset, but SPDC is faster on the remaining two datasets. In addition, due to the outer-inner loop structure of the ASDCA algorithm, its error rate oscillates and might be bad at early iterations. In contrast, the curve of SPDC is almost linear and it is more stable than ASDCA.

Figure 4 plots the convergence results on the last two datasets, where both the sample size n and the dimension d are big. If the regularization parameter λ is also relatively large, then the stochastic algorithms (SPDC, SAG and SDCA) will guarantee to converge very quickly, making it an easy optimization problem. We report experiments on small regularization values $\lambda = 10^{-6}$ and $\lambda = 10^{-8}$. The ASDCA algorithm is reported on $\lambda = 10^{-8}$ because it satisfies the constraint $\lambda \leq \frac{R^2}{10n}$. Comparing results on the RCV1 and RCV1-test datasets, the SPDC algorithm has a more significant advantage over the batch methods (AFG and L-BFGS) on the bigger dataset, because the stochastic algorithm converges faster with a larger sample size. On the other hand, the performance gaps between SPDC and the two other stochastic methods (SAG and SDCA) are less significant on the bigger dataset. We observe the same phenomenon on the URL dataset.

Summarizing Figure 2, Figure 3 and Figure 4, the performance of the SPDC algorithm are always comparable or better than the other methods, for various of relations between the sample size n and the dimension d, and on both small and large datasets.

7.3 Uniform Sampling versus Non-Uniform Sampling

In this subsection, we compare the uniform sampling strategy (Algorithm 1) and the non-uniform sampling strategy (Algorithm 3) for SPDC. We repeat the binary classification experiments on the Covtype, RCV1 and News20 datasets, but this time without performing feature normalization. More precisely, for each data point taking the form of (a_i, b_i), we don't normalize the feature vector a_i to the unit ℓ_2-norm. But instead, we multiply a constant number to every feature vector so that the average ℓ_2-norm $\overline{R}$ is equal to one. It ensures that the overall loss function is 1-smooth.

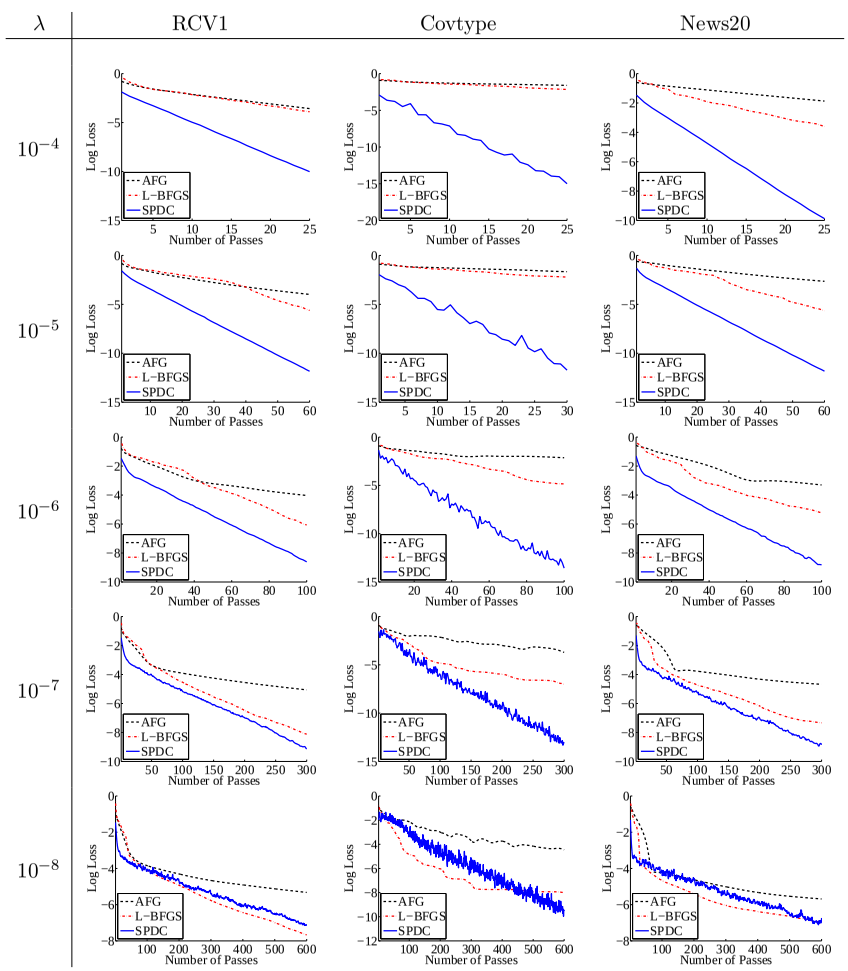


Figure 2: Comparing SPDC with AFG and L-BFGS on three real datasets with smoothed hinge loss. The horizontal axis is the number of passes through the entire dataset, and the vertical axis is the logarithmic optimality gap $\log(P(x^{(t)}) - P(x^\star))$. The SPDC algorithm is faster than the two batch methods when λ is relatively large.

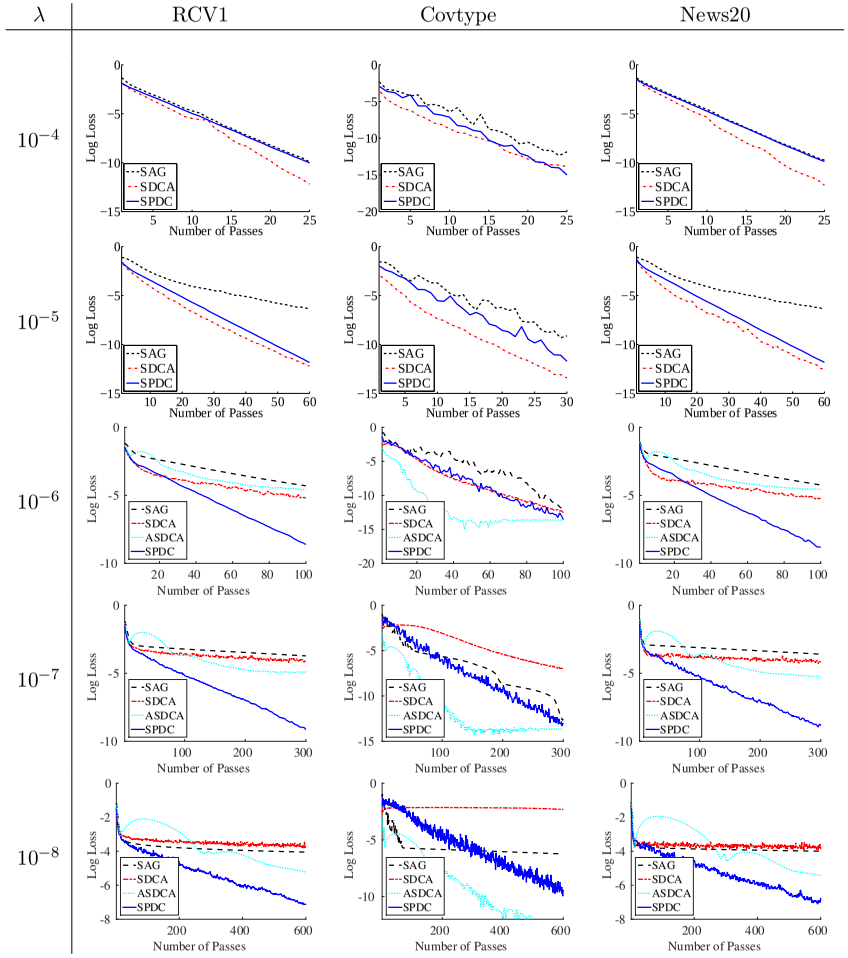

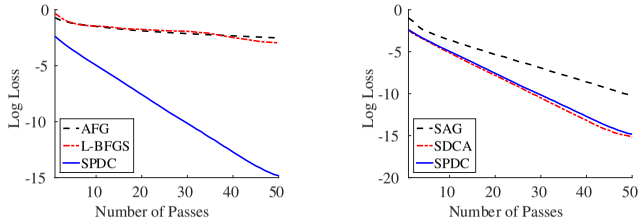

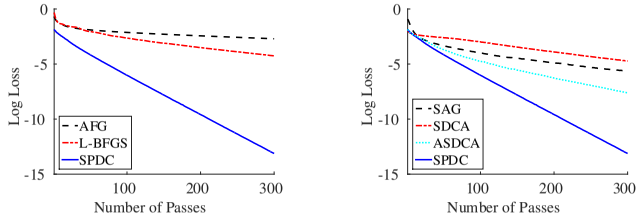

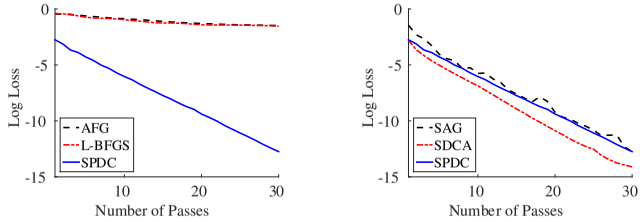

Figure 3: Comparing SPDC with SAG, SDCA and ASDCA on three real datasets with smoothed hinge loss. The horizontal axis is the number of passes through the entire dataset, and the vertical axis is the logarithmic optimality gap $\log(P(x^{(T)}) - P(x^\star))$. The SPDC algorithm is faster than SAG and SDCA when λ is small. It is faster than ASDCA on datasets RCV1 and News20.

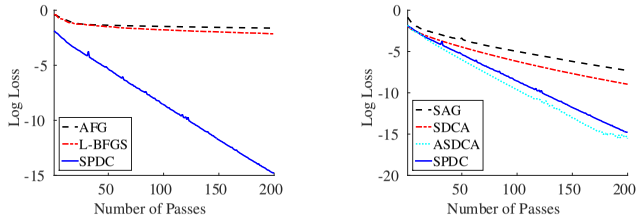
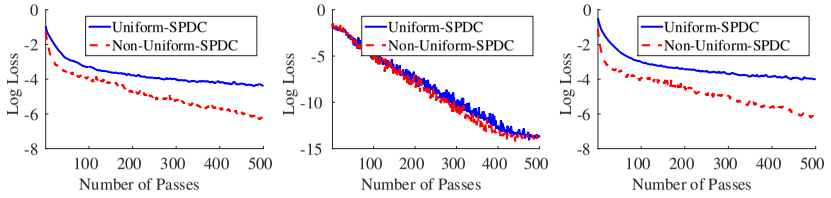


(a) RCV1-test ($\lambda = 10^{-6}$)

(b) RCV1-test ($\lambda = 10^{-8}$)



(c) URL ($\lambda = 10^{-6}$)

(d) URL ($\lambda = 10^{-8}$)

Figure 4: Comparing SPDC with other methods on the two larger datasets. The vertical axis is the logarithmic optimality gap $\log(P(x^{(t)}) - P(x^\star))$.

(a) RCV1 ($R/\overline{R} = 3.87$) (b) Covtype ($R/\overline{R} = 1.25$) (c) News20 ($R/\overline{R} = 6.71$)

Figure 5: Comparing the uniform sampling and non-uniform sampling strategies for SPDC, where the vertical axis is the logarithmic optimality gap $\log(P(x^{(t)}) - P(x^\star))$. The quantity $R/\overline{R}$ represents the ratio between the largest feature norm and the average feature norm. When this quantity is large, the non-uniform sampling algorithm converges significantly faster.

For this experiment, we use a small regularization parameter $\lambda = 10^{-8}$, so that the problem has a large condition number. The hyper-parameters τ, σ, θ are chosen by their theoretical values in (12) and (24), respectively for the two sampling strategies. For non-uniform sampling, the hyper-parameter α is chosen by the optimal value given in (25). Figure 5 plots their convergence profiles. On all of the three datasets, the non-uniform sampling algorithm converges faster. The margin is quite significant when the ratio between the largest feature norm R and the average feature norm $\overline{R}$ is relatively large. This is consistent with our analysis in Theorem 1 and Theorem 6, which state that the convergence rate of the uniform sampling algorithm depends R, while that of the non-uniform sampling algorithm depends on $\overline{R}$.

Acknowledgments

We are grateful to Qihang Lin for helpful discussions, especially on the proof of Lemma 3.

Appendix A. Proof of Theorem 1

We focus on characterizing the values of x and y after the t-th update in Algorithm 2. For any $i \in \{1, \ldots, n\}$, let $\widetilde{y}_i$ be the value of $y_i^{(t+1)}$ if $i \in K$, i.e.,

$$\widetilde{y}_i = \arg\max_{\beta \in \mathbb{R}} \left\{ \beta \langle a_i, \overline{x}^{(t)} \rangle - \phi_i^*(\beta) - \frac{(\beta - y_i^{(t)})^2}{2\sigma} \right\}.$$

Since by assumption ϕ_i is $(1/\gamma)$-smooth, its convex conjugate ϕ_i^* is γ-strongly convex (see, e.g., Hiriart-Urruty and Lemaréchal, 2001, Theorem 4.2.2). Thus the function being maxi-

mized above is $(1/\sigma+\gamma)$-strongly concave. Therefore,

$$-y_i^\star\langle a_i,\overline{x}^{(t)}\rangle+\phi_i^*(y_i^\star)+\frac{(y_i^\star-y_i^{(t)})^2}{2\sigma}\geq-\widetilde{y}_i\langle a_i,\overline{x}^{(t)}\rangle+\phi_i^*(\widetilde{y}_i)+\frac{(\widetilde{y}_i-y_i^{(t)})^2}{2\sigma}+\Big(\frac{1}{\sigma}+\gamma\Big)\frac{(\widetilde{y}_i-y_i^\star)^2}{2}.$$

Multiplying both sides of the above inequality by m/n and re-arrange terms, we have

$$\frac{m}{2\sigma n}(y_i^{(t)}-y_i^\star)^2\geq\Big(\frac{1}{\sigma}+\gamma\Big)\frac{m}{2n}(\widetilde{y}_i-y_i^\star)^2+\frac{m}{2\sigma n}(\widetilde{y}_i-y_i^{(t)})^2-\frac{m}{n}(\widetilde{y}_i-y_i^\star)\langle a_i,\overline{x}^{(t)}\rangle+\frac{m}{n}\big(\phi_i^*(\widetilde{y}_i)-\phi_i^*(y_i^\star)\big).\tag{45}$$

According to Algorithm 2, the set K of indices to be updated are chosen randomly. For every specific index i, the event $i\in K$ happens with probability m/n. If $i\in K$, then $y_i^{(t+1)}$ is updated to the value $\widetilde{y}_i$, which satisfies inequality (45). Otherwise, $y_i^{(t+1)}$ is assigned by its old value $y_i^{(t)}$. Let $\mathcal{F}_t$ be the sigma field generated by all random variables defined before round t, and taking expectation conditioned on $\mathcal{F}_t$, we have

$$\begin{aligned}\mathbb{E}[(y_i^{(t+1)}-y_i^\star)^2|\mathcal{F}_t]&=\frac{m(\widetilde{y}_i-y_i^\star)^2}{n}+\frac{(n-m)(y_i^{(t)}-y_i^\star)^2}{n},\\ \mathbb{E}[(y_i^{(t+1)}-y_i^{(t)})^2|\mathcal{F}_t]&=\frac{m(\widetilde{y}_i-y_i^{(t)})^2}{n},\\ \mathbb{E}[y_i^{(t+1)}|\mathcal{F}_t]&=\frac{m\widetilde{y}_i}{n}+\frac{(n-m)y_i^{(t)}}{n}\\ \mathbb{E}[\phi_i^*(y_i^{(t+1)})|\mathcal{F}_t]&=\frac{m}{n}\phi_i^*(\widetilde{y}_i)+\frac{n-m}{n}\phi_i^*(y_i^{(t)}).\end{aligned}$$

As a result, we can represent $(\widetilde{y}_i-y_i^\star)^2$, $(\widetilde{y}_i-y_i^{(t)})^2$, $\widetilde{y}_i$ and $\phi_i^*(\widetilde{y}_i)$ in terms of the conditional expectations on $(y_i^{(t+1)}-y_i^\star)^2$, $(y_i^{(t+1)}-y_i^{(t)})^2$, $y_i^{(t+1)}$ and $\phi_i^*(y_i^{(t+1)})$, respectively. Plugging these representations into inequality (45) and re-arranging terms, we obtain

$$\begin{aligned}\Big(\frac{1}{2\sigma}+\frac{(n-m)\gamma}{2n}\Big)(y_i^{(t)}-y_i^\star)^2\geq&\Big(\frac{1}{2\sigma}+\frac{\gamma}{2}\Big)\mathbb{E}[(y_i^{(t+1)}-y_i^\star)^2|\mathcal{F}_t]+\frac{1}{2\sigma}\mathbb{E}[(y_i^{(t+1)}-y_i^{(t)})^2|\mathcal{F}_t]\\&-\Big(\frac{m}{n}(y_i^{(t)}-y_i^\star)+\mathbb{E}[y_i^{(t+1)}-y_i^{(t)}|\mathcal{F}_t]\Big)\langle a_i,\overline{x}^{(t)}\rangle\\&+\mathbb{E}[\phi_i^*(y_i^{(t+1)})|\mathcal{F}_t]-\phi_i^*(y_i^{(t)})+\frac{m}{n}\big(\phi_i^*(y_i^{(t)})-\phi_i^*(y_i^\star)\big).\end{aligned}\tag{46}$$

Then summing over all indices $i=1,2,\ldots,n$ and dividing both sides of the resulting inequality by m, we have

$$\begin{aligned}\Big(\frac{1}{2\sigma}+\frac{(n-m)\gamma}{2n}\Big)\frac{\|y^{(t)}-y^\star\|_2^2}{m}\geq&\Big(\frac{1}{2\sigma}+\frac{\gamma}{2}\Big)\frac{\mathbb{E}[\|y^{(t+1)}-y^\star\|_2^2|\mathcal{F}_t]}{m}+\frac{1}{2\sigma}\frac{\mathbb{E}[\|y^{(t+1)}-y^{(t)}\|_2^2|\mathcal{F}_t]}{m}\\&+\mathbb{E}\Big[\frac{1}{m}\sum_{k\in K}\big(\phi_k^*(y_k^{(t+1)})-\phi_k^*(y_k^{(t)})\big)\Big|\mathcal{F}_t\Big]+\frac{1}{n}\sum_{i=1}^n\big(\phi_i^*(y_i^{(t)})-\phi_i^*(y_i^\star)\big)\\&-\mathbb{E}\Big[\Big\langle u^{(t)}-u^\star+\frac{n}{m}(u^{(t+1)}-u^{(t)}),\,\overline{x}^{(t)}\Big\rangle\Big|\mathcal{F}_t\Big],\end{aligned}\tag{47}$$

where we used the shorthand notations (appeared in Algorithm 2)

$$u^{(t)}=\frac{1}{n}\sum_{i=1}^n y_i^{(t)}a_i,\qquad u^{(t+1)}=\frac{1}{n}\sum_{i=1}^n y_i^{(t+1)}a_i,\qquad\text{and}\qquad u^\star=\frac{1}{n}\sum_{i=1}^n y_i^\star a_i.\tag{48}$$

Since only the dual coordinates with indices in K are updated, we have

$$\frac{n}{m}(u^{(t+1)}-u^{(t)})=\frac{1}{m}\sum_{i=1}^n(y_i^{(t+1)}-y_i^{(t)})a_i=\frac{1}{m}\sum_{k\in K}(y_k^{(t+1)}-y_k^{(t)})a_k.$$

We also derive an inequality characterizing the relation between $x^{(t+1)}$ and $x^{(t)}$. Since the function being minimized on the right-hand side of (10) has strong convexity parameter $1/\tau+\lambda$ and $x^{(t+1)}$ is the minimizer, we have

$$\begin{aligned}&g(x^\star)+\Big\langle u^{(t)}+\frac{n}{m}(u^{(t+1)}-u^{(t)}),\;x^\star\Big\rangle+\frac{\|x^{(t)}-x^\star\|_2^2}{2\tau}\\\geq\;&g(x^{(t+1)})+\Big\langle u^{(t)}+\frac{n}{m}(u^{(t+1)}-u^{(t)}),\;x^{(t+1)}\Big\rangle+\Big(\frac{1}{2\tau}+\frac{\lambda}{2}\Big)\|x^{(t+1)}-x^\star\|_2^2\\&+\frac{\|x^{(t+1)}-x^{(t)}\|_2^2}{2\tau}.\end{aligned}\tag{49}$$

Rearranging terms and taking expectation conditioned on $\mathcal{F}_t$, we have

$$\begin{aligned}\frac{\|x^{(t)}-x^\star\|_2^2}{2\tau}\geq&\Big(\frac{1}{2\tau}+\frac{\lambda}{2}\Big)\mathbb{E}[\|x^{(t+1)}-x^\star\|_2^2|\mathcal{F}_t]+\frac{\mathbb{E}[\|x^{(t+1)}-x^{(t)}\|_2^2|\mathcal{F}_t]}{2\tau}\\&+\mathbb{E}\Big[g(x^{(t+1)})-g(x^\star)|\mathcal{F}_t\Big]\\&+\mathbb{E}\Big[\Big\langle u^{(t)}+\frac{n}{m}(u^{(t+1)}-u^{(t)}),\;x^{(t+1)}-x^\star\Big\rangle\Big|\mathcal{F}_t\Big].\end{aligned}\tag{50}$$

In addition, we consider a particular combination of the saddle-point function values at different points. By the definition of $f(x,y)$ in (4) and the notations in (48), we have

$$\begin{aligned}&f(x^{(t+1)},y^\star)-f(x^\star,y^\star)+\frac{n}{m}\Big(f(x^\star,y^\star)-f(x^\star,y^{(t+1)})\Big)-\frac{n-m}{m}\Big(f(x^\star,y^\star)-f(x^\star,y^{(t)})\Big)\\=\;&f(x^{(t+1)},y^\star)-f(x^\star,y^{(t)})+\frac{n}{m}\Big(f(x^\star,y^{(t)})-f(x^\star,y^{(t+1)})\Big)\\=\;&\langle u^\star,x^{(t+1)}\rangle-\frac{1}{n}\sum_{i=1}^n\phi_i^*(y_i^\star)+g(x^{(t+1)})-\langle u^{(t)},x^\star\rangle+\frac{1}{n}\sum_{i=1}^n\phi_i^*(y_i^{(t)})-g(x^\star)\\&+\frac{n}{m}\Big(\langle u^{(t)},x^\star\rangle-\frac{1}{n}\sum_{i=1}^n\phi_i^*(y_i^{(t)})+g(x^\star)-\langle u^{(t+1)},x^\star\rangle+\frac{1}{n}\sum_{i=1}^n\phi_i^*(y_i^{(t+1)})-g(x^\star)\Big)\\=\;&\frac{1}{n}\sum_{i=1}^n\Big(\phi_i^*(y_i^{(t)})-\phi_i^*(y_i^\star)\Big)+\frac{1}{m}\sum_{k\in K}\Big(\phi_i^*(y_k^{(t+1)})-\phi_i^*(y_k^{(t)})\Big)+g(x^{(t+1)})-g(x^\star)\\&+\langle u^\star,x^{(t+1)}\rangle-\langle u^{(t)},x^\star\rangle+\frac{n}{m}\langle u^{(t)}-u^{(t+1)},x^\star\rangle.\end{aligned}\tag{51}$$

Next we add both sides of the inequalities (47) and (50) together, and then subtract equality (51) after taking expectation with respect to $\mathcal{F}_t$. This leads to the following inequality:

$$\begin{aligned}
&\frac{\|x^{(t)}-x^\star\|_2^2}{2\tau}+\left(\frac{1}{2\sigma}+\frac{(n-m)\gamma}{2n}\right)\frac{\|y^{(t)}-y^\star\|_2^2}{m}+\frac{n-m}{m}\left(f(x^\star,y^\star)-f(x^\star,y^{(t)})\right)\\
&\geq\left(\frac{1}{2\tau}+\frac{\lambda}{2}\right)\mathbb{E}[\|x^{(t+1)}-x^\star\|_2^2|\mathcal{F}_t]+\left(\frac{1}{2\sigma}+\frac{\gamma}{2}\right)\frac{\mathbb{E}[\|y^{(t+1)}-y^\star\|_2^2|\mathcal{F}_t]}{m}+\frac{\mathbb{E}[\|x^{(t+1)}-x^{(t)}\|_2^2|\mathcal{F}_t]}{2\tau}\\
&\quad+\frac{\mathbb{E}[\|y^{(t+1)}-y^{(t)}\|_2^2|\mathcal{F}_t]}{2\sigma m}+\mathbb{E}\left[f(x^{(t+1)},y^\star)-f(x^\star,y^\star)+\frac{n}{m}\left(f(x^\star,y^\star)-f(x^\star,y^{(t+1)})\right)\Big|\mathcal{F}_t\right]\\
&\quad+\mathbb{E}\left[\left\langle u^{(t)}-u^\star+\frac{n}{m}(u^{(t+1)}-u^{(t)}),\ x^{(t+1)}-\overline{x}^{(t)}\right\rangle\Big|\mathcal{F}_t\right]. \qquad (52)
\end{aligned}$$

We need to lower bound the last term on the right-hand-side of the above inequality. To this end, we have

$$\begin{aligned}
&\left\langle u^{(t)}-u^\star+\frac{n}{m}(u^{(t+1)}-u^{(t)}),\ x^{(t+1)}-\overline{x}^{(t)}\right\rangle\\
=&\left(\frac{y^{(t)}-y^\star}{n}+\frac{y^{(t+1)}-y^{(t)}}{m}\right)^T A(x^{(t+1)}-x^{(t)}-\theta(x^{(t)}-x^{(t-1)}))\\
=&\frac{(y^{(t+1)}-y^\star)^TA(x^{(t+1)}-x^{(t)})}{n}-\frac{\theta(y^{(t)}-y^\star)^TA(x^{(t)}-x^{(t-1)})}{n}\\
&+\frac{n-m}{mn}(y^{(t+1)}-y^{(t)})^TA(x^{(t+1)}-x^{(t)})-\frac{\theta}{m}(y^{(t+1)}-y^{(t)})^TA(x^{(t)}-x^{(t-1)}). \qquad (53)
\end{aligned}$$

Recall that $\|a_k\|_2\leq R$ and, according to (12), $1/\tau=4\sigma R^2$. Therefore,

$$\begin{aligned}
|(y^{(t+1)}-y^{(t)})^TA(x^{(t+1)}-x^{(t)})|&\leq\frac{\|x^{(t+1)}-x^{(t)}\|_2^2}{4\tau/m}+\frac{\|(y^{(t+1)}-y^{(t)})^TA\|_2^2}{m/\tau}\\
&\leq\frac{\|x^{(t+1)}-x^{(t)}\|_2^2}{4\tau/m}+\frac{(\sum_{k\in K}|y_k^{(t+1)}-y_k^{(t)}|\cdot\|a_k\|_2)^2}{4m\sigma R^2}\\
&\leq\frac{m\|x^{(t+1)}-x^{(t)}\|_2^2}{4\tau}+\frac{\|y^{(t+1)}-y^{(t)}\|_2^2}{4\sigma},
\end{aligned}$$

Similarly, we have

$$|(y^{(t+1)}-y^{(t)})^TA(x^{(t)}-x^{(t-1)})|\leq\frac{m\|x^{(t)}-x^{(t-1)}\|_2^2}{4\tau}+\frac{\|y^{(t+1)}-y^{(t)}\|_2^2}{4\sigma}.$$

The above upper bounds on the absolute values imply

$$\begin{aligned}
(y^{(t+1)}-y^{(t)})^TA(x^{(t+1)}-x^{(t)})&\geq-\frac{m\|x^{(t+1)}-x^{(t)}\|_2^2}{4\tau}-\frac{\|y^{(t+1)}-y^{(t)}\|_2^2}{4\sigma},\\
(y^{(t+1)}-y^{(t)})^TA(x^{(t)}-x^{(t-1)})&\geq-\frac{m\|x^{(t)}-x^{(t-1)}\|_2^2}{4\tau}-\frac{\|y^{(t+1)}-y^{(t)}\|_2^2}{4\sigma}.
\end{aligned}$$

Combining the above two inequalities with (52) and (53), we obtain

$$\begin{aligned}
&\frac{\|x^{(t)}-x^\star\|_2^2}{2\tau}+\left(\frac{1}{2\sigma}+\frac{(n-m)\gamma}{2n}\right)\frac{\|y^{(t)}-y^\star\|_2^2}{m}\\
&+\theta\big(f(x^{(t)},y^\star)-f(x^\star,y^\star)\big)+\frac{n-m}{m}\left(f(x^\star,y^\star)-f(x^\star,y^{(t)})\right)\\
&+\theta\frac{\|x^{(t)}-x^{(t-1)}\|_2^2}{4\tau}+\theta\frac{(y^{(t)}-y^\star)^TA(x^{(t)}-x^{(t-1)})}{n}\\
\geq&\left(\frac{1}{2\tau}+\frac{\lambda}{2}\right)\mathbb{E}[\|x^{(t+1)}-x^\star\|_2^2|\mathcal{F}_t]+\left(\frac{1}{2\sigma}+\frac{\gamma}{2}\right)\frac{\mathbb{E}[\|y^{(t+1)}-y^\star\|_2^2|\mathcal{F}_t]}{m}\\
&+\mathbb{E}\left[f(x^{(t+1)},y^\star)-f(x^\star,y^\star)+\frac{n}{m}\left(f(x^\star,y^\star)-f(x^\star,y^{(t+1)})\right)\Big|\mathcal{F}_t\right]\\
&+\frac{\mathbb{E}[\|x^{(t+1)}-x^{(t)}\|_2^2|\mathcal{F}_t]}{4\tau}+\frac{\mathbb{E}[(y^{(t+1)}-y^\star)^TA(x^{(t+1)}-x^{(t)})|\mathcal{F}_t]}{n}. \qquad (54)
\end{aligned}$$

Note that we have added the nonnegative term $\theta\big(f(x^{(t)},y^\star)-f(x^\star,y^\star)\big)$ to the left-hand side in (54) to ensure that each term on one side of the inequality has a corresponding term on the other side.

If the parameters τ, σ, and θ are chosen as in (12), that is,

$$\tau=\frac{1}{2R}\sqrt{\frac{m\gamma}{n\lambda}},\quad\sigma=\frac{1}{2R}\sqrt{\frac{n\lambda}{m\gamma}},\quad\text{and}\quad\theta=1-\frac{1}{(n/m)+2R\sqrt{(n/m)/(\lambda\gamma)}},$$

Then the ratios between the coefficients of the corresponding terms on both sides of the inequality (54) are either equal to θ or bounded by θ. More specifically,

$$\begin{aligned}
\frac{n-m}{m}\Big/\frac{n}{m}=1-\frac{m}{n}&\ \leq\ \theta,\\
\frac{1}{2\tau}\Big/\left(\frac{1}{2\tau}+\frac{\lambda}{2}\right)=1-\frac{1}{1+2R\sqrt{(n/m)/(\lambda\gamma)}}&\ \leq\ \theta,\\
\left(\frac{1}{2\sigma}+\frac{(n-m)\gamma}{2n}\right)\Big/\left(\frac{1}{2\sigma}+\frac{\gamma}{2}\right)=1-\frac{1}{n/m+2R\sqrt{(n/m)/(\lambda\gamma)}}&\ =\ \theta.
\end{aligned}$$

Therefore, if we define the following sequence,

$$\begin{aligned}
\widetilde{\Delta}^{(t)}=&\left(\frac{1}{2\tau}+\frac{\lambda}{2}\right)\|x^{(t)}-x^\star\|_2^2+\left(\frac{1}{2\sigma}+\frac{\gamma}{2}\right)\frac{\|y^{(t)}-y^\star\|_2^2}{m}\\
&+f(x^{(t)},y^\star)-f(x^\star,y^\star)+\frac{n}{m}\left(f(x^\star,y^\star)-f(x^\star,y^{(t)})\right)\\
&+\frac{\|x^{(t)}-x^{(t-1)}\|_2^2}{4\tau}+\frac{(y^{(t)}-y^\star)^TA(x^{(t)}-x^{(t-1)})}{n},
\end{aligned}$$

then inequality (54) implies $\mathbb{E}\big[\widetilde{\Delta}^{(t+1)}|\mathcal{F}_t\big]\leq\theta\,\widetilde{\Delta}^{(t)}$. Apply this relation recursively and taking expectation with respect to all random variables up to time t, we have

$$\mathbb{E}\big[\widetilde{\Delta}^{(t)}\big]\ \leq\ \theta^t\,\widetilde{\Delta}^{(0)}. \qquad (55)$$

Comparing the definition of $\Delta^{(t)}$ in (11), we have

$$\widetilde{\Delta}^{(t)} = \Delta^{(t)} + \frac{\|y^{(t)} - y^\star\|_2^2}{4\sigma m} + \frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} + \frac{(y^{(t)} - y^\star)^T A(x^{(t)} - x^{(t-1)})}{n}. \tag{56}$$

For $t = 0$, by letting $x^{(-1)} = x^{(0)}$, the last two terms in (56) for $\widetilde{\Delta}^{(0)}$ disappears. Moreover, we can show that the sum of the last three terms in (56) are nonnegative, and therefore we can replace $\widetilde{\Delta}^{(t)}$ with $\Delta^{(t)}$ on the left-hand side of (55). To see this, we bound the absolute value of the last term:

$$\begin{aligned}
\frac{\left|(y^{(t)} - y^\star)^T A(x^{(t)} - x^{(t-1)})\right|}{n} &\le \frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} + \frac{\|A\|_2^2 \, \|y^{(t)} - y^\star\|_2^2}{n^2/\tau} \\
&\le \frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} + \frac{nR^2\|y^{(t)} - y^\star\|_2^2}{n^2/\tau} \\
&= \frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} + \frac{\|y^{(t)} - y^\star\|_2^2}{4n\sigma} \\
&\le \frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} + \frac{\|y^{(t)} - y^\star\|_2^2}{4m\sigma},
\end{aligned}$$

where in the second inequality we used $\|A\|_2^2 \le \|A\|_F^2 \le nR^2$, in the equality we used $\tau\sigma = 1/(4R^2)$, and in the last inequality we used $m \le n$. The above upper bound on absolute value implies

$$\frac{(y^{(t)} - y^\star)^T A(x^{(t)} - x^{(t-1)})}{n} \ge -\frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} - \frac{\|y^{(t)} - y^\star\|_2^2}{4m\sigma}.$$

To summarize, we have proved

$$\mathbb{E}\left[\Delta^{(t)}\right] \le \theta^t \left(\Delta^{(0)} + \frac{\|y^{(0)} - y^\star\|_2^2}{4m\sigma}\right),$$

which is the desired result.

Appendix B. Proof of Lemma 3

We can write $P(x) = F(x) + g(x)$ where

$$F(x) = \frac{1}{n}\sum_{i=1}^n \phi_i(a_i^T x) = \max_{y\in\mathbb{R}^n}\left\{\frac{1}{n}y^T Ax - \frac{1}{n}\sum_{i=1}^n \phi_i^*(y_i)\right\}.$$

Assumption A implies that $F(x)$ is smooth and $\nabla F(x)$ is Lipschitz continuous with constant $\|A\|_2^2/(n\gamma)$. We can bound the spectral norm with the Frobenius norm, i.e., $\|A\|_2^2 \le \|A\|_F^2 \le nR^2$, which results in $\|A\|_2^2/(n\gamma) \le nR^2/(n\gamma) = R^2/\gamma$. By definition of the saddle point,

the gradient of F at $x^\star$ is $\nabla F(x^\star) = (1/n)A^T y^\star$. Therefore, we have

$$\begin{aligned}
F(x) &\le F(x^\star) + \langle \nabla F(x^\star), x - x^\star\rangle + \frac{R^2}{2\gamma}\|x - x^\star\|_2^2 \\
&= \max_{y\in\mathbb{R}^n}\left\{\frac{1}{n}y^T Ax^\star - \frac{1}{n}\sum_{i=1}^n \phi_i^*(y_i)\right\} + \frac{1}{n}(y^\star)^T A(x - x^\star) + \frac{R^2}{2\gamma}\|x - x^\star\|_2^2 \\
&= \left\{\frac{1}{n}(y^\star)^T Ax^\star - \frac{1}{n}\sum_{i=1}^n \phi_i^*(y_i^\star)\right\} + \frac{1}{n}(y^\star)^T A(x - x^\star) + \frac{R^2}{2\gamma}\|x - x^\star\|_2^2 \\
&= \frac{1}{n}(y^\star)^T Ax - \frac{1}{n}\sum_{i=1}^n \phi_i^*(y_i^\star) + \frac{R^2}{2\gamma}\|x - x^\star\|_2^2.
\end{aligned}$$

Combining the above inequality with $P(x) = F(x) + g(x)$, we have

$$P(x) \le \frac{1}{n}(y^\star)^T Ax - \frac{1}{n}\sum_{i=1}^n \phi_i^*(y_i^\star) + \frac{R^2}{2\gamma}\|x - x^\star\|_2^2 + g(x) = f(x, y^\star) + \frac{R^2}{2\gamma}\|x - x^\star\|_2^2,$$

which is the first desired inequality.

Similarly, the second inequality can be shown by first writing

$$D(y) = -\frac{1}{n}\sum_{i=1}^n \phi_i^*(y_i) - G^*(y),$$

where

$$G^*(y) = g^*\left(-\frac{1}{n}A^T y\right) = \max_{x\in\mathbb{R}^d}\left\{-\frac{1}{n}x^T A^T y - g(x)\right\}.$$

In this case, $\nabla G^*(y)$ is Lipschitz continuous with constant

$$\|A\|_2^2/(n^2\lambda) \le nR^2/(n^2\lambda) = R^2/(n\lambda).$$

Again by definition of the saddle-point, we have $\nabla G^*(y^\star) = -(1/n)Ax^\star$. Therefore,

$$\begin{aligned}
G^*(y) &\le G^*(y^\star) + \langle \nabla G^*(y^\star), y - y^\star\rangle + \frac{R^2}{2n\lambda}\|y - y^\star\|_2^2 \\
&= \max_{x\in\mathbb{R}^d}\left\{-\frac{1}{n}x^T A^T y^\star - g(x)\right\} - \frac{1}{n}(y - y^\star)^T Ax^\star + \frac{R^2}{2n\lambda}\|y - y^\star\|_2^2 \\
&= \left\{-\frac{1}{n}(x^\star)^T A^T y^\star - g(x^\star)\right\} - \frac{1}{n}(y - y^\star)^T Ax^\star + \frac{R^2}{2n\lambda}\|y - y^\star\|_2^2 \\
&= -\frac{1}{n}y^T Ax^\star - g(x^\star) + \frac{R^2}{2n\lambda}\|y - y^\star\|_2^2.
\end{aligned}$$

Recalling that $D(y) = -\frac{1}{n}\sum_{i=1}^n \phi_i^*(y_i) - G^*(y)$, we conclude with

$$D(y) \ge -\frac{1}{n}\phi_i^*(y_i) + \frac{1}{n}y^T Ax^\star + g(x^\star) - \frac{R^2}{2n\lambda}\|y - y^\star\|_2^2 = f(x^\star, y) - \frac{R^2}{2n\lambda}\|y - y^\star\|_2^2.$$

This finishes the proof.

Appendix C. Proof of Theorem 6

The proof of Theorem 6 follows similar steps for proving Theorem 1. We start by establishing relation between $(y^{(t)}, y^{(t+1)})$ and between $(x^{(t)}, x^{(t+1)})$. Suppose that the quantity $\widetilde{y}_i$ minimizes the function $\phi_i^*(\beta) - \beta\langle a_i, \overline{x}^{(t)}\rangle + \frac{p_i n}{2\sigma}(\beta - y_i^{(t)})^2$. Also notice that $\phi_i^*(\beta) - \beta\langle a_i, x^\star\rangle$ is a γ-strongly convex function minimized by y_i^*, which implies

$$\phi_i^*(\widetilde{y}_i) - \widetilde{y}_i\langle a_i, x^\star\rangle \geq \phi_i^*(y_i^*) - y_i^*\langle a_i, x^\star\rangle + \frac{\gamma}{2}(\widetilde{y}_i - y_i^*)^2. \tag{57}$$

Then, following the same argument for establishing inequality (45) and plugging in inequality (57), we obtain

$$\frac{p_i n}{2\sigma}(y_i^{(t)} - y_i^\star)^2 \geq \Big(\frac{p_i n}{2\sigma} + \gamma\Big)(\widetilde{y}_i - y_i^\star)^2 + \frac{p_i n(\widetilde{y}_i - y_i^{(t)})^2}{2\sigma} + \langle a_i, x^\star - \overline{x}^{(t)}\rangle(\widetilde{y}_i - y_i^\star). \tag{58}$$

Note that $i = k$ with probability p_i. Therefore, we have

$$\begin{aligned}
(\widetilde{y}_i - y_i^\star)^2 &= \frac{1}{p_i}\mathbb{E}[(y_i^{(t+1)} - y_i^\star)^2|\mathcal{F}_t] - \frac{1-p_i}{p_i}(y_i^{(t)} - y_i^\star)^2,\\
(\widetilde{y}_i - y_i^{(t)})^2 &= \frac{1}{p_i}\mathbb{E}[(y_i^{(t+1)} - y_i^{(t)})^2|\mathcal{F}_t],\\
\widetilde{y}_i &= \frac{1}{p_i}\mathbb{E}[y_i^{(t+1)}|\mathcal{F}_t] - \frac{1-p_i}{p_i}y_i^{(t)},
\end{aligned}$$

where $\mathcal{F}_t$ represents the sigma field generated by all random variables defined before iteration t. Substituting the above equations into inequality (58), and averaging over $i = 1, 2, \ldots, n$, we have

$$\begin{aligned}
&\sum_{i=1}^n \left(\frac{1}{2\sigma} + \frac{(1-p_i)\gamma}{p_i n}\right)(y_i^{(t)} - y_i^\star)^2\\
\geq\ &\sum_{i=1}^n \left(\frac{1}{2\sigma} + \frac{\gamma}{p_i n}\right)\mathbb{E}[(y_i^{(t+1)} - y_i^\star)^2|\mathcal{F}_t] + \frac{\mathbb{E}[(y_k^{(t+1)} - y_k^{(t)})^2|\mathcal{F}_t]}{2\sigma}\\
&+ \mathbb{E}\Big[\Big\langle (u^{(t)} - u^\star) + \frac{1}{p_k}(u^{(t+1)} - u^{(t)}),\ x^\star - \overline{x}^{(t)}\Big\rangle\Big|\mathcal{F}_t\Big],
\end{aligned} \tag{59}$$

where $u^\star = \frac{1}{n}\sum_{i=1}^n y_i^\star a_i$ and $u^{(t)} = \frac{1}{n}\sum_{i=1}^n y_i^{(t)} a_i$ have the same definition as in the proof of Theorem 1.

For the relation between $x^{(t)}$ and $x^{(t+1)}$, we first notice that $\langle u^*, x\rangle + g(x)$ is a λ-strongly convex function minimized by x^*, which implies

$$\langle u^*, x^{(t+1)}\rangle + g(x^{(t+1)}) \geq \langle u^*, x^*\rangle + g(x^*) + \frac{\lambda}{2}(x^{(t+1)} - x^*)^2. \tag{60}$$

Following the same argument for establishing inequality (49) and plugging in inequality (60), we obtain

$$\begin{aligned}
\frac{\|x^{(t)} - x^\star\|_2^2}{2\tau} \geq &\left(\frac{1}{2\tau} + \lambda\right)\|x^{(t+1)} - x^\star\|_2^2 + \frac{\|x^{(t+1)} - x^{(t)}\|_2^2}{2\tau}\\
&+ \Big\langle (u^{(t)} - u^\star) + \frac{1}{p_k}(u^{(t+1)} - u^{(t)}),\ x^{(t+1)} - x^\star\Big\rangle.
\end{aligned} \tag{61}$$

Taking expectation over both sides of inequality (61) and adding it to inequality (59) yields

$$\begin{aligned}
\frac{\|x^{(t)} - x^\star\|_2^2}{2\tau} + &\sum_{i=1}^n \left(\frac{1}{2\sigma} + \frac{(1-p_i)\gamma}{p_i n}\right)(y_i^{(t)} - y_i^\star)^2 \geq \left(\frac{1}{2\tau} + \lambda\right)\mathbb{E}[\|x^{(t+1)} - x^\star\|_2^2|\mathcal{F}_t]\\
&+ \sum_{i=1}^n \left(\frac{1}{2\sigma} + \frac{\gamma}{p_i n}\right)\mathbb{E}[(y_i^{(t+1)} - y_i^\star)^2|\mathcal{F}_t] + \frac{\|x^{(t+1)} - x^{(t)}\|_2^2}{2\tau} + \frac{\mathbb{E}[(y_k^{(t+1)} - y_k^{(t)})^2|\mathcal{F}_t]}{2\sigma}\\
&+ \mathbb{E}\Big[\underbrace{\Big(\frac{(y^{(t)} - y^\star)^T A}{n} + \frac{(y_k^{(t+1)} - y_k^{(t)})a_k^T}{p_k n}\Big)((x^{(t+1)} - x^{(t)}) - \theta(x^{(t)} - x^{(t-1)}))}_{v}\Big|\mathcal{F}_t\Big],
\end{aligned} \tag{62}$$

where the matrix A is a n-by-d matrix, whose i-th row is equal to the vector a_i^T.

Next, we lower bound the last term on the right-hand side of inequality (62). Indeed, it can be expanded as

$$\begin{aligned}
v = &\frac{(y^{(t+1)} - y^\star)^T A(x^{(t+1)} - x^{(t)})}{n} - \frac{\theta(y^{(t)} - y^\star)^T A(x^{(t)} - x^{(t-1)})}{n}\\
&+ \frac{1-p_k}{p_k n}(y_k^{(t+1)} - y_k^{(t)})a_k^T(x^{(t+1)} - x^{(t)}) - \frac{\theta}{p_k n}(y_k^{(t+1)} - y_k^{(t)})a_k^T(x^{(t)} - x^{(t-1)}).
\end{aligned} \tag{63}$$

Note that the probability p_k given in (20) satisfies

$$p_k = \frac{1-\alpha}{n} + \frac{\alpha\|a_k\|_2}{\sum_{i=1}^n \|a_i\|_2} \geq \frac{(1-\alpha)\|a_k\|_2}{nR} + \frac{\alpha\|a_k\|_2}{\sum_{i=1}^n \|a_i\|_2} = \frac{\|a_k\|_2}{nR_\alpha}, \qquad k = 1, \ldots, n.$$

Since the parameters τ and σ satisfies $\sigma\tau R_\alpha^2 = 1/4$, we have $p_k^2 n^2/\tau \geq 4\sigma\|a_k\|_2^2$ and consequently

$$\begin{aligned}
\frac{|(y_k^{(t+1)} - y_k^{(t)})a_k^T(x^{(t+1)} - x^{(t)})|}{p_k n} &\leq \frac{\|x^{(t+1)} - x^{(t)}\|_2^2}{4\tau} + \frac{\|(y_k^{(t+1)} - y_k^{(t)})a_k\|_2^2}{p_k^2 n^2/\tau}\\
&\leq \frac{\|x^{(t+1)} - x^{(t)}\|_2^2}{4\tau} + \frac{(y_k^{(t+1)} - y_k^{(t)})^2}{4\sigma}.
\end{aligned}$$

Similarly, we have

$$\frac{|(y_k^{(t+1)} - y_k^{(t)})a_k^T(x^{(t)} - x^{(t-1)})|}{p_k n} \leq \frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} + \frac{(y_k^{(t+1)} - y_k^{(t)})^2}{4\sigma}.$$

Combining the above two inequalities with lower bounds (62) and (63), we obtain

$$\begin{aligned}
\frac{\|x^{(t)} - x^\star\|_2^2}{2\tau} + &\sum_{i=1}^n \left(\frac{1}{2\sigma} + \frac{(1-p_i)\gamma}{p_i n}\right)(y_i^{(t)} - y_i^\star)^2 \geq \left(\frac{1}{2\tau} + \lambda\right)\mathbb{E}[\|x^{(t+1)} - x^\star\|_2^2|\mathcal{F}_t]\\
&+ \sum_{i=1}^n \left(\frac{1}{2\sigma} + \frac{\gamma}{p_i n}\right)\mathbb{E}[(y_i^{(t+1)} - y_i^\star)^2|\mathcal{F}_t] + \frac{\mathbb{E}[\|x^{(t+1)} - x^{(t)}\|_2^2|\mathcal{F}_t] - \theta\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau}\\
&+ \frac{\mathbb{E}[(y^{(t+1)} - y^\star)^T A(x^{(t+1)} - x^{(t)})|\mathcal{F}_t] - \theta(y^{(t)} - y^\star)A(x^{(t)} - x^{(t-1)})}{n}.
\end{aligned} \tag{64}$$

Recall that the parameters τ, σ, and θ are chosen to be

$$\tau = \frac{1}{2R_\alpha}\sqrt{\frac{\gamma}{n\lambda}}, \quad \sigma = \frac{1}{2R_\alpha}\sqrt{\frac{n\lambda}{\gamma}}, \quad \text{and} \quad \theta = 1 - \left(\frac{n}{1-\alpha} + R_\alpha\sqrt{\frac{n}{\lambda\gamma}}\right)^{-1}.$$

Plugging in these assignments and using the fact that $p_i \geq \frac{1-\alpha}{n}$, we find that

$$\frac{1/(2\tau)}{1/(2\tau)+\lambda} = 1 - \left(1 + \frac{1}{2\tau\lambda}\right)^{-1} = 1 - \left(1 + R_\alpha\sqrt{\frac{n}{\lambda\gamma}}\right)^{-1} \leq \theta,$$

and for $i = 1, 2, \ldots, n$,

$$\frac{1/(2\sigma) + (1-p_i)\gamma/(p_i n)}{1/(2\sigma)+\gamma/(p_i n)} = 1 - \left(\frac{1}{p_i} + \frac{n}{2\sigma}\right)^{-1} \leq 1 - \left(\frac{n}{1-\alpha} + \frac{n}{2\sigma\gamma}\right)^{-1} = \theta.$$

Therefore, if we define a sequence $\Delta^{(t)}$ such that

$$\Delta^{(t)} = \left(\frac{1}{2\tau}+\lambda\right)\mathbb{E}[\|x^{(t)} - x^\star\|_2^2] + \sum_{i=1}^n \left(\frac{1}{2\sigma} + \frac{\gamma}{p_i n}\right)\mathbb{E}[(y_i^{(t)} - y_i^\star)^2] + \frac{\mathbb{E}[\|x^{(t)} - x^{(t-1)}\|_2^2]}{4\tau} + \frac{\mathbb{E}[(y^{(t)} - y^\star)^T A(x^{(t)} - x^{(t-1)})]}{n},$$

then inequality (64) implies the recursive relation $\Delta^{(t+1)} \leq \theta \cdot \Delta^{(t)}$, which implies

$$\left(\frac{1}{2\tau}+\lambda\right)\mathbb{E}[\|x^{(t)} - x^\star\|_2^2] + \left(\frac{1}{2\sigma} + \frac{\gamma}{n}\right)\mathbb{E}[\|y^{(t)} - y^\star\|_2^2] + \frac{\mathbb{E}[\|x^{(t)} - x^{(t-1)}\|_2^2]}{4\tau} + \frac{\mathbb{E}[(y^{(t)} - y^\star)^T A(x^{(t)} - x^{(t-1)})]}{n} \leq \theta^t \Delta^{(0)}, \tag{65}$$

where

$$\begin{aligned}\Delta^{(0)} &= \left(\frac{1}{2\tau}+\lambda\right)\|x^{(0)} - x^\star\|_2^2 + \sum_{i=1}^n \left(\frac{1}{2\sigma} + \frac{\gamma}{p_i n}\right)(y_i^{(0)} - y_i^\star)^2 \\ &\leq \left(\frac{1}{2\tau}+\lambda\right)\|x^{(0)} - x^\star\|_2^2 + \left(\frac{1}{2\sigma} + \frac{\gamma}{1-\alpha}\right)\|y^{(0)} - y^\star\|_2^2.\end{aligned}$$

To eliminate the last two terms on the left-hand side of inequality (65), we notice that

$$\begin{aligned}\frac{|(y^{(t)} - y^\star)^T A(x^{(t)} - x^{(t-1)})|}{n} &\leq \frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} + \frac{\|y^{(t)} - y^\star\|_2^2 \|A\|_2^2}{n^2/\tau} \\ &\leq \frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} + \frac{\|y^{(t)} - y^\star\|_2^2 \|A\|_F^2}{n^2/\tau} \\ &= \frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} + \frac{\|y^{(t)} - y^\star\|_2^2 \sum_{i=1}^n \|a_i\|_2^2}{4\sigma(\sum_{i=1}^n \|a_i\|_2)^2} \\ &\leq \frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} + \frac{\|y^{(t)} - y^\star\|_2^2}{4\sigma},\end{aligned}$$

where in the equality we used $n^2/\tau = 4\sigma n^2 R_\alpha^2 \geq 4\sigma n^2 \overline{R} = 4\sigma\left(\sum_{i=1}^n \|a_i\|_2\right)^2$. This implies

$$\frac{(y^{(t)} - y^\star)^T A(x^{(t)} - x^{(t-1)})}{n} \geq -\frac{\|x^{(t)} - x^{(t-1)}\|_2^2}{4\tau} - \frac{\|y^{(t)} - y^\star\|_2^2}{4\sigma}.$$

Substituting the above inequality into inequality (65) completes the proof.

Abstract

Classification is an important supervised learning technique with numerous applications. We develop an angle-based multicategory distance-weighted support vector machine (MDWSVM) classification method that is motivated from the binary distance-weighted support vector machine (DWSVM) classification method. The new method has the merits of both support vector machine (SVM) and distance-weighted discrimination (DWD) but also alleviates both the *data piling* issue of SVM and the imbalanced data issue of DWD. Theoretical and numerical studies demonstrate the advantages of MDWSVM method over existing angle-based methods.

Keywords: Discriminant analysis, Imbalanced data, High dimension, Support vector machine, Distance-weighted discrimination

1. Introduction

Classification is important in both statistics and machine learning. The goal of classification is to build a classifier such that it can predict the category of a new observation. Popular classification methods include Fisher's linear discriminant analysis, logistic regression, support vector machine (SVM), and boosting. See Hastie et al. (2001) for an introduction to various classification methods.

SVM (Schölkopf and Burges, 1999; Cristianini and Shawe-Taylor, 2000) has been shown to be a very popular and powerful method. It is well known that the binary SVM searches for a hyperplane in the feature space (that is a type of projection space from the original data) that maximizes the margin (a gap between the two groups). SVM has numerous applications, such as image classification (Chapelle et al., 1999; Foody and Mathur, 2006) and cancer diagnostics (Duan et al., 2005; Wang and Huang, 2011).

In a high-dimensional, low sample size (HDLSS) setting, Marron et al. (2007) and Ahn and Marron (2010) observed a *data-piling* phenomenon with the binary SVM and other classification methods. A SVM-type linear classifier is a margin-based classifier. It has a separating hyperplane, and its normal vector is essentially the discriminant direction. Data-piling is the phenomenon when projecting the data points to the discriminant direction that many of these projections are identical. This phenomenon indicates that the resulting separating hyperplane might be affected by noise artifacts in the data. Noise artifacts result in a discrimination direction far away from the Bayes direction. See more discussion in Ahn and Marron (2010).

To alleviate the *data-piling* issue, Marron et al. (2007) proposed the binary distance-weighted discrimination (DWD) classifier. The idea of DWD is to minimize the total inverse margin of all the data points. This method works quite well in the HDLSS setting. However, because the DWD method uses all the observations to estimate the decision boundary, it is very sensitive to imbalanced sample sizes (Qiao et al., 2010). In particular, when the sample size of one class is much larger than the other, the classification boundary will be pushed towards the minority class and all future data will be assigned to the majority class. See more discussion in Qiao and Zhang (2015a,b) for the HDLSS overfitting issue of SVM and imbalanced data issue of DWD. To deal with both problems, Qiao and Zhang (2015a) proposed a binary distance-weighted support vector machine (DWSVM) method, which can be viewed as a combination of the binary SVM and DWD. The new method inherits both the merits of SVM and DWD yet outperforms both SVM and DWD in the HDLSS and imbalanced context.

In practice, many classification problems have more than two classes. A natural way to deal with multiclass classification problems is to take a one-versus-one or one-versus-rest approach, see examples in Hastie et al. (1998) and Allwein et al. (2000). Though both approaches are intuitive, the one-versus-one approach can lead to a tie-in-vote problem and the one-versus-rest approach suffers from inconsistency when there is no dominant class (Lee et al., 2004).

It is more desirable to consider all classes simultaneously. In a multiclass setting, the observed data are $(\boldsymbol{x}_i, y_i), i = 1, \ldots, n$, where $\boldsymbol{x}_i \in \mathbb{R}^d$ is a multivariate predictor, the scalar $y_i \in \{1, \ldots, K\}$ is the corresponding class label, with K as the number of classes. Many classification approaches map x to $\boldsymbol{f}(x) \in \mathbb{R}^K$, and the corresponding prediction rule is $\hat{y} = \arg\max_i f_j(\boldsymbol{x})$, where f_j is the jth element of $\boldsymbol{f}$. In this type of approach, a constraint such as $\sum_{j=1}^K \boldsymbol{f}_j = 0$ is usually imposed to remove redundancy and reduce the dimension of the problem. See Zhu and Hastie (2001); Lee et al. (2004); Liu and Shen (2006); Liu (2007); Liu and Yuan (2011) for more discussion. Fisher consistency for several existing multicategory hinge loss functions are also provided in Liu (2007).

It is straightforward to see that the sum-to-zero constraint can be removed if we redefine $\boldsymbol{f}$ in $\mathbb{R}^K$ to be in $\mathbb{R}^{K-1}$, as the degrees of freedom of $\boldsymbol{f}$ is essentially $K-1$. Several classifiers have been proposed using this fact. For example, Lange and Wu (2008) proposed a vertex based model that maps the data $\boldsymbol{x}$ in $\mathbb{R}^d$ to a $\boldsymbol{f}(\boldsymbol{x}) \in \mathbb{R}^{K-1}$, and predicts the label based on the distance of $\boldsymbol{f}(\boldsymbol{x})$ to K predefined vertices. Zhang and Liu (2014) proposed a similar idea where they define the same K vertices in the $\mathbb{R}^{k-1}$ space, and use the angle between $\boldsymbol{f}$ to these vertex vectors to predict labels. More details are given in Section 2 of this paper.

The angle-based method can be viewed as a natural extension of the binary large margin classifier to the multiclass context. Zhang and Liu (2014) replace the usual functional margin by the angle (or inner product) between the projection $\boldsymbol{f}$ and the vertices. Their simulation results show that these angle-based classifiers have good prediction performance. The Fisher consistency of a family of large margin classifiers is also proved. However, as a specific case in large margin classifiers, the angle-based SVM (MSVM) method is not Fisher consistent because its loss function is not a strictly monotone decreasing function. In Zhang and Liu (2014), Fisher consistency of a proximal SVM was proposed and proven instead.

In our experiment in Section 2, under HDLSS and imbalanced data setting, we observed that MSVM suffers from *data piling* issue. Binary DWD, based on the idea of Zhang and Liu (2014), can be extended to multicategory angle-based DWD (MDWD). Though free from the *data piling* concern, MDWD suffers from the imbalanced issue. Both these issues were previously observed in the binary case (Marron et al., 2007; Qiao and Zhang, 2015a).

Note that Huang et al. (2013) extended the binary DWD to a version of multiclass DWD (MDWDH). It adopts the idea of pairwise comparisons from one-versus-one idea. MDWDH considers a data point with label i being misclassified if the difference of projections on ith member and jth member is negative ($i \neq j$). Even though it has nice theoretical properties and empirical performance as shown in their paper, the angle-based methods have better geometric interpretation. In addition, the pair-wise natural of the method will have more expensive computational cost, compared to angle-based approaches. We also observed that the performance is slightly better than angled-based MDWD method. If the angle-based MDWD approach also incorporates the pairwise idea, the two approaches will have similar empirical performance.

In this paper, we adapt the idea in Qiao and Zhang (2015a) to develop a hybrid of MSVM and MDWD. The work can also be viewed as an extension of the binary DWSVM to the multiclass context. We prove its Fisher consistency and use extensive simulation studies to show the usefulness of our approach. For many cases, the novel approach outperforms both MDWD and MSVM, especially under HDLSS and the imbalanced case.

The rest of this article is organized as follows. In Section 2, we briefly review the existing multicategory classifiers, and introduce our angle-based distance-weighted support vector machine (MDWSVM) model. In Section 3, we prove the Fisher consistency and show some imbalance properties of our new approach. In Section 4, we perform simulation studies to compare our model with MSVM and MDWD. The sensitivity of the prediction performance in terms of the tuning parameters is also explored in this section. Section 5 involves a real application and Section 6 discusses some future work for this model. The proofs of all theorems and lemmas are given in the appendix.

2. Methodology

In this section, we give a general introduction to classification, including the angle-based multicategory classifier. We then show some drawbacks of this angle-based classification, which motivates our MDWSVM. We conclude with a detailed introduction of our approach, along with its implementation.

2.1 Classification and Loss Function

Consider a binary classification problem with observed data $(\boldsymbol{x}_i, y_i), i = 1, \ldots, n$. The $\boldsymbol{x}_i \in \mathbb{R}^d$ is a multivariate predictor and the scalar $y_i \in \{1, -1\}$ is the corresponding class label. The goal is to find a decision function f along with its prediction $\hat{y}(\boldsymbol{x}) = \text{sign}(f(\boldsymbol{x}))$ to minimize the misclassification error $E(\hat{Y} \neq Y)$. Note that when $yf(\boldsymbol{x}) > 0$, $f(\boldsymbol{x})$ gives a correct prediction; otherwise $f(\boldsymbol{x})$ gives a misclassification. A natural way to estimate the misclassification error is to use the empirical error $1/n \sum \mathbb{I}(\hat{y}_i(\boldsymbol{x}) \neq y_i) = 1/n \sum \mathbb{I}(y_i f(\boldsymbol{x}_i) < 0)$, where $\mathbb{I}(.)$ is the indicator function. However, due to the discontinuity and nonconvexity of $\mathbb{I}(y_i f(\boldsymbol{x}_i) < 0)$, it is hard to conduct a direct minimization.

A common surrogate is a convex loss function $\ell(.)$, which is commonly used in large margin classifiers (Hastie et al., 2001). A large margin classifier can be viewed as minimizing the loss function given a constraint

$$\min_{f \in \mathbb{F}} \quad \sum_{i=1}^{n} \ell(f(\boldsymbol{x}_i), y_i) + \frac{\lambda}{2} J(f),$$

where $\mathbb{F}$ denotes the function space and $J(.)$ is a type of norm, which is used to control the complexity of the model. The function $\ell(f, y)$ is a loss function surrogate for the 0-1 loss. The tuning parameter λ balances the loss and the norm. For example, the popular linear SVM uses the hinge loss function $\ell_S(u) = (1-u)_+$ where $u = yf(\boldsymbol{x})$, and the L_2 norm.

The SVM method can also be viewed as maximizing the smallest distances of all observations to the separating hyperplane. As discussed in Section 1, SVM suffers from the *data piling* problem in HDLSS setting. Marron et al. (2007) proposed the DWD method, which improves the performance of SVM in the HDLSS setting. Essentially, DWD minimizes the mean of inverse distance of all data vectors to the separating hyperplane. As is discussed in Bartlett et al. (2006); Liu et al. (2011); Qiao and Zhang (2015a), DWD is also a large margin classifier, and its loss function is

$$\ell_D(u) = \begin{cases} 2 - u & u \leq 1 \\ 1/u & \text{otherwise.} \end{cases} \tag{1}$$

In practice, lots of applications deal with multicategory rather than binary classification. For multiclass problems, $y_i \in \{1, 2, \ldots, K\}, i = 1, \ldots, n$, with K the number of classes. The common simultaneous procedure is to map $\boldsymbol{x}$ to $\boldsymbol{f}(\boldsymbol{x}) \in \mathbb{R}^K$, and the corresponding prediction rule is $\hat{y} = \arg\max_j f_j(\boldsymbol{x})$, where f_j is the jth element of $\boldsymbol{f}$. Commonly a sum to zero constraint on $\boldsymbol{f}$ is used as discussed in Section 1 to overcome identifiability issues, see more discussion in Vapnik and Vapnik (1998); Lee et al. (2004); Liu and Yuan (2011).

Many multicategory classification methods can be viewed as the following constrained optimization problem,

$$\begin{aligned} \min_{f \in \mathbb{F}} \quad & \sum_{i=1}^{n} \ell(\boldsymbol{f}(\boldsymbol{x}_i), y_i) + \frac{\lambda}{2} \sum_{j=1}^{K} J(f_j), \\ \text{s.t.} \quad & \sum_{j=1}^{K} f_j(\boldsymbol{x}) = 0. \end{aligned}$$

For example, a multicategory SVM with hinge loss (Vapnik and Vapnik, 1998) uses the loss function $\ell(\boldsymbol{f}(\boldsymbol{x}), y) = (1 - f_y(\boldsymbol{x}))_+$. However, unlike binary classification, multicategory classification with a sum to zero constraint does not have a clear geometric explanation. It also suffers from expensive computation (Zhang and Liu, 2014). To overcome these limitations, Lange and Wu (2008) proposed the vertex idea where they define $\boldsymbol{f}$ as a $K-1$ dimensional function instead of a K dimensional function. This removes the need for a sum-to-zero constraint. A similar idea is used later by Zhang and Liu (2014) to conduct angle-based classification, which will be discussed next.

2.2 Angle-based Classification Framework

The idea of angle-based classification is to map $\boldsymbol{x}$ to $\boldsymbol{f}(\boldsymbol{x})$, where $\boldsymbol{f} = (f_1, \ldots, f_{K-1})$, with a set of K predefined vertices in $\mathbb{R}^{K-1}$. We then assess which vertex has the smallest angle to the projection $\boldsymbol{f}$, and the corresponding label is the prediction. In Zhang and Liu (2014), the vertices $W = (W_1, W_2, \ldots, W_K)$ are defined as a collection of K vectors in $\mathbb{R}^{K-1}$ with elements

$$W_j = \begin{cases} (K-1)^{-1/2}\zeta, & j = 1, \\ -(1+K^{1/2})/\{(K-1)^{3/2}\}\zeta + \{K/(K-1)\}^{1/2} e_{j-1}, & 2 \le j \le K. \end{cases}$$

The unit vector ζ is of length $K-1$, and e_j is a vector in $\mathbb{R}^{K-1}$ such that all of its element are 0, except the jth is 1.

In this setting, W form a simplex with K vertices in a $(K-1)$ dimensional space. The center of W is at the origin, and each of the $W_j, j = 1, \ldots, K$ has Euclidean norm of 1. Further, it is easy to check that the angle between each pair of vertices W_i and W_j, $i \neq j$ is the same. Instead of y_i, W_{y_i} is used to represent the observed class. The prediction function is $\hat{y} = \arg\max_j \langle W_j, \hat{\boldsymbol{f}} \rangle$, where the inner product $\langle ., . \rangle$ between the two vectors denotes the projection of $\hat{\boldsymbol{f}}$ to W_j. The larger the inner product, the smaller the angle between $\hat{\boldsymbol{f}}$ and W_j.

With this prediction rule, Zhang and Liu (2014) proposed the optimization model for the angle-based classification

$$\min_{\boldsymbol{f} \in \mathbb{F}} \frac{1}{n} \sum_{i=1}^{n} \ell(\langle \boldsymbol{f}(\boldsymbol{x}_i), W_{y_i} \rangle) + \frac{\lambda}{2} J(\boldsymbol{f}). \tag{2}$$

The product $\langle \boldsymbol{f}(\boldsymbol{x}_i), W_{y_i} \rangle$ can be viewed as a new functional margin of $(\boldsymbol{x}, y)$. Defining $u = \langle \boldsymbol{f}(\boldsymbol{x}_i), W_{y_i} \rangle$, one of the examples given in Zhang and Liu (2014) is the multicategory angle-based SVM (MSVM) where the loss function is replaced by hinge loss $\ell_S(u) = (1-u)_+$ and with L_2 norm. DWD loss can be applied to this framework as well, along with more generalizations of binary large margin classifiers. See Zhang and Liu (2014) for more details.

2.3 From Binary DWSVM to MDWSVM

Through the exploration of the angle-based classification method, we found that MSVM has similar *data piling* issues; while MDWD does not have *data piling* problems, it suffers from imbalanced issues. To demonstrate the *data piling* and imbalanced issues, we show projection plots of a simulated example. In this example, we randomly simulate three

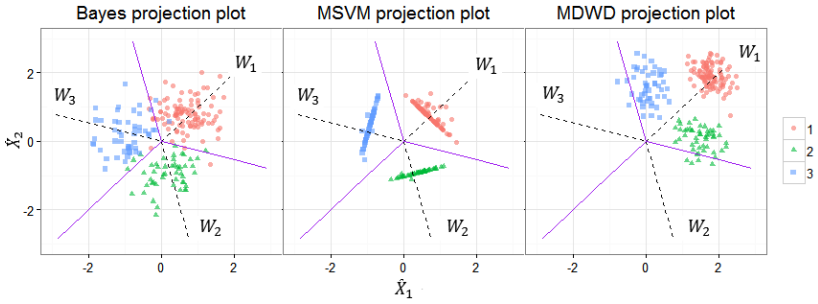

Figure 1: Plots of projections and W_j's in $\mathbb{R}^2$ space. Dashed lines are the W_j's, $j = 1, \ldots, 3$; Dots, triangles and squares represent the points from the three different classes. The left panel shows the projection plot for the Bayes classification, the middle one is for angle-based MSVM, and the right one is for the angle-based MDWD. The middle panel shows the MSVM has severe *data piling* issues (the middle panel), and MDWD in the right panel suffers from imbalanced issues (the right panel).

classes of observations with 500 covariates, the sample sizes for each class are 100, 50, 50 respectively. For each group, the first two covariates are distributed $N(\mu_j, \sigma^2 I_2)$, where μ_j's are three fixed points equally spaced on the unit circle, and $\sigma = 0.5$. All other covariates are independently and identically distributed $N(0, \sigma^2)$. Note that the data are HDLSS and imbalanced.

One representation of the projection plots is given in Figure 1. This plot is used to visualize the n projections $\boldsymbol{f}(x_i)$'s, $i = 1, \ldots, n$ and vectors W_j's, $j = 1, \ldots, 3$ (dashed lines) in the $\mathbb{R}^2$ plane. The different colors and shapes correspond to different groups. The solid purple lines are the Bayesian decision boundaries. $\tilde{X}_1$ and $\tilde{X}_2$ are the two axes in this $\mathbb{R}^2$ plane.

From Figure 1 it is clear that MSVM has severe *data piling* issues since almost all the points project to a single point on the W direction. Furthermore, MDWD suffers from the imbalanced issue as the angle-based classification assigns almost all the points to the dominant Class 1. These findings agree with those in Qiao and Zhang (2015a) for the binary case.

To alleviate both data piling and imbalanced issues, Qiao and Zhang (2015a) proposed binary DWSVM, a combination of SVM and DWD. The method has the form

$$\min_{f \in \mathbb{F}} \frac{1}{n} \sum_{i=1}^{n} \alpha \ell_D(y_i f_0(\boldsymbol{x}_i)) + (1-\alpha)\ell_S(y_i f(\boldsymbol{x}_i)) + \frac{\lambda}{2} J(f), \tag{3}$$

where $f_0(\boldsymbol{x}) = \boldsymbol{x}\boldsymbol{\omega} + \beta_0$ and $f(\boldsymbol{x}) = \boldsymbol{x}\boldsymbol{\omega} + \beta$, $\boldsymbol{\omega} \in \mathbb{R}^d$ is the coefficient direction vector and scalar $\beta, \beta_0 \in \mathbb{R}$. The loss function ℓ_D is from formula (1) and ℓ_S is the hinge loss. Notice that β is the SVM intercept and β_0 is the DWD intercept, which is called auxillary intercept in the DWSVM paper. The prediction function is $\hat{y} = \text{sign}(f(\boldsymbol{x})) = \text{sign}(\boldsymbol{x}_i^T \boldsymbol{\omega} + \beta)$. The tuning parameter $0 < \alpha < 1$ is used to balance SVM and DWD losses.

Qiao and Zhang (2015a) show that in binary classification, by choosing the appropriate α, the DWSVM method will result in a smaller misclassification error compared to both the DWD method and SVM method in HDLSS and imbalanced data context. Furthermore, in terms of the similarity to the Bayes classifier, the DWSVM are similar to the DWD but better than the SVM.

The DWSVM method motivated us to build a multicategory DWSVM within the angle-based framework. Applying DWSVM to the angle-based framework, we propose a multicategory angle-based DWSVM (MDWSVM)

$$\min_{\boldsymbol{f}\in\mathbb{F}} \frac{1}{n}\sum_{i=1}^{n} \alpha\ell_D(\langle \boldsymbol{f_0}(\boldsymbol{x}_i), W_{y_i}\rangle) + (1-\alpha)\ell_S(\langle \boldsymbol{f}(\boldsymbol{x}_i), W_{y_i}\rangle) + \frac{\lambda}{2}J(\boldsymbol{f}). \tag{4}$$

In this model $\boldsymbol{f}(\boldsymbol{x}_i) = \boldsymbol{x}_i B + \beta_0$ and $\boldsymbol{f_0}(\boldsymbol{x}_i) = \boldsymbol{x}_i B + \beta_0^d$, where $B = (B_1, B_2, \ldots, B_{K-1})$, each of the $B_j, j = 1, \ldots, K-1$ is a vector of length d, which does not include the intercept.The parameters $\beta_0, \beta_0^d \in \mathbb{R}^{K-1}$ are intercept vectors. Note that $\boldsymbol{f_0}$ and $\boldsymbol{f}$ are only different in terms of the intercept β_0 and β_0^d respectively. In this model, the interest is to find B, β_0 and β_0^d to minimize the loss function. For prediction $\hat{y} = \arg\max_j \langle W_j, \hat{\boldsymbol{f}}\rangle = \arg\max_j \langle W_j, \boldsymbol{x}_i B + \beta_0\rangle$, however, only β_0 and B are used. This avoids the imbalanced issue cost by β_0^d. Note that the prediction $\arg\max_j \langle W_j, \hat{\boldsymbol{f}}\rangle$ is equivalent to $\arg\min_j \angle(W_j, \hat{\boldsymbol{f}})$ where $\angle(a, b)$ represents the angle between vector a and b . We predict $\boldsymbol{x}$ with the label j such that vertex W_j and $\boldsymbol{f}(\boldsymbol{x})$ has the smallest angle among all $\angle(W_j, \hat{\boldsymbol{f}}), j = 1, \ldots, K$. Observe that $\sum_{j=1}^{K} \langle W_j, \hat{\boldsymbol{f}}\rangle = 0$ for all $\boldsymbol{x}$, which means the angle-based classification framework automatically includes sum-to-zero constraints.

2.4 Implementation of MDWSVM

In Qiao and Zhang (2015a), the implementation of the binary DWSVM (3) was through second-order cone programming. Mathematically, the DWSVM model can be written as

$$\begin{aligned} \min_{\boldsymbol{\omega},\beta,\beta_0,\eta_i,\xi_i} \quad & \sum_{i=1}^{n}\{\alpha(\frac{1}{r_i} + \eta_i) + (1-\alpha)\xi_i\}, \\ \text{s.t.} \quad & r_i = y_i(x_i^T\boldsymbol{\omega} + \beta) + \eta_i, \quad r_i \geq 0 \quad \text{and} \quad \eta_i \geq 0, \\ & y_i(x_i^T\boldsymbol{\omega} + \beta) + \xi_i \geq 1, \quad \xi_i \geq 0, \\ & \|\boldsymbol{\omega}\|^2 \leq C. \end{aligned} \tag{5}$$

The first constraint $r_i = y_i(x_i^T\boldsymbol{\omega} + \beta) + \eta_i$ is the distance from each data vector i to its separating hyperplane (adding slackness to allow misclassification), which corresponds to the DWD optimization. The second constraint $y_i(x_i^T\boldsymbol{\omega} + \beta) + \xi_i \geq 1$ is a standard constraint in SVM optimization. Both η_i and ξ_i control the misclassification rate, but with different decision boundaries. The third constraint $\|\boldsymbol{\omega}\|^2 \leq C$ is equivalent to the second term in (2), the Euclidean norm.

To extend (5) to multiclass, we replace the distances (functional margins) to the inner product as introduced earlier in (2). Thus our MDWSVM will have the following mathematical form:

$$\begin{aligned} \min_{\boldsymbol{f},\boldsymbol{f_0}} \quad & \sum_{i=1}^{n}\{\alpha(\frac{1}{r_i} + \eta_i) + (1-\alpha)\xi_i\}, \\ \text{s.t.} \quad & r_i = \langle \boldsymbol{f_0}(x_i), W_{y_i}\rangle + \eta_i, \quad r_i \geq 0 \quad \text{and} \quad \eta_i \geq 0, \\ & \langle \boldsymbol{f}(x_i), W_{y_i}\rangle + \xi_i \geq 1, \quad \xi_i \geq 0, \\ & \sum_{j=1}^{k-1} B_j^T B_j \leq C. \end{aligned} \tag{6}$$

In this form $\boldsymbol{f_0}$ and $\boldsymbol{f}$ are the same as in (4). It is verified in Zhang and Liu (2014) that the first term in the objective function $\sum_{i=1}^{n}(\frac{1}{r_i} + \eta_i)$ along with its constraint is equivalent to the objective of the MDWD method, and the second term in the objective function $\sum_{i=1}^{n}\xi_i$ along with its constraint is equivalent to the objective in the MSVM method. In this case, MDWSVM can be viewed as a convex combination of MDWD and MSVM losses where the parameter α balances the two.

Model (6) can be easily implemented in Matlab using the CVX package (Grant et al., 2008). Notice the only difference between $\boldsymbol{f}(\boldsymbol{x})$ and $\boldsymbol{f_0}(\boldsymbol{x})$ is their location vectors β_0 and β_0^d. For prediction we only adopt the location vector from MSVM, which shows insensitivity to the imbalanced issue from Figure 1. Moreover, by combining the discriminant direction of MDWD and MSVM, our new model will have a better discriminant direction (closer to the Bayes direction) than the MSVM method alone. Both improvements will be shown in Sections 4 and 5 using simulations and real examples.

3. Theoretical Properties

Fisher consistency is a fundamental requirement for a classification method. Fisher consistency implies that when the sample size approaches infinity, the classifier becomes closer and closer to the Bayes classification rule, which corresponds to the minimum misclassification rate. Qiao and Zhang (2015a) explored Fisher consistency of the binary DWSVM model. In the multiclass context, Zhang and Liu (2014) extended Fisher consistency to all large margin classification models under the angle-based framework.

Let $P_j = \Pr(Y = j|X = \boldsymbol{x})$ for $j = 1, \ldots, K$. Note that $\hat{y} = \arg\max_j P_j$ is the Bayes rule. Assume that for a given $\boldsymbol{x}$, the vector $\boldsymbol{f^*}(\boldsymbol{x})$ minimizes $E[\ell\{\langle \boldsymbol{f}(X), W_Y\rangle\}|X = \boldsymbol{x}]$, and the corresponding decision boundary will then be $\hat{y} = \arg\max_j \langle \boldsymbol{f^*}(\boldsymbol{x}), W_Y\rangle$. Note that this is essentially the limit minimizer of (2) when sample size diverges to infinity. Fisher consistency assures that these two decision functions are the same ($\arg\max_j P_j = \arg\max_j \langle \boldsymbol{f^*}(\boldsymbol{x}), W_Y\rangle$).

In this section, we will prove that if using the approximate SVM loss function from Zhang and Liu (2014) in replacement of hinge loss, our MDWSM is Fisher consistent.

Theorem 1 *The MDWSVM is Fisher consistent for any* $0 < \alpha < 1$.

Fisher consistency in Theorem 1 ensures that the minimizer of the expected loss function will assign an observation to the same class as what Bayes rule does. Furthermore, in our numerical study in Section 4.2, we notice that for MDWSVM method, as long as C is fixed, different α's will give similar performance in both prediction error and closeness to

the Bayes rule. Thus we will fix α to be 0.5 in this paper and not discuss the choice of α further.

In the next theorem, we want to prove that MDWSVM is insensitive to imbalance. Using a similar paradigm as in Owen (2007), we consider the case that the sample size of one class diverges to infinity. Qiao and Zhang (2015a) showed that, in binary classification, the intercept term of DWD diverges, but the intercept of SVM and DWSVM will not diverge. This shows that SVM is not sensitive to imbalance, but DWD will be severely affected. In our multiclass setting, for simplicity, it is assumed that only one of the classes is the dominant one, and the sample size of all other classes are equally fixed. Without loss of generality, we assume their sample sizes are all 1. Under this setting, we can simply assume observation $1, \ldots, K-1$ belongs to the class $1, \ldots, K-1$ respectively, and observations $K \ldots, n$ belong to class K. As n goes to infinity, the classifier tends to classify all the points to the dominant class K. If this happens, $\langle \beta_0, W_{yK} \rangle$ goes to infinity. In the next proposition, we prove that this will be not be the case for the angle-based SVM. Furthermore, we present in Theorem 3 that the intercept of our MDWSVM model is not sensitive to imbalance either.

Proposition 2 *In MSVM setting, when the size of the majority class goes to infinity,* $\langle \beta_0, W_{yK} \rangle < \sqrt{2C}K \max |x_{ij}| + 1$.

Theorem 3 *In the MDWSVM setting, when the size of the majority class goes to infinity,* $\langle \beta_0, W_{yK} \rangle < \sqrt{2C}K \max |x_{ij}| + 1$.

Note that Theorem 3 does not ensure that the MDWSVM method completely overcomes the imbalanced issue. When the sample size of the majority group goes to infinity, the method still will ignore some observations in minority groups.

4. Simulation

In this section, we use three simulation examples to demonstrate the performance of our MDWSVM method. We compare it to the angle-based SVM (MSVM) described in Section 2 and the angle-based DWD (MDWD) naturally developed using the ideas from Zhang and Liu (2014).

In each example, we simulate a training data set, a tuning data set, and a testing data set. The training data and tuning data have the same sample sizes and are used to estimate the model and to find the optimal tuning parameters. The size of the testing data set is ten times the size of the training data, and is used to evaluate the prediction performance. As we are interested in the misclassification rate in both the dominant class and the minority classes, we will not use the total error rate $1/n \sum_i I(\hat{y}_i \neq y_i)$ in this paper. Instead, we use the average within-group error rate as follows

$$r = \frac{1}{K} \sum_{j=1}^{K} \left\{ \frac{1}{n_j} \sum_{i: x_i \in C_j} I(\hat{y}_i \neq j | x_i \in C_j) \right\}.$$

Here C_j stands for class j and n_j is the sample size for class j. This measure was previously introduced in Qiao and Liu (2009). Note that the term within the bracket is the error rate for each group, so r is the arithmetic average of all these error rates.

We also want to measure the closeness of the estimated classifier to the Bayes rule. For the binary case, we can measure the angle between the two linear decision boundaries. For the multiclass case, we develop a similar measure as follows. Note that B is the projection matrix from $\mathbb{R}^d$ to $\mathbb{R}^{K-1}$ (the projection space). In the binary case, B is the discrimination direction vector, we can use the Euclidean inner product $\langle B, B_{\text{Bayes}} \rangle$ to measure the angle between the estimated and the Bayes rule. For the multiclass case, both B and B_{Bayes} are matrices. In matrix form, we want to measure the angle between the jth columns in both B and B_{Bayes}, and then calculate an average of these angles.

In this paper, we use the Frobenius inner product: $\langle B, B_{\text{Bayes}} \rangle_F = \sum_{i,j} B_{ij} B_{\text{Bayes } ij}$. Essentially, this is the sum of entries of the Hadamard product between B and B_{Bayes}. One can see that this is the same idea as the inner product of the corresponding columns in B and B_{Bayes}, a scaled mean of the inner products. To make this quantity directly linked to angle, we normalize both B and B_{Bayes} to have Frobenius norm of 1, and thus $\angle \langle B, B_{\text{Bayes}} \rangle = \arccos(\langle B, B_{\text{Bayes}} \rangle_F)$ will be the angle used in this paper.

In all examples, α is set as 0.5, the reason for this is described in Section 4.2. We want to choose C in $\mathbb{R}^+$. For convenience, we use the log scale, and set $\log_2 C$ from -3 to 15. For the first two examples, we generate datasets that have signal based on only a few covariates, and then we add pure noise as additional covariates. To better compare the performance for both balanced and imbalanced scenarios, all the examples are conducted under both balance and imbalance cases. Let $p = \Pr(Y = 1)$ and $\Pr(Y = j) = \frac{1}{K-1}(1-p)$ for $j \neq 1$. We will consider $p = 1/K$ for the balanced case and $p = 1/2$ and $p = 1/3$ for the imbalanced case for all examples. The size of the training dataset for each example is 300, 600 and 300 respectively. In each example, five sets of dimensions are considered: 2, 10, 100, 500 and 1000. The noise covariates are identically independent distributed as $N(0, \sigma^2)$. For the third example, all covariates are signal variables. And for all simulation settings, we repeat the experiments 100 times and report the average performance.

4.1 Performance Comparison

Example 1 *We generate a three class dataset, where the first two covariates are distributed* $N(u_j, \sigma^2 I_2)$. *In this setting, the* u_j*'s are three points equally spaced on a unit circle, and* σ *is chosen such that the Bayes error is 0.1. As we can see, this example is similar to the Example 1 in Zhang and Liu (2014) other than that our case considered both the balanced and imbalanced scenarios.*

Example 2 *We generate a five class dataset, Let* $Pr(Y = 1) = p$, *and the first five covariates are distributed* $N(u_j, \sigma^2 I_5)$. *Here* u_j*'s are five points equally spaced on the sphere of unit ball in* $\mathbb{R}^4$, *and* $\sigma = 0.55$. *When dimension is larger than 4, the last* $d - 4$ *covariates are identically independent distributed as* $N(0, \sigma^2)$.

Example 3 *A three groups dataset is generated with dimension d, the centers of the three groups are equally distributed on the sphere of an unit ball in* $\mathbb{R}^d$. *A random noise* $N(0, \sigma^2 = 0.55^2)$ *was added to each dimension.*

We report the average prediction error rate and the average angle to the Bayes rule in Figures 2. Take Figure 2(a), which corresponds to Example 1, as an example. We report

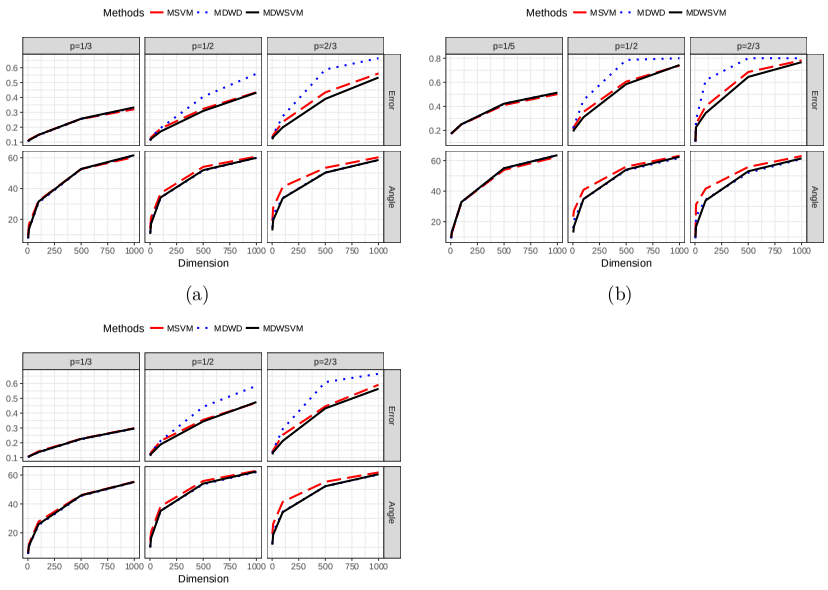

Figure 2: Performance comparison plot between the three methods for Examples 1, 2, and 3. The top row of each graph plots the misclassification rate for different dimensions (the x axis) and different prior probabilities (left, middle and right panels). The bottom row is the angle between the estimated and the Bayes rule. For all measures, smaller implies better result. We can see that our method (the solid black line) performs almost the same as the other two methods (MSVM, the red dashed line, MDWD, the dotted blue line) for balanced case, but outperforms the other two for the imbalanced cases.

both misclassification rate (the top row) and the angle between the estimated classifiers and the Bayes rule. In the plot, we use black solid lines for our MDWSVM method, red dashed lines for MSVM method, and blue dotted lines for MDWD method. The grid points on the x axis represents the different dimensions d. The y axis corresponds to the performance measure. In our plot, the smaller the y axis value, the better the performance. Different imbalance ratios are visualized in different panels from left to right. The left two panels correspond to the balanced case; the middle panels are mild imbalance ($p = 1/2$); and the right two panels are more severe imbalanced case ($p = 2/3$). For the balanced case, our approach performs similar to the MSVM and MDWD methods. However, for the imbalanced cases (the middle and right panels), we can see clear gaps between the performance of our method and the other two methods, demonstrating that our method outperforms the other two. Note that a similar pattern can also be seen in Figures 2(b) and 2(c). All suggests that the novel approach is better than MSVM and MDWD.

It is also shown in these plots that as the dimension of training data changes from small to large (2 to 1000), the classifier's performances become worse and worse. Furthermore, the performance differences of the three methods become more pronounced. Note that MDWD gives the worst prediction error rate compared to the other two methods, and MSVM gives the worst classification direction compared to the other two methods. Our MDWSVM gives comparably the best performance in both aspects.

4.2 Sensitivity to Parameters

There are two parameters C and α in our MDWSVM method. We have conducted many simulations to evaluate the performance of these two parameters. In this section, we will only use Example 1 to show the performance. We set α to be fixed, varied C, and evaluated its performance. Then we fixed an optimal C to evaluate the sensitivity of our approach to different α's. At the beginning, we let $\alpha = 0.5$, and allow C to change from 2^{-3} to 2^{12}. The simulation is conducted under different dimensions $(100, 500, 1000)$. All the simulation results are based on 100 replicates. The left panel of Figure 3 is the prediction error under different values of C with different dimensions of training data. It is clearly shown from the graph that as C increases, the prediction error rate first decreases and then increases. It shows that a minimal prediction error can be reached within this range. The right panel shows the relationship between prediction error rate and different α's. It is also clear that the prediction error rate stays the same as α changes from 0.1 to 0.9, regardless of the slightly increase as α approaches to 1.

Based on the performance from Figure 3, the change of α has little impact on the prediction error rate compared to a change of C. The performance is quite stable for different α's. Since the property of the parameters are not the focus in this paper, this simulation gives us an easy suggestion of choosing parameters. One can simply fix $\alpha = 0.5$ and use cross-validation to choose C. This is why we fix $\alpha = 0.5$ in our simulation.

4.3 Computation Time

In this subsection, we will compare the computational time for these methods (MDWSVM, MSVM and MDWD). To test the computational complexity, we only consider the simulation

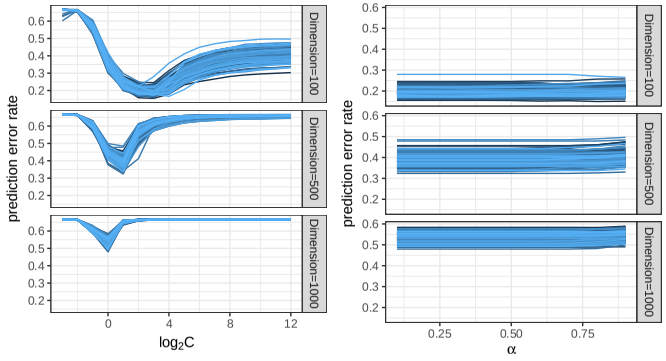

Figure 3: Average within-group error rate change under different parameters. Left panel is the prediction error rate change under different C value for fixed $\alpha = 0.5$; right panel is prediction error rate change for different α when C is fixed at its optimal value

Dimension	MDWSVM	MDWD	MSVM
10	8.31(0.04)	8.22(0.04)	0.88(0.01)
100	14.52(0.07)	12.80(0.05)	2.79(0.01)
1000	41.66(0.20)	27.43(0.12)	9.30(0.07)

Table 1: Computation time comparison for MDWSVM, MDWD and MSVM based on 100 runs of Example 1. The number shows average computing time in seconds, and the number in the parenthesis is the corresponding standard error.

of Example 1. We let the dimension change from 10 to 1000. Table 1 gives the average computation time in seconds for 100 replicates along with their standard error. All numerical experiments were carried out on an Intel Xeon E3-1284L (2.5 GHz) processor.

Table 1 shows that the most efficient method is MSVM and the most time-consuming method is our MDWSVM. Note that MSVM can still be viewed as a quadratic programming problem, while both MDWD and MDWSVM are conic program problems. It is not surprising that MSVM is the most computational efficient one. It is our expectation that MDWSVM would have the longest time to run, since it combines both MSVM and MDWD. From equation 6, we can see that the number of parameters can be viewed as the sum of the ones for MDWD and MSVM. Thus the computation times it takes to solve the problem increases as well. It is good enough that the computational time of MDWSVM is shorter than the sum of the computing time of each individual methods. It is worth mentioning that as dimension increases, the CPU times for the three methods increase.

Table 2: Six national holidays on weekdays that are removed

5. Real Data Application

In this section, we apply our MDWSVM method to a real data used in Shen and Huang (2005). The data were gathered at an inbound call center of a major northeastern U.S financial firm in 2002, and describe the call volume from 7:00am-12:00am. Each day is divided into 408 150-second intervals and the number of phone calls is recorded in each interval. Due to equipment malfunctioning, there are 6 missing weekdays within the whole year. The call volume data form a 360×408 matrix, where each row corresponds to a day and each column is the call volume for one of the 150-second intervals.

Note that the data have been thoroughly analyzed in Shen and Huang (2005). Here we simply add some new insights from the data by using our novel approach. According to their analysis, the pattern for Saturday and Sunday is very different from the weekdays. Thus in this analysis, we only focus on the weekdays. Shen and Huang (2005) show that for weekdays, by using singular value decomposition to analyze the number of phone calls, Monday and Friday are slightly different from all other weekdays, see Section 5.3 and Figure 6 of Shen and Huang (2005) for more details. Tuesday, Wednesday and Thursday are hard to tell apart from each other. In this section, we only focus on classifying Monday, Friday and other weekdays (Tuesday, Wednesday and Thursday). In addition, due to the fact that the center has very low volumes on national holidays, we remove the holidays that fall on weekdays. Table 2 provides the national holidays excluded in our analysis. These days, along with some other more holidays, were also removed in Shen and Huang (2005).

After removing these holidays, we have 48, 50, 51, 50, 52 days for Monday to Friday respectively. The data are divided into three groups, Group 1: Monday (size 48); Group 2: Tuesday to Thursday (size 151); Group 3: Friday (size 52). This dataset is a typical imbalanced HDLSS dataset with Group 2 as the dominant group. The average number of phone calls on each time interval are presented in Figure 4. From Figure 4, we can see that the average number of phone calls on Monday is quite distinct from the other days as it is larger than the other two groups. However, Group 2 and 3 are hard to distinguish from each other by only looking at the average number of phone calls. For this data set, we will compare the performance of three classifiers: our MDWSVM, MSVM, MDWD.

To obtain a good evaluation, all three methods use five-fold cross validation. And the evaluation measures are the total error rate (TER) and the average within-group error rate (AER). We also report the prediction error within each group. Table 3 provides these results for the three different methods.

From Table 3 it is straightforward to conclude that the prediction error of MDWSVM for each of the groups is the smallest, as well as the total error rate and average with-group prediction error rate. Our MDWSVM model works very well for this data set.

Taking another look at the Table 3, the prediction error rate for Monday and Friday are more than 30%, which seems to be large. The result could be explained by the fact

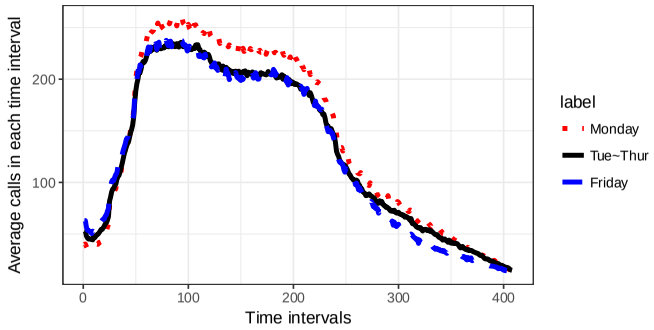

Figure 4: Average number of calls in each time interval for the three classes Monday, Tuesday to Thursday and Friday. In this plot, the red dotted line is the number of phone calls for Mondays, the black solid line is for Tuesday to Thursday, and the blue dashed line is for Friday.

	MDWD	MSVM	MDWSVM
Mon.	0.8156	0.6200	0.4111
Tue. - Thu.	0.0396	0.0594	0.0985
Fri.	0.6145	0.5527	0.3200
TER	0.3098	0.2702	0.2053
AER	0.4899	0.4107	0.2765

Table 3: Prediction error for number of phone calls. The top 3 rows report the cross-validation prediction error for each class, and the bottom two rows are the total error rate and the average within-group error rate.

that the DWSVM used here is a linear classifier, while the nature of the data may not be well classified by a linear classifier. If we incorporate a kernel approach to our classifier, the performance should improve.

6. Discussion

In this paper, we proposed a new angle-based method MDWSVM. We show in this paper that in HDLSS and the imbalanced case, our novel MDWSVM method has smaller misclassification error relative to both MDWD and MSVM. In addition, it is closer to the Bayes discriminant direction compared to that of MSVM. The MDWSVM can be viewed as an extension of the binary DWSVM to the multicategory case. Furthermore, as our model considers both SVM and DWD loss, it can be treated as a weighted hybridization of MSVM and MDWD.

One of the limitations of DWD-type methods is that it suffers from slow computation time compared to SVM-type methods (See Chapter 4.3 for examples). Recently an alternating direction method of multipliers (ADMM) algorithm has been implemented by Lam et al. (2016) for the DWD type methods, which can handle large size data more efficiently. A similar implementation for our MDWSVM method will be explored in the future.

Note that we only consider linear classifiers for simplicity. This method can be extended to a kernel approach (Liu and Yuan, 2011) by allowing $\boldsymbol{f}$ to be a nonlinear mapping. The implementation of such a generalization will be our immediate future work.

Our MDWSVM uses the squared norm as the regularization component so it does not have a variable selection property. To better deal with data of high dimension, variable selection penalties can be added to the model, *e.g.* LASSO (Tibshirani, 1996) or Elastic net (Zou and Hastie, 2005). Work on this type of generalization will follow.

Acknowledgments

We would like to thank the reviewers for the valuable comments and suggestions. Also thank Cheng Li (Purdue University) for the insightful discussion on proof of theorems.

Appendix A.

In this appendix we prove the following theorems and proposition from Section 3:

Lemma 1 *(Zhang and Liu, 2014): Suppose we have an arbitrary $\boldsymbol{f} \in \mathbb{R}^{K-1}$. For any $u, v \in \{1, \ldots, K\}$ such that $u \neq v$, define $T_{u,v} = W_u - W_v$. For any scalar $z \in \mathbb{R}$, $\langle (\boldsymbol{f} + zT_{u,v}), W_w \rangle = \langle \boldsymbol{f}, W_w \rangle$, where $w \in \{1, \ldots, K\}$ and $w \neq u, v$. Furthermore, we have that $\langle (\boldsymbol{f} + zT_{u,v}), W_u \rangle - \langle \boldsymbol{f}, W_u \rangle = -\langle (\boldsymbol{f} + zT_{u,v}), W_v \rangle + \langle \boldsymbol{f}, W_v \rangle$.* ■

The proof of Lemma 1 is given in Zhang and Liu (2014). From Lemma 1, one can see that for a given $\boldsymbol{f}$, if we move it along the direction of $T_{u,v}$, the inner product of $\boldsymbol{f}$ and W_w will stay the same when $w \neq u, v$. Furthermore, the sum of inner product $\langle \boldsymbol{f}, W_u \rangle + \langle \boldsymbol{f}, W_u \rangle, W_u \rangle$ will remain unchanged as well. This lemma will help us to prove the Fisher consistency of the MDWSVM method.

Theorem 1. *The MDWSVM is Fisher consistent for any $0 < \alpha < 1$.*

Proof. Recall the definition of $\boldsymbol{f}^*$ is that

$$(\boldsymbol{f}^*, \boldsymbol{f}_0^*) = \arg\min_{\boldsymbol{f}, \boldsymbol{f}_0} E[(1-\alpha)\ell_s\{\langle \boldsymbol{f}(X), W_Y \rangle\} + \alpha \ell_d\{\langle \boldsymbol{f}_0(X), W_Y \rangle\} | X = x].$$

We need to show that when $P_1 > P_2$, $\langle W_1, \boldsymbol{f}^* \rangle > \langle W_2, \boldsymbol{f}^* \rangle$. This can be easily proved by contradiction.

If $\langle W_1, \boldsymbol{f}^* \rangle = \langle W_2, \boldsymbol{f}^* \rangle$, Let $\boldsymbol{f}_0^* = \boldsymbol{f}^* - \Delta$, here we can see that as Δ is only the difference of intercept, which is independent of X. Let $(\boldsymbol{f}^{**}, \boldsymbol{f}_0^{**}) = (\boldsymbol{f}^{**}, \boldsymbol{f}_0^*)$ be such that $\langle W_j, \boldsymbol{f}^{**} \rangle = \langle W_j, \boldsymbol{f}^* \rangle$ for $j \geq 3$ and $\langle W_1, \boldsymbol{f}^{**} \rangle = \langle W_1, \boldsymbol{f}^* \rangle + \epsilon$, $\langle W_2, \boldsymbol{f}^{**} \rangle = \langle W_2, \boldsymbol{f}^* \rangle - \epsilon$. This $(\boldsymbol{f}^{**}, \boldsymbol{f}_0^{**})$ exists based on Lemma 1 and the fact that inner product is continuous. To get the required $\boldsymbol{f}^{**}$, we only need to move $\boldsymbol{f}^*$ along the direction of $T_{1,2}$.

Then it is easy to get

$$\begin{aligned}
&\sum_{j=1}^{K} P_j[(1-\alpha)\ell_s\{\langle \boldsymbol{f}^{**}, W_j \rangle\} + \alpha \ell_d\{\langle \boldsymbol{f}_0^{**}, W_j \rangle\}] \\
&- \sum_{j=1}^{K} P_j[(1-\alpha)\ell_s\{\langle \boldsymbol{f}^{*}, W_j \rangle\} + \alpha \ell_d\{\langle \boldsymbol{f}_0^{*}, W_j \rangle\}] \\
=&\epsilon(P_1 - P_2)(1-\alpha)\ell_s'\{\langle \boldsymbol{f}^*, W_1 \rangle\} + o(\epsilon)
\end{aligned}$$

Since we are using proximal hinge loss, ℓ_s is differentiable, $P_1 - P_2 > 0$, $\ell_s' < 0$ and $0 < \alpha < 1$. we have $\sum_{j=1}^{K} P_j[(1-\alpha)\ell_s\{\langle \boldsymbol{f}^{**}, W_j \rangle\} + \alpha \ell_d\{\langle \boldsymbol{f}_0^{**}, W_j \rangle\}] < \sum_{j=1}^{K} P_j[(1-\alpha)\ell_s\{\langle \boldsymbol{f}^{*}, W_j \rangle\} + \alpha \ell_d\{\langle \boldsymbol{f}_0^{*}, W_j \rangle\}]$, which is a contradiction.

For $\langle W_1, \boldsymbol{f}^* \rangle < \langle W_2, \boldsymbol{f}^* \rangle$ case, if $P_1\ell_s'\{\langle \boldsymbol{f}^*, W_1 \rangle\} - P_2\ell_s'\{\langle \boldsymbol{f}^*, W_2 \rangle\} < 0$, then choose $(\boldsymbol{f}^{**}, \boldsymbol{f}_0^{**}) = (\boldsymbol{f}^{**}, \boldsymbol{f}_0^*)$ be such that $\langle W_j, \boldsymbol{f}^{**} \rangle = \langle W_j, \boldsymbol{f}^* \rangle$ for $j \geq 3$ and $\langle W_1, \boldsymbol{f}^{**} \rangle = \langle W_1, \boldsymbol{f}^* \rangle + \epsilon$, $\langle W_2, \boldsymbol{f}^{**} \rangle = \langle W_2, \boldsymbol{f}^* \rangle - \epsilon$. Then we have

$$\begin{aligned}
&\sum_{j=1}^{K} P_j[(1-\alpha)\ell_s\{\langle \boldsymbol{f}^{**}, W_j \rangle\} + \alpha \ell_d\{\langle \boldsymbol{f}_0^{**}, W_j \rangle\}] \\
&- \sum_{j=1}^{K} P_j[(1-\alpha)\ell_s\{\langle \boldsymbol{f}^{*}, W_j \rangle\} + \alpha \ell_d\{\langle \boldsymbol{f}_0^{*}, W_j \rangle\}] \\
=&\epsilon(1-\alpha)\{P_1\ell_s'\{\langle \boldsymbol{f}^*, W_1 \rangle\} - P_2\ell_s'\{\langle \boldsymbol{f}^*, W_2 \rangle\}\} + o(\epsilon) < 0
\end{aligned}$$

We can see that If $P_1\ell_s'\{\langle \boldsymbol{f}^*, W_1 \rangle\} - P_2\ell_s'\{\langle \boldsymbol{f}^*, W_2 \rangle\} > 0$, then choose $(\boldsymbol{f}^{**}, \boldsymbol{f}_0^{**}) = (\boldsymbol{f}^{**}, \boldsymbol{f}_0^*)$ be such that $\langle W_j, \boldsymbol{f}^{**} \rangle = \langle W_j, \boldsymbol{f}^* \rangle$ for $j \geq 3$ and $\langle W_1, \boldsymbol{f}^{**} \rangle = \langle W_1, \boldsymbol{f}^* \rangle - \epsilon$, $\langle W_2, \boldsymbol{f}^{**} \rangle = \langle W_2, \boldsymbol{f}^* \rangle + \epsilon$. Then we have

$$\begin{aligned}
&\sum_{j=1}^{K} P_j[(1-\alpha)\ell_s\{\langle \boldsymbol{f}^{**}, W_j \rangle\} + \alpha \ell_d\{\langle \boldsymbol{f}_0^{**}, W_j \rangle\}] \\
&- \sum_{j=1}^{K} P_j[(1-\alpha)\ell_s\{\langle \boldsymbol{f}^{*}, W_j \rangle\} + \alpha \ell_d\{\langle \boldsymbol{f}_0^{*}, W_j \rangle\}] \\
=&\epsilon(1-\alpha)\{-P_1\ell_s'\{\langle \boldsymbol{f}^*, W_1 \rangle\} + P_2\ell_s'\{\langle \boldsymbol{f}^*, W_2 \rangle\}\} + o(\epsilon) < 0
\end{aligned}$$

We can see that this is a contradiction. This completes the proof. ■

Proposition 2. *In MSVM setting, when the size of the majority class goes to infinity, $\langle \beta_0, W_{y_K} \rangle < \sqrt{2C}K \max |x_{ij}| + 1$.*

Proof. Assume observations $1, \ldots, K-1$ belong to the class $1, \ldots, K-1$ respectively, and observations $K, \ldots, n$ belong to class K.

$$\begin{aligned}
\text{Loss} =& \sum_{i=1}^{n} \ell_s\{\langle f(x_i), W_{y_i} \rangle\} \\
=& \sum_{i=1}^{K-1} \ell_s\{\langle f(x_i), W_i \rangle\} + \sum_{i=K}^{n} \ell_s\{\langle f(x_i), W_K \rangle\} \\
=& \sum_{i=1}^{K-1} \ell_s\{\langle x_i^T B, W_i \rangle + \langle \beta_0, W_i \rangle\} + \sum_{i=K}^{n} \ell_s\{\langle x_i^T B, W_K \rangle + \langle \beta_0, W_K \rangle\}
\end{aligned}$$

Now we prove that $\forall B \in \mathbb{R}^{p \times (K-1)}$, we have

$$\langle \beta_0, W_K \rangle < \sup_i |\langle x_i^T B, W_i \rangle| K + 1 < \sqrt{2C}K \max |x_{ij}| + 1.$$

We can use contradiction to prove it, if $\langle \beta_0, W_K \rangle > \sup_i |\langle x_i^T B, W_i \rangle| K + 1$, then

$$\ell_s\{\langle x_i^T B, W_K \rangle + \langle \beta_0, W_K \rangle\} = 0$$

for all $i \in \{K, \ldots, n\}$ as $\langle x_i^T B, W_K \rangle + \langle \beta_0, W_K \rangle > 1$.

$$\text{Loss} = \sum_{i=1}^{n} \ell_s\{\langle f(x_i), W_{y_i}\rangle\} = \sum_{i=1}^{K-1} \ell_s\{\langle x_i^T B, W_i\rangle + \langle \beta_0, W_i\rangle\}.$$

Then $\frac{dL}{d\beta_0} = \sum_{i=1}^{K-1} l_s'\{\langle x_i^T B, W_i\rangle + \langle \beta_0, W_i\rangle\} W_i'$. Since $\langle \beta_0, W_K\rangle > \sup_i |\langle x_i^T B, W_i\rangle| K + 1$, one can get that $u_K = \langle x_K^T B, W_K\rangle + \langle \beta_0, W_K\rangle > 1$. Based on the property of W, we have $\sum_{i=1}^{K} \langle \beta_0, W_i\rangle = 0$. Furthermore, it is easy to deduct that $\min\langle \beta_0, W_i\rangle < -\sup_i |\langle x_i^T B, W_i\rangle|$ for $i \in \{1, \ldots, K-1\}$. Then $\min u_i = \langle x_i^T B, W_i\rangle + \min\langle \beta_0, W_i\rangle < 0$ for $i = 1, \ldots, K-1$. Thus we can choose $K-1$ different values $K_1, K_2, , \ldots, K_{K-1}$ from $1, \ldots, K-1$ such that $u_{K_1} \geq u_{K_2} \geq \ldots \geq 0 \geq \ldots \geq u_{K_{K-1}}$. Assume $i_0 = \max\{i, u_{K_i} < 1\}$, then $\frac{dL}{d\beta_0} = -\sum_{i=K_{K-1}}^{K_{i_0}} W_{K_i}'$. One can simply verify that $\frac{dL}{d\beta_0} \neq 0$ based on the property of vertex W. Thus β_0 cannot be the β_0 that minimize the loss function given B. This step completes the prove. ■

Theorem 3. *In the MDWSVM setting, when the size of the majority class goes to infinity,* $\langle \beta_0, W_{y_K}\rangle < \sqrt{2C} K \max |x_{ij}| + 1$.

Proof. Based on the proof of Proposition 2, for any $\forall B \in \mathbb{R}^{p\times(K-1)}$, we have

$$\langle \beta_0, W_K\rangle < \sup_i |\langle x_i^T B, W_i\rangle| K + 1 < \sqrt{2C} K \max |x_{ij}| + 1.$$

Thus for MDWSVM model, no matter what B we get, the intercept only comes from MSVM part. Therefore, from the conclusion of Proposition 2, Theorem 3 is proved. ■

Abstract

In this paper, we study the minimax estimation of the Bochner integral

$$\mu_k(P) := \int_{\mathcal{X}} k(\cdot, x)\, dP(x),$$

also called as the *kernel mean embedding*, based on random samples drawn i.i.d. from P, where $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is a positive definite kernel. Various estimators (including the empirical estimator), $\hat{\theta}_n$ of $\mu_k(P)$ are studied in the literature wherein all of them satisfy $\|\hat{\theta}_n - \mu_k(P)\|_{\mathcal{H}_k} = O_P(n^{-1/2})$ with $\mathcal{H}_k$ being the reproducing kernel Hilbert space induced by k. The main contribution of the paper is in showing that the above mentioned rate of $n^{-1/2}$ is minimax in $\|\cdot\|_{\mathcal{H}_k}$ and $\|\cdot\|_{L^2(\mathbb{R}^d)}$-norms over the class of discrete measures and the class of measures that has an infinitely differentiable density, with k being a continuous translation-invariant kernel on $\mathbb{R}^d$. The interesting aspect of this result is that the minimax rate is independent of the smoothness of the kernel and the density of P (if it exists).

Keywords: Bochner integral, Bochner's theorem, kernel mean embeddings, minimax lower bounds, reproducing kernel Hilbert space, translation invariant kernel

1. Introduction

Over the last few years, kernel embedding of distributions (Smola et al., 2007; Sriperumbudur et al., 2010) has gained a lot of attention in the machine learning community due to the wide variety of applications it has been employed in. Some of these applications include kernel two-sample testing (Gretton et al., 2007, 2012), kernel independence and conditional independence tests (Gretton et al., 2008; Fukumizu et al., 2008), covariate-shift (Smola et al., 2007), density estimation (Sriperumbudur, 2011), feature selection (Song et al., 2012), causal inference (Lopez-Paz et al., 2015), kernel Bayes' rule (Fukumizu et al., 2013) and distribution regression (Szabó et al., 2015).

Formally, let $\mathcal{H}_k$ be a separable reproducing kernel Hilbert space (RKHS) (Aronszajn, 1950) with a continuous reproducing kernel $k : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ defined on a separable topological space $\mathcal{X}$. Given a Borel probability measure P defined over $\mathcal{X}$ such that $\int_{\mathcal{X}} \sqrt{k(x,x)}\, dP(x) < \infty$, the kernel mean or the mean element is defined as the Bochner integral

$$\mu_P := \int_{\mathcal{X}} k(\cdot, x)\, dP(x) \in \mathcal{H}_k. \tag{1}$$

We refer the reader to Diestel and Uhl (1977, Chapter 2) and Dinculeanu (2000, Chapter 1) for the definition of a Bochner integral. The mean element in (1) can be viewed as an embedding of P in $\mathcal{H}_k$,

$$\mu_k : M_+^1(\mathcal{X}) \to \mathcal{H}_k, \qquad \mu_k(P) = \mu_P,$$

where $M_+^1(\mathcal{X})$ denotes the set of all Borel probability measures on $\mathcal{X}$. Hence, we also refer to μ_k as the *kernel mean embedding* (KME). The mean embedding can be seen as a generalization of the classical kernel feature map that embeds points of an input space $\mathcal{X}$ as elements in $\mathcal{H}_k$. The mean embedding μ_k can also be seen as a generalization of the classical notions of characteristic function, moment generation function (if it exists), and Weierstrass transform of P (all defined on $\mathbb{R}^d$) to an arbitrary topological space $\mathcal{X}$ as the choice of $k(\cdot, x)$ as $(2\pi)^{-d/2} e^{-\sqrt{-1}\langle \cdot, x\rangle}$, $e^{\langle \cdot, x\rangle}$, and $(4\pi)^{-d/2} e^{-\|\cdot - x\|_2^2}$, $x \in \mathbb{R}^d$ respectively reduces μ_k to these notions. The mean embedding μ_k is closely related to the *maximum mean discrepancy* (MMD) (Gretton et al., 2007), which is the RKHS distance between the mean embeddings of two probability measures. We refer the reader to (Sriperumbudur et al., 2010; Sriperumbudur, 2016) for more details on the properties of μ_k and the corresponding MMD.

In all the above mentioned statistical and machine learning applications, since the underlying distribution P is known only through random samples $X_1, \ldots, X_n$ drawn i.i.d. from it, an estimator of μ_P is employed. The goal of this paper is to study the minimax optimal estimation of μ_P. In the literature, various estimators of μ_P have been proposed. The simplest and most popular is the empirical estimator μ_{P_n}, which is constructed by replacing P by its empirical counterpart, $P_n := \frac{1}{n}\sum_{i=1}^n \delta_{X_i}$, where δ_x denotes a Dirac measure at $x \in \mathcal{X}$. In fact, all the above mentioned applications deal with the empirical estimator of μ_P because of its simplicity. Using Bernstein's inequality in separable Hilbert spaces (Yurinsky, 1995, Theorem 3.3.4), it follows that for bounded continuous kernels, $\|\mu_{P_n} - \mu_P\|_{\mathcal{H}_k} = O_P(n^{-1/2})$ for any P, i.e., the empirical estimator is a $\sqrt{n}$-consistent estimator of μ_P in $\mathcal{H}_k$-norm. This result is also proved in Smola et al. (2007, Theorem 2), Gretton et al. (2012), and Lopez-Paz et al. (2015) using McDiarmid's inequality, which we improve in Proposition A.1 (also see Remark A.2 in Appendix A) by providing a better constant. Assuming $\mathcal{X} = \mathbb{R}^d$ and P to have a density p, Sriperumbudur (2016, Theorem 4.1) proposed to estimate $\mu_P = \int_{\mathbb{R}^d} k(\cdot, x)p(x)\, dx$ by replacing p with a kernel density estimator, which is then shown to be $\sqrt{n}$-consistent in $\mathcal{H}_k$-norm if k is a bounded continuous *translation invariant kernel*—see Section 2 for its definition—on $\mathbb{R}^d$. Recently, Muandet et al. (2016, Section 2.4, Theorem 7) proposed a non-parametric shrinkage estimator of μ_P and established its $\sqrt{n}$-consistency in $\mathcal{H}_k$-norm for bounded continuous kernels on $\mathcal{X}$. Muandet et al. (2016, Section 3, Theorem 10) also proposed a penalized M-estimator for μ_P

where the penalization parameter is computed in a completely data-driven manner using leave-one-out cross validation and showed that it is also $\sqrt{n}$-consistent in $\mathcal{H}_k$-norm. In fact, the $\sqrt{n}$-consistency of all these estimators is established by showing that they are all within a $\|\cdot\|_{\mathcal{H}_k}$-ball of size $o_P(n^{-1/2})$ around the empirical estimator μ_{P_n}.

In the above discussion, it is important to note that the convergence rate of μ_{P_n} (and also other estimators) to μ_P in $\mathcal{H}_k$-norm does not depend on the smoothness of k or the density, p (if it exists). Under some mild conditions on the kernel (defined on $\mathbb{R}^d$), it can be shown (see Section 4) that $\mathcal{H}_k$ is continuously included in $L^2(\mathbb{R}^d)$ and $\|f\|_{L^2(\mathbb{R}^d)} \leq c_k \|f\|_{\mathcal{H}_k}$ for all $f \in \mathcal{H}_k$, where c_k is a constant that depends only on the kernel. This means, $\|\cdot\|_{L^2(\mathbb{R}^d)}$ is a weaker norm than $\|\cdot\|_{\mathcal{H}_k}$ and therefore it could be possible that μ_{P_n} converges to μ_P in $L^2(\mathbb{R}^d)$ at a rate faster than $n^{-1/2}$ (depending on the smoothness of k). In Proposition A.1 (also see Remark A.3 in Appendix A) we show that $\|\mu_{P_n} - \mu_P\|_{L^2(\mathbb{R}^d)} = O_P(n^{-1/2})$. Now given these results, it is of interest to understand whether these rates are optimal in a minimax sense, i.e., whether the above mentioned estimators are minimax rate optimal or can they be improved upon? Therefore the goal of this work is to obtain minimax rates for the estimation of μ_P in $\|\cdot\|_{\mathcal{H}_k}$ and $\|\cdot\|_{L^2(\mathbb{R}^d)}$.

Formally, we would like to find the minimax rate $r_{n,k}(\mathcal{F}, \mathcal{P})$ and a positive constant $c_k(\mathcal{F}, \mathcal{P})$ (independent of n) such that

$$\inf_{\hat{\theta}_n} \sup_{P \in \mathcal{P}} P^n \left\{ r_{n,k}^{-1}(\mathcal{F}, \mathcal{P}) \|\hat{\theta}_n - \mu_P\|_{\mathcal{F}} \geq c_k(\mathcal{F}, \mathcal{P}) \right\} > 0, \tag{2}$$

where $\mathcal{F}$ is either $\mathcal{H}_k$ or $L^2(\mathbb{R}^d)$, $\mathcal{P}$ is a suitable subset of Borel probability measures on $\mathcal{X}$, and the infimum is taken over all estimators $\hat{\theta}_n$ mapping the i.i.d. sample $X_1, \ldots, X_n$ to $\mathcal{F}$. Suppose $k(x, y) = \langle x, y \rangle$, $x, y \in \mathbb{R}^d$. Norms $\|\cdot\|_{\mathcal{H}_k}$ and $\|\cdot\|_{L^2(\mathbb{R}^d)}$ match for this choice of k and the corresponding RKHS is finite dimensional, i.e., $\mathcal{H}_k = \mathbb{R}^d$. For a distribution P on $\mathbb{R}^d$ satisfying $\int_{\mathbb{R}^d} \|x\|_2 \, dP(x) < \infty$, this choice of kernel yields $\mu_P = \int x \, dP(x)$ as the mean embedding of P which simply is the mean of P. It is well-known (Lehmann and Casella, 2008, Chapter 5, Example 1.14) that the minimax rate of estimating $\mu_P \in \mathbb{R}^d$ based on $(X_i)_{i=1}^n$ is $r_{n,k}(\mathcal{F}, \mathcal{P}) = n^{-1/2}$ for the class $\mathcal{P}$ of Gaussian distributions on $\mathbb{R}^d$. In fact, this rate is attained by the empirical estimator $\mu_{P_n} = \frac{1}{n} \sum_{i=1}^n X_i$, which is the sample mean. Based on this observation, while one can intuitively argue that the minimax rate of estimating μ_P is $n^{-1/2}$ even if $\mathcal{H}_k$ is an infinite dimensional RKHS, it is difficult to extend the finite dimensional argument in a rigorous manner to the estimation of the infinite dimensional object, μ_P. In this paper, through a key inequality—see (3)— we rigorously show that it is indeed the case.

The main result of the paper is that if k is translation invariant on $\mathcal{X} = \mathbb{R}^d$ (see Theorems 1 and 9 for precise conditions on the kernel) and $\mathcal{P}$ is the set of all Borel discrete probability measures on $\mathbb{R}^d$, then the minimax rate $r_{n,k}(\mathcal{F}, \mathcal{P})$ is $n^{-1/2}$ for both $\mathcal{F} = \mathcal{H}_k$ and $\mathcal{F} = L^2(\mathbb{R}^d)$. Next, we show in Theorems 6 and 12 that the minimax rate for the estimation of μ_P in both $\|\cdot\|_{\mathcal{H}_k}$ and $\|\cdot\|_{L^2(\mathbb{R}^d)}$ still remains $n^{-1/2}$ even when $\mathcal{P}$ is restricted to the class of Borel probability measures which have densities, p that are continuously infinitely differentiable. The reason for considering such a class of distributions with smooth densities is that μ_P, which is the convolution of k and p, is smoother than k. Therefore one might wonder if it could be possible to estimate μ_P at a rate faster than $n^{-1/2}$ that depends on

the smoothness of k and p. Our result establishes that even for the class of distributions with very smooth densities, the minimax rate is independent of the smoothness of k and the density of P. The key ingredient in the proofs of Theorems 6 and 12 is the non-trivial inequality (see Proposition 3)

$$\|\mu_{G_0} - \mu_{G_1}\|_{\mathcal{F}} \geq c'_{k,\sigma^2} \|\tau_0 - \tau_1\|_2, \tag{3}$$

which relates the $\mathcal{F}$-distance between the mean embeddings of the Gaussian distributions, $G_0 = N(\tau_0, \sigma^2 I)$ and $G_1 = N(\tau_1, \sigma^2 I)$ to the Euclidean distance between the means of these Gaussians, where c'_{k,σ^2} is a constant that depends only on σ^2 and the translation invariant characteristic kernel k. Combining (3) with Le Cam's method (see Appendix B) implies that the estimation of an infinite dimensional object μ_P is as hard as the estimation of finite dimensional mean of a Gaussian distribution, thereby establishing the minimax rate to be $n^{-1/2}$. These results show that the empirical estimator—and other estimators we discussed above—of μ_P is minimax rate optimal.

Ramdas et al. (2015, Corollary 1) derived a special case of (3) for the Gaussian kernel k by ignoring small terms in the Taylor series expansion of $\|\mu_{G_0} - \mu_{G_1}\|_{\mathcal{H}_k}$ (refer to Remark 4). They used this result to show that the MMD between G_0 and G_1 decreases to zero exponentially/polynomially fast in d even when the Kullback-Leibler divergence between the two is kept constant, which in turn sheds some light on the decaying power of MMD-based hypothesis tests in high dimensions. Proposition 3 is more general, as it holds for *any* translation-invariant kernel k and does not require a truncation of small reminder terms.

The paper is organized as follows. Various notations used throughout the paper and definitions are collected in Section 2. The main results on minimax estimation of μ_P in $\|\cdot\|_{\mathcal{H}_k}$ and $\|\cdot\|_{L^2(\mathbb{R}^d)}$ for translation invariant kernels (and also *radial* kernels) on $\mathbb{R}^d$ are presented in Sections 3 and 4 respectively. The proofs of the results are provided in Section 5 while some supplementary results needed in the proofs are collected in appendices.

2. Definitions & Notation

Define $\|a\|_2 := \sqrt{\sum_{i=1}^d a_i^2}$ and $\langle a, b \rangle := \sum_{i=1}^d a_i b_i$, where $a := (a_1, \ldots, a_d) \in \mathbb{R}^d$ and $b := (b_1, \ldots, b_d) \in \mathbb{R}^d$. $C(\mathbb{R}^d)$ (*resp.* $C_b(\mathbb{R}^d)$) denotes the space of all continuous (*resp.* bounded continuous) functions on $\mathbb{R}^d$. $f \in C(\mathbb{R}^d)$ is said to *vanish at infinity* if for every $\epsilon > 0$ the set $\{x : |f(x)| \geq \epsilon\}$ is compact. The class of all continuous f on $\mathbb{R}^d$ which vanish at infinity is denoted as $C_0(\mathbb{R}^d)$. For $f \in C_b(\mathbb{R}^d)$, $\|f\|_\infty := \sup_{x \in \mathbb{R}^d} |f(x)|$ denotes the supremum norm of f. $M_b(\mathbb{R}^d)$ (*resp.* $M_+^b(\mathbb{R}^d)$) denotes the set of all finite (*resp.* finite non-negative) Borel measures on $\mathbb{R}^d$. $\text{supp}(\mu)$ denotes the support of $\mu \in M_b(\mathbb{R}^d)$ which is defined as $\text{supp}(\mu) = \{x \in \mathbb{R}^d \mid \text{for any open set } U \text{ such that } x \in U, |\mu|(U) \neq 0\}$, where $|\mu|$ is the total-variation of μ. $M_+^1(\mathbb{R}^d)$ denotes the set of Borel probability measures on $\mathbb{R}^d$. For $\mu \in M_+^b(\mathbb{R}^d)$, $L^r(\mathbb{R}^d, \mu)$ denotes the Banach space of r-power ($r \geq 1$) μ-integrable functions and we will use $L^r(\mathbb{R}^d)$ for $L^r(\mathbb{R}^d, \mu)$ if μ is a Lebesgue measure on $\mathbb{R}^d$. For $f \in L^r(\mathbb{R}^d, \mu)$, $\|f\|_{L^r(\mathbb{R}^d, \mu)} := \left(\int_{\mathbb{R}^d} |f|^r \, d\mu \right)^{1/r}$ denotes the L^r-norm of f for $1 \leq r < \infty$ and we denote it as $\|\cdot\|_{L^r(\mathbb{R}^d)}$ if μ is the Lebesgue measure. The convolution $f * g$ of two measurable functions

f and g on $\mathbb{R}^d$ is defined as

$$(f * g)(x) := \int_{\mathbb{R}^d} f(y)g(x-y)\,dy,$$

provided the integral exists for all $x \in \mathbb{R}^d$. The Fourier transforms of $f \in L^1(\mathbb{R}^d)$ and $\mu \in M_b(\mathbb{R}^d)$ are defined as

$$f^\wedge(y) := \mathscr{F}[f](y) = (2\pi)^{-d/2} \int_{\mathbb{R}^d} f(x)\, e^{-i\langle y,x\rangle}\,dx, \qquad y \in \mathbb{R}^d$$

and

$$\mu^\wedge(y) := \mathscr{F}[\mu](y) = (2\pi)^{-d/2} \int_{\mathbb{R}^d} e^{-i\langle y,x\rangle}\,d\mu(x), \qquad y \in \mathbb{R}^d$$

respectively, where i denotes the imaginary unit $\sqrt{-1}$.

A kernel $k\colon \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ is called *translation invariant* if there exists a symmetric positive definite function, ψ such that $k(x,y) = \psi(x-y)$ for all $x, y \in \mathbb{R}^d$. Bochner's theorem (see Wendland, 2005, Theorem 6.6) provides a complete characterization for a positive definite function ψ: A continuous function $\psi\colon \mathbb{R}^d \to \mathbb{R}$ is positive definite if and only if it is the Fourier transform of $\Lambda_\psi \in M_+^b(\mathbb{R}^d)$, i.e.,

$$\psi(x) = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-i\langle x,w\rangle} d\Lambda_\psi(w), \quad x \in \mathbb{R}^d. \tag{4}$$

A kernel k is called *radial* if there exists $\phi : \mathbb{R}_+ \to \mathbb{R}$ such that $k(x,y) = \phi(\|x-y\|_2^2)$ for all $x, y \in \mathbb{R}^d$. From Schönberg's representation (Schoenberg, 1938; Wendland, 2005, Theorems 7.13 & 7.14) it is known that a kernel k is radial on every $\mathbb{R}^d$ if and only if there exists $\nu \in M_+^b([0,\infty))$ such that the following holds for all $x, y \in \mathbb{R}^d$:

$$k(x,y) = \phi(\|x-y\|^2) = \int_0^\infty e^{-t\|x-y\|^2} d\nu(t). \tag{5}$$

Some examples of reproducing kernels on $\mathbb{R}^d$ (in fact all these are radial) that appear throughout the paper are:

1. *Gaussian:* $k(x,y) = \exp\left(-\frac{\|x-y\|_2^2}{2\eta^2}\right)$, $\eta > 0$;
2. *Mixture of Gaussians:* $k(x,y) = \sum_{i=1}^M \beta_i \exp\left(-\frac{\|x-y\|_2^2}{2\eta_i^2}\right)$, where $M \geq 2$, $\eta_1^2 \geq \eta_2^2 \geq \cdots \geq \eta_M^2 > 0$, and positive constants $\beta_1, \ldots, \beta_M$ such that $\sum_{i=1}^M \beta_i = C_M < \infty$;
3. *Inverse Multiquadrics:* $k(x,y) = (c^2 + \|x-y\|_2^2)^{-\gamma}$, $c, \gamma > 0$;
4. *Matérn:* $k(x,y) = \frac{c^{2\tau-d}}{\Gamma(\tau-\frac{d}{2})2^{\tau-1-d/2}} \left(\frac{\|x-y\|_2}{c}\right)^{\tau-\frac{d}{2}} \mathcal{K}_{\frac{d}{2}-\tau}(c\|x-y\|_2)$, $\tau > d/2$, $c > 0$, where $\mathcal{K}_\alpha$ is the *modified Bessel function of the third kind* of order α and Γ is the Gamma function.

A kernel k is said to be *characteristic* if the mean embedding, $\mu_k : P \to \mu_P$ is injective, where μ_P is defined in (1). Various characterizations for the injectivity of μ_k (or k being characteristic) are known in literature (for details, see Sriperumbudur et al., 2011 and references therein). If k is a bounded continuous translation invariant positive definite kernel on $\mathbb{R}^d$, a simple characterization can be obtained for it to be characteristic (Sriperumbudur et al., 2010, Theorem 9): k is characteristic if and only if $\operatorname{supp}(\Lambda_\psi) = \mathbb{R}^d$ where Λ_ψ is defined in (4). This characterization implies that the above mentioned examples are characteristic kernels. Examples of non-characteristic kernels of translation invariant type include $k(x,y) = \frac{\sin(x-y)}{x-y}$, $x, y \in \mathbb{R}$ and $k(x,y) = \cos(x-y)$, $x, y \in \mathbb{R}$. More generally, polynomial kernels of any finite order are non-characteristic.

3. Minimax Estimation of μ_P in the RKHS Norm

In this section, we present our main results related to the minimax estimation of kernel mean embeddings (KMEs) in the RKHS norm. As discussed in Section 1, various estimators of $\mu_k(P)$ are known in literature and all these have a convergence rate of $n^{-1/2}$ if the kernel is bounded. The main goal of this section is to show that the rate $n^{-1/2}$ is actually minimax optimal for different choices of $\mathcal{P}$ (see (2)) under some mild conditions on k.

First, choosing $\mathcal{P}$ to be the set of all discrete probability measures on $\mathbb{R}^d$, in Section 3.1 (see Theorem 1 and Corollary 2), we present the minimax lower bounds of order $\Omega(n^{-1/2})$ with constant factors depending only on the properties of the kernel for translation invariant and radial kernels respectively. Next we will show in Section 3.2 that the rate $n^{-1/2}$ remains minimax optimal for translation invariant and radial kernels even if we choose the class $\mathcal{P}$ to contain only probability distributions with infinitely continuously differentiable densities. For translation invariant kernels the result (see Theorem 6) is based on a key inequality, which relates the RKHS distance between embeddings of Gaussian distributions to the Euclidean distance between the mean vectors of these distributions (see Proposition 3). The minimax lower bound for radial kernels (see Theorem 8) is derived using a slightly different argument. Instead of applying the bound of Theorem 6 to the particular case of radial kernels, we will present a direct analysis based on the special properties of radial kernels. This will lead us to the lower bound with almost optimal constant factors, depending only on the shape of Borel measure ν corresponding to the kernel.

Our analysis is based on the following simple idea: if a kernel k is characteristic, there is a one-to-one correspondence between any given set of Borel probability measures $\mathcal{P}$ defined over $\mathbb{R}^d$ and a set $\mu_k(\mathcal{P})$ of their embeddings into the RKHS $\mathcal{H}_k$. This means that distributions in $\mathcal{P}$ are indexed by their embeddings $\Theta := \mu_k(\mathcal{P})$ and so (2) can be equivalently written as

$$\inf_{\hat{\theta}_n} \sup_{\theta \in \Theta} \mathbb{P}_\theta \left\{ r_{n,k}^{-1}(\mathcal{H}_k, \mathcal{P}) \|\hat{\theta}_n - \theta\|_{\mathcal{H}_k} \geq c_k(\mathcal{H}_k, \mathcal{P}) \right\} > 0, \tag{6}$$

where the goal is to find the minimax rate $r_{n,k}(\mathcal{H}_k, \mathcal{P})$ and a positive constant $c_k(\mathcal{H}_k, \mathcal{P})$ (independent of n) such that (6) holds and $\mathbb{P}_\theta = P^n$ when $\theta = \mu_k(P)$. Using this equivalence, we obtain the minimax rates by employing Le Cam's method (Tsybakov, 2008)—see Theorems B.1 and B.2 for a reference.

3.1 Lower Bounds for Discrete Probability Measures

The following result (proved in Section 5.1) presents a minimax rate of $n^{-1/2}$ for estimating $\mu_k(P)$, where k is assumed to be translation invariant on $\mathbb{R}^d$.

Theorem 1 (Translation invariant kernels) *Let $\mathcal{P}$ be the set of all Borel discrete probability measures on $\mathbb{R}^d$. Suppose $k(x,y) = \psi(x-y)$, where $\psi \in C_b(\mathbb{R}^d)$ is positive definite and k is characteristic. Assume there exists $z \in \mathbb{R}^d$ and $\beta > 0$, such that $\psi(0) - \psi(z) \geq \beta$. Then the following holds:*

$$\inf_{\hat{\theta}_n} \sup_{P \in \mathcal{P}} P^n \left\{ \|\hat{\theta}_n - \mu_k(P)\|_{\mathcal{H}_k} \geq \frac{1}{6}\sqrt{\frac{2\beta}{n}} \right\} \geq \frac{1}{4}.$$

The result is based on Le Cam's method involving two hypotheses (see Theorem B.1), where we choose them to be KMEs of discrete measures, both supported on the same pair of points separated by z in $\mathbb{R}^d$.

Remark (Choosing z and β) *As discussed in Sriperumbudur et al. (2010, Section 3.4), if k is translation invariant and characteristic on $\mathbb{R}^d$, then it is also strictly positive definite. This means that $\psi(0) > 0$. Moreover, the following hold: (a) Since ψ is positive definite, we have $|\psi(x)| \leq \psi(0)$ for all $x \in \mathbb{R}^d$ and (b) since ψ is characteristic, it cannot be a constant function. Together these facts show that there always exist $z \in \mathbb{R}^d$ and $\beta > 0$ satisfying the assumptions of Theorem 1. For instance, a Gaussian kernel $k(x,v) = \exp\left(-\|x-v\|_2^2/(2\eta^2)\right)$ satisfies $\psi(0) - \psi(z) \geq \|z\|_2^2/(4\eta^2)$ if $\|z\|_2^2 \leq 2\eta^2$, where we used a simple fact that $1 - e^{-x} \geq x/2$ for $0 \leq x \leq 1$.*

While Theorem 1 dealt with general translation invariant kernels, the following result (proved in Section 5.2) specializes it to radial kernels, i.e., kernels of the form in (5), by providing a simple condition on ν under which Theorem 1 holds.

Corollary 2 (Radial kernels) *Let $\mathcal{P}$ be the set of all Borel discrete probability measures on $\mathbb{R}^d$ and k be radial on $\mathbb{R}^d$, i.e., $k(x,y) = \psi_\nu(x-y) := \int_0^\infty e^{-t\|x-y\|_2^2} d\nu(t)$, where $\nu \in M_+^b([0,\infty))$ such that $\operatorname{supp}(\nu) \neq \{0\}$. Assume there exist $0 < t_1 < \infty$ and $\alpha > 0$ satisfying $\nu([t_1,\infty)) \geq \alpha$. Then the following holds:*

$$\inf_{\hat{\theta}_n} \sup_{P \in \mathcal{P}} P^n \left\{ \|\hat{\theta}_n - \mu_k(P)\|_{\mathcal{H}_k} \geq \frac{1}{6}\sqrt{\frac{\alpha}{n}} \right\} \geq \frac{1}{4}.$$

Remark (Choosing t_1 and α) *Since $\operatorname{supp}(\nu) \neq \{0\}$ the assumption of $\nu[t_1,\infty) \geq \alpha$ is always satisfied. For instance, if ν is a probability measure with positive median η then we can set $t_1 = \eta$ and $\alpha = \frac{1}{2}$. Based on this, it is easy to verify (see Appendix D.1) that $\alpha = 1$ for Gaussian, $\alpha = C_M$ for mixture of Gaussian kernels, $\alpha = \frac{c^{-2\gamma}}{2}$ for inverse multiquadrics and $\alpha = \frac{1}{2}$ for Matérn kernels.*

3.2 Lower Bounds for Probability Measures with Smooth Densities

So far, we have shown that the rate $n^{-1/2}$ is minimax optimal for the problem of KME estimation (both for translation invariant and radial kernels). As discussed in Section 1,

since this rate is independent of the smoothness of the estimand (which is determined by the smoothness of the kernel), one might wonder whether the minimax rate can be improved by restricting $\mathcal{P}$ to distributions with smooth densities. We show in this section (see Theorems 6 and 8) that this is not the case by restricting $\mathcal{P}$ to contain only distributions with infinitely continuously differentiable densities and proving the minimax lower bound of order $n^{-1/2}$.

We will start the analysis with translation invariant kernels and present a corresponding lower bound in Theorem 6. The proof of this result is again based on an application of Le Cam's method involving two hypotheses (see Theorem B.1), where this time these hypotheses are chosen to be embeddings of the d-dimensional Gaussian distributions. One of the main steps, when applying Theorem B.1, is to lower bound the distance between these embeddings. This is done in the following result (proved in Section 5.3), which essentially shows that if we take two Gaussian distributions $G(\mu_0, \sigma^2 I)$ and $G(\mu_1, \sigma^2 I)$ with the mean vectors $\mu_0, \mu_1 \in \mathbb{R}^d$ which are close enough to each other, then the RKHS distance between the corresponding embeddings can be lower bounded by the Euclidean distance $\|\mu_0 - \mu_1\|_2$.

Proposition 3 *Let $\sigma > 0$. Suppose $k(x,y) = \psi(x-y)$, where $\psi \in C_b(\mathbb{R}^d)$ is positive definite and k is characteristic. Then there exist constants $\epsilon_{\psi,\sigma^2}, c_{\psi,\sigma^2} > 0$ depending only on ψ and σ^2, such that the following condition holds for any $a \in \mathbb{R}^d$ with $\|a\|_2^2 \leq \epsilon_{\psi,\sigma^2}$:*

$$c_{\psi,\sigma^2} \leq \min_{e_z \in S^{d-1}} \frac{2}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2} \langle e_z, w\rangle^2 \cos\left(\langle a, w\rangle\right) d\Lambda_\psi(w) < \infty, \tag{7}$$

where S^{d-1} is a unit sphere in $\mathbb{R}^d$ and $\Lambda_\psi \in M_+^b(\mathbb{R}^d)$ is defined in (4). Moreover, for all vectors $\mu_0, \mu_1 \in \mathbb{R}^d$ satisfying $\|\mu_0 - \mu_1\|_2^2 \leq \epsilon_{\psi,\sigma^2}$, the following holds:

$$\|\theta_0 - \theta_1\|_{\mathcal{H}_k} \geq \sqrt{\frac{c_{\psi,\sigma^2}}{2}} \|\mu_0 - \mu_1\|_2, \tag{8}$$

where θ_0 and θ_1 are KMEs of Gaussian measures $G(\mu_0, \sigma^2 I)$ and $G(\mu_1, \sigma^2 I)$ respectively.

Remark 4 (KME expands small distances) *For a Gaussian kernel, it is possible to show (Sriperumbudur et al., 2012, Example 3; Ramdas et al., 2015, Proposition 1) that $\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2 = C_1\left(1 - \exp(-C_2\|\mu_0 - \mu_1\|_2^2)\right)$, where C_1 and C_2 are positive constants that depend only on σ^2 and η^2. This shows that (8) holds for $\|\mu_0 - \mu_1\|_2 \in [0, D]$, where D satisfies $C_1\left(1 - \exp(-C_2 D^2)\right) = \frac{1}{2} D^2 c_{\psi,\sigma^2}$. In other words, Proposition 3 states that the mapping $f_{\sigma^2} \colon \mathbb{R}^d \to \mathcal{H}_k$ defined by $f_{\sigma^2}(x) := \mu_k\left(G(x, \sigma^2 I)\right)$ expands small distances.*

Remark 5 (Computing c_{ψ,σ^2} and ϵ_{ψ,σ^2}) *Generally it may be very hard to compute (or bound) the constants c_{ψ,σ^2} and ϵ_{ψ,σ^2} appearing in the statement of Proposition 3. However, in some cases this may be still possible. In Appendix E we will provide an extensive analysis for the case of radial kernels.*

Based on Proposition 3, the following result shows that the rate of $n^{-1/2}$ remains minimax optimal for the problem of KME estimation with translation invariant kernels, even if we restrict the class of distributions $\mathcal{P}$ to contain only measures with smooth densities.

Theorem 6 (Translation invariant kernels) *Let $\mathcal{P}$ be the set of distributions over $\mathbb{R}^d$ whose densities are continuously infinitely differentiable. Suppose $k(x,y) = \psi(x-y)$, where $\psi \in C_b(\mathbb{R}^d)$ is positive definite and k is characteristic. Define $c_\psi := c_{\psi,1}$ and $\epsilon_\psi := \epsilon_{\psi,1}$ where $c_{\psi,1}$ and $\epsilon_{\psi,1}$ are positive constants that satisfy (7) in Proposition 3. Then for any $n \geq \frac{1}{\epsilon_\psi}$, the following holds:*

$$\inf_{\hat{\theta}_n} \sup_{P \in \mathcal{P}} P^n \left\{ \|\hat{\theta}_n - \mu_k(P)\|_{\mathcal{H}_k} \geq \frac{1}{2}\sqrt{\frac{c_\psi}{2n}} \right\} \geq \frac{1}{4}.$$

Proof The proof will be based on Theorem B.1. For this we need to find two probability measures P_0 and P_1 on $\mathbb{R}^d$ and corresponding KMEs θ_0 and θ_1, such that $\|\theta_0 - \theta_1\|_{\mathcal{H}_k}$ is of the order $\Omega(n^{-1/2})$, while $\mathrm{KL}(P_0^n \| P_1^n)$ is upper bounded by a constant independent of n. Here $\mathrm{KL}(P_0\|P_1)$ denotes the Kullback-Leibler divergence between P_0 and P_1, which is defined as $\mathrm{KL}(P_0\|P_1) = \int \log \frac{dP_0}{dP_1}\, dP_0$ where P_0 is absolutely continuous w.r.t. P_1.

Pick two Gaussian distributions $G_0 := G(\mu_0, \sigma^2 I)$ and $G_1 := G(\mu_1, \sigma^2 I)$ for $\mu_0, \mu_1 \in \mathbb{R}^d$, and $\sigma^2 > 0$. It is known that (Tsybakov, 2008, Section 2.4)

$$\mathrm{KL}(G_0^n \| G_1^n) = n \cdot \frac{\|\mu_0 - \mu_1\|_2^2}{2\sigma^2}, \tag{9}$$

where G_0^n and G_1^n are n-fold product distributions. Choose μ_0 and μ_1 such that

$$\|\mu_0 - \mu_1\|_2^2 = \frac{1}{n}.$$

Denote KMEs of G_0 and G_1 using θ_0 and θ_1 respectively. Next we will take $\sigma^2 = 1$ and apply Proposition 3. Since c_ψ and ϵ_ψ satisfy (7) in Proposition 3, it follows from Proposition 3 that for $1/n \leq \epsilon_\psi$,

$$\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2 \geq \frac{c_\psi}{2}\|\mu_0 - \mu_1\|_2^2 = \frac{c_\psi}{2n}.$$

This shows that the first condition of Theorem B.1 is satisfied for θ_0 and θ_1 with $s := \frac{1}{2}\sqrt{c_\psi/(2n)}$. Moreover, using (9) we can show that the second condition of Theorem B.1 is satisfied with $\alpha = \frac{1}{2}$. We conclude the proof with an application of Theorem B.1. ■

Remark 7 (Lower bound on the sample size n) *Note that Theorem 6 holds only for large enough sample size n (i.e., $n \geq 1/\epsilon_\psi$). This assumption on n can be dropped if we set $\|\mu_0 - \mu_1\|_2^2 = \epsilon_\psi/n$ in the proof. In this case, the lower bound $\frac{1}{2}\sqrt{c_\psi/(2n)}$ will be replaced with $\frac{1}{2}\sqrt{c_\psi \epsilon_\psi/(2n)}$, while the lower bound on the minimax probability $1/4$ will be replaced with*

$$\max\left(\frac{1}{4}e^{-\frac{\epsilon_\psi}{2}}, \frac{1-\sqrt{\epsilon_\psi/4}}{2}\right).$$

The latter is generally undesirable, especially if ϵ_ψ grows with $d \to \infty$, since we want the minimax probability to be lower bounded by some universal non-zero constant that does not depend on the properties of the problem at hand.

Since radial kernels are particular instances of translation invariant kernels, Theorem 6 can be specialized by explicitly computing the constants c_ψ and ϵ_ψ to derive a minimax lower bound of order $\Omega(n^{-1/2})$. Unfortunately, the resulting lower bound will depend on the dimensionality d in a rather bad way and, as a consequence, is suboptimal in some situations. For instance, if we consider a Gaussian kernel $k(x,y) = \exp\big(-\frac{1}{2\eta^2}\|x-y\|_2^2\big)$, then a straightforward computation of c_ψ shows that the lower bound in Theorem 6 has the form $\sqrt{(1+2/\eta^2)^{-d/2}/n}$ which shrinks to zero as $d \to \infty$, while Proposition A.1 (also see Remark A.2) provides a dimension independent upper bound of the order $O_p(n^{-1/2})$. Therefore, instead of specializing Theorem 6 to radial kernels, we obtain the following result for radial kernels by using a refined analysis which yields a minimax rate of $\Omega(n^{-1/2})$ that matches the upper bound of Proposition A.1 up to constant factors that depend only on the shape of Borel measure ν. In particular, when specialized to the Gaussian kernel, the result matches the upper bound up to a constant factor independent of d.

Theorem 8 (Radial kernels) *Let k be radial on $\mathbb{R}^d$, i.e., $k(x,y) = \int_0^\infty e^{-t\|x-y\|_2^2}\, d\nu(t)$, where $\nu \in M_+^b([0,\infty))$ and $\mathcal{P}$ be the set of distributions over $\mathbb{R}^d$ whose densities are continuously infinitely differentiable. Assume that $\mathrm{supp}(\nu) \neq \{0\}$ and there exist $0 < t_0 \leq t_1 < \infty$, $0 < \beta < \infty$ such that $\nu([t_0, t_1]) \geq \beta$. Then the following holds:*

$$\inf_{\hat{\theta}_n} \sup_{P \in \mathcal{P}} P^n \left\{ \|\hat{\theta}_n - \mu_k(P)\|_{\mathcal{H}_k} \geq \frac{1}{50}\sqrt{\frac{1}{n} \cdot \frac{\beta t_0}{t_1 e}\left(1 - \frac{2}{2+d}\right)} \right\} \geq \frac{1}{5}.$$

Proof The proof, which is presented in Section 5.4, is based on an application of Le Cam's method involving multiple hypotheses (see Theorem B.2), where we use exponential (in d) number of Gaussian distributions with variances decaying as $\frac{1}{d}$. ■

Remark (Non-trivial lower bound as $d \to \infty$) *The proof of Theorem 8 is based on Gaussian distributions with variances decaying as $1/d$. As $d \to \infty$, it is obvious the densities of these distributions do not have uniformly bounded Lipschitz constants, i.e., they are arbitrarily "peaky". Hence, if we choose $\mathcal{P}$ to be class of distributions with infinitely differentiable densities that have uniformly bounded Lipschitz constants, then as $d \to \infty$, the densities considered in the proof of Theorem 8 do not belong to $\mathcal{P}$. On the other hand, the densities considered in the proof of Theorem 6 still belong to $\mathcal{P}$ but yielding an uninteresting result since $c_\psi \to 0$ when $d \to \infty$. Therefore, it is an open question whether a non-trivial lower bound can be obtained for radial kernels (or any other translation invariant kernels) if we choose $\mathcal{P}$ to contain only distributions with densities having uniformly bounded Lipschitz constants.*

Remark (Alternative Proof) *For completeness, we also present an alternative proof of Theorem 8 in Appendix E. It is based on Proposition 3, which holds for any translation invariant kernel. As a result, this proof leads to slightly worse constants compared to Theorem 8 (where we used an analysis specific to radial kernels), as well as a superfluous condition on the minimal sample size n.*

In Appendix D.2, we compute the positive constant $B_k := \frac{\beta t_0}{t_1}$ that appears in the lower bound in Theorem 8 in a closed form for Gaussian, mixture of Gaussian, inverse multiquadric and Matérn kernels.

4. Minimax Estimation of μ_P in the $L^2(\mathbb{R}^d)$ Norm

So far, we have discussed the minimax estimation of the kernel mean embedding (KME) in the RKHS norm. In this section, we investigate the minimax estimation of KME in $L^2(\mathbb{R}^d)$ norm. The reason for this investigation is as follows. Let $k(x,y) = \psi(x-y)$, $x, y \in \mathbb{R}^d$, where $\psi \in L^1(\mathbb{R}^d) \cap C(\mathbb{R}^d)$ is strictly positive definite. The corresponding RKHS is given by (see Wendland, 2005, Theorem 10.12)

$$\mathcal{H}_k = \left\{ f \in L^2(\mathbb{R}^d) \cap C(\mathbb{R}^d) \, : \, \int_{\mathbb{R}^d} \frac{|f^\wedge(\omega)|^2}{\psi^\wedge(\omega)} \, d\omega < \infty \right\}, \tag{10}$$

which is endowed with the inner product $\langle f, g \rangle_{\mathcal{H}_k} = \int_{\mathbb{R}^d} \frac{f^\wedge(\omega)\overline{g^\wedge(\omega)}}{\psi^\wedge(\omega)} d\omega$ with $f^\wedge$ being the Fourier transform of f in the L^2-sense. It follows from (10) that for any $f \in \mathcal{H}_k$,

$$\|f\|^2_{L^2(\mathbb{R}^d)} \overset{(\star)}{=} \|f^\wedge\|^2_{L^2(\mathbb{R}^d)} = \int_{\mathbb{R}^d} \left|f^\wedge(\omega)\right|^2 d\omega = \int_{\mathbb{R}^d} \frac{|f^\wedge(\omega)|^2}{\psi^\wedge(\omega)} \psi^\wedge(\omega) \, d\omega \overset{(\dagger)}{\leq} \|\psi^\wedge\|_\infty \|f\|^2_{\mathcal{H}_k} \overset{(\ddagger)}{<} \infty, \tag{11}$$

where $(\star)$ follows from Plancherel theorem (Wendland, 2005, Corollary 5.25), $\|f\|_{\mathcal{H}_k}$ is defined in (10), $(\dagger)$ follows from Hölder's inequality, and $(\ddagger)$ holds since $\psi^\wedge \in C_0(\mathbb{R}^d)$ (by Riemann-Lebesgue lemma, Folland, 1999, Theorem 8.22). Note that $\psi^\wedge$ is non-negative (Wendland, 2005, Theorem 6.11) and so the inequality in $(\dagger)$ is valid. It therefore follows from (11) that $\mathcal{H}_k$ is continuously included in $L^2(\mathbb{R}^d)$ and $\|\cdot\|_{L^2(\mathbb{R}^d)}$ is a weaker norm than $\|\cdot\|_{\mathcal{H}_k}$.[1] This means it is possible that the minimax rate of estimating μ_P in $\|\cdot\|_{L^2(\mathbb{R}^d)}$ could be faster than its RKHS counterpart with the rate possibly depending on the smoothness of k. Hence, it is of interest to analyze the minimax rates of estimating μ_P in $\|\cdot\|_{L^2(\mathbb{R}^d)}$. Interestingly, we show in this section that the minimax rate in the L^2 setting is still $n^{-1/2}$.

The analysis in the L^2 setting follows ideas similar to those of the RKHS setting wherein, first, in Section 4.1, we consider the minimax rate of estimating μ_P for translation invariant and radial kernels when $\mathcal{P}$ is the set of all Borel discrete probability measures on $\mathbb{R}^d$ (see Theorem 9 and Corollary 10). Next, in Section 4.2, we choose $\mathcal{P}$ to be the set of all probability distributions that have infinitely continuously differentiable densities and study the question of minimax rates for translation invariant (see Theorem 12) and radial kernels (see Theorem 13). For both these choices of $\mathcal{P}$, we show that the rate is $n^{-1/2}$ irrespective of the smoothness of k. Exploiting the injectivity of mean embedding for characteristic kernels (see the paragraph below and the paragraph around (6)), these results are derived using Le Cam's method (see Theorems B.1 and B.2). Combined with Proposition A.1 (also see Remark A.3), these results show that the empirical estimator, μ_{P_n} is minimax optimal. Finally, in Section 4.3 we discuss the relation between our results and some classical results of nonparametric density estimation, particularly, those of the kernel density estimator.

1. The continuous inclusion of $\mathcal{H}_k$ in $L^2(\mathbb{R}^d)$ is known for Gaussian kernels on $\mathbb{R}^d$ (e.g., see Vert and Vert, 2006, Lemma 11). Similar result is classical for Sobolev spaces in general (e.g., see Folland, 1999, Section 9.3, p.302) and particularly for those induced by Matérn kernels. Steinwart and Christmann (2008, Theorem 4.26) provides a general result for continuous inclusion of $\mathcal{H}_k$ in $L^2(\mu)$ assuming $\int_{\mathcal{X}} \sqrt{k(x,x)} \, d\mu(x) < \infty$ where μ is a σ-finite measure. However, the result does not hold for translation invariant kernels on $\mathbb{R}^d$ as the integrability condition is violated.

Before we proceed to the main results of this section, we briefly discuss the difference between estimation in RKHS and $L^2(\mathbb{R}^d)$ norms. Suppose $k(x,y) = \psi(x-y)$, $x, y \in \mathbb{R}^d$ where $\psi \in L^1(\mathbb{R}^d) \cap L^2(\mathbb{R}^d) \cap C(\mathbb{R}^d)$ is positive definite and characteristic. It is easy to verify that $\mu_P \in L^1(\mathbb{R}^d) \cap L^2(\mathbb{R}^d)$. Since $\mu_P = \psi * P$, (10) implies

$$\|\mu_P\|^2_{\mathcal{H}_k} = \int_{\mathbb{R}^d} \frac{|(\psi * P)^\wedge|^2}{\psi^\wedge(\omega)} \, d\omega = \int_{\mathbb{R}^d} |\phi_P(\omega)|^2 \psi^\wedge(\omega) \, d\omega = \|\phi_P\|^2_{L^2(\mathbb{R}^d, \psi^\wedge)} \tag{12}$$

whereas

$$\|\mu_P\|^2_{L^2(\mathbb{R}^d)} \overset{(\star)}{=} \int_{\mathbb{R}^d} |\mu_P^\wedge(\omega)|^2 \, d\omega = \int_{\mathbb{R}^d} |\phi_P(\omega)|^2 (\psi^\wedge)^2(\omega) \, d\omega = \|\phi_P\|^2_{L^2(\mathbb{R}^d, (\psi^\wedge)^2)}, \tag{13}$$

where $\phi_P(\omega) := \int e^{-i\omega^T x} dP(x)$ is the characteristic function of P and $(\star)$ follows from Plancherel's theorem. It follows from (12) and (13) that the RKHS norm emphasizes the high frequencies of ϕ_P compared to that of the L^2-norm. Since ψ is characteristic, i.e., $P \mapsto \mu_k(P) \in \mathcal{H}_k$ is injective, which is guaranteed if and only if $\text{supp}(\psi^\wedge) = \mathbb{R}^d$ (Sriperumbudur et al., 2010, Theorem 9), it follows from (13) that $P \mapsto \mu_k(P) \in L^1(\mathbb{R}^d) \cap L^2(\mathbb{R}^d)$ is injective. Therefore (2) can be equivalently written as (6) by replacing $\|\cdot\|_{\mathcal{H}_k}$ with $\|\cdot\|_{L^2(\mathbb{R}^d)}$ (see the discussion around (6)) and we obtain minimax rates by employing Le Cam's method as we did in the previous section.

4.1 Lower Bounds for Discrete Probability Measures

The following result (proved in Section 5.5) for translation invariant kernels is based on an application of Le Cam's method involving two hypotheses (see Theorem B.1), where we choose them to be KMEs of discrete measures, both supported on the same pair of points separated by a vector z in $\mathbb{R}^d$.

Theorem 9 (Translation invariant kernels) *Let $\mathcal{P}$ be the set of all Borel discrete probability measures on $\mathbb{R}^d$. Suppose $k(x,y) = \psi(x-y)$, $x, y \in \mathbb{R}^d$ where $\psi \in L^2(\mathbb{R}^d) \cap C(\mathbb{R}^d)$ is positive definite and k is characteristic. Define*

$$C_z^\psi := 2 \left(\|\psi\|^2_{L^2(\mathbb{R}^d)} - \int_{\mathbb{R}^d} \psi(y)\psi(y+z) dy \right) \tag{14}$$

for some $z \in \mathbb{R}^d \setminus \{0\}$. Then $C_z^\psi > 0$ and

$$\inf_{\hat{\theta}_n} \sup_{P \in \mathcal{P}} P^n \left\{ \|\hat{\theta}_n - \mu_k(P)\|_{L^2(\mathbb{R}^d)} \geq \frac{1}{6} \sqrt{\frac{C_z^\psi}{n}} \right\} \geq \frac{1}{4}.$$

Using Cauchy-Schwartz inequality, the constant C_z^ψ in Theorem 9 can be shown (see the proof of Lemma 15 in Section 5.5) to be positive for every $z \in \mathbb{R}^d \setminus \{0\}$ if k is characteristic, i.e., $\text{supp}(\Lambda_\psi) = \mathbb{R}^d$ (see (4) for Λ_ψ). The following result (proved in Section 5.6) specializes Theorem 9 to radial kernels.

Corollary 10 (Radial kernels) *Let $\mathcal{P}$ be the set of all Borel discrete probability measures on $\mathbb{R}^d$ and k be radial on $\mathbb{R}^d$, i.e., $k(x,y) = \psi_\nu(x-y) := \int_0^\infty e^{-t\|x-y\|_2^2} d\nu(t)$, where $\nu \in M_+^b([0,\infty))$ such that $\mathrm{supp}(\nu) \neq \{0\}$ and*

$$\int_0^\infty t^{-d/2} d\nu(t) < \infty. \tag{15}$$

Assume that there exist $0 < \delta_0 \leq \delta_1 < \infty$ and $\beta > 0$ such that $\nu([\delta_0, \delta_1]) \geq \beta$. Then the following holds:

$$\inf_{\hat{\theta}_n} \sup_{P \in \mathcal{P}} P^n \left\{ \|\hat{\theta}_n - \mu_k(P)\|_{L^2(\mathbb{R}^d)} \geq \frac{\beta}{6} \sqrt{\frac{1}{n} \left(\frac{\pi}{2\delta_1} \right)^{d/2}} \right\} \geq \frac{1}{4}.$$

In Corollary 10, since $\mathrm{supp}(\nu) \neq \{0\}$, the assumption of $\nu([\delta_0, \delta_1]) \geq \beta$ is always satisfied. In addition, the condition (15) on ν is satisfied by Gaussian, mixture of Gaussians, inverse multiquadric (while (15) is satisfied for $\gamma > d/2$, the result in Corollary 10 holds for $\gamma > d/4$) and Matérn kernels—refer to Remark A.3 for more details. Also, for these examples of kernels, the positive constant $A_k := \beta^2 \delta_1^{-d/2}$ in the lower bound in Corollary 10 can be computed in a closed form (see Appendix D.3 for details).

4.2 Lower Bounds for Probability Measures with Smooth Densities

Next, as we did in Section 3.2, we choose $\mathcal{P}$ to be the set of all probability measures that have infinitely continuously differentiable densities and show that the minimax rate of estimating μ_P in L^2-norm for translation invariant (see Theorem 12) and radial kernels (see Theorem 13) is $n^{-1/2}$. The proof of these results are again based on an application of Le Cam's method involving two (see Theorem B.1) and multiple hypotheses (see Theorem B.2), where these hypotheses are chosen to be embeddings of the d-dimensional Gaussian distributions. As in Section 3.2, the results of this section are based on the following result (proved in Section 5.7), which is conceptually similar to that of Proposition 3.

Proposition 11 *Let $\sigma > 0$. Suppose $k(x,y) = \psi(x-y)$, where $\psi \in L^1(\mathbb{R}^d) \cap C_b(\mathbb{R}^d)$ is positive definite and k is characteristic. Then there exist constants $\epsilon_{\psi,\sigma^2}, c_{\psi,\sigma^2} > 0$ depending only on ψ and σ^2, such that the following condition holds for any $a \in \mathbb{R}^d$ with $\|a\|_2^2 \leq \epsilon_{\psi,\sigma^2}$:*

$$c_{\psi,\sigma^2} \leq \min_{e_z \in S^{d-1}} 2 \int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2} \langle e_z, w \rangle^2 \cos\left(\langle a, w \rangle\right) \left(\psi^\wedge(w)\right)^2 dw < \infty, \tag{16}$$

where S^{d-1} is a unit sphere in $\mathbb{R}^d$. Moreover, for all vectors $\mu_0, \mu_1 \in \mathbb{R}^d$ satisfying $\|\mu_0 - \mu_1\|_2^2 \leq \epsilon_{\psi,\sigma^2}$, the following holds:

$$\|\theta_0 - \theta_1\|_{L^2(\mathbb{R}^d)} \geq \sqrt{\frac{c_{\psi,\sigma^2}}{2}} \|\mu_0 - \mu_1\|_2,$$

where θ_0 and θ_1 are KMEs of the Gaussian measures $G(\mu_0, \sigma^2 I)$ and $G(\mu_1, \sigma^2 I)$ respectively.

The following result for translation invariant kernels is established using the above result wherein the proof is exactly the same as that of Theorem 6 except for an application of Proposition 11 in place of Proposition 3.

Theorem 12 (Translation invariant kernels) *Let $\mathcal{P}$ be the set of distributions over $\mathbb{R}^d$ whose densities are continuously infinitely differentiable. Suppose $k(x,y) = \psi(x-y)$, where $\psi \in L^1(\mathbb{R}^d) \cap C_b(\mathbb{R}^d)$ is positive definite and k is characteristic. Define $c_\psi := c_{\psi,1}$ and $\epsilon_\psi := \epsilon_{\psi,1}$ where $c_{\psi,1}$ and $\epsilon_{\psi,1}$ are positive constants that satisfy (16) in Proposition 11. Then for any $n \geq \frac{1}{\epsilon_\psi}$, the following holds:*

$$\inf_{\hat{\theta}_n} \sup_{P \in \mathcal{P}} P^n \left\{ \|\hat{\theta}_n - \mu_k(P)\|_{L^2(\mathbb{R}^d)} \geq \frac{1}{2} \sqrt{\frac{c_\psi}{2n}} \right\} \geq \frac{1}{4}.$$

As discussed in Remark 7, it is possible to remove the requirement of minimal sample size in Theorem 12. Also, as discussed in Remark 5 and in the paragraph following Remark 7, the constants c_ψ and ϵ_ψ appearing in the bound in Theorem 12 are not only difficult to compute but also may depend on the dimensionality d in a sup-optimal manner, particularly as $d \to \infty$. Therefore, similar to what was done in Section 3.2, we will not specialize Theorem 12 to radial kernels but instead present the following result (proved in Section 5.8 and the proof closely follows that of Theorem 8), which is based on a direct analysis involving the properties of radial kernels. For the particular case of a Gaussian kernel, this lower bound matches the upper bound of Proposition A.1 (also see Remark A.3) up to a constant factor independent of d.

Theorem 13 (Radial kernels) *Let k be radial on $\mathbb{R}^d$, i.e., $k(x,y) = \int_0^\infty e^{-t\|x-y\|_2^2} d\nu(t)$, where $\nu \in M_+^b([0,\infty))$ and $\mathcal{P}$ be the set of distributions over $\mathbb{R}^d$ whose densities are continuously infinitely differentiable. Assume that (15) holds, $\mathrm{supp}(\nu) \neq \{0\}$ and there exist $0 < \delta_0 \leq \delta_1 < \infty$, $0 < \beta < \infty$ such that $\nu([\delta_0, \delta_1]) \geq \beta$. Then the following holds:*

$$\inf_{\hat{\theta}_n} \sup_{P \in \mathcal{P}} P^n \left\{ \|\hat{\theta}_n - \mu_k(P)\|_{L^2(\mathbb{R}^d)} \geq \frac{1}{50} \sqrt{\frac{1}{n} \left(\frac{\pi}{2\delta_1} \right)^{d/2} \frac{\beta^2 \delta_0}{\delta_1 e} \left(1 - \frac{2}{2+d} \right)} \right\} \geq \frac{1}{5}.$$

The constant $B_k := \beta^2 \delta_0 \delta_1^{-\frac{d+2}{2}}$ in the lower bound in the above result can be computed in a closed form for Gaussian, mixture of Gaussian, inverse multiquadric, and Matérn kernels (see Appendix D.4 for details). The factor $(\pi/2)^{d/4}$ can be eliminated from the lower bound by considering a rescaled kernel $(\pi/2)^{-d/4}\psi(x-y)$. Nevertheless, the bound will still depend on d exponentially as captured by the constant B_k. This can be further overcome by using the normalized kernel $k(x,y)/\|\psi\|_{L^2(\mathbb{R}^d)}$. In the particular case of normalized Gaussian kernels $(\pi\eta^2)^{-d/2} \exp\left(-\frac{1}{2\eta^2}\|x-y\|_2^2\right)$ this will lead to dimension-free lower bounds.

4.3 Relation to Kernel Density Estimation

In this section, we discuss the relation between the estimation of μ_P and density estimation. The problem of density estimation deals with estimating an unknown density, p based on

random samples $(X_i)_{i=1}^n$ drawn i.i.d. from it. One of the popular non-parametric methods for density estimation is kernel density estimation (KDE), where the estimator is of the form (Tsybakov, 2008, Section 1.2)

$$\hat{p}_n(x_1,\dots,x_d) = \frac{1}{n\prod_{i=1}^d h_i}\sum_{i=1}^n K\left(\frac{X_{i,1}-x_1}{h_1},\cdots,\frac{X_{i,d}-x_d}{h_d}\right).$$

Here $K\colon \mathbb{R}^d \to \mathbb{R}$ is the *smoothing kernel* (this kernel should not be confused with the reproducing kernel k which we used throughout the paper), $h_1,\dots,h_d > 0$ are bandwidths, and $X_{i,j}$ is the j-th coordinate of the i-th sample point. Assuming $p \in L^2(\mathbb{R}^d)$, the consistency of $\hat{p}_n$ is usually studied in the sense of *mean integrated squared error* (MISE) $\mathbb{E}\|\hat{p}_n - p\|^2_{L^2(\mathbb{R}^d)}$, which can be decomposed into variance and bias terms as:

$$\mathbb{E}\|\hat{p}_n - p\|^2_{L^2(\mathbb{R}^d)} = \mathbb{E}\big\|\hat{p}_n - \mathbb{E}[\hat{p}_n]\big\|^2_{L^2(\mathbb{R}^d)} + \big\|p - \mathbb{E}[\hat{p}_n]\big\|^2_{L^2(\mathbb{R}^d)}. \tag{17}$$

Assume K to be bounded and $h_1 = \cdots = h_d = h$. Define $K_h := h^{-d}K(\cdot/h)$. Then for any fixed $x \in \mathbb{R}^d$,

$$\hat{p}_n(x) = \frac{1}{nh^d}\sum_{i=1}^n K\left(\frac{X_i - x}{h}\right) = \frac{1}{n}\sum_{i=1}^n K_h(X_i - x) = \int_{\mathbb{R}^d} K_h(z-x)\,dP_n(z)$$

and

$$\mathbb{E}[\hat{p}_n(x)] = \frac{1}{h^d}\int_{\mathbb{R}^d} K\left(\frac{z-x}{h}\right)p(z)dz = (K_h * p)(x).$$

This shows that $\hat{p}_n = \mu_{K_h}(P_n)$ and $\mathbb{E}[\hat{p}_n] = \mu_{K_h}(P)$ where P is the distribution with p as its density w.r.t. the Lebesgue measure and P_n is the empirical measure constructed based on samples $(X_i)_{i=1}^n$ drawn from p. Therefore the results of Section 4 (and more generally of this paper) are about the minimax rates for $\mathbb{E}[\hat{p}_n]$. However, note that K_h need not be positive definite (and therefore need not be the reproducing kernel of some RKHS). On the other hand, K has to be positive, i.e., $K(x) \geq 0$, $\forall\, x \in \mathbb{R}^d$ and normalized, i.e., $\int_{\mathbb{R}^d} K(x)\,dx = 1$ to yield an estimator that is a valid density, unlike in kernel mean estimation where k need not be positive nor normalized. The minimax rate of $n^{-1/2}$ for estimating $\mathbb{E}[\hat{p}_n]$ is achieved by the kernel density estimator $\hat{p}_n$ (which is nothing but the empirical estimator of $\mu_{K_h}(P)$) as it is known (based on a straightforward generalization of Tsybakov, 2008, Proposition 1.4 for multiple dimensions) that

$$\mathbb{E}\big\|\hat{p}_n - \mathbb{E}[\hat{p}_n]\big\|^2_{L^2(\mathbb{R}^d)} \leq \frac{\|K\|^2_{L^2(\mathbb{R}^d)}}{nh^d},$$

where we assume $K \in L^2(\mathbb{R}^d)$. The bandwidth parameter h is immaterial in the estimation of $\mu_{K_h}(P)$ and can be treated as a constant (independent of n) unlike in the problem of estimating p where h should decay to zero at an appropriate rate for the bias $\big\|p - \mathbb{E}[\hat{p}_n]\big\|_{L^2(\mathbb{R}^d)}$ to converge to zero as $n \to \infty$. In particular, if p lies in a Sobolev space of smoothness index s, then the bias-squared term in (17) behaves as h^{2s}, which combined with the above bound on the variance yields a rate of $n^{-\frac{2s}{2s+1}}$ for $h = n^{-\frac{1}{2s+1}}$. This rate is known to be minimax optimal for the problem of estimating p while our rates are minimax optimal for the problem of smoothed density estimation where the smoothing is carried out by the kernel.

5. Proofs

In this section we present all the missing proofs of results of Sections 3 and 4.

5.1 Proof of Theorem 1

Pick two discrete distributions $P_0 = p_0\delta_x + (1-p_0)\delta_v$ and $P_1 = p_1\delta_x + (1-p_1)\delta_v$, where $x, v \in \mathbb{R}^d$, $0 < p_0 < 1$, $0 < p_1 < 1$ and δ_x denotes a Dirac measure supported at x. Define $\theta_0 = \mu_k(P_0)$ and $\theta_1 = \mu_k(P_1)$. Since $\|\theta_0\|^2_{\mathcal{H}_k} = \int\int k(x,y)\,dP_0(x)\,dP_0(y)$, which follows from the reproducing property of k, it is easy to verify that

$$\|\theta_0 - \theta_1\|^2_{\mathcal{H}_k} = \mathbb{E}[k(\xi,\xi')] + \mathbb{E}[k(\eta,\eta')] - 2\,\mathbb{E}[k(\xi,\eta)],$$

where ξ and η are random variables distributed according to P_0 and P_1 respectively, and ξ' and η' are independent copies of ξ and η. Since k is translation invariant, we have $k(v,v) = k(x,x) = \psi(0)$ and $k(x,v) = k(v,x) = \psi(x-v)$, which imply

$$\|\theta_0 - \theta_1\|^2_{\mathcal{H}_k} = 2(p_0-p_1)^2\big(\psi(0) - \psi(x-v)\big). \tag{18}$$

Also note that

$$\begin{aligned}
\mathrm{KL}(P_0\|P_1) &= p_0\log\frac{p_0}{p_1} + (1-p_0)\log\frac{1-p_0}{1-p_1}\\
&= p_0\log\left(1 + \frac{p_0-p_1}{p_1}\right) + (1-p_0)\log\left(1 + \frac{p_1-p_0}{1-p_1}\right)\\
&\overset{(*)}{\leq} \log\left\{p_0\left(1 + \frac{p_0-p_1}{p_1}\right) + (1-p_0)\left(1 + \frac{p_1-p_0}{1-p_1}\right)\right\}\\
&= \log\left(1 + (p_0-p_1)\left(\frac{p_0}{p_1} - \frac{1-p_0}{1-p_1}\right)\right),
\end{aligned}$$

where we used Jensen's inequality in $(*)$ for the logarithmic function, which is concave. Next, using a simple inequality $\log(1+x) \leq x$, which holds for all $x > -1$, we get

$$\mathrm{KL}(P_0\|P_1) \leq (p_0-p_1)\left(\frac{p_0}{p_1} - \frac{1-p_0}{1-p_1}\right) = \frac{(p_0-p_1)^2}{p_1(1-p_1)}.$$

Note that a maximal value of denominator is achieved when $p_1 = \frac{1}{2}$. Setting $p_1 = \frac{1}{2}$ we get the following upper bound: $\mathrm{KL}(P_0\|P_1) \leq 4\left(p_0 - \frac{1}{2}\right)^2$, which when used in the chain rule of KL-divergence yields

$$\mathrm{KL}(P_0^n\|P_1^n) \leq 4n\left(p_0 - \frac{1}{2}\right)^2.$$

Choosing p_0 such that $(p_0 - \frac{1}{2})^2 = \frac{1}{9n}$ yields $\mathrm{KL}(P_0^n\|P_1^n) \leq \frac{4}{9}$ and $\|\theta_0 - \theta_1\|^2_{\mathcal{H}_k} = \frac{2}{9n}\big(\psi(0) - \psi(x-v)\big)$. Choose x and v in such a way that $x - v = z$, where $z \in \mathbb{R}^d$ is a point for which $\psi(0) - \psi(z) \geq \beta$ and $\beta > 0$. This yields

$$\|\theta_0 - \theta_1\|^2_{\mathcal{H}_k} \geq \frac{2\beta}{9n},$$

which shows that the assumptions of Theorem B.1 are satisfied with $s := \frac{1}{6}\sqrt{\frac{2\beta}{n}}$ and $\alpha := \frac{4}{9}$. The result follows from an application of Theorem B.1 by noticing that $\frac{1-\sqrt{\alpha/2}}{2} > 1/4$.

Remark (Measures with bounded support) *It is evident from the above proof that exactly the same lower bound holds if we restrict $\mathcal{P}$ to contain only probability measures with bounded support. We can proceed further and assume that for each $P \in \mathcal{P}$ the radius of* $\mathrm{supp}(P)$ *is upper bounded by some positive constant R. In this case the same reasoning will work as long as ψ is not "flat" on the ball of radius R centered around origin.*

5.2 Proof of Corollary 2

The proof is based on application of Theorem 1. Since $\mathrm{supp}(\nu) \neq \{0\}$, it follows from (Sriperumbudur et al., 2011, Proposition 5) that k is characteristic. We now show that there exist $z \in \mathbb{R}^d$ and $\beta > 0$, such that $\psi_\nu(0) - \psi_\nu(z) \geq \beta$. Note that for any $x \in \mathbb{R}^d$

$$\begin{aligned}\psi_\nu(0) - \psi_\nu(x) &= \int_0^\infty \left(1 - e^{-t\|x\|_2^2}\right) d\nu(t) \geq \int_{t_1}^\infty \left(1 - e^{-t\|x\|_2^2}\right) d\nu(t) \\ &\geq \int_{t_1}^\infty \left(1 - e^{-t_1\|x\|_2^2}\right) d\nu(t) = \nu([t_1,\infty))\left(1 - e^{-t_1\|x\|_2^2}\right) \\ &\geq \alpha\left(1 - e^{-t_1\|x\|_2^2}\right) \geq \frac{\alpha t_1}{2}\|x\|_2^2,\end{aligned}$$

where the last inequality holds whenever $\|x\|_2^2 \leq \frac{1}{t_1}$. Choosing z such that $\|z\|_2^2 = \frac{1}{t_1}$ yields $\psi_\nu(0) - \psi_\nu(z) \geq \frac{\alpha}{2}$. The result therefore follows from Theorem 1 by choosing $\beta = \frac{\alpha}{2}$.

5.3 Proof of Proposition 3

Before we prove Proposition 3, first we will derive a closed form expression for the RKHS distance between KMEs of two d-dimensional Gaussian distributions with the kernel being translation invariant, i.e., $k(x,y) = \psi(x-y)$. Throughout this section Λ_ψ will denote a finite non-negative Borel measure corresponding to the positive-definite function ψ from (4).

Lemma 14 *Let θ_0 and θ_1 be KME of Gaussian measures $G(\mu_0, \sigma^2 I)$ and $G(\mu_1, \sigma^2 I)$ for $\mu_0, \mu_1 \in \mathbb{R}^d$ and $\sigma^2 > 0$. Suppose $k(x,y) = \psi(x-y)$, where $\psi \in C_b(\mathbb{R}^d)$ is positive definite. Then*

$$\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2 = \frac{2}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2} \left(1 - \cos\left(\langle \mu_0 - \mu_1, w\rangle\right)\right) d\Lambda_\psi(w). \tag{19}$$

Proof Note that

$$\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2 = \|\theta_0\|_{\mathcal{H}_k}^2 + \|\theta_1\|_{\mathcal{H}_k}^2 - 2\langle \theta_0, \theta_1\rangle_{\mathcal{H}_k}, \tag{20}$$

where $\langle \theta_0, \theta_1\rangle_{\mathcal{H}_k} = \mathbb{E}_X \mathbb{E}_Y[k(X,Y)]$ with $X \sim G(\mu_0, \sigma^2 I)$ and $Y \sim G(\mu_1, \sigma^2 I)$. We will now derive the closed form for the inner product:

$$\begin{aligned}\langle \theta_0, \theta_1\rangle_{\mathcal{H}_k} &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \psi(x-y) \frac{1}{(2\pi\sigma^2)^d} e^{-\frac{1}{2\sigma^2}\|x-\mu_0\|_2^2 - \frac{1}{2\sigma^2}\|y-\mu_1\|_2^2} dx\, dy \\ &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-i\langle x-y, w\rangle} d\Lambda_\psi(w) \frac{1}{(2\pi\sigma^2)^d} e^{-\frac{1}{2\sigma^2}\|x-\mu_0\|_2^2 - \frac{1}{2\sigma^2}\|y-\mu_1\|_2^2} dx\, dy,\end{aligned}$$

where we used (4). The function appearing under the integral is absolutely integrable and so by Tonelli-Fubini theorem (Dudley, 2002, Theorem 4.4.5) we obtain

$$\begin{aligned}\langle \theta_0, \theta_1\rangle_{\mathcal{H}_k} &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \frac{e^{i\langle y, w\rangle} e^{-\frac{1}{2\sigma^2}\|y-\mu_1\|_2^2}}{(2\pi\sigma^2)^{d/2}(2\pi)^{d/2}} \left\{\int_{\mathbb{R}^d} \frac{e^{-i\langle x, w\rangle}}{(2\pi\sigma^2)^{d/2}} e^{-\frac{1}{2\sigma^2}\|x-\mu_0\|_2^2} dx\right\} dy\, d\Lambda_\psi(w) \\ &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d} \frac{1}{(2\pi\sigma^2)^{d/2}} \frac{1}{(2\pi)^{d/2}} e^{i\langle y, w\rangle} e^{-\frac{1}{2\sigma^2}\|y-\mu_1\|_2^2} e^{-i\langle \mu_0, w\rangle - \frac{\sigma^2\|w\|_2^2}{2}} dy\, d\Lambda_\psi(w) \\ &= \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} \left\{\int_{\mathbb{R}^d} \frac{1}{(2\pi\sigma^2)^{d/2}} e^{i\langle y, w\rangle} e^{-\frac{1}{2\sigma^2}\|y-\mu_1\|_2^2} dy\right\} e^{-i\langle \mu_0, w\rangle - \frac{\sigma^2\|w\|_2^2}{2}} d\Lambda_\psi(w) \\ &= \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{i\langle \mu_1, w\rangle - \frac{\sigma^2\|w\|_2^2}{2}} e^{-i\langle \mu_0, w\rangle - \frac{\sigma^2\|w\|_2^2}{2}} d\Lambda_\psi(w),\end{aligned}$$

where we used Lemma C.1 to compute the Fourier transform for a Gaussian density. Using Euler's formula and the fact that Λ_ψ is symmetric according to Lemma C.2, while $\sin(x)$ is an odd function, we get

$$\langle \theta_0, \theta_1\rangle_{\mathcal{H}_k} = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} \cos\left(\langle \mu_0 - \mu_1, w\rangle\right) e^{-\sigma^2\|w\|_2^2} d\Lambda_\psi(w). \tag{21}$$

The result in (19) follows by using (21) in (20). ■

Proof of Proposition 3: Define $a := \mu_0 - \mu_1$ and

$$G(a) := \frac{2}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2} \left(1 - \cos\langle a, w\rangle\right) d\Lambda_\psi(w).$$

Note that $G(0) = 0$. Next, since for any $i = 1, \ldots, d$

$$\left|\frac{\partial}{\partial a_i} e^{-\sigma^2\|w\|_2^2}(1 - \cos\langle a, w\rangle)\right| = \left|e^{-\sigma^2\|w\|_2^2} w_i \sin\langle a, w\rangle\right| \leq \left|e^{-\sigma^2\|w\|_2^2} w_i\right| \in L_1(\Lambda_\psi),$$

we can differentiate G under the integral sign (Folland, 1999, Theorem 2.27) and get $\nabla G(0) = 0$.

If a function $f\colon \mathbb{R}^d \to \mathbb{R}$ is *strongly convex* with parameter $m > 0$ on some set $A \subseteq \mathbb{R}^d$, then for all $x, y \in A$:

$$f(x) \geq f(y) + \langle \nabla f(y), x - y\rangle + \frac{m}{2}\|x - y\|_2^2.$$

If we can show that G is strongly convex on $B_\epsilon := \{b \in \mathbb{R}^d\colon \|b\|_2^2 \leq \epsilon\}$ for some $\epsilon > 0$, then we can apply previous inequality with $y = 0$ and $x = a$ to obtain

$$G(a) \geq \frac{m}{2}\|a\|_2^2, \ \forall a \in B_\epsilon.$$

It is known that a twice continuously differentiable function f is strongly convex on $A \subseteq \mathbb{R}^d$ with parameter $m > 0$ if the matrix $\nabla^2 f(x) - m \cdot I$ is positive definite for all $x \in A$, where

$\nabla^2 f$ is the Hessian and $I \in \mathbb{R}^{d\times d}$ is an identity matrix. Next we compute the Hessian of G by once again employing differentiation under the integral sign (justified in the similar way as above) to obtain

$$\frac{\partial^2 G(a)}{\partial a_i \partial a_j} = \frac{2}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2} w_i w_j \cos\left(\langle a, w\rangle\right) d\Lambda_\psi(w), \quad 0 \le i, j \le d.$$

Thus

$$\nabla^2 G(a) = \frac{2}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2} w w^T \cos\left(\langle a, w\rangle\right) d\Lambda_\psi(w).$$

In order to prove that G is strongly convex on $B_\epsilon \subseteq \mathbb{R}^d$ we need to show that $\nabla^2 G(a) - m \cdot I$ is positive definite for each $a \in B_\epsilon$ and some $m > 0$. In other words, we need to show that there is $m > 0$ such that for each $z \in \mathbb{R}^d \setminus \{0\}$ and $a \in B_\epsilon$ the following holds:

$$\langle z, \nabla^2 G(a) z\rangle \ge m\|z\|_2^2,$$

or, equivalently,

$$\frac{2}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2} \langle e_z, w\rangle^2 e^{-i\langle a, w\rangle} d\Lambda_\psi(w) \ge m, \tag{22}$$

where $e_z := z/\|z\|_2 \in \mathbb{R}^d$ is a vector of unit length pointed in the direction of z. Note that l.h.s. of (22) is the Fourier transform of a measure $\mathcal{T}_z$ on $\mathbb{R}^d$, which is absolutely continuous with respect to Λ_ψ with Radon-Nikodym derivative $2e^{-\sigma^2\|w\|_2^2}\langle e_z, w\rangle^2$.

Fix any $z \in \mathbb{R}^d$. We will first show that we can apply Bochner's Theorem (see (4)) for the measure $\mathcal{T}_z$. For this we need to check that it is (a) non-negative and (b) finite. Part (a) is apparent from the facts that Λ_ψ is non-negative and $\mathcal{T}_z$ has a non-negative density with respect to Λ_ψ. To check (b) we write

$$\int_{\mathbb{R}^d} d\mathcal{T}_z(x) = \frac{2}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2} \langle e_z, w\rangle^2 d\Lambda_\psi(w) < \infty,$$

as $e^{-\sigma^2\|w\|_2^2}\langle e_z, w\rangle^2$ is positive and bounded for any $z \in \mathbb{R}^d$, while Λ_ψ is finite. We conclude from Bochner's Theorem, that function $\tilde{\psi}_z(x)$ defined in the following way:

$$\tilde{\psi}_z(x) = \int_{\mathbb{R}^d} e^{-i\langle x, w\rangle} d\mathcal{T}_z(w),$$

is positive-definite. Moreover it is well known (Dudley, 2002, Theorem 9.4.4) that $\tilde{\psi}_z \in C_b(\mathbb{R}^d)$ as $\tilde{\psi}_z$ is the characteristic function of $\mathcal{T}_z$. Finally, it follows from the discussion in (Sriperumbudur et al., 2011, Section 3.3), that if $\mathrm{supp}(\mathcal{T}_z) = \mathbb{R}^d$, then a bounded and continuous function $\tilde{\psi}_z(x)$ is *strictly* positive definite. To check the condition $\mathrm{supp}(\mathcal{T}_z) = \mathbb{R}^d$ we note that $\mathrm{supp}(\Lambda_\psi) = \mathbb{R}^d$ since ψ is characteristic (Sriperumbudur et al., 2010, Theorem 9), and no open sets of $\mathbb{R}^d$ are contained in the region where $e^{-\sigma^2\|w\|_2^2}\langle e_z, w\rangle^2 = 0$.

Summarizing, we have established that the l.h.s. of (22) is equal to $\tilde{\psi}_z(a)$, where $\tilde{\psi}_z \colon \mathbb{R}^d \to \mathbb{R}$ is a bounded, continuous and strictly positive definite function for each

$z \in \mathbb{R}^d \setminus \{0\}$. In particular, we have $\tilde{\psi}_z(0) > 0$ for all $z \in \mathbb{R}^d$. Note that $\tilde{\psi}_z(0)$ depends on z only through its direction. Next we want to show that

$$\inf_{z\in S_d} \tilde{\psi}_z(0) > 0, \tag{23}$$

where the infimum is over the unit sphere $S_d := \{b \in \mathbb{R}^d \colon \|b\|_2^2 = 1\}$. Note that the function $F \colon z \to \tilde{\psi}_z(0)$ defined on S_d is continuous. Since S_d is closed and bounded, we know that F attains its minimum on it. In other words, there is $z^* \in S_d$, such that

$$\inf_{z\in S_d} \tilde{\psi}_z(0) = \tilde{\psi}_{z^*}(0).$$

Thus, if $\inf_{z\in S_d} \tilde{\psi}_z(0) = 0$, we will also get $\tilde{\psi}_{z^*}(0) = 0$, which will contradict the fact that $\tilde{\psi}_z(0) > 0$ for each $z \in \mathbb{R}^d\backslash\{0\}$. This proves (23). Using Lemma C.3 we also conclude that $\inf_{z\in S_d} \tilde{\psi}_z \colon \mathbb{R}^d \to \mathbb{R}$ is a continuous function. Now we may finally conclude that there are constants $c_{\psi,\sigma^2}, \epsilon_{\psi,\sigma^2} > 0$ such that

$$\inf_{z\in S_d} \tilde{\psi}_z(a) \ge c_{\psi,\sigma^2}$$

for all $a \in B_{\epsilon_{\psi,\sigma^2}}$. Finally, we take $m = c_{\psi,\sigma^2}$ and this concludes the proof.

5.4 Proof of Theorem 8

The proof is based on application of Theorem B.2 where we choose $\theta_0, \ldots, \theta_M$ to be KMEs of d-dimensional Gaussian measures with variances decaying to zero as $d \to \infty$.

Let $G(\mu_0, \sigma^2 I)$ and $G(\mu_1, \sigma^2 I)$ be two d-dimensional Gaussian distributions with mean vectors $\mu_0, \mu_1 \in \mathbb{R}^d$ and variance $\sigma^2 > 0$. Define θ_0 and θ_1 to be the embeddings of $G(\mu_0, \sigma^2 I)$ and $G(\mu_1, \sigma^2 I)$ respectively.

(A) Deriving a closed form expression for $\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2$.

Using Lemma 14, presented in Section 5.3, we have

$$\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2 = \frac{2}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2} \left(1 - \cos\left(\langle \mu_0 - \mu_1, w\rangle\right)\right) d\Lambda_\psi(w), \tag{24}$$

where Λ_ψ is a finite non-negative Borel measure from the Bochner's Theorem corresponding to the kernel k. We now show that Λ_ψ is absolutely continuous with respect to the Lebesgue measure on $\mathbb{R}^d$ and has the following density:

$$\lambda_\psi(w) = \int_0^\infty \frac{1}{(2t)^{d/2}} e^{-\frac{\|w\|_2^2}{4t}} d\nu(t), \quad w \in \mathbb{R}^d.$$

Indeed, by noticing that

$$\int_0^\infty \left(\int_{\mathbb{R}^d} \left| e^{-i\langle w, x\rangle} \frac{1}{(2t)^{d/2}} e^{-\frac{\|w\|_2^2}{4t}} \right| dw \right) d\nu(t) < \infty$$

we may apply Tonelli-Fubini theorem (Dudley, 2002, Theorem 4.4.5) to interchange the order of integration and get

$$\int_{\mathbb{R}^d} \frac{e^{-i\langle w,x\rangle}}{(2\pi)^{d/2}} \left(\int_0^\infty \frac{1}{(2t)^{d/2}} e^{-\frac{\|w\|_2^2}{4t}} d\nu(t) \right) dw = \int_0^\infty \left(\int_{\mathbb{R}^d} \frac{e^{-i\langle w,x\rangle}}{(2\pi)^{d/2}} \frac{1}{(2t)^{d/2}} e^{-\frac{\|w\|_2^2}{4t}} dw \right) d\nu(t)$$
$$= \int_0^\infty e^{-t\|x\|_2^2} d\nu(t).$$

Substituting the form of λ_ψ into (24) we can write

$$\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2 = \frac{2}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} \int_0^\infty e^{-\sigma^2\|w\|_2^2} \left(1 - \cos\left(\langle \mu_0 - \mu_1, w\rangle\right)\right) \frac{1}{(2t)^{d/2}} e^{-\frac{\|w\|_2^2}{4t}} \, d\nu(t)\, dw.$$

Applying Tonelli-Fubini theorem once again and using Lemma C.1 together with Euler's formula we obtain

$$\begin{aligned}
\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2 &= \frac{2}{(2\pi)^{d/2}} \int_0^\infty \frac{1}{(2t)^{d/2}} \int_{\mathbb{R}^d} e^{-\frac{\|w\|_2^2}{2}(2\sigma^2 + \frac{1}{2t})} \left(1 - \cos\left(\langle \mu_0 - \mu_1, w\rangle\right)\right) dw\, d\nu(t) \\
&= \int_0^\infty \frac{2}{(4\sigma^2 t + 1)^{d/2}} d\nu(t) - \int_0^\infty \frac{2}{(4\sigma^2 t + 1)^{d/2}} e^{-\frac{t\|\mu_0 - \mu_1\|_2^2}{4\sigma^2 t + 1}} d\nu(t) \\
&= \int_0^\infty 2 \left(\frac{1}{1 + 4t\sigma^2} \right)^{d/2} \left(1 - \exp\left(-\frac{t\|\mu_0 - \mu_1\|_2^2}{1 + 4t\sigma^2} \right) \right) d\nu(t). \qquad (25)
\end{aligned}$$

(B) Lower bounding $\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2$ in terms of $\|\mu_0 - \mu_1\|_2^2$.

It follows from (25) that

$$\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2 \geq \int_{t_0}^{t_1} 2 \left(\frac{1}{1 + 4t\sigma^2} \right)^{d/2} \left(1 - \exp\left(-\frac{t\|\mu_0 - \mu_1\|_2^2}{1 + 4t\sigma^2} \right) \right) d\nu(t),$$

where $0 < t_0 \leq t_1 < \infty$. Note that $1 - e^{-x} \geq \frac{x}{2}$ for $0 \leq x \leq 1$. Using this we get

$$1 - \exp\left(-\frac{t\|\mu_0 - \mu_1\|_2^2}{1 + 4t\sigma^2} \right) \geq \frac{t\|\mu_0 - \mu_1\|_2^2}{2(1 + 4t\sigma^2)}, \quad \forall t \in [t_0, t_1]$$

as long as

$$t_1 \|\mu_0 - \mu_1\|_2^2 \leq 1 + 4t_1\sigma^2. \qquad (26)$$

Thus, as long as (26) holds, we can lower bound the RKHS distance as:

$$\begin{aligned}
\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2 &\geq \int_{t_0}^{t_1} \left(\frac{1}{1 + 4t\sigma^2} \right)^{d/2} \frac{t\|\mu_0 - \mu_1\|_2^2}{1 + 4t\sigma^2} \, d\nu(t) \\
&= \|\mu_0 - \mu_1\|_2^2 \int_{t_0}^{t_1} \frac{t}{(1 + 4t\sigma^2)^{(d+2)/2}} \, d\nu(t). \qquad (27)
\end{aligned}$$

Note that the function $t \mapsto \frac{t}{(1+4t\sigma^2)^{(d+2)/2}}$ monotonically increases on $[0, \frac{1}{2d\sigma^2}]$, reaches its global maximum at $t = \frac{1}{2d\sigma^2}$ and then decreases on $[\frac{1}{2d\sigma^2}, \infty)$. Thus we have

$$\int_{t_0}^{t_1} \frac{t}{(1 + 4t\sigma^2)^{(d+2)/2}} \, d\nu(t) \geq \beta \min\left\{ \frac{t_0}{(1 + 4t_0\sigma^2)^{(d+2)/2}}, \frac{t_1}{(1 + 4t_1\sigma^2)^{(d+2)/2}} \right\}.$$

Setting

$$\sigma^2 = \frac{1}{2t_1 d} \qquad (28)$$

yields that $t = t_1$ is the global maximum of the function $t \mapsto \frac{t}{\left(1 + \frac{2t}{t_1 d}\right)^{(d+2)/2}}$, in which case

$$\frac{t_0}{(1 + 4t_0\sigma^2)^{(d+2)/2}} \leq \frac{t_1}{(1 + 4t_1\sigma^2)^{(d+2)/2}}.$$

With this choice of σ^2 we get

$$\begin{aligned}
\int_{t_0}^{t_1} \frac{t}{(1 + 4t\sigma^2)^{(d+2)/2}} \, d\nu(t) &\geq \frac{\beta t_0}{\left(1 + \frac{2t_0}{t_1 d}\right)^{(d+2)/2}} \geq \frac{\beta t_0}{\left(1 + \frac{2}{d}\right)^{(d+2)/2}} \\
&= \beta t_0 \left(1 - \frac{2}{2 + d} \right)^{(d+2)/2} \geq \frac{\beta t_0}{e} \left(1 - \frac{2}{2 + d} \right), \qquad (29)
\end{aligned}$$

where we used the fact that $(1 - \frac{1}{x})^{x-1}$ monotonically decreases to $\frac{1}{e}$. Using (29) in (27), we obtain

$$\|\theta_0 - \theta_1\|_{\mathcal{H}_k}^2 \geq \frac{\beta t_0}{e} \left(1 - \frac{2}{2 + d} \right) \|\mu_0 - \mu_1\|_2^2. \qquad (30)$$

(C.1) Application of Theorem B.2: Choosing $\theta_0, \ldots, \theta_M$.

Now we are going to apply Theorem B.2. First of all, we need to choose $M + 1$ embeddings. Recall that Theorem B.2 requires these embeddings to be sufficiently distant from each other, while the corresponding distributions should be close. We will choose the embeddings $\{\theta_0, \ldots, \theta_M\}$ to be KMEs of Gaussian distributions $G(\mu_i, \sigma^2 I)$ for specific choice of $\sigma^2 > 0$ and $\mu_i \in \mathbb{R}^d$, $i = 0, \ldots, M$. Mean vectors $\{\mu_i\}_{i=0}^M$ will be constrained to live in the ball $B(c_\nu, n) := \left\{ x \in \mathbb{R}^d \colon \|x\|_2^2 \leq c_\nu / n \right\}$, where c_ν is a positive constant to be specified later. This guarantees that KL-divergences between the Gaussian distributions will remain small. At the same time, it was shown in (30) that the RKHS distance between embeddings θ_i and θ_j is lower bounded by the Euclidean distance between μ_i and μ_j. In other words, in order for the embeddings $\theta_0, \ldots, \theta_M$ to be sufficiently separated we need to make sure that the mean vectors $\mu_0, \ldots, \mu_M$ are not too close to each other. Summarizing, we face the problem of choosing a finite collection of pairwise distant points in the Euclidean ball. This question is closely related to the concepts of *packing* and *covering numbers*.

For any set $A \in \mathbb{R}^d$ its *ϵ-packing number* $M(A, \epsilon)$ is the largest number of points in A separated from each other by at least a distance of ϵ. An *ϵ-covering number* $N(A, \epsilon)$ of A

is the minimal number of balls of radius ϵ needed to cover A. Packing numbers are lower bounded by the covering numbers (Dudley, 1999, Theorem 1.2.1):

$$N(A,\epsilon) \le M(A,\epsilon).$$

Also, it is well known that the ϵ-covering number of a unit d-dimensional Euclidean ball is lower bounded by $\lfloor \epsilon^{-d} \rfloor$. Together, these facts state that we can find at least $\lfloor \epsilon^{-d} \rfloor$ points in the d-dimensional unit ball, which are at least ϵ away from each other. Similarly (just by a simple scaling) we can find at least $\lfloor \epsilon^{-d} \rfloor$ points in the d-dimensional ball of radius $R > 0$, which are at least $R \cdot \epsilon$ away from each other. Applying this fact to $B(c_\nu, n)$ we can finally argue that there are at least N^d points in $B(c_\nu, n)$ which are at least $N^{-1}\sqrt{c_\nu/n}$ away from each other, where $N \ge 3$ is an integer to be specified later. Now, take $M = N^d - 1 \ge 2$ (which explains the lower bound $N \ge 3$) and fix $\mu_0, \dots, \mu_M$ to be these $M+1$ points.

(C.2) Application of Theorem B.2: Lower bounding $\|\theta_i - \theta_j\|_{\mathcal{H}_k}$.

With this choice of parameters $\mu_0, \dots, \mu_M$, for any $0 \le i < j \le M$, we have

$$\|\theta_i - \theta_j\|^2_{\mathcal{H}_k} \ge \frac{c_\nu}{N^2 n} \frac{\beta t_0}{e} \left(1 - \frac{2}{2+d}\right),$$

where we used (30) and the lower bound on $\|\mu_i - \mu_j\|_2$. Setting

$$c_\nu = \frac{C}{\beta t_0} \tag{31}$$

for some $C > 0$ we obtain

$$\|\theta_i - \theta_j\|^2_{\mathcal{H}_k} \ge \frac{C}{N^2 e n} \left(1 - \frac{2}{2+d}\right).$$

This satisfies the first assumption of Theorem B.2 with $s := \frac{1}{2N}\sqrt{\frac{C}{en}\left(1 - \frac{2}{2+d}\right)}$.

(C.3) Application of Theorem B.2: Upper bounding $\mathrm{KL}(P_{\theta_i} \| P_{\theta_j})$.

Note that for any $0 \le i < j \le M$ we have

$$\mathrm{KL}\big(G^n(\mu_i, \sigma^2 I) \| G^n(\mu_j, \sigma^2 I)\big) = n \cdot \frac{\|\mu_i - \mu_j\|_2^2}{2\sigma^2} \le \frac{2c_\nu}{\sigma^2} = 4C\frac{t_1 d}{\beta t_0},$$

where the inequality holds since $\mu_i \in B(c_\nu, n)$ and the equality follows from (28) and (31). Here we used the fact that for any points x and y contained in a ball of radius R we obviously have $\|x - y\| \le 2R$. Also note that we chose $M = N^d - 1 \ge 2$ and thus

$$\log(M) = d\log(N) + \log(1 - N^{-d}) \ge d\log(N) + 1 - \frac{N^d}{N^d - 1} \ge d\log(N) - \frac{1}{N-1}$$

for $d \ge 1$, where we used the inequality $\log(x) \ge 1 - \frac{1}{x}$ which holds for $x \ge 0$. Taking

$$C = \frac{\beta t_0}{32 t_1}\left(\log N - \frac{1}{N-1}\right) \tag{32}$$

we get

$$4C\frac{t_1 d}{\beta t_0} = \frac{1}{8}\left(d\log N - \frac{d}{N-1}\right) \le \frac{1}{8}\left(d\log N - \frac{1}{N-1}\right) \le \frac{1}{8}\log(M)$$

for any $d \ge 1$. Concluding, we get

$$\mathrm{KL}\big(G^n(\mu_i, \sigma^2 I) \| G^n(\mu_j \| \sigma^2 I)\big) \le \frac{1}{8}\log(M)$$

and thus the second assumption of Theorem B.2 is satisfied with $\alpha = \frac{1}{8}$. Finally, it is easy to check that if we take $N = 5$ then condition (26) will be satisfied. Indeed,

$$t_1\|\mu_0 - \mu_1\|_2^2 \le \frac{4t_1 c_\nu}{n} = \frac{4t_1}{\beta t_0 n}\frac{\beta t_0}{32 t_1}\left(\log N - \frac{1}{N-1}\right) = \frac{1}{8n}\left(\log N - \frac{1}{N-1}\right),$$

while

$$1 + 4t_1\sigma^2 \ge 1.$$

Thus (26) holds whenever

$$\log N - \frac{1}{N-1} \le 8n,$$

which obviously holds for $N = 5$ and any $n \ge 1$.

To conclude the proof we insert (32) into $s := \frac{1}{2N}\sqrt{\frac{C}{en}\left(1 - \frac{2}{2+d}\right)}$, lower bound this value using $\frac{1}{8}\left(\log N - \frac{1}{N-1}\right) \ge \frac{4}{25}$, and notice that

$$\frac{\sqrt{M}}{1+\sqrt{M}}\left(1 - 2\alpha - \sqrt{\frac{2\alpha}{\log(M)}}\right) \ge \frac{1}{5}.$$

5.5 Proof of Theorem 9

The proof is based on the following result, which gives a closed form expression for the $L^2(\mathbb{R}^d)$ distance between embeddings of two discrete distributions supported on the same pair of points in $\mathbb{R}^d$.

Lemma 15 *Suppose $k(x,y) = \psi(x-y)$, where $\psi \in L^2(\mathbb{R}^d) \cap C_b(\mathbb{R}^d)$ is positive definite and k is characteristic. Define $P_0 = p_0\delta_x + (1-p_0)\delta_v$ and $P_1 = p_1\delta_x + (1-p_1)\delta_v$, where $0 < p_0 < 1$, $0 < p_1 < 1$, $x, v \in \mathbb{R}^d$, and $x \ne v$. Then*

$$\|\mu_k(P_0) - \mu_k(P_1)\|^2_{L^2(\mathbb{R}^d)} = C^\psi_{x,v}(p_0 - p_1)^2,$$

where

$$C^\psi_{x,v} := 2\left(\|\psi\|^2_{L^2(\mathbb{R}^d)} - \int_{\mathbb{R}^d}\psi(y)\psi(y+x-v)dy\right) > 0.$$

Proof We have

$$\begin{aligned}\|\mu_k(P_0) - \mu_k(P_1)\|^2_{L^2(\mathbb{R}^d)} &= (p_0-p_1)^2\,\|k(x,\cdot) - k(v,\cdot)\|^2_{L^2(\mathbb{R}^d)}\\ &= (p_0-p_1)^2\int_{\mathbb{R}^d}\big(\psi(x-y)-\psi(v-y)\big)^2 dy\\ &\overset{(\star)}{=} (p_0-p_1)^2\int_{\mathbb{R}^d}\big(\psi(y)-\psi(y+x-v)\big)^2 dy\\ &= 2(p_0-p_1)^2\int_{\mathbb{R}^d}\psi(y)\big(\psi(y)-\psi(y+x-v)\big)dy\\ &= 2(p_0-p_1)^2\left(\|\psi\|^2_{L^2(\mathbb{R}^d)} - \int_{\mathbb{R}^d}\psi(y)\psi(y+x-v)dy\right),\end{aligned}$$

where we used the symmetry of ψ in $(\star)$. Cauchy-Schwartz inequality states that

$$\int_{\mathbb{R}^d}\psi(y)\psi(y+x-v)dy \overset{(\star)}{\leq} \sqrt{\int_{\mathbb{R}^d}\psi^2(y)dy}\sqrt{\int_{\mathbb{R}^d}\psi^2(y+x-v)dy} = \|\psi\|^2_{L^2(\mathbb{R}^d)},$$

where the equality in $(\star)$ holds if and only if $\psi(y) = \lambda\,\psi(y+x-v)$ for some constant λ and all $y\in\mathbb{R}^d$. If we take $y = v-x$ the above condition implies $\psi(v-x) = \lambda\,\psi(0)$ and with $y=0$ we get $\psi(0) = \lambda\,\psi(x-v)$. Together these identities show that $\psi(0) = \lambda^2\,\psi(0)$. Since the kernel is characteristic and translation invariant, ψ is strictly positive definite, which means $\psi(0) > 0$. We conclude that $\lambda = \pm 1$. Assume that $\lambda = -1$. In this case $\psi(x-v) = -\psi(0) < 0$. Repeating the argument we can show that $\psi\big(2(x-v)\big) = \psi(0)$ and generally $\psi\big(m(x-v)\big) = (-1)^m\psi(0)$ for all $m\in\mathbb{N}$. Since $\psi\in L^2(\mathbb{R}^d)$ we need ψ^2 to be integrable on $\mathbb{R}^d$. Summarizing, we showed that a non-negative, integrable, and continuous function takes the same strictly positive value $\psi^2(0) > 0$ infinitely many times, leading to a contradiction. Arguing similarly for $\lambda = 1$ will result in a contradiction. This means the equality in $(\star)$ is never attained which concludes the proof. ■

The proof of Theorem 9 is carried out by simply repeating the proof of Theorem 1 but replacing (18) with the result in Lemma 15 and using $x - v := z$.

5.6 Proof of Corollary 10

The proof will be based on Theorem 9. The moment condition (15) on ν is sufficient for $\psi_\nu \in L^2(\mathbb{R}^d)$ to hold (see Remark A.3). Thus we only need to compute the expression $\|\psi_\nu\|^2_{L^2(\mathbb{R}^d)} - \int_{\mathbb{R}^d}\psi_\nu(y)\psi_\nu(y+z)dy$ appearing in (14). Note that

$$\int_{\mathbb{R}^d}\psi_\nu(y)\psi_\nu(y+z)dy = \int_{\mathbb{R}^d}\int_0^\infty\int_0^\infty e^{-t_1\|y\|_2^2 - t_2\|y+z\|_2^2}d\nu(t_1)d\nu(t_2)dy. \tag{33}$$

Since

$$\begin{aligned}\int_0^\infty\int_0^\infty\int_{\mathbb{R}^d} e^{-t_1\|y\|_2^2-t_2\|y+z\|_2^2}dy\,d\nu(t_1)d\nu(t_2) &= \int_0^\infty\int_0^\infty\left(\frac{\pi}{t_1+t_2}\right)^{d/2} e^{-\frac{t_1t_2\|z\|_2^2}{t_1+t_2}}d\nu(t_1)d\nu(t_2)\\ &\leq \nu([0,\infty))\int_0^\infty\left(\frac{\pi}{t_1}\right)^{d/2}d\nu(t_1) < \infty,\end{aligned}$$

we may apply Tonelli-Fubini theorem to switch the order of integration in (33) and get

$$\int_{\mathbb{R}^d}\psi_\nu(y)\psi_\nu(y+z)dy = \int_0^\infty\int_0^\infty\left(\frac{\pi}{t_1+t_2}\right)^{d/2} e^{-\frac{t_1t_2\|z\|_2^2}{t_1+t_2}}d\nu(t_1)d\nu(t_2).$$

Using this we get

$$\begin{aligned}\|\psi_\nu\|^2_{L^2(\mathbb{R}^d)} - \int_{\mathbb{R}^d}\psi_\nu(y)\psi_\nu(y+z)dy &= \int_0^\infty\int_0^\infty\left(\frac{\pi}{t_1+t_2}\right)^{d/2}\left(1-e^{-\frac{t_1t_2\|z\|_2^2}{t_1+t_2}}\right)d\nu(t_1)d\nu(t_2)\\ &\geq \left(\frac{\pi}{2\delta_1}\right)^{d/2}\int_{\delta_0}^{\delta_1}\int_{\delta_0}^{\delta_1}\left(1-e^{-\frac{t_1t_2\|z\|_2^2}{t_1+t_2}}\right)d\nu(t_1)d\nu(t_2).\end{aligned}$$

Since t_1 and t_2 are bounded below by $\delta_0 > 0$ we may take $\|z\|_2$ large enough so that the following will hold:

$$\|\psi_\nu\|^2_{L^2(\mathbb{R}^d)} - \int_{\mathbb{R}^d}\psi_\nu(y)\psi_\nu(y+z)dy \geq \frac{\beta^2}{2}\left(\frac{\pi}{2\delta_1}\right)^{d/2}.$$

5.7 Proof of Proposition 11

The proof is based on the following result, which provides a closed form expression for the $L^2(\mathbb{R}^d)$ distance between the embeddings of Gaussian measures.

Lemma 16 *Let θ_0 and θ_1 be KME of Gaussian measures $G(\mu_0,\sigma^2 I)$ and $G(\mu_1,\sigma^2 I)$ for $\mu_0,\mu_1\in\mathbb{R}^d$ and $\sigma^2 > 0$. Suppose $k(x,y) = \psi(x-y)$, where $\psi\in L^1(\mathbb{R}^d)\cap C_b(\mathbb{R}^d)$ is positive definite and and k is characteristic. Then*

$$\|\theta_0-\theta_1\|^2_{L^2(\mathbb{R}^d)} = 2\int_{\mathbb{R}^d}\left(1-e^{-i\langle w,\mu_0-\mu_1\rangle}\right)\big(\psi^\wedge(w)\big)^2 e^{-\sigma^2\|w\|^2}dw. \tag{34}$$

Proof First of all, note that $\psi\in L^2(\mathbb{R}^d)$ since $\psi\in L^1(\mathbb{R}^d)$ and ψ is bounded. This shows that $\theta_0,\theta_1\in L^2(\mathbb{R}^d)$. We will use P_0 and P_1 to denote the corresponding Gaussian distributions $G(\mu_0,\sigma^2 I)$ and $G(\mu_1,\sigma^2 I)$. By definition we have

$$\begin{aligned}\langle\theta_0,\theta_1\rangle_{L^2(\mathbb{R}^d)} &= \int_{\mathbb{R}^d}\left(\int_{\mathbb{R}^d}k(x,y)\,dP_0(x)\right)\left(\int_{\mathbb{R}^d}k(z,y)\,dP_1(z)\right)dy\\ &= \int_{\mathbb{R}^d}\left(\int_{\mathbb{R}^d}\int_{\mathbb{R}^d}k(x,y)k(z,y)\,dP_0(x)\,dP_1(z)\right)dy.\end{aligned}$$

Using the fact that ψ is bounded (Wendland, 2005, Theorem 6.2) we get

$$\begin{aligned}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\big|k(x,y)k(z,y)\big|\,dy\,dP_0(x)\,dP_1(z) &\leq \psi(0)\iiint_{\mathbb{R}^d}\big|k(x,y)\big|\,dy\,dP_0(x)\,dP_1(z)\\ &= \psi(0)\iiint_{\mathbb{R}^d}\big|\psi(x-y)\big|dy\,dP_0(x)dP_1(z)\\ &= \psi(0)\|\psi\|_{L^1(\mathbb{R}^d)}\iint_{\mathbb{R}^d}dP_0(x)dP_1(z) < \infty.\end{aligned}$$

This allows us to use Tonelli-Fubini theorem (Dudley, 2002, Theorem 4.4.5) and get

$$\begin{aligned}\langle \theta_0, \theta_1 \rangle_{L^2(\mathbb{R}^d)} &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\left(\int_{\mathbb{R}^d} k(x,y)k(z,y)dy\right) dP_0(x)dP_1(z)\\ &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\left(\int_{\mathbb{R}^d} \psi(y)\psi(y+z-x)dy\right) dP_0(x)dP_1(z)\\ &\overset{(\star)}{=} \frac{1}{(2\pi)^{d/2}}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\left(\int_{\mathbb{R}^d}\psi(y)\int_{\mathbb{R}^d} e^{-i\langle y+z-x,w\rangle} d\Lambda_\psi(w)dy\right) dP_0(x)dP_1(z)\\ &= \frac{1}{(2\pi)^{d/2}}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\left(\int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\psi(y)e^{-i\langle y+z-x,w\rangle} d\Lambda_\psi(w)dy\right) dP_0(x)dP_1(z),\end{aligned}$$

where we used (4) in $(\star)$. Since $\psi \in L^1(\mathbb{R}^d)$ we have

$$\int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\left|e^{-i\langle y,w\rangle}\psi(y)e^{-i\langle z-x,w\rangle}\right| dy\, d\Lambda_\psi(w) = \int_{\mathbb{R}^d}\int_{\mathbb{R}^d}|\psi(y)|\, dy\, d\Lambda_\psi(w) < \infty$$

and thus we can use Tonelli-Fubini theorem to switch the order of integration:

$$\begin{aligned}\langle \theta_0, \theta_1 \rangle_{L^2(\mathbb{R}^d)} &= \frac{1}{(2\pi)^{d/2}}\int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\left(\int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\psi(y)e^{-i\langle y+z-x,w\rangle} dy\, d\Lambda_\psi(w)\right) dP_0(x)dP_1(z)\\ &= \int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\left(\int_{\mathbb{R}^d}\psi^\wedge(w)e^{-i\langle z-x,w\rangle}\, d\Lambda_\psi(w)\right) dP_0(x)dP_1(z). \qquad (35)\end{aligned}$$

Next we are going to argue that if both ψ and $\psi^\wedge$ belong to $L^1(\mathbb{R}^d)$ (the latter is true as it follows from Wendland, 2005, Corollary 6.12) then $\psi^\wedge$ is the Radon-Nikodym derivative of Λ_ψ with respect to the Lebesgue measure. To this end, since $\psi^\wedge \in L^1(\mathbb{R}^d)$, Fourier inversion theorem (Wendland, 2005, Corollary 5.24) yields that for all $x \in \mathbb{R}^d$, the following holds:

$$\psi(x) = \frac{1}{(2\pi)^{d/2}}\int_{\mathbb{R}^d} e^{i\langle w,x\rangle}\psi^\wedge(w)dw.$$

On the other hand, using (4) and Lemma C.2, we also have

$$\psi(x) = \frac{1}{(2\pi)^{d/2}}\int_{\mathbb{R}^d} e^{i\langle w,x\rangle} d\Lambda_\psi(w).$$

These two identities show that for all $x \in \mathbb{R}^d$

$$\int_{\mathbb{R}^d} e^{i\langle w,x\rangle}\psi^\wedge(w)dw = \int_{\mathbb{R}^d} e^{i\langle w,x\rangle} d\Lambda_\psi(w). \qquad (36)$$

Note that since k is translation invariant and characteristic, ψ is a strictly positive definite function (Sriperumbudur et al., 2010, Section 3.4) and therefore it follows from (Wendland, 2005, Theorem 6.11) that $\psi^\wedge$ is non-negative (and nonvanishing). Since $\psi^\wedge \in L^1(\mathbb{R}^d)$ we conclude that $\psi^\wedge$ is the Radon-Nikodym derivative of a finite non-negative measure $\mathcal{T}_\psi$ on $\mathbb{R}^d$, which is absolutely continuous with respect to the Lebesgue measure. (36) (after proper normalization) shows that the characteristic functions of measures Λ_ψ and $\mathcal{T}_\psi$ coincide. We finally conclude from (Dudley, 2002, Theorem 9.5.1) that $\Lambda_\psi = \mathcal{T}_\psi$, which means that Λ_ψ is absolutely continuous with respect to the Lebesgue measure and has a density $\psi^\wedge$.

Returning to (35) we can write it as

$$\langle \theta_0, \theta_1 \rangle_{L^2(\mathbb{R}^d)} = \int_{\mathbb{R}^d}\int_{\mathbb{R}^d}\left(\int_{\mathbb{R}^d}\left(\psi^\wedge(w)\right)^2 e^{-i\langle z-x,w\rangle}\, dw\right) dP_0(x)dP_1(z).$$

We already showed that $\psi \in L^2(\mathbb{R}^d)$. From Plancherel's theorem (Wendland, 2005, Corollary 5.25), we have $\|\psi\|_{L^2(\mathbb{R}^d)} = \|\psi^\wedge\|_{L^2(\mathbb{R}^d)}$ and thus $\psi^\wedge \in L^2(\mathbb{R}^d)$. Another application of Tonelli-Fubini theorem yields

$$\begin{aligned}\langle \theta_0, \theta_1 \rangle_{L^2(\mathbb{R}^d)} &= \int_{\mathbb{R}^d}\left(\psi^\wedge(w)\right)^2\left(\int_{\mathbb{R}^d}\int_{\mathbb{R}^d} e^{-i\langle z-x,w\rangle} dP_0(x)dP_1(z)\right) dw\\ &= \int_{\mathbb{R}^d}\left(\psi^\wedge(w)\right)^2 e^{i\langle w,\mu_0-\mu_1\rangle} e^{-\sigma^2\|w\|_2^2} dw.\end{aligned}$$

Noticing that the Fourier transform of a real and even function is also even, we conclude that $\psi^\wedge$ is also even. This finishes the proof since $\|\theta_0-\theta_1\|^2_{L^2(\mathbb{R}^d)} = \|\theta_1\|^2_{L^2(\mathbb{R}^d)} + \|\theta_0\|^2_{L^2(\mathbb{R}^d)} - 2\langle \theta_0, \theta_1 \rangle_{L^2(\mathbb{R}^d)}$. ■

Now we turn to the proof of Theorem 11. We will write $\tilde{\Lambda}_\psi$ to denote a non-negative finite measure, absolutely continuous with respect to the Lebesgue measure with density $(2\pi)^{d/2}(\psi^\wedge)^2$. Then (34) in Lemma 16 can be written as

$$\begin{aligned}\|\theta_0-\theta_1\|^2_{L^2(\mathbb{R}^d)} &= \frac{2}{(2\pi)^{d/2}}\int_{\mathbb{R}^d}\left(1-e^{i\langle w,\mu_0-\mu_1\rangle}\right) e^{-\sigma^2\|w\|_2^2} d\tilde{\Lambda}_\psi(w).\\ &= \frac{2}{(2\pi)^{d/2}}\int_{\mathbb{R}^d}\left(1-\cos(\langle w,\mu_0-\mu_1\rangle)\right) e^{-\sigma^2\|w\|_2^2} d\tilde{\Lambda}_\psi(w),\end{aligned}$$

which is exactly of the form in Lemma 14 but with Λ_ψ replaced by $\tilde{\Lambda}_\psi$. From the proof of Lemma 16, since $\psi^\wedge$ is even and non-vanishing, the corresponding measure $\tilde{\Lambda}_\psi$ is symmetric and $\mathrm{supp}(\tilde{\Lambda}_\psi) = \mathbb{R}^d$. The result therefore follows by carrying out the proof of Proposition 3 verbatim but for replacing Λ_ψ with $\tilde{\Lambda}_\psi$.

5.8 Proof of Theorem 13

The proof will closely follow that of Theorem 8. Let $G(\mu_0, \sigma^2 I)$ and $G(\mu_1, \sigma^2 I)$ be two d-dimensional Gaussian distributions with mean vectors $\mu_0, \mu_1 \in \mathbb{R}^d$ and variance $\sigma^2 > 0$. Let θ_0 and θ_1 denote the kernel mean embeddings of $G(\mu_0, \sigma^2 I)$ and $G(\mu_1, \sigma^2 I)$ respectively.

(A) Deriving a closed form expression for $\|\theta_0-\theta_1\|^2_{L^2(\mathbb{R}^d)}$.

The condition in (15) ensures that $\psi_\nu \in L^2(\mathbb{R}^d)$ (see Remark A.3). In fact, using a similar argument it can be shown that $\psi_\nu \in L^1(\mathbb{R}^d)$. Also it is easy to verify that $\psi_\nu \in C_b(\mathbb{R}^d)$. Next, under this moment condition we may apply Tonelli-Fubini theorem to compute the Fourier transform of ψ_ν:

$$\psi_\nu^\wedge(w) = \frac{1}{(2\pi)^{d/2}}\int_{\mathbb{R}^d} e^{-i\langle w,x\rangle}\int_0^\infty e^{-t\|x\|_2^2} d\nu(t)dx = \int_0^\infty \frac{1}{(2t)^{d/2}} e^{-\frac{\|w\|_2^2}{4t}} d\nu(t). \qquad (37)$$

It is immediate to see that $\psi_\nu^\wedge \in L_1(\mathbb{R}^d)$. Therefore Lemma 16 yields

$$\|\theta_0 - \theta_1\|^2_{L^2(\mathbb{R}^d)} = 2\int_{\mathbb{R}^d} \left(1 - e^{-i\langle w, \mu_0 - \mu_1\rangle}\right) \left(\psi_\nu^\wedge(w)\right)^2 e^{-\sigma^2\|w\|_2^2} dw. \tag{38}$$

Denoting $G(w) := \psi_\nu^\wedge(w) e^{-\frac{\sigma^2\|w\|_2^2}{2}}$ and using a well-known property of the Fourier transform we get

$$(G^2)^\wedge(\tau) = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-i\langle w,\tau\rangle} G^2(w) dw = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} G^\wedge(x) G^\wedge(\tau - x) dx. \tag{39}$$

Next we compute the Fourier transform of G using (37):

$$G^\wedge(x) = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-i\langle w,x\rangle} \left(\int_0^\infty \frac{1}{(2t)^{d/2}} e^{-\frac{\|w\|_2^2}{4t}} d\nu(t)\right) e^{-\frac{\sigma^2\|w\|_2^2}{2}} dw.$$

Using the moment condition on ν we have

$$\begin{aligned}\int_0^\infty \frac{1}{(4\pi t)^{d/2}} \int_{\mathbb{R}^d} e^{-\frac{\|x\|_2^2}{4t}} e^{-\frac{\sigma^2\|x\|_2^2}{2}} dx d\nu(t) &= \frac{1}{(2\sigma^2)^{d/2}} \int_0^\infty \left(t + \frac{1}{2\sigma^2}\right)^{-d/2} d\nu(t) \\ &\le \frac{1}{(2\sigma^2)^{d/2}} \int_0^\infty t^{-d/2} d\nu(t) < \infty. \end{aligned} \tag{40}$$

This allows us to use Tonelli-Fubini theorem and write

$$\begin{aligned} G^\wedge(x) &= \frac{1}{(2\pi)^{d/2}} \int_0^\infty \frac{1}{(2t)^{d/2}} \int_{\mathbb{R}^d} e^{-i\langle w,x\rangle} e^{-\frac{\|w\|_2^2}{4t}} e^{-\frac{\sigma^2\|w\|_2^2}{2}} dw\, d\nu(t) \\ &= \int_0^\infty \frac{1}{(2t\sigma^2+1)^{d/2}} \exp\left(-\frac{t\|x\|_2^2}{2t\sigma^2+1}\right) d\nu(t). \end{aligned}$$

Returning to (39) and denoting $\Delta_1 := 2t_1\sigma^2 + 1$, $\Delta_2 := 2t_2\sigma^2 + 1$ we obtain

$$(G^2)^\wedge(\tau) = \int_{\mathbb{R}^d} \int_0^\infty \int_0^\infty \frac{1}{(2\pi\Delta_1\Delta_2)^{d/2}} \exp\left(-\frac{t_1\|x\|_2^2}{\Delta_1} - \frac{t_2\|\tau - x\|_2^2}{\Delta_2}\right) d\nu(t_1)\, d\nu(t_2)\, dx.$$

Using a simple identity

$$a\|x\|_2^2 + b\|x - y\|_2^2 = (a+b)\left\|x - \frac{b}{a+b}y\right\|_2^2 + \frac{ab}{a+b}\|y\|_2^2,$$

which holds for any $x, y \in \mathbb{R}^d$ and $a, b \in \mathbb{R}$ with $a + b \neq 0$, we obtain

$$\begin{aligned}(G^2)^\wedge(\tau) = \int_{\mathbb{R}^d} \int_0^\infty \int_0^\infty \frac{1}{(2\pi\Delta_1\Delta_2)^{d/2}} \exp\left(-\left(\frac{t_1}{\Delta_1} + \frac{t_2}{\Delta_2}\right)\left\|x - \frac{t_2\Delta_1\tau}{t_1\Delta_2 + t_2\Delta_1}\right\|_2^2\right) \\ \times \exp\left(-\frac{t_1t_2\|\tau\|_2^2}{t_1\Delta_2 + t_2\Delta_1}\right) d\nu(t_1)\, d\nu(t_2)\, dx.\end{aligned}$$

Using an argument similar to (40) we can show that Tonelli-Fubini theorem is applicable to the r.h.s. of the above equation. Therefore, changing the order of integration we get

$$(G^2)^\wedge(\tau) = \int_0^\infty \int_0^\infty \left(\frac{1}{2(t_1\Delta_2 + t_2\Delta_1)}\right)^{d/2} \exp\left(-\frac{t_1t_2\|\tau\|_2^2}{t_1\Delta_2 + t_2\Delta_1}\right) d\nu(t_1)\, d\nu(t_2).$$

Noticing that $(G^2)^\wedge(0) = \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} G^2(w)\, dw$ and returning to (38) we get

$$\begin{aligned}\|\theta_0 - \theta_1\|^2_{L^2(\mathbb{R}^d)} &= 2(2\pi)^{d/2} \left((G^2)^\wedge(0) - (G^2)^\wedge(\mu_0 - \mu_1)\right) \\ &= 2\int_0^\infty \int_0^\infty \left(\frac{\pi}{t_1\Delta_2 + t_2\Delta_1}\right)^{d/2} \left(1 - \exp\left(-\frac{t_1t_2\|\mu_0 - \mu_1\|_2^2}{t_1\Delta_2 + t_2\Delta_1}\right)\right) d\nu(t_1) d\nu(t_2).\end{aligned}$$

(B) Lower bounding $\|\theta_0 - \theta_1\|^2_{L^2(\mathbb{R}^d)}$ in terms of $\|\mu_0 - \mu_1\|_2^2$.

Consider

$$\begin{aligned}&\|\theta_0 - \theta_1\|^2_{L_2(\mathbb{R}^d)} \\ &\ge 2\int_{\delta_0}^{\delta_1} \int_{\delta_0}^{\delta_1} \left(\frac{\pi}{t_1\Delta_2 + t_2\Delta_1}\right)^{d/2} \left(1 - \exp\left(-\frac{t_1t_2\|\mu_0 - \mu_1\|_2^2}{t_1\Delta_2 + t_2\Delta_1}\right)\right) d\nu(t_1) d\nu(t_2) \\ &= 2\int_{\delta_0}^{\delta_1} \int_{\delta_0}^{\delta_1} \left(\frac{\pi}{4t_1t_2\sigma^2 + t_1 + t_2}\right)^{d/2} \left(1 - \exp\left(-\frac{t_1t_2\|\mu_0 - \mu_1\|_2^2}{4t_1t_2\sigma^2 + t_1 + t_2}\right)\right) d\nu(t_1) d\nu(t_2).\end{aligned}$$

Using the fact that $1 - e^{-x} \ge \frac{x}{2}$ for $0 \le x \le 1$, we obtain

$$\|\theta_0 - \theta_1\|^2_{L^2(\mathbb{R}^d)} \ge \int_{\delta_0}^{\delta_1} \int_{\delta_0}^{\delta_1} \left(\frac{\pi}{4t_1t_2\sigma^2 + t_1 + t_2}\right)^{d/2} \frac{t_1t_2\|\mu_0 - \mu_1\|_2^2}{4t_1t_2\sigma^2 + t_1 + t_2} d\nu(t_1)\, d\nu(t_2) \tag{41}$$

whenever

$$\frac{t_1t_2\|\mu_0 - \mu_1\|_2^2}{4t_1t_2\sigma^2 + t_1 + t_2} \le 1.$$

Note that the expression on the left hand side of the previous inequality is increasing both in t_1 and t_2. This means that for $t_1, t_2 \in [\delta_0, \delta_1]$ we have:

$$\frac{t_1t_2\|\mu_0 - \mu_1\|_2^2}{4t_1t_2\sigma^2 + t_1 + t_2} \le \frac{\delta_1\|\mu_0 - \mu_1\|_2^2}{4\delta_1\sigma^2 + 2}$$

and thus (41) holds whenever

$$\delta_1\|\mu_0 - \mu_1\|_2^2 \le 4\delta_1\sigma^2 + 2$$

which will be satisfied later. (41) can be rewritten as

$$\begin{aligned}\|\theta_0 - \theta_1\|^2_{L^2(\mathbb{R}^d)} &\ge \int_{\delta_0}^{\delta_1} \int_{\delta_0}^{\delta_1} \frac{(\pi)^{d/2} t_1t_2\|\mu_0 - \mu_1\|_2^2}{(4t_1t_2\sigma^2 + t_1 + t_2)^{d/2+1}} d\nu(t_1)\, d\nu(t_2) \\ &= \int_{\delta_0}^{\delta_1} \left(\frac{\pi}{t_1 + t_2}\right)^{d/2} \int_{\delta_0}^{\delta_1} \frac{\frac{t_1t_2}{t_1+t_2}\|\mu_0 - \mu_1\|_2^2}{\left(4\frac{t_1t_2}{t_1+t_2}\sigma^2 + 1\right)^{d/2+1}} d\nu(t_1)\, d\nu(t_2) \\ &\ge \left(\frac{\pi}{2\delta_1}\right)^{d/2} \int_{\delta_0}^{\delta_1} \int_{\delta_0}^{\delta_1} \frac{S(t_1,t_2)\|\mu_0 - \mu_1\|_2^2}{\left(4S(t_1,t_2)\sigma^2 + 1\right)^{d/2+1}} d\nu(t_1)\, d\nu(t_2),\end{aligned} \tag{42}$$

where $S(t_1,t_2) := \frac{t_1 t_2}{t_1+t_2}$. Note that $S(t_1,t_2)$ takes values in $[\frac{\delta_0}{2}, \frac{\delta_1}{2}]$ as t_1 and t_2 varies in $[\delta_0, \delta_1]$. We can now repeat part of the proof of Theorem 8 where we showed that the function $t \mapsto \frac{t}{(1+4t\sigma^2)^{(d+2)/2}}$ monotonically increases on $[0, \frac{1}{2d\sigma^2}]$, reaches its global maximum at $t = \frac{1}{2d\sigma^2}$, and then decreases on $[\frac{1}{2d\sigma^2}, \infty)$. Using this fact we have

$$\int_{\delta_0}^{\delta_1}\int_{\delta_0}^{\delta_1} \frac{S(t_1,t_2)}{\left(4S(t_1,t_2)\sigma^2+1\right)^{\frac{d}{2}+1}} d\nu(t_1)d\nu(t_2) \geq \frac{\beta^2}{2}\min\left\{\frac{\delta_0}{(1+2\delta_0\sigma^2)^{\frac{d}{2}+1}}, \frac{\delta_1}{(1+2\delta_1\sigma^2)^{\frac{d}{2}+1}}\right\}.$$

By setting $\sigma^2 := \frac{1}{\delta_1 d}$ we ensure that $t = \frac{\delta_1}{2}$ is the global maximum of the function $t \mapsto \frac{t}{\left(1+\frac{4t}{\delta_1 d}\right)^{\frac{d}{2}+1}}$ and thus $\frac{\delta_0}{(1+2\delta_0\sigma^2)^{\frac{d}{2}+1}} \leq \frac{\delta_1}{(1+2\delta_1\sigma^2)^{\frac{d}{2}+1}}$. Combining this with (42) we have

$$\begin{aligned}
\|\theta_0-\theta_1\|^2_{L^2(\mathbb{R}^d)} &\geq \frac{\beta^2\delta_0}{2\left(1+\frac{2\delta_0}{\delta_1 d}\right)^{\frac{d}{2}+1}}\left(\frac{\pi}{2\delta_1}\right)^{d/2}\|\mu_0-\mu_1\|_2^2 \\
&\geq \frac{\beta^2\delta_0}{2(1+\frac{2}{d})^{\frac{d}{2}+1}}\left(\frac{\pi}{2\delta_1}\right)^{d/2}\|\mu_0-\mu_1\|_2^2 \geq \frac{\beta^2\delta_0}{2e}\left(1-\frac{2}{2+d}\right)\left(\frac{\pi}{2\delta_1}\right)^{d/2}\|\mu_0-\mu_1\|_2^2,
\end{aligned}$$

where we used an analysis similar to (29).

(C) Application of Theorem B.2.

We finish by repeating all the remaining steps carried out in the proof of Theorem 8 (steps C.1, C.2, and C.3), where we set

$$\sigma^2 := \frac{1}{\delta_1 d} \quad \text{and} \quad c_\nu := \frac{1}{16\delta_1}\left(\log N - \frac{1}{N-1}\right).$$

Acknowledgements

The authors thank the action editor and two anonymous reviewers for their detailed comments, which helped to improve the presentation. The authors would also like to thank David Lopez-Paz, Jonas Peters, Bernhard Schölkopf, and Carl-Johann Simon-Gabriel for useful discussions.

Appendix A. $\sqrt{n}$-consistency of $\mu_k(P_n)$

In the following, we present a general result whose special cases establishes the convergence rate of $n^{-1/2}$ for $\|\mu_k(P_n)-\mu_k(P)\|_{\mathcal{F}}$ when $\mathcal{F}=\mathcal{H}_k$ and $\mathcal{F}=L^2(\mathbb{R}^d)$.

Proposition A.1 *Let $(X_i)_{i=1}^n$ be random samples drawn i.i.d. from P defined on a separable topological space $\mathcal{X}$. Suppose $r:\mathcal{X}\to H$ is continuous and*

$$\sup_{x\in\mathcal{X}}\|r(x)\|_H^2 \leq C_k < \infty, \tag{43}$$

where H is a separable Hilbert space of real-valued functions. Then for any $0<\delta\leq 1$ with probability at least $1-\delta$ we have

$$\left\|\int_{\mathcal{X}} r(x)\,dP_n(x) - \int_{\mathcal{X}} r(x)\,dP(x)\right\|_H \leq \sqrt{\frac{C_k}{n}} + \sqrt{\frac{2C_k\log(1/\delta)}{n}}.$$

Proof Note that $r:\mathcal{X}\to H$ is a H-valued measurable function as r is continuous and H is separable (Steinwart and Christmann, 2008, Lemma A.5.18). The condition in (43) ensures that $\int\|r(x)\|_H dQ(x) \leq \sqrt{C_k} < \infty$ for any $Q\in M_+^1(\mathcal{X})$ and therefore $\int r(x)\,dQ(x)$ is well defined as a Bochner integral for any $Q\in M_+^1(\mathcal{X})$ (Diestel and Uhl, 1977, Theorem 2, p.45). By McDiarmid's inequality, it is easy to verify that with probability at least $1-\delta$,

$$\begin{aligned}
\left\|\int_{\mathcal{X}} r(x)\,dP_n(x) - \int_{\mathcal{X}} r(x)\,dP(x)\right\|_H \leq \mathbb{E}\left\|\int_{\mathcal{X}} r(x)\,dP_n(x) - \int_{\mathcal{X}} r(x)\,dP(x)\right\|_H \\
+\sqrt{\frac{2C_k\log(1/\delta)}{n}},
\end{aligned} \tag{44}$$

where

$$\begin{aligned}
&\mathbb{E}\left\|\int_{\mathcal{X}} r(x)\,dP_n(x) - \int_{\mathcal{X}} r(x)\,dP(x)\right\|_H \leq \sqrt{\mathbb{E}\left\|\int_{\mathcal{X}} r(x)\,dP_n(x) - \int_{\mathcal{X}} r(x)\,dP(x)\right\|_H^2} \\
&= \sqrt{\mathbb{E}\left\|\int_{\mathcal{X}} r(x)\,dP_n(x)\right\|_H^2 + \left\|\int_{\mathcal{X}} r(x)\,dP(x)\right\|_H^2 - 2\mathbb{E}\left\langle\int_{\mathcal{X}} r(x)\,dP_n(x), \int_{\mathcal{X}} r(x)\,dP(x)\right\rangle_H} \\
&= \sqrt{\mathbb{E}\left\|\int_{\mathcal{X}} r(x)\,dP_n(x)\right\|_H^2 + \left\|\int_{\mathcal{X}} r(x)\,dP(x)\right\|_H^2 - \frac{2}{n}\sum_{i=1}^n \mathbb{E}\left\langle r(X_i), \int_{\mathcal{X}} r(x)\,dP(x)\right\rangle_H}.
\end{aligned} \tag{45}$$

To simplify the r.h.s. of (45), we make the following observation. Note that for any $g\in H$, $T_g : H\to\mathbb{R}$, $f\mapsto\langle g,f\rangle_H$ is a bounded linear functional on H. Choose $f=\int_{\mathcal{X}} r(y)\,dP(y)$. It follows from (Diestel and Uhl, 1977, Theorem 6, p.47) that

$$\left\langle g, \int_{\mathcal{X}} r(y)\,dP(y)\right\rangle_H = T_g\left(\int_{\mathcal{X}} r(y)\,dP(y)\right) = \int_{\mathcal{X}} T_g(r(y))\,dP(y) = \int_{\mathcal{X}}\langle g, r(y)\rangle_H\,dP(y). \tag{46}$$

Applying (46) to the third term in the r.h.s. of (45) with $g=\int_{\mathcal{X}} r(x)\,dP(x)$, we obtain

$$\mathbb{E}\left\langle r(X_i), \int_{\mathcal{X}} r(x)\,dP(x)\right\rangle_H = \int_{\mathcal{X}}\langle r(x_i), g\rangle_H\,dP(x_i) = \left\langle\int_{\mathcal{X}} r(x_i)\,dP(x_i), g\right\rangle_H = \|g\|_H^2$$

and so (45) reduces to

$$\mathbb{E}\left\|\int_{\mathcal{X}} r(x)\,dP_n(x) - \int_{\mathcal{X}} r(x)\,dP(x)\right\|_H \leq \sqrt{\mathbb{E}\left\|\int_{\mathcal{X}} r(x)\,dP_n(x)\right\|_H^2 - \left\|\int_{\mathcal{X}} r(x)\,dP(x)\right\|_H^2}. \tag{47}$$

Consider

$$\mathbb{E}\left\|\int_{\mathcal{X}} r(x)\,dP_n(x)\right\|_H^2 = \mathbb{E}\left\|\frac{1}{n}\sum_{i=1}^n r(X_i)\right\|_H^2 = \frac{1}{n^2}\sum_{i,j=1}^n \mathbb{E}\langle r(X_i), r(X_j)\rangle_H$$
$$= \frac{1}{n^2}\sum_{i=j}\mathbb{E}\langle r(X_i), r(X_j)\rangle_H + \frac{1}{n^2}\sum_{i\neq j}\mathbb{E}\langle r(X_i), r(X_j)\rangle_H$$
$$= \frac{1}{n}\mathbb{E}_{X\sim P}\|r(X)\|_H^2 + \frac{n-1}{n}\mathbb{E}_{X\sim P, Y\sim P}\langle r(X), r(Y)\rangle_H. \qquad (48)$$

Using (46), the second term in (48) can be equivalently written as

$$\mathbb{E}_{X\sim P, Y\sim P}\langle r(X), r(Y)\rangle_H = \int_{\mathcal{X}}\left(\int_{\mathcal{X}}\langle r(x), r(y)\rangle_H\, dP(y)\right) dP(x)$$
$$\overset{(\star)}{=} \int_{\mathcal{X}}\left\langle r(x), \int_{\mathcal{X}} r(y)\,dP(y)\right\rangle_H dP(x)$$
$$\overset{(\star)}{=} \left\langle \int_{\mathcal{X}} r(x)\,dP(x), \int_{\mathcal{X}} r(y)\,dP(y)\right\rangle_H x = \left\|\int_{\mathcal{X}} r(x)\,dP(x)\right\|_H^2,$$

where we invoked (46) in ($\star$). Combining the above with (48) and using the result in (47) yields

$$\mathbb{E}\left\|\int_{\mathcal{X}} r(x)\,dP_n(x) - \int_{\mathcal{X}} r(x)\,dP(x)\right\|_H \leq \sqrt{\frac{\mathbb{E}_{X\sim P}\|r(X)\|_H^2 - \|\int_{\mathcal{X}} r(x)\,dP(x)\|_H^2}{n}} \leq \sqrt{\frac{C_k}{n}}$$

and the result follows. ■

Remark A.2 *Suppose H is an RKHS with a reproducing kernel k that is continuous and satisfies $\sup_{x\in\mathcal{X}} k(x,x) < \infty$. Choosing $r(x) = k(\cdot, x)$, $x \in \mathcal{X}$ in Proposition A.1 yields a concentration inequality for $\|\mu_k(P_n) - \mu_k(P)\|_H$ with $C_k := \sup_{x\in\mathcal{X}} k(x,x)$, thereby establishing a convergence rate of $n^{-1/2}$ for $\|\mu_k(P_n) - \mu_k(P)\|_H$. While such a result has already appeared in Smola et al. (2007, Theorem 2), Gretton et al. (2012) and Lopez-Paz et al. (2015), the result derived from Proposition A.1 improves upon them by providing better constants. While all these works including Proposition A.1 are based on McDiarmid's inequality (see (44)), the latter obtains better constants by carefully bounding the expectation term in (44). It is easy to verify that $C_k = 1$ for Gaussian and $C_k = C_M$ for mixture of Gaussian kernels, $C_k = c^{-2\gamma}$ for inverse multiquadrics, and $C_k = 1$ for Matérn kernels.*

Remark A.3 *Assuming $\mathcal{X} = \mathbb{R}^d$, $H = L^2(\mathbb{R}^d)$ and $r(x) = k(\cdot, x)$, $x \in \mathbb{R}^d$, where k is a continuous positive definite kernel on $\mathbb{R}^d$, Proposition A.1 establishes a convergence rate of $n^{-1/2}$ for $\|\mu_k(P_n) - \mu_k(P)\|_{L^2(\mathbb{R}^d)}$ under the condition that $\sup_{x\in\mathbb{R}^d}\|k(x,\cdot)\|_{L^2(\mathbb{R}^d)}^2 < \infty$. If k is translation invariant on $\mathbb{R}^d$, i.e., $k(x,y) = \psi(x-y)$, $x, y \in \mathbb{R}^d$ where $\psi \in C(\mathbb{R}^d)$ is positive definite, then $\psi \in L^2(\mathbb{R}^d)$ ensures that $\sup_{x\in\mathbb{R}^d}\|k(x,\cdot)\|_{L^2(\mathbb{R}^d)}^2 = \sup_{x\in\mathbb{R}^d}\|\psi(x-\cdot)\|_{L^2(\mathbb{R}^d)}^2 = \|\psi\|_{L^2(\mathbb{R}^d)}^2$ and therefore Propositions A.1 holds with $C_k := \|\psi\|_{L^2(\mathbb{R}^d)}^2$. On the other hand, for radial kernels on $\mathbb{R}^d$, i.e., kernels of the form in (5), the condition in (43) is ensured if*

$$\int_0^\infty t^{-d/2} d\nu(t) < \infty \qquad (49)$$

since

$$\sup_{x\in\mathbb{R}^d}\|k(x,\cdot)\|_{L^2(\mathbb{R}^d)}^2 = \sup_{x\in\mathbb{R}^d}\int_{\mathbb{R}^d}\left(\int_0^\infty e^{-t\|x-y\|^2} d\nu(t)\right)^2 dy$$
$$\overset{(\dagger)}{\leq} \nu([0,\infty))\sup_{x\in\mathbb{R}^d}\int_{\mathbb{R}^d}\int_0^\infty e^{-2t\|x-y\|^2} d\nu(t) dy$$
$$\overset{(\ddagger)}{=} \nu([0,\infty))\sup_{x\in\mathbb{R}^d}\int_0^\infty\int_{\mathbb{R}^d} e^{-2t\|x-y\|^2} dy\, d\nu(t) = \frac{\nu([0,\infty))}{(2/\pi)^{d/2}}\int_0^\infty \frac{d\nu(t)}{t^{d/2}},$$

where we used Jensen's inequality in (†) and Fubini's theorem in (‡). Therefore the bound in Proposition A.1 holds with $C_k := \nu([0,\infty))\int_0^\infty \left(\frac{\pi}{2t}\right)^{d/2} d\nu(t)$. (49) is satisfied by Gaussian, mixture of Gaussian and Matérn (see Sriperumbudur, 2016, Equation 6.17) kernels. For inverse multiquadrics, while (49) holds for $\gamma > d/2$ since $\nu = c^{-2\gamma}Gamma(\gamma, c^2)$ (see Wendland, 2005, Theorem 7.15), in fact the condition in (43) holds for $\gamma > d/4$ (see Lemma C.4).

Appendix B. Minimax Lower Bounds and Le Cam's Method

Let Θ be a set of parameters (or functions) containing the element θ which we want to estimate. Assume there is a class $\mathcal{P} = \{P_\theta : \theta \in \Theta\}$ of probability measures on $\mathbb{R}^d$ indexed by Θ. Suppose $d\colon \Theta\times\Theta \to [0,\infty)$ is a metric on Θ. Le Cam's method provides a lower bound on the minimax probability, $\inf_{\hat{\theta}_n}\sup_{\theta\in\Theta} P_\theta^n(d(\hat{\theta}_n, \theta) \geq s)$ for $s > 0$, where the infimum is taken over all possible estimators $\hat{\theta}_n\colon \mathbb{R}^d \to \Theta$ that are constructed from an i.i.d. sample $(X_i)_{i=1}^n$ drawn from P_θ. The following two results which we used throughout this work are based on Le Cam's method and they provide a lower bound on the minimax probability. The first one follows from Theorem 2.2 and Equation (2.9) of Tsybakov (2008). It requires a construction of two sufficiently distant elements of the set Θ corresponding to the probability distributions similar in the Kullback-Leibler (KL) divergence sense, where the KL divergence between two distributions P and Q with P absolutely continuous w.r.t. Q is defined as $\mathrm{KL}(P\|Q) = \int \log\frac{dP}{dQ}\, dP$.

Theorem B.1 (Lower bound based on two hypotheses) *Assume Θ contains θ_0 and θ_1 such that $d(\theta_0, \theta_1) \geq 2s$ and $\mathrm{KL}(P_{\theta_0}^n\|P_{\theta_1}^n) \leq \alpha$ for some $s > 0$ and $0 < \alpha < \infty$. Then*

$$\inf_{\hat{\theta}_n}\sup_{\theta\in\Theta} P_\theta^n\left\{d(\hat{\theta}_n, \theta) \geq s\right\} \geq \max\left(\frac{1}{4}e^{-\alpha}, \frac{1-\sqrt{\alpha/2}}{2}\right).$$

Note that the second condition of the theorem bounds the distance between the n-fold product distributions by a constant independent of n. Recalling the chain rule of the KL-divergence, which states that $\mathrm{KL}(P_{\theta_0}^n\|P_{\theta_1}^n) = n\cdot\mathrm{KL}(P_{\theta_0}\|P_{\theta_1})$, we can see that this condition is rather restrictive and requires the marginal distributions to satisfy $\mathrm{KL}(P_{\theta_0}\|P_{\theta_1}) = O(n^{-1})$. This condition is slightly relaxed in the following result, which follows from Theorem 2.5 of Tsybakov (2008).

Theorem B.2 (Lower bound based on many hypotheses) *Assume $M \geq 2$ and suppose that there exist $\theta_0, \ldots, \theta_M \in \Theta$ such that (i) $d(\theta_i, \theta_j) \geq 2s > 0$, $\forall\, 0 \leq i < j \leq M$; (ii) P_{θ_j} is absolutely continuous w. r. t. P_{θ_0} for all $j = 1, \ldots, M$, and $\frac{1}{M}\sum_{i=1}^{M} \mathrm{KL}(P_{\theta_j}^n \| P_{\theta_0}^n) \leq \alpha \log M$ with $0 < \alpha < 1/8$. Then*

$$\inf_{\hat{\theta}_n} \sup_{\theta \in \Theta} P_\theta^n \left\{ d(\hat{\theta}_n, \theta) \geq s \right\} \geq \frac{\sqrt{M}}{1+\sqrt{M}} \left(1 - 2\alpha - \sqrt{\frac{2\alpha}{\log M}} \right) > 0.$$

The above result is commonly used with M tending to infinity as $n \to \infty$. In this case the second condition on the KL-divergence indeed becomes less restrictive than the one of Theorem B.1, since the upper bound $\alpha \log M$ may now grow with the sample size n. At the same time, Theorem B.2 still provides a lower bound on the minimax probability independent of n, since $\sqrt{M}/(1+\sqrt{M})$ and $\log M$ can be lower bounded by $1/2$ and $\log 2$ respectively.

Appendix C. Technical Lemmas

The following technical results are used to prove the main results of Sections 3 and 4.

Lemma C.1 (Theorem 5.18, Wendland, 2005) *For any $\mu \in \mathbb{R}^d$ and $\sigma^2 > 0$ the following holds:*

$$\left[\frac{1}{(2\pi\sigma^2)^{d/2}} e^{-\frac{\|x-\mu\|_2^2}{2\sigma^2}} \right]^\wedge (w) = \frac{1}{(2\pi)^{d/2}} \exp\left(-i\langle \mu, w \rangle - \frac{\sigma^2 \|w\|_2^2}{2} \right), \quad w \in \mathbb{R}^d.$$

Lemma C.2 *Let $\psi\colon \mathbb{R}^d \to \mathbb{R}$ be a symmetric and positive definite function. Let Λ_ψ be the corresponding finite non-negative Borel measure from (4). Then Λ_ψ is symmetric, i.e., $\Lambda_\psi(A) = \Lambda_\psi(-A)$ for all $A \subset \mathbb{R}^d$.*

Proof From the definition of Λ_ψ we know that it is finite, non-negative, and

$$\psi(x) = \int_{\mathbb{R}^d} e^{-i\langle w, x\rangle} \Lambda_\psi(dw) = \int_{\mathbb{R}^d} \cos(\langle w, x\rangle) \Lambda_\psi(dw) - i \cdot \int_{\mathbb{R}^d} \sin(\langle w, x\rangle) \Lambda_\psi(dw).$$

Since $\psi(-x) = \psi(x)$ for all $x \in \mathbb{R}^d$, we get $\int_{\mathbb{R}^d} \sin(\langle w, x\rangle)\Lambda_\psi(dw) = 0$. Note that $\psi(-x)$ is by definition a characteristic function of measure Λ_ψ, and we have just proved that it is real-valued. It is known (Bogachev, 2007, Corollary 3.8.7) that in this case the measure Λ_ψ is invariant under the mapping $x \to -x$. ■

Lemma C.3 *Assume $X, Y \subseteq \mathbb{R}^d$. If $f\colon X \times Y \to \mathbb{R}$ is a continuous function and Y is a compact set then $g(x) := \inf_{y \in Y} f(x, y)$ is continuous.*

Proof First, the map $g\colon X \to \mathbb{R}$ is well defined since $f_x(y) := f(x, y)$ is a continuous function for any $x \in X$ and thus f_x achieves its infimum since Y is a compact set. We will prove that the map $g\colon X \to \mathbb{R}$ is continuous by showing that $g^{-1}(-\infty, a)$ and $g^{-1}(a, \infty)$ are open sets for all $a \in \mathbb{R}$ (Dudley, 2002, Corollary 2.2.7 (a)).

Now we will show that $g^{-1}(-\infty, a)$ is open for any $a \in \mathbb{R}$. It suffices to show that for any $x \in g^{-1}(-\infty, a)$ there is an open neighborhood U_x of x which also belongs to $g^{-1}(-\infty, a)$. The set $g^{-1}(-\infty, a)$ consists of elements $x \in X$ for which $g(x) < a$. In other words, it consists of such elements $x \in X$ for which there is corresponding $y_x \in Y$ satisfying $f(x, y_x) < a$. Take any $x \in g^{-1}(-\infty, a)$. Since f is continuous, $f^{-1}(-\infty, a)$ is open and contains (x, y_x). Moreover $f^{-1}(-\infty, a)$ contains $U_x \times V_y$, where U_x and V_y are open sets with $x \in U_x$ and $y_x \in V_y$. Now suppose $x' \in U_x$. Then for any $y \in V_y$ we have $f(x', y) < a$. In particular, $f(x', y_x) < a$, which means that $g(x') < a$ and $x' \in g^{-1}(-\infty, a)$. This shows that $g^{-1}(-\infty, a)$ is open.

Next we will show that $g^{-1}(a, \infty)$ is also an open set for any $a \in \mathbb{R}$. Assume this is not the case. Then there is $x \in g^{-1}(a, \infty)$ such that for any neighborhood U_x of x there is a point $x' \in U_x$ such that $x' \notin g^{-1}(a, \infty)$. This means that for any such x' there is $y_{x'}$ satisfying $f(x', y_{x'}) \leq a$. Using this we can construct a sequence $\{x_n, y_n\}$ from $X \times Y$, such that $x_n \notin g^{-1}(a, \infty)$ for every n, $\lim_{n\to\infty} x_n = x$ and for any n it holds that $f(x_n, y_n) \leq a$. Since Y is compact we conclude that $\{y_n\}$ has a converging subsequence $\{y_{n(k)}\}$ (Dudley, 2002, Theorem 2.3.1) with limit $y^* \in Y$. We just showed that there is a sequence $\{x_{n(k)}, y_{n(k)}\}$ in $X \times Y$, which converges to (x, y^*), such that $\lim_{k\to\infty} f(x_{n(k)}, y_{n(k)}) \leq a$. Since f is continuous, this also means that $\lim_{k\to\infty} f(x_{n(k)}, y_{n(k)}) = f(x, y^*) \leq a$. This means that $\inf_{y\in Y} f(x, y) \leq f(x, y^*) \leq a$. In other words, this shows that $x \notin g^{-1}(a, \infty)$ leading to a contradiction and therefore $g^{-1}(a, \infty)$ is open. ■

Lemma C.4 (L^2 norm of inverse multiquadrics kernels) *For any $c > 0$ and $\gamma > \frac{d}{4}$,*

$$\int_{\mathbb{R}^d} (c^2 + \|x\|_2^2)^{-2\gamma}\, dx = c^{d-4\gamma} \pi^{d/2} \frac{\Gamma(2\gamma - \frac{d}{2})}{\Gamma(2\gamma)}.$$

Proof

$$\begin{aligned}
\int_{\mathbb{R}^d} (c^2 + \|x\|_2^2)^{-2\gamma} dx &= c^{-4\gamma} \int_{\mathbb{R}^d} \left(1 + \left\| \frac{x}{c} \right\|_2^2 \right)^{-2\gamma} dx = c^{d-4\gamma} \int_{\mathbb{R}^d} \left(1 + \|x\|_2^2 \right)^{-2\gamma} dx \\
&= c^{d-4\gamma} \frac{2\pi^{d/2}}{\Gamma(d/2)} \int_0^\infty \left(1 + r^2 \right)^{-2\gamma} r^{d-1} dr \\
&= c^{d-4\gamma} \frac{\pi^{d/2}}{\Gamma(d/2)} \int_0^\infty (1 + x)^{-2\gamma} x^{d/2-1} dx \\
&= c^{d-4\gamma} \frac{\pi^{d/2}}{\Gamma(d/2)} \frac{\Gamma(d/2)\Gamma(2\gamma - d/2)}{\Gamma(2\gamma)},
\end{aligned}$$

where last identity can be found in (Gradshteyn and Ryzhik, 2000, 3.194.3). ■

Appendix D. Bounds on Constants for Various Radial Kernels

In this appendix, we present bounds on the constants that appear in Corollaries 2, 10 and Theorems 8, 13. for various radial kernels.

D.1 α in Corollary 2

In Corollary 2, we assumed that there exist $0 < t_1 < \infty$ and $\alpha > 0$ such that $\nu([t_1, \infty)) \geq \alpha$. In the following, we present the values of t_1 and α for various radial kernels.

(i) Gaussian kernel: $\nu = \delta_{\frac{1}{2\eta^2}}$ and so for any $t_1 < \frac{1}{2\eta^2}$, we obtain $\alpha = 1$.

(ii) Mixture of Gaussians: $\nu = \sum_{i=1}^M \beta_i \delta_{\frac{1}{2\eta_i^2}}$ and so $\alpha = C_M$ for any $t_1 < \frac{1}{2\eta_1^2}$.

(iii) Inverse multiquadric kernel: It follows from (Wendland, 2005, Theorem 7.15) that

$$k(x,y) = \int_0^\infty e^{-t\|x-y\|_2^2} \frac{t^{\gamma-1}e^{-c^2 t}}{\Gamma(\gamma)} dt, \tag{50}$$

and so

$$\nu = c^{-2\gamma}\text{Gamma}(\gamma, c^2) \tag{51}$$

where the density of a Gamma distribution with parameters $a, b > 0$ is defined as

$$\text{Gamma}(t; a, b) = \frac{b^a}{\Gamma(a)} t^{a-1} e^{-tb}, \ t \geq 0.$$

Therefore choosing t_1 to be the median of ν, we obtain $\alpha = \frac{c^{-2\gamma}}{2}$.

(iv) Matérn kernel: We know from (Wendland, 2005, Theorem 6.13) that Matérn kernel is related to the Fourier transform of the inverse multiquadric kernel as

$$\frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-i\langle v, w\rangle} \left(c^2 + \|v\|_2^2\right)^{-\tau} dv = \frac{2^{1-\tau}}{\Gamma(\tau)} K_{d/2-\tau}(c\|w\|_2) \left(\frac{\|w\|_2}{c}\right)^{\tau - d/2},$$

where $c > 0$ and $\tau > d/2$. Using this together with the representation (50) of an inverse multiquadrics kernel we obtain the following identity, which already appeared in (Sriperumbudur, 2016, Equation (72)):

$$\begin{aligned}
k(x,y) &= \frac{\Gamma(\tau) c^{2\tau-d} 2^{d/2}}{\Gamma(\tau - d/2)} \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-i\langle v, x-y\rangle} \left[\int_0^\infty e^{-t\|v\|_2^2} \frac{t^{\tau-1}e^{-c^2 t}}{\Gamma(\tau)} dt\right] dv \\
&\overset{(\star)}{=} \frac{c^{2\tau-d} 2^{d/2}}{\Gamma(\tau - d/2)} \int_0^\infty t^{\tau-1} e^{-c^2 t} \frac{1}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-i\langle v, x-y\rangle} e^{-t\|v\|_2^2} dv\, dt \\
&= \frac{c^{2\tau-d} 2^{d/2}}{\Gamma(\tau - d/2)} \int_0^\infty t^{\tau-1} e^{-c^2 t} \frac{1}{(2t)^{d/2}} e^{-\frac{\|x-y\|_2^2}{4t}} dt \\
&= \frac{c^{2\tau-d}}{\Gamma(\tau - d/2)} \int_0^\infty t^{\tau-d/2-1} e^{-c^2 t} e^{-\frac{\|x-y\|_2^2}{4t}} dt,
\end{aligned}$$

where we invoked Tonelli-Fubini theorem (Dudley, 2002, Theorem 4.4.5) in $(\star)$ since $\left(c^2 + \|\cdot\|_2^2\right)^{-\tau} \in L_1(\mathbb{R}^d)$ for $\tau > d/2$. After change of variables we finally obtain

$$k(x,y) = \frac{1}{\Gamma\left(\tau - \frac{d}{2}\right)} \left(\frac{c^2}{4}\right)^{\tau - \frac{d}{2}} \int_0^\infty e^{-t\|x-y\|^2} t^{d/2-\tau-1} e^{-\frac{c^2}{4t}} dt,$$

which shows that Matérn kernel is a particular instance of radial kernels with

$$\nu = \text{InvGamma}\left(\tau - \frac{d}{2}, \frac{c^2}{4}\right),$$

where the density of an inverse-Gamma distribution with parameters $a, b > 0$ has the form

$$\text{InvGamma}(t; a, b) = \frac{b^a}{\Gamma(a)} t^{-a-1} e^{-b/t}.$$

Therefore $\alpha = \frac{1}{2}$ for the choice of t_1 to be the median of ν.

D.2 $\frac{\beta t_0}{t_1}$ in Theorem 8

In Theorem 8, we assumed that there exist $0 < t_0 \leq t_1 < \infty$ and $0 < \beta < \infty$ such that $\nu([t_0, t_1]) \geq \beta$. Define $B_k := \frac{\beta t_0}{t_1}$. In the following, we present the values of B_k for various radial kernels.

(i) Gaussian kernel: Choose $t_0 = t_1 = \frac{1}{2\eta^2}$ so that $\beta = 1$ and $B_k = 1$.

(ii) Mixture of Gaussians: Set $t_0 = \frac{1}{2\eta_1^2}$, $t_1 = \frac{1}{2\eta_M^2}$ so that $\beta = C_M$ implying $B_k = \frac{C_M \eta_M^2}{\eta_1^2}$.

(iii) Inverse multiquadric kernel: From (51), we have $\nu = c^{-2\gamma}\text{Gamma}(\gamma, c^2)$. Therefore

$$\begin{aligned}
\nu\left(\left[\frac{\gamma}{2c^2}, \frac{\gamma}{c^2}\right]\right) &= \frac{1}{\Gamma(\gamma)} \int_{\gamma/(2c^2)}^{\gamma/c^2} t^{\gamma-1} e^{-tc^2} dt \\
&\geq \begin{cases} \frac{1}{\Gamma(\gamma)} \left(\frac{\gamma}{2c^2}\right)^{\gamma-1} \exp\left(-\frac{\gamma}{c^2}c^2\right) \frac{\gamma}{2c^2}, & \text{for } \gamma \geq 1; \\ \frac{1}{\Gamma(\gamma)} \left(\frac{\gamma}{c^2}\right)^{\gamma-1} \exp\left(-\frac{\gamma}{c^2}c^2\right) \frac{\gamma}{2c^2}, & \text{for } \gamma \in (0,1). \end{cases}
\end{aligned}$$

Therefore with $t_0 = \frac{\gamma}{2c^2}$, $t_1 = \frac{\gamma}{c^2}$ and $\beta = \begin{cases} \frac{c^{-2\gamma}}{\Gamma(\gamma)} \left(\frac{\gamma}{2e}\right)^\gamma, & \text{for } \gamma \geq 1; \\ \frac{c^{-2\gamma}}{2\Gamma(\gamma)} \left(\frac{\gamma}{e}\right)^\gamma, & \text{for } \gamma \in (0,1) \end{cases}$, we obtain

$$B_k = \begin{cases} \frac{c^{-2\gamma}}{2\Gamma(\gamma)} \left(\frac{\gamma}{2e}\right)^\gamma, & \text{for } \gamma \geq 1; \\ \frac{c^{-2\gamma}}{4\Gamma(\gamma)} \left(\frac{\gamma}{e}\right)^\gamma, & \text{for } \gamma \in (0,1) \end{cases}.$$

(iv) Matérn kernel: It is easy to check that if $X \sim \text{Gamma}(a, b)$ and $Y \sim \text{InvGamma}(a, b)$ for $a, b > 0$ then for any $0 < x \leq y < \infty$ the following holds:

$$\mathbb{P}\{x \leq X \leq y\} = \mathbb{P}\{1/y \leq Y \leq 1/x\}.$$

This means, the above calculations for inverse multiquadrics can be used to obtain the following for the Matérn kernel:

$$B_k = \begin{cases} \frac{1}{2\Gamma(\tau - \frac{d}{2})} \left(\frac{2\tau-d}{4e}\right)^{\tau - \frac{d}{2}}, & \text{for } \tau - \frac{d}{2} \geq 1; \\ \frac{1}{4\Gamma(\tau - \frac{d}{2})} \left(\frac{2\tau-d}{2e}\right)^{\tau - \frac{d}{2}}, & \text{for } \tau - \frac{d}{2} \in (0,1) \end{cases}.$$

D.3 $\beta^2\delta_1^{-d/2}$ in Corollary 10

In Corollary 10, we assumed that there exist $0 < \delta_0 \leq \delta_1 < \infty$ and $0 < \beta < \infty$ such that $\nu([\delta_0, \delta_1]) \geq \beta$. Define $A_k := \beta^2\delta_1^{-d/2}$. Based on the analysis carried out in Appendix D.2, in the following, we present the values of A_k for various radial kernels.

(i) Gaussian kernel: Choose $\delta_0 = \delta_1 = \frac{1}{2\eta^2}$ so that $\beta = 1$ and $A_k = (2\eta^2)^{d/2}$.

(ii) Mixture of Gaussians: Set $\delta_0 = \frac{1}{2\eta_1^2}$, $\delta_1 = \frac{1}{2\eta_M^2}$ so that $\beta = C_M$ implying $A_k = C_M^2(2\eta_M^2)^{d/2}$.

(iii) Inverse multiquadric kernels: Choosing $\delta_0 = t_0$ and $\delta_1 = t_1$ as in Appendix D.2, we obtain

$$A_k = \begin{cases} \frac{c^{d-4\gamma}}{\Gamma^2(\gamma)} \frac{\gamma^{2\gamma-\frac{d}{2}}}{(2e)^{2\gamma}}, & \text{for } \gamma \geq 1; \\ \frac{c^{d-4\gamma}}{4\Gamma^2(\gamma)} \frac{\gamma^{2\gamma-\frac{d}{2}}}{e^{2\gamma}}, & \text{for } \gamma \in (0,1) \end{cases}.$$

(iv) Matérn kernel: Define $\tilde{\gamma} := \tau - \frac{d}{2}$ and $\tilde{c} := \frac{c}{2}$. Choosing $\delta_0 = \frac{\tilde{c}^2}{\tilde{\gamma}}$ and $\delta_1 = \frac{2\tilde{c}^2}{\tilde{\gamma}}$, we obtain

$$\beta = \begin{cases} \frac{1}{\Gamma(\tilde{\gamma})} \left(\frac{\tilde{\gamma}}{2e}\right)^{\tilde{\gamma}}, & \text{for } \tilde{\gamma} \geq 1; \\ \frac{1}{2\Gamma(\tilde{\gamma})} \left(\frac{\tilde{\gamma}}{e}\right)^{\tilde{\gamma}}, & \text{for } \tilde{\gamma} \in (0,1) \end{cases},$$

using the analysis in Appendix D.2. Therefore,

$$A_k = \begin{cases} \frac{c^{-d}e^{-2\tilde{\gamma}}}{\Gamma^2(\tilde{\gamma})} \left(\frac{\tilde{\gamma}}{2}\right)^{2\tilde{\gamma}+\frac{d}{2}}, & \text{for } \tilde{\gamma} \geq 1; \\ \frac{c^{-d}e^{-2\tilde{\gamma}}}{\Gamma^2(\tilde{\gamma})} \frac{\tilde{\gamma}^{2\tilde{\gamma}+\frac{d}{2}}}{2^{2+\frac{d}{2}}}, & \text{for } \tilde{\gamma} \in (0,1) \end{cases}.$$

D.4 $\beta^2\delta_0\delta_1^{-\frac{d+2}{2}}$ in Theorem 13

In Theorem 13, we assumed that there exist $0 < \delta_0 \leq \delta_1 < \infty$ and $0 < \beta < \infty$ such that $\nu([\delta_0, \delta_1]) \geq \beta$. Define $B_k := \beta^2\delta_0\delta_1^{-\frac{d+2}{2}}$. Based on the analysis carried out in Appendix D.2, in the following, we present the values of B_k for various radial kernels.

(i) Gaussian kernel: Choose $\delta_0 = \delta_1 = \frac{1}{2\eta^2}$ so that $\beta = 1$ and $B_k = (2\eta^2)^{d/2}$.

(ii) Mixture of Gaussians: Set $\delta_0 = \frac{1}{2\eta_1^2}$, $\delta_1 = \frac{1}{2\eta_M^2}$ so that $\beta = C_M$ implying $B_k = \frac{C_M^2 2^{d/2}\eta_M^{d+2}}{\eta_1^2}$.

(iii) Inverse multiquadric kernels: Choosing $\delta_0 = t_0$ and $\delta_1 = t_1$ as in Appendix D.2, we obtain

$$B_k = \begin{cases} \frac{c^{d-4\gamma}}{2\Gamma^2(\gamma)} \frac{\gamma^{2\gamma-\frac{d}{2}}}{(2e)^{2\gamma}}, & \text{for } \gamma \geq 1; \\ \frac{c^{d-4\gamma}}{8\Gamma^2(\gamma)} \frac{\gamma^{2\gamma-\frac{d}{2}}}{e^{2\gamma}}, & \text{for } \gamma \in (0,1) \end{cases}.$$

(iv) Matérn kernel: With the choice of δ_0 and δ_1 as in Appendix D.3, we obtain

$$B_k = \begin{cases} \frac{c^{-d}e^{-2\tilde{\gamma}}}{2\Gamma^2(\tilde{\gamma})} \left(\frac{\tilde{\gamma}}{2}\right)^{2\tilde{\gamma}+\frac{d}{2}}, & \text{for } \tilde{\gamma} \geq 1; \\ \frac{c^{-d}e^{-2\tilde{\gamma}}}{\Gamma^2(\tilde{\gamma})} \frac{\tilde{\gamma}^{2\tilde{\gamma}+\frac{d}{2}}}{2^{3+\frac{d}{2}}}, & \text{for } \tilde{\gamma} \in (0,1) \end{cases}.$$

Appendix E. Alternate Proof of Theorem 8

In Theorem 8 we presented a minimax lower bound for radial kernels based on an appropriate construction of d-dimensional Gaussian distributions. By a clever choice of the variance σ^2, which decays to zero as $d \to \infty$, we obtained a lower bound of the order $\Omega(n^{-1/2})$ independent of d. This result was based on the direct analysis and special properties of radial kernels. In this appendix we will show that we can recover almost the same result using only Proposition 3, which holds for any translation invariant kernel. As we will see, this leads to slightly worse constant factors and an additional lower bound on the sample size n in terms of the properties of distribution ν, which specifies the kernel. Essentially we will repeat the main steps of the proof of Theorem 8. However, we will use Proposition 3 instead of direct computations (based on the form of radial kernels) to lower bound the RKHS distance between embeddings of Gaussian distributions with the Euclidean distance between their mean vectors.

Theorem E.1 *Let $\mathcal{P}$ be the set of distributions over $\mathbb{R}^d$ whose densities are continuously infinitely differentiable and k be radial on $\mathbb{R}^d$, i.e.,*

$$k(x,y) = \int_0^\infty e^{-t\|x-y\|_2^2}\, d\nu(t),$$

where $\nu \in M_+^b([0,\infty))$ such that $\operatorname{supp}(\nu) \neq \{0\}$. Assume that there exist $0 < t_0 \leq t_1 < \infty$ and $0 < \beta < \infty$ such that $\nu([t_0, t_1]) \geq \beta$. Suppose $n \geq 24\frac{t_1 Z_\nu}{\beta t_0}$ where $Z_\nu := \nu([0,\infty))$. Then

$$\inf_{\hat{\theta}_n} \sup_{P \in \mathcal{P}} P^n \left\{ \|\hat{\theta}_n - \mu_k(P)\|_{\mathcal{H}_k} \geq \frac{1}{50}\sqrt{\frac{1}{2n} \cdot \frac{\beta t_0}{t_1 e}\left(1 - \frac{2}{2+d}\right)} \right\} \geq \frac{1}{5}.$$

Proof We apply Proposition 3 to the radial kernel k. In order to do so, we need to lower bound the quantity appearing in r.h.s. of Condition (7), which we do as follows. We already saw in the proof of Theorem 8 that in our case Λ_ψ is absolutely continuous with respect to the Lebesgue measure on $\mathbb{R}^d$ and has the following density:

$$\lambda_\psi(w) = \int_0^\infty \frac{1}{(2t)^{d/2}} e^{-\frac{\|w\|_2^2}{4t}}\, d\nu(t), \quad w \in \mathbb{R}^d.$$

Therefore the r.h.s. of (7) reduces to

$$\begin{aligned} &\frac{2}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2} \langle e_z, w\rangle^2 \cos\left(\langle a, w\rangle\right) d\Lambda_\psi(w) \\ &= \frac{2}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2} \langle e_z, w\rangle^2 \cos\left(\langle a, w\rangle\right) \left(\int_0^\infty \frac{1}{(2t)^{d/2}} e^{-\frac{\|w\|_2^2}{4t}}\, d\nu(t)\right) dw \end{aligned}$$

$$= \frac{2}{(2\pi)^{d/2}} \int_0^\infty \frac{1}{(2t)^{d/2}} \underbrace{\int_{\mathbb{R}^d} e^{-\frac{1}{2}\left(2\sigma^2+\frac{1}{2t}\right)\|w\|_2^2} \langle e_z, w\rangle^2 e^{-i\langle a,w\rangle} dw}_{\clubsuit} \, d\nu(t), \tag{52}$$

where we used Euler's formula and Tonelli-Fubini theorem in the last equality. Denoting $\delta := 2\sigma^2 + \frac{1}{2t}$, we have

$$\clubsuit = \int_{\mathbb{R}^d} \exp\left(-\frac{\delta}{2}\sum_{\ell=1}^d w_\ell^2\right)\left(\sum_{j=1}^d (e_z)_j^2 w_j^2 + \sum_{j\neq\ell}(e_z)_j(e_z)_\ell w_j w_\ell\right)\exp\left(-i\sum_{\ell=1}^d a_\ell w_\ell\right) dw$$
$$= \bigstar + \spadesuit,$$

where

$$\bigstar := \sum_{j=1}^d \int_{\mathbb{R}^d} e^{-\frac{1}{2}\delta\|w\|_2^2}(e_z)_j^2 w_j^2 e^{-i\langle a,w\rangle} dw$$

and

$$\spadesuit := \sum_{j\neq l}^d \int_{\mathbb{R}^d} e^{-\frac{1}{2}\delta\|w\|_2^2}(e_z)_j(e_z)_l w_j w_l e^{-i\langle a,w\rangle} dw.$$

Note that

$$(e_z)_j^2 \int_{\mathbb{R}^d} e^{-\frac{1}{2}\delta\|w\|_2^2} w_j^2 e^{-i\langle a,w\rangle} dw = (e_z)_j^2 \left(\prod_{\ell\neq j}\int_{-\infty}^\infty e^{-\frac{\delta}{2}w_\ell^2} e^{-ia_\ell w_\ell} dw_\ell\right)$$
$$\times \left(\int_{-\infty}^\infty e^{-\frac{\delta}{2}w_j^2} w_j^2 e^{-ia_j w_j} dw_j\right)$$
$$= (e_z)_j^2 \left(\prod_{\ell\neq j}\sqrt{\frac{2\pi}{\delta}} e^{-\frac{a_\ell^2}{2\delta}}\right)\cdot\left(\int_{-\infty}^\infty e^{-\frac{\delta}{2}w_j^2} w_j^2 e^{-ia_j w_j} dw_j\right),$$

where we used Lemma C.1. It follows from (Folland, 1999, Theorem 8.22(d)) that if $g = x^2 f \in L^1(\mathbb{R})$, then $f^\wedge$ is twice differentiable and

$$g^\wedge(y) = -\frac{\partial^2 f^\wedge(y)}{\partial^2 y},$$

which together with Lemma C.1 shows that

$$\int_{-\infty}^\infty e^{-\frac{\delta}{2}w_j^2} w_j^2 e^{-ia_j w_j} dw_j = \frac{1}{\delta}\sqrt{\frac{2\pi}{\delta}} e^{-\frac{a_j^2}{2\delta}}\left(1 - \frac{a_j^2}{\delta}\right).$$

Therefore, we get

$$(e_z)_j^2 \int_{\mathbb{R}^d} e^{-\frac{1}{2}\delta\|w\|_2^2} w_j^2 e^{-i\langle a,w\rangle} dw = (e_z)_j^2 \left(\prod_{\ell\neq j}\sqrt{\frac{2\pi}{\delta}} e^{-\frac{a_\ell^2}{2\delta}}\right)\sqrt{\frac{2\pi}{\delta}}\frac{1}{\delta} e^{-\frac{a_j^2}{2\delta}}\left(1 - \frac{a_j^2}{\delta}\right)$$
$$= \frac{(e_z)_j^2}{\delta}\left(\frac{2\pi}{\delta}\right)^{d/2} e^{-\frac{\|a\|_2^2}{2\delta}}\left(1 - \frac{a_j^2}{\delta}\right).$$

Summing over $j = 1, \ldots, d$ we get

$$\bigstar = \sum_{j=1}^d (e_z)_j^2 \int_{\mathbb{R}^d} e^{-\frac{1}{2}\delta\|w\|_2^2} w_j^2 e^{-i\langle a,w\rangle} dw = \frac{1}{\delta}\left(\frac{2\pi}{\delta}\right)^{d/2} e^{-\frac{\|a\|_2^2}{2\delta}} - \sum_{j=1}^d \frac{(e_z)_j^2 a_j^2}{\delta^2}\left(\frac{2\pi}{\delta}\right)^{d/2} e^{-\frac{\|a\|_2^2}{2\delta}}.$$

Next, for any $j \neq \ell$ we compute

$$\int_{\mathbb{R}^d} \exp\left(-\frac{\delta}{2}\sum_{\ell=1}^d w_\ell^2\right)(e_z)_j(e_z)_\ell w_j w_\ell \exp\left(-i\sum_{\ell=1}^d a_\ell w_\ell\right) dw$$
$$= (e_z)_j(e_z)_\ell \left(\prod_{q\notin\{j,\ell\}}\int_{-\infty}^\infty e^{-\frac{\delta}{2}w_q^2} e^{-ia_q w_q} dw_q\right)\left(\prod_{q\in\{j,\ell\}}\int_{-\infty}^\infty e^{-\frac{\delta}{2}w_q^2} w_q e^{-ia_q w_q} dw_q\right)$$
$$= (e_z)_j(e_z)_\ell \left(\prod_{q\notin\{j,\ell\}}\sqrt{\frac{2\pi}{\delta}} e^{-\frac{a_q^2}{2\delta}}\right)\left(\prod_{q\in\{j,\ell\}}\sqrt{\frac{2\pi}{\delta}}\frac{ia_q}{\delta} e^{-\frac{a_q^2}{2\delta}}\right)$$
$$= (e_z)_j(e_z)_\ell \left(\frac{2\pi}{\delta}\right)^{d/2} e^{-\frac{\|a\|_2^2}{2\delta}}\left(-\frac{a_j a_\ell}{\delta^2}\right).$$

Summing over $j \neq \ell$ we get

$$\spadesuit = -\frac{\langle e_z, a\rangle^2}{\delta^2}\left(\frac{2\pi}{\delta}\right)^{d/2} e^{-\frac{\|a\|_2^2}{2\delta}} + \sum_{j=1}^d \frac{(e_z)_j^2 a_j^2}{\delta^2}\left(\frac{2\pi}{\delta}\right)^{d/2} e^{-\frac{\|a\|_2^2}{2\delta}}.$$

Returning to (52), we get

$$\frac{2}{(2\pi)^{d/2}}\int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2}\langle e_z, w\rangle^2 \cos\left(\langle a, w\rangle\right) d\Lambda_\psi(w)$$
$$= \frac{2}{(2\pi)^{d/2}}\int_0^\infty \frac{1}{(2t)^{d/2}} e^{-\frac{\|a\|_2^2}{2\delta}}\left(\frac{2\pi}{\delta}\right)^{d/2}\frac{1}{\delta}\left(1 - \frac{\langle e_z, a\rangle^2}{\delta}\right) d\nu(t)$$
$$= 4\int_0^\infty \exp\left(-\frac{1}{2}\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right)\frac{t}{(4\sigma^2 t+1)^{1+d/2}}\left(1 - \frac{2t\langle e_z, a\rangle^2}{4\sigma^2 t+1}\right) d\nu(t).$$

In order to apply Proposition 3 we need to lower bound the following value, appearing in Condition (7):

$$\Delta(a) := \min_{z\in\mathbb{R}^d\setminus\{0\}} \frac{2}{(2\pi)^{d/2}}\int_{\mathbb{R}^d} e^{-\sigma^2\|w\|_2^2}\langle e_z, w\rangle^2 \cos\left(\langle a, w\rangle\right) d\Lambda_\psi(w)$$
$$= 4\int_0^\infty \exp\left(-\frac{1}{2}\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right)\frac{t}{(4\sigma^2 t+1)^{1+d/2}}\left(1 - \frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right) d\nu(t).$$

Next we will separately treat two different cases.

Case 1: $d > 2$. Note that the function $\rho(t) = t(4\sigma^2 t+1)^{-(d+2)/2}$ is positive and bounded on $[0, \infty)$ for any $d > 0$. Thus, we can define a non-negative and finite measure

$\tilde{\tau}$, absolutely continuous with respect to ν with density $\rho(t)$. If we denote $Z_\tau := \int_0^\infty 1\, d\tilde{\tau}(t)$ and write τ for the normalized version of $\tilde{\tau}$, then we can rewrite

$$\begin{aligned}\Delta(a) &= 4\int_0^\infty \exp\left(-\frac{1}{2}\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right)\left(1-\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right)d\tilde{\tau}(t)\\ &= 4\,Z_\tau \mathbb{E}_{t\sim\tau}\left[\exp\left(-\frac{1}{2}\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right)\left(1-\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right)\right]\\ &= 4\,Z_\tau \mathbb{E}_{t\sim\tau}\left[\exp\left(-\frac{1}{2}\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right)\right] - 4\,Z_\tau \mathbb{E}_{t\sim\tau}\left[\exp\left(-\frac{1}{2}\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right)\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right].\end{aligned}$$

Note that for $d>2$, $\mathbb{E}_{t\sim\tau}[|t|]$ is finite, since in this case $t\mapsto \frac{t^2}{(4\sigma^2 t+1)^{(d+2)/2}}$ is bounded and ν is a finite measure. Denote $\mu_\tau := \mathbb{E}_{t\sim\tau}[t]$ and note that $t\mapsto \exp\left(-\frac{1}{2}\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right)$ is a convex function on $[0,\infty)$. Thus, for $d>2$ we can use Jensen's inequality to get

$$\mathbb{E}_{t\sim\tau}\left[\exp\left(-\frac{1}{2}\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right)\right] \geq \exp\left(-\frac{1}{2}\frac{2\mu_\tau\|a\|_2^2}{4\sigma^2\mu_\tau+1}\right).$$

Also note that

$$-4\,Z_\tau\mathbb{E}_{t\sim\tau}\left[\exp\left(-\frac{1}{2}\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right)\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right] \geq 4\,Z_\tau\mathbb{E}_{t\sim\tau}\left[-\frac{2t\|a\|_2^2}{4\sigma^2 t+1}\right] \geq -4\,Z_\tau\frac{2\mu_\tau\|a\|_2^2}{4\sigma^2\mu_\tau+1},$$

where we used inequality $e^{-x}\leq 1$, which holds for $x\geq 0$, together with Jensen's inequality and the fact that $t\mapsto -\frac{2t\|a\|_2^2}{4\sigma^2 t+1}$ is concave on $[0,\infty)$. Summarizing, we have

$$\begin{aligned}\Delta(a) &\geq 4Z_\tau\left(\exp\left(-\frac{1}{2}\frac{2\mu_\tau\|a\|_2^2}{4\sigma^2\mu_\tau+1}\right)-\frac{2\mu_\tau\|a\|_2^2}{4\sigma^2\mu_\tau+1}\right)\\ &\geq 4Z_\tau\left(1-\frac{1}{2}\frac{2\mu_\tau\|a\|_2^2}{4\sigma^2\mu_\tau+1}-\frac{2\mu_\tau\|a\|_2^2}{4\sigma^2\mu_\tau+1}\right)\\ &= 2Z_\tau\left(2-3\frac{2\mu_\tau\|a\|_2^2}{4\sigma^2\mu_\tau+1}\right),\end{aligned}$$

where we used a simple inequality $e^x\geq 1+x$. If the following condition is satisfied:

$$\frac{2\mu_\tau\|a\|_2^2}{4\sigma^2\mu_\tau+1}\leq\frac{1}{3}, \tag{53}$$

then we get

$$\Delta(a)\geq 2Z_\tau = 2\int_0^\infty \frac{t}{(4\sigma^2 t+1)^{1+d/2}}d\nu(t). \tag{54}$$

Together with Proposition 3 this leads to the following lower bound, which holds for any $\mu_0,\mu_1\in\mathbb{R}^d$ and $\sigma^2>0$ satisfying (53) with $a:=\mu_0-\mu_1$:

$$\|\theta_0-\theta_1\|_{\mathcal{H}_k}^2 \geq \int_0^\infty \frac{t\|\mu_0-\mu_1\|_2^2}{(4\sigma^2 t+1)^{1+d/2}}d\nu(t),$$

where θ_0 and θ_1 are KME's of Gaussian measures $G(\mu_0,\sigma^2 I)$ and $G(\mu_1,\sigma^2 I)$ respectively. Note that this lower bound is identical to the one in (27), which we obtained using direct analysis for the radial kernels. However, condition (26) is now replaced with the stronger one in (53). We can now repeat the proof of Theorem 8 starting from inequality (27) and making sure that condition (53) is satisfied when we choose constants appearing in definitions of μ_0,μ_1 and σ^2.

In order to check condition (53) we need to upper bound the expectation μ_τ. It is easily seen that for $d>2$, $t\mapsto\frac{t^2}{(4\sigma^2 t+1)^{(d+2)/2}}$ achieves its maximum on $[0,\infty)$ for $t^*=\frac{1}{\sigma^2(d-2)}$. Using this fact, denoting $Z_\nu=\int_0^\infty 1\,d\nu(t)$, and setting $\sigma^2=\frac{1}{2t_1 d}$ we get

$$\begin{aligned}\mu_\tau &= \frac{1}{Z_\tau}\int_0^\infty\frac{t^2}{(4\sigma^2 t+1)^{1+d/2}}d\nu(t)\leq\frac{Z_\nu}{Z_\tau}\frac{(t^*)^2}{(4\sigma^2 t^*+1)^{1+d/2}}\\ &= \frac{4t_1^2 Z_\nu}{Z_\tau}\frac{d^2}{(d-2)^2}\frac{1}{(\frac{4}{d-2}+1)^{1+d/2}}\\ &= \frac{4t_1^2 Z_\nu}{Z_\tau}\left(1+\frac{2}{d-2}\right)^2\left(\left(1-\frac{4}{d+2}\right)^{(d+2)/4}\right)^2\leq\frac{4t_1^2 Z_\nu}{Z_\tau e^2}\left(1+\frac{2}{d-2}\right)^2.\end{aligned}$$

We may finally use (29) to get

$$Z_\tau\geq\frac{\beta t_0}{e}\left(1-\frac{2}{d+2}\right),$$

which leads to the following upper bound on the expectation μ_τ:

$$\mu_\tau\leq\frac{4t_1^2 Z_\nu}{\beta t_0 e}\frac{d(d+2)}{(d-2)^2}.$$

This upper bound shows that the condition (53) is satisfied if the following holds:

$$t_1\|a\|_2^2\leq\frac{2}{3}t_1\sigma^2+\frac{\beta t_0 e}{24t_1 Z_\nu}\frac{(d-2)^2}{d(d+2)}. \tag{55}$$

We conclude the proof by repeating the remaining steps of the proof of Theorem 8 and replacing condition (26) on the value $\|\mu_0-\mu_1\|_2^2$ with (55) specified to $a=\mu_0-\mu_1$.

Case 2: $d\leq 2$. We can use a simple inequality $e^{-x/2}(1-x)\geq 1-3x/2$ which holds for any x and get the following lower bound:

$$\Delta(a)\geq 4\int_0^\infty\frac{t}{(4\sigma^2 t+1)^{1+d/2}}\left(1-\frac{3t\|a\|_2^2}{4\sigma^2 t+1}\right)d\nu(t).$$

Assuming $\|a\|_2^2\leq\sigma^2$ we further get

$$\left(1-\frac{3t\|a\|_2^2}{4\sigma^2 t+1}\right)\geq\left(1-\frac{3t\sigma^2}{4\sigma^2 t+1}\right)\geq\left(1-\frac{3t\sigma^2}{4\sigma^2 t}\right)=\frac{1}{4}$$

and as a consequence, we also get

$$\Delta(a) \geq \int_0^\infty \frac{t}{(4\sigma^2 t + 1)^{1+d/2}} d\nu(t),$$

which coincides with (54) up to an additional factor of 2. We can now repeat all the steps for the previous case, and it is also easy to check that in this case $\|\mu_0 - \mu_1\|_2^2 \leq \sigma^2$ will be indeed satisfied. This concludes the proof. ■

Remark E.2 *This result should be compared to Theorem 8, which was based on the direct analysis for radial kernels. We see that apart from an extra factor* 2 *appearing under the square root in the lower bound, Theorem E.1 also requires a superfluous condition on the minimal sample size* n*, which depends on properties of* ν*. For instance, for Gaussian kernel with* ν *concentrated on a single point* $\frac{1}{2\eta^2}$ *for some* $\eta^2 > 0$*, the result holds as long as* $n \geq 24$*, because in this case we can take* $t_0 = t_1 = \frac{1}{2\eta^2}$ *and* $\beta = 1$*. However, other choices of* ν *may lead to quite restrictive lower bounds on* n*.*

Remark E.3 *Conceptually, the main difference between the proofs of Theorems 8 and E.1 lies in the way we lower bound the RKHS distance between embeddings of Gaussian measures with the Euclidean distance between their mean vectors. In Theorem 8 we derived a closed-form expression for the RKHS distance in* (25) *and then lower bounded it directly using the properties specific to its form. On the other hand, in Theorem E.1 we resorted to the lower bound of Lemma 3, which holds for any translation invariant kernel and hence is less tight.*

Abstract

Clustering is a central approach for unsupervised learning. After clustering is applied, the most fundamental analysis is to quantitatively compare clusterings. Such comparisons are crucial for the evaluation of clustering methods as well as other tasks such as consensus clustering. It is often argued that, in order to establish a baseline, clustering similarity should be assessed in the context of a random ensemble of clusterings. The prevailing assumption for the random clustering ensemble is the permutation model in which the number and sizes of clusters are fixed. However, this assumption does not necessarily hold in practice; for example, multiple runs of K-means clustering returns clusterings with a fixed number of clusters, while the cluster size distribution varies greatly. Here, we derive corrected variants of two clustering similarity measures (the Rand index and Mutual Information) in the context of two random clustering ensembles in which the number and sizes of clusters vary. In addition, we study the impact of one-sided comparisons in the scenario with a reference clustering. The consequences of different random models are illustrated using synthetic examples, handwriting recognition, and gene expression data. We demonstrate that the choice of random model can have a drastic impact on the ranking of similar clustering pairs, and the evaluation of a clustering method with respect to a random baseline; thus, the choice of random clustering model should be carefully justified.

Keywords: clustering comparison, clustering evaluation, adjustment for chance, Rand index, normalized mutual information

1. Introduction

Clustering is one of the most fundamental techniques of unsupervised learning and one of the most common ways to analyze data. Naturally, numerous methods have been developed and studied (Jain, 2010). To interpret clustering results, it is crucial to compare them to each other. For instance, the evaluation of a clustering method is usually carried out by comparing the method's results with a planted reference clustering, assuming that the more similar the method's solution is to the reference clustering, the better the method. This is particularly common in the field of complex networks in which clustering similarity measures are used to justify the performance of community detection methods (Danon et al., 2005; Lancichinetti and Fortunato, 2009). As quantitative comparison is a fundamental operation, it plays a key role in many other tasks. For instance, comparisons of clusterings can facilitate taxonomies for clustering solutions, can be used as a criteria for parameter estimation, and form the basis of consensus clustering methods (Meila, 2005; Vinh et al., 2009; Yeung et al., 2001).

Among the many clustering comparison methods (see, e.g. Meila, 2005; Pfitzner et al., 2009), two of the most prominent measures are the Rand index (Rand, 1971) and the Normalized Mutual Information (NMI, Danon et al., 2005). In both cases, the similarity score exists in the range $[0, 1]$, where 1 corresponds to identical clusterings and 0 implies maximally dissimilar clusterings. However, in practice, both measures do not efficiently use the full range of values in between 0 and 1, with many comparisons concentrating near the extreme values (Vinh et al., 2009; Hubert and Arabie, 1985). This makes it difficult to directly interpret the results of a comparison.

Thus, it is often argued that clustering similarity should be assessed in the context of a random ensemble of clusterings (Vinh et al., 2009; Hubert and Arabie, 1985; DuBien and Warde, 1981; DuBien et al., 2004; Albatineh et al., 2006; Romano et al., 2014; Zhang, 2015; Romano et al., 2016) and rescaled (see Equation 1). Such a correction for chance establishes a baseline by using the expected similarity of all pair-wise comparisons between clusterings specified by a random model; the resulting similarity values have a new interpretation that facilitates comparisons within a set of clusterings. Specifically, once corrected for chance, a similarity value of 1 still corresponds to identical clusterings, but a value of 0 now corresponds to the expected value amongst random clusterings. Positive values of corrected similarity better reflect an intuitive comparison of clusterings (Hubert and Arabie, 1985; Steinley et al., 2016). The correction may also introduce negative values when two clusterings are less similar than expected by chance.

The correction procedure requires two choices: *a model for random clusterings* and *how clusterings are drawn from the random model*. However, even the existence of these choices is usually ignored or relegated to the status of technical trivialities. Here, we demonstrate that these choices may dramatically affect results, and therefore the choice of a particular model for random clusterings should be justified based on the understanding of the clustering scenario. A poor choice of the random model may "not be random enough" and encode crucial features of the clusterings in all of the random clusterings, providing a poor baseline. At the same time, a random model may be "too random" in which crucial features are lost in a sea of random clusterings that are not representative of the particular problem. Characterizing random models is an important topic of research across statistical physics, network science, and combinatorial mathematics (Sethna, 2006; Goldenberg et al., 2010; Mansour, 2012). Yet, despite the importance of random model selection, almost no study that uses clustering comparison provides a justification for their choice of random model.

By far, the most common approach to correct clustering similarity for chance assumes that both clusterings are uniformly and independently sampled from the *permutation model* (M_{perm}). In the permutation model, the number and size of clusters within a clustering are fixed, and all random clusterings are generated by shuffling the elements between the fixed clusters. However, the premises of the permutation model are frequently violated; in many clustering scenarios, either the number of clusters, the size distribution of those clusters, or both vary drastically (Hubert and Arabie, 1985; Wallace, 1983). For example, K-means clustering, probably the most common technique, fixes the number of clusters but not the sizes of those clusters (Jain, 2010). Later, we explore a real example in which K-means

produces clusterings with large variations in the clusterings' cluster size sequences. This suggests that comparing K-means clusterings based on M_{perm} is misleading.

Furthermore, even the assumption that both clusterings were randomly drawn from the same random model (a two-sided comparison) is often problematic. For example, when comparing against a given reference clustering, it is more reasonable to find the expected similarity of the reference clustering with all of the random clusterings from the random model. This *one-sided* comparison accounts for the fixed structure of the reference clustering which is always present in the comparisons, providing a more meaningful baseline.

Here, we present a general framework to adjust measures of clustering similarity for chance by considering a broader class of random clustering models and one-sided comparisons. Specifically, we consider two other random models for clusterings: a uniform distribution over the ensemble of all clusterings of N elements with the same number of clusters (M_{num}), and a uniform distribution over the ensemble of all clusterings of N elements (M_{all}). The resulting expectations for the Rand index under all three random models are summarized in Table 1 and for Mutual Information in Table 2, with the full derivations given in Section 4 and Section 5 respectively. The adjusted similarity measures used throughout this work rescale the Rand and MI measures by these expectations according to Equation 1. We

Table 2: The expected Mutual Information between two random clusterings $\mathcal{A}$ and $\mathcal{B}$ of N elements, or random clustering $\mathcal{A}$ and reference clustering $\mathcal{G}$ under different random models. Details and derivations are given in Section 5.

also introduce one-sided variants of the adjusted Rand index and adjusted Mutual Information when using the M_{num} or M_{all} random models (for M_{perm}, the one-sided similarity is equivalent to the two-sided case).

The impact of our framework is illustrated in the case of two common tasks for adjusted clustering similarity measures: 1) ranking the similarity between pairs of clusterings (or finding the most similar clustering pair), and 2) evaluating the performance of a clustering method with respect to a random baseline. In Section 6, these tasks are demonstrated in the context of several examples: a synthetic clustering example, K-means clustering of a handwritten digits data set (MNIST), and an evaluation of hierarchical clustering applied to gene expression data. Our results demonstrate that both the choice of random model for clusterings and the choice of one-sided comparisons can affect results significantly. Therefore, we argue that clustering comparisons should be accompanied by a proper justification for the random model.

2. Clusterings

We first explicitly introduce a clustering of elements. Given a set of N distinct elements $V = \{v_1, \ldots, v_N\}$ (i.e. data points or vertices), a clustering is a partition of V into a set $\mathcal{C} = \{C_1, \ldots, C_{K_\mathcal{C}}\}$ of $K_\mathcal{C}$ non-empty disjoint subsets of V, the clusters, C_k, such that

1. $\forall C_i, C_j$ if $i \neq j$, then $C_i \cap C_j = \varnothing$
2. $\bigcup_{k=1}^{K_\mathcal{C}} C_k = V$.

Each clustering specifies a sequence of cluster sizes, namely, letting $c_i = |C_i|$ be the size of the i-th cluster, then the sequence of cluster sizes is $[c_1, c_2, \ldots, c_{K_\mathcal{C}}]$.

Throughout this paper, we focus on the similarity of two clusterings over the same set of N labeled elements, $\mathcal{A} = \{A_1, \ldots, A_{K_\mathcal{A}}\}$ (with $K_\mathcal{A}$ clusters of sizes a_i) and $\mathcal{B} = \{B_1, \ldots, B_{K_\mathcal{B}}\}$ (with $K_\mathcal{B}$ clusters of sizes b_j).

3. Correction for Chance

Given a clustering similarity measure s and a random model for clusterings: model, the expected clustering similarity $\mathbb{E}_{\text{model}}[s]$ of pair-wise comparisons within the random ensemble defined by the model corrects s for chance as follows (Hubert and Arabie, 1985)

$$\frac{s - \mathbb{E}_{\text{model}}[s]}{s_{\max} - \mathbb{E}_{model}[s]}. \tag{1}$$

The denominator rescales the adjusted similarity by the maximum similarity of pair-wise comparisons within the ensemble $s_{\max}$ so identical clusterings always have a similarity of 1.0. For some clustering similarity measures, the value of $s_{\max}$ is independent of the random model used; for example, the Rand index is always bounded above by 1.0. However, in the case of mutual information, the value of $s_{\max}$ depends on the random model used.

4. Rand Index

The Rand index (Rand, 1971) compares the number of element pairs which are either co-assigned to the same cluster, or assigned to different clusters in both clusterings, to the

$\mathcal{A}/\mathcal{B}$	B_1	B_2	$\ldots$	$B_{K_\mathcal{B}}$	Sums
A_1	n_{11}	n_{12}	$\ldots$	$n_{1K_\mathcal{B}}$	a_1
A_2	n_{21}	n_{22}	$\ldots$	$n_{2K_\mathcal{B}}$	a_2
$\vdots$	$\vdots$	$\vdots$	$\ddots$	$\vdots$	$\vdots$
$A_{K_\mathcal{A}}$	$n_{K_\mathcal{A}1}$	$n_{K_\mathcal{A}2}$	$\ldots$	$n_{K_\mathcal{A}K_\mathcal{B}}$	$a_{K_\mathcal{A}}$
Sums	b_1	b_2	$\ldots$	$b_{K_\mathcal{B}}$	$\sum_{ij} n_{ij} = N$

Table 3: The contingency table $\mathcal{T}$ for two clusterings $\mathcal{A} = \{A_1, \ldots, A_{K_\mathcal{A}}\}$ and $\mathcal{B} = \{B_1, \ldots, B_{K_\mathcal{B}}\}$ of N elements, where $n_{ij} = |A_i \cap B_j|$ are the number of elements that are in both cluster $A_i \in \mathcal{A}$ and cluster $B_j \in \mathcal{B}$.

total number of element pairs. The most common formulation of the Rand index focuses on the following four sets of the $\binom{N}{2}$ element pairs: N_{11} the number of element pairs which are grouped in the same cluster in both clusterings, N_{10} the number of element pairs which are grouped in the same cluster by $\mathcal{A}$ but in different clusters by $\mathcal{B}$, N_{01} the number of element pairs which are grouped in the same cluster by $\mathcal{B}$ but in different clusters by $\mathcal{A}$, and N_{00} the number of element pairs which are grouped in different clusters by both $\mathcal{A}$ and $\mathcal{B}$. Intuitively, N_{11} and N_{00} are indicators of the agreement between the two clusterings, while N_{10} and N_{01} reflect the disagreement between the clusterings.

The aforementioned pair counts are identified from the contingency table $\mathcal{T}$ between two clusterings, shown in Table 3, by the following set of equations

$$\begin{aligned}
N_{11} &= \sum_{k,m=1}^{K_\mathcal{A},K_\mathcal{B}} \binom{n_{km}}{2} = \frac{1}{2}\left(\sum_{k,m=1}^{K_\mathcal{A},K_\mathcal{B}} n_{km}^2 - N\right) \\
N_{10} &= \sum_{k=1}^{K_\mathcal{A}} \binom{a_k}{2} - N_{11} = \frac{1}{2}\left(\sum_{k=1}^{K_\mathcal{A}} a_k^2 - \sum_{k,m=1}^{K_\mathcal{A},K_\mathcal{B}} n_{km}^2\right) \\
N_{01} &= \sum_{m=1}^{K_\mathcal{B}} \binom{b_m}{2} - N_{11} = \frac{1}{2}\left(\sum_{m=1}^{K_\mathcal{B}} b_m^2 - \sum_{k,m=1}^{K_\mathcal{A},K_\mathcal{B}} n_{km}^2\right) \\
N_{00} &= \binom{N}{2} - N_{11} - N_{10} - N_{01}
\end{aligned} \tag{2}$$

The Rand index between clusterings $\mathcal{A}$ and $\mathcal{B}$, $\text{RI}(\mathcal{A}, \mathcal{B})$ is then given by the function

$$\begin{aligned}
\text{RI}(\mathcal{A}, \mathcal{B}) &= \frac{N_{11} + N_{00}}{\binom{N}{2}} \\
&= \frac{2\sum_{k,m=1}^{K_\mathcal{A},K_\mathcal{B}} \binom{n_{km}}{2} - \sum_{k=1}^{K_\mathcal{A}} \binom{a_k}{2} - \sum_{m=1}^{K_\mathcal{B}} \binom{b_m}{2} + \binom{N}{2}}{\binom{N}{2}}.
\end{aligned} \tag{3}$$

It lies between 0 and 1, where 1 indicates the clusterings are identical and 0 occurs for clusters which do not share a single pair of elements (this only happens when one clustering

is the full set of elements and the other clustering groups each element into its own cluster). As the number of clustered elements increases, the measure becomes dominated by the number of pairs which were classified into different clusters (N_{00}), resulting in decreased sensitivity to co-occurring element pairs (Fowlkes and Mallows, 1983).

Another formulation of the Rand index, used in our later derivations, focuses on a binary representation of the element pairs. Specifically, consider the vector $U_{\mathcal{A}} = [u_1, \ldots, u_{\binom{N}{2}}]$ with binary entries $u_\alpha \in \{-1, 1\}$ corresponding to all possible element pairs. Using α to index over all element pairs by $\alpha = \binom{N}{2} - \binom{N-i+1}{2} + j - i$, for $i < j \leq N$, then $u_\alpha = 1$ if elements v_i and v_j are in the same cluster in $\mathcal{A}$ and $u_\alpha = -1$ if elements v_i and v_j are in different clusters in $\mathcal{A}$. There are $Q_1^{\mathcal{A}}$ 1s in $U_{\mathcal{A}}$ and $Q_{-1}^{\mathcal{A}}$ -1s in $U_{\mathcal{A}}$ with

$$Q_1^{\mathcal{A}} = \sum_{k=1}^{K_{\mathcal{A}}} \binom{a_k}{2}, \quad Q_{-1}^{\mathcal{A}} = \binom{N}{2} - \sum_{k=1}^{K_{\mathcal{A}}} \binom{a_k}{2}. \tag{4}$$

The Rand index is found from the vectors $U_{\mathcal{A}}$ and $U_{\mathcal{B}}$, for clusterings $\mathcal{A}$ and $\mathcal{B}$ respectively, as the number of 1s in their product vector, $U_{\mathcal{A}} \odot U_{\mathcal{B}}$, using element-wise multiplication and normalized by the total size of the vectors, $\binom{N}{2}$.

4.1 Expected Rand Index, Permutation Model (M_{perm})

The expectation of the Rand index with respect to the permutation model follows from drawing the entries in Table 3 from the generalized hypergeometric distribution. Utilizing the previous notation with $Q_1^{\mathcal{A}} = \sum_{k=1}^{K_{\mathcal{A}}} \binom{a_k}{2}$, the expectation $\mathbb{E}_{\text{perm}}[RI(\mathcal{A}, \mathcal{B})]$ of the Rand index with respect to the permutation model for the cluster size sequences of clusterings $\mathcal{A}$ and $\mathcal{B}$ is given by

$$\mathbb{E}_{\text{perm}}[\text{RI}(\mathcal{A}, \mathcal{B})] = \frac{2Q_1^{\mathcal{A}}Q_1^{\mathcal{B}} - \binom{N}{2}\left(Q_1^{\mathcal{A}} + Q_1^{\mathcal{B}}\right) + \binom{N}{2}^2}{\binom{N}{2}^2} \tag{5}$$

(see Fowlkes and Mallows, 1983, Hubert and Arabie, 1985, or Albatineh and Niewiadomska-Bugaj, 2011 for the full derivation).

The commonly used adjusted Rand index (ARI) of Hubert and Arabie (1985) uses M_{perm} to calculate the expectation of the Rand index, $\mathbb{E}_{\text{perm}}[\text{RI}(\mathcal{A}, \mathcal{B})]$, as found in Equation 5. This expectation is then used in Equation 1, along with the fact that the maximum value of the Rand index is $\max_{\text{perm}}[\text{RI}] = 1.0$, to give

$$\text{ARI}_{\text{perm}}(\mathcal{A}, \mathcal{B}) = \frac{\binom{N}{2}\sum_{k,m=1}^{K_{\mathcal{A}}K_{\mathcal{B}}} \binom{n_{km}}{2} - \sum_{k=1}^{K_{\mathcal{A}}} \binom{a_k}{2} \sum_{m=1}^{K_{\mathcal{B}}} \binom{b_m}{2}}{\frac{1}{2}\binom{N}{2}\left[\sum_{k=1}^{K_{\mathcal{A}}} \binom{a_k}{2} + \sum_{m=1}^{K_{\mathcal{B}}} \binom{b_m}{2}\right] - \sum_{k=1}^{K_{\mathcal{A}}} \binom{a_k}{2} \sum_{m=1}^{K_{\mathcal{B}}} \binom{b_m}{2}}. \tag{6}$$

4.2 Expected Rand Index, Fixed Number of Clusters

We follow DuBien and Warde (1981) to calculate the Rand index between two clusterings under the assumptions that both clusterings were independently and uniformly drawn from the ensemble of clusterings with a fixed number of clusters (M_{num}). Recall that the Rand index between two clusterings $\mathcal{A}$ and $\mathcal{B}$ is given by the number of 1s in the element-wise

product of the binary representations vectors $U_{\mathcal{A}}$ and $U_{\mathcal{B}}$. The expected Rand index under any random model is then the expected number of 1s in this product vector, normalized by the total size of the vector

$$\begin{aligned}\mathbb{E}[RI(\mathcal{A}, \mathcal{B})] &= \mathbb{E}\left[\frac{1}{\binom{N}{2}} \sum_{\alpha=1}^{\binom{N}{2}} \mathbf{1}_{u_\alpha^{\mathcal{A}} \cdot u_\alpha^{\mathcal{B}} = 1}\right] \\ &= \frac{1}{\binom{N}{2}} \sum_{\alpha=1}^{\binom{N}{2}} \mathbb{E}\left[\mathbf{1}_{u_\alpha^{\mathcal{A}} \cdot u_\alpha^{\mathcal{B}} = 1}\right] \\ &= \frac{1}{\binom{N}{2}} \sum_{\alpha=1}^{\binom{N}{2}} P(u_\alpha^{\mathcal{A}} \cdot u_\alpha^{\mathcal{B}} = 1)\end{aligned} \tag{7}$$

The product $u_\alpha^{\mathcal{A}} \cdot u_\alpha^{\mathcal{B}}$ equals 1 when either $u_\alpha^{\mathcal{A}} = 1$ and $u_\alpha^{\mathcal{B}} = 1$, or $u_\alpha^{\mathcal{A}} = -1$ and $u_\alpha^{\mathcal{B}} = -1$. Since we assumed both clusterings were independent, this gives

$$P(u_\alpha^{\mathcal{A}} \cdot u_\alpha^{\mathcal{B}} = 1) = P(u_\alpha^{\mathcal{A}} = 1)P(u_\alpha^{\mathcal{B}} = 1) + P(u_\alpha^{\mathcal{A}} = -1)P(u_\alpha^{\mathcal{B}} = -1) \tag{8}$$

where $P(u_\alpha^{\mathcal{A}} = 1)$ is the probability that the two elements v_i and v_j are in the same cluster in clustering $\mathcal{A}$, where the element pair is indexed by $\alpha = \binom{N}{2} - \frac{(N-i)(N-i+1)}{2} + j - i$ with $i < j \leq N$. Likewise, $P(u_\alpha^{\mathcal{A}} = -1)$ is the probability that the two elements v_i and v_j are in different clusters.

Under the assumption of M_{num}, there is a uniform probability of selecting a clustering from the $S(N, K_{\mathcal{A}})$ clusterings of N elements into $K_{\mathcal{A}}$ clusters; we define, $P_{\text{num}}(u_\alpha^{\mathcal{A}} = 1)$ as the proportion of these clusterings with elements v_i and v_j in the same cluster. To find this proportion, notice that we can ensure v_i is in the same cluster as v_j by first partitioning all elements besides v_i into $K_{\mathcal{A}}$ clusters; then, we can add v_i to the same cluster as v_j. Since there are $S(N-1, K_{\mathcal{A}})$ such clusterings without element v_i, this gives

$$P_{\text{num}}(u_\alpha^{\mathcal{A}} = 1) = \frac{S(N-1, K_{\mathcal{A}})}{S(N, K_{\mathcal{A}})} \tag{9}$$

$$P_{\text{num}}(u_\alpha^{\mathcal{A}} = -1) = 1 - \frac{S(N-1, K_{\mathcal{A}})}{S(N, K_{\mathcal{A}})}. \tag{10}$$

Finally, the expected Rand index between two clusterings $\mathcal{A}$ and $\mathcal{B}$ with $K_{\mathcal{A}}$ and $K_{\mathcal{B}}$ clusters assuming M_{num} is given by

$$\begin{aligned}\mathbb{E}_{\text{num}}[\text{RI}(\mathcal{A}, \mathcal{B})] = &\frac{S(N-1, K_{\mathcal{A}})}{S(N, K_{\mathcal{A}})} \frac{S(N-1, K_{\mathcal{B}})}{S(N, K_{\mathcal{B}})} \\ &+ \left(1 - \frac{S(N-1, K_{\mathcal{A}})}{S(N, K_{\mathcal{A}})}\right)\left(1 - \frac{S(N-1, K_{\mathcal{B}})}{S(N, K_{\mathcal{B}})}\right).\end{aligned} \tag{11}$$

When N is large, we can approximate the Stirling numbers of the second kind for a fixed K by $S(N, K) \approx \frac{K^N}{K!}$. This can be inserted into equation (11) to give the following approximation for the mean of the Rand index assuming M_{num}

$$\mathbb{E}_{\text{num}}[\text{RI}(\mathcal{A}, \mathcal{B})] \approx \frac{1}{K_{\mathcal{A}}K_{\mathcal{B}}} + \left(1 - \frac{1}{K_{\mathcal{A}}}\right)\left(1 - \frac{1}{K_{\mathcal{B}}}\right). \tag{12}$$

Interestingly, this suggests that the Rand index goes to 1 at a rate inversely related to the smaller number of clusters $\mathcal{O}(\max\{K_{\mathcal{A}}^{-1}, K_{\mathcal{B}}^{-1}\})$.

4.3 Expected Rand Index, All Clusterings M_{all}

The average of the Rand index between two clusterings under the assumption that the clusterings were drawn with uniform probability from the set of all clusterings directly follows from the random model with a fixed number of clusters previously discussed. Namely, because Bell numbers are related to Stirling numbers of the second kind by $B_N = \sum_{k=1}^{N} S(N,k)$, a similar reasoning as followed for equation (9) gives

$$\begin{aligned} P_{\text{all}}(u_\alpha = 1) &= \sum_{k=1}^{N} \frac{S(N,k)}{B_N} P_{\text{num}}(u_\alpha^k = 1) \qquad (13) \\ &= \frac{1}{B_N} \sum_{k=1}^{N} S(N,k) \frac{S(N-1,k)}{S(N,k)} \\ &= \frac{B_{N-1}}{B_N}. \qquad (14) \end{aligned}$$

Using this probability for the expectation in equation (7) gives the expected Rand index under the assumption that both clusterings were uniformly drawn from the set of all clusterings of N elements

$$\mathbb{E}_{\text{all}}[\text{RI}(\mathcal{A},\mathcal{B})] = \left(\frac{B_{N-1}}{B_N}\right)^2 + \left(1 - \frac{B_{N-1}}{B_N}\right)^2. \qquad (15)$$

When N is large, we can approximate the ratio of successive Bell numbers by $\frac{B_{N+1}}{B_N} \approx \frac{N}{\log N}$. Using this approximation in equation (15) gives the following approximation for the mean of the Rand index in M_{all}

$$\mathbb{E}_{\text{all}}[\text{RI}(\mathcal{A},\mathcal{B})] \approx \left(\frac{\log N}{N}\right)^2 + \left(1 - \frac{\log N}{N}\right)^2. \qquad (16)$$

Interestingly, this suggests that the expected Rand index between two random clusterings goes to 1 at a rate $\mathcal{O}\left(\frac{\log(N)}{N}\right)$, inversely proportional to the number of elements.

4.4 One-Sided Rand

Consider a reference clustering $\mathcal{G}$ that has the cluster size sequence $[g_1, \ldots, g_{K_\mathcal{G}}]$. The binary pair vector representation of $\mathcal{G}$ has $Q_1^{\mathcal{G}}$ 1s and $Q_{-1}^{\mathcal{G}} = \binom{N}{2} - Q_1^{\mathcal{G}}$, -1s. The one-sided expectation of the Rand index under the assumption that clustering $\mathcal{A}$ was randomly drawn from either the M_{num} or M_{all} random models follows from treating the two clusterings independently as in equation (8). Since the cluster sequence for the reference clustering is fixed, the probability that a random entry in the binary pair vector is 1 is given by the

fraction of 1s in the vector

$$\begin{aligned} P_{\text{num}}(u_\alpha^{\mathcal{G}} = 1) &= \frac{1}{\binom{N}{2}} Q_1^{\mathcal{G}} \qquad (17) \\ &= \frac{1}{\binom{N}{2}} \sum_{i=1}^{K_\mathcal{G}} \binom{g_i}{2}. \end{aligned}$$

The one-sided expectation of the Rand index under the assumption that clustering $\mathcal{A}$ was randomly drawn from the set of all clusterings with a fixed number of clusters M_{num}^1 is

$$\mathbb{E}_{\text{num}}^1[\text{RI}(\mathcal{A},\mathcal{G})] = \left(\frac{S(N-1,K_\mathcal{A})}{S(N,K_\mathcal{A})} \frac{Q_1^{\mathcal{G}}}{\binom{N}{2}}\right) + \left(1 - \frac{S(N-1,K_\mathcal{A})}{S(N,K_\mathcal{A})}\right)\left(1 - \frac{Q_1^{\mathcal{G}}}{\binom{N}{2}}\right). \qquad (18)$$

The one-sided expectation of the Rand index with the assumption that the random clustering $\mathcal{A}$ is drawn from the ensemble of all partitions M_{all}^1 is

$$\mathbb{E}_{\text{all}}^1[\text{RI}(\mathcal{A},\mathcal{G})] = \frac{B_{N-1}}{B_N} \frac{Q_1^{\mathcal{G}}}{\binom{N}{2}} + \left(1 - \frac{B_{N-1}}{B_N}\right)\left(1 - \frac{Q_1^{\mathcal{G}}}{\binom{N}{2}}\right). \qquad (19)$$

5. Mutual Information

Another prominent family of clustering similarity measures is based on the Shannon information between probabilistic representations of each clustering. These probability distributions are also calculated from the contingency table $\mathcal{T}$, Table 3. The partition entropy H of a clustering $\mathcal{A}$ is given by

$$H(\mathcal{A}) = -\sum_{k=1}^{K_\mathcal{A}} \frac{a_k}{N} \log \frac{a_k}{N}. \qquad (20)$$

Using this entropy, the mutual information $\text{MI}(\mathcal{A},\mathcal{B})$ between two clusterings $\mathcal{A}$ and $\mathcal{B}$ is given by

$$\begin{aligned} \text{MI}(\mathcal{A},\mathcal{B}) &= H(\mathcal{A}) + H(\mathcal{B}) - H(\mathcal{A},\mathcal{B}) \\ &= \sum_{k,m=1}^{K_\mathcal{A},K_\mathcal{B}} \frac{n_{km}}{N} \log \frac{n_{km} N}{a_k b_m}. \qquad (21) \end{aligned}$$

The mutual information can be interpreted as an inverse measure of independence between the clusterings, or a measure of the amount of information each clustering has about the other. As it can vary in the range $[0, \min\{H(\mathcal{A}), H(\mathcal{B})\}]$, to facilitate comparisons, it is desirable to normalize it to the range $[0,1]$. There are at least six proposals in the literature for this upper bound, each with different advantages and drawbacks

$$\begin{aligned} &\min\{H(\mathcal{A}), H(\mathcal{B})\} \leq \sqrt{H(\mathcal{A})H(\mathcal{B})} \leq \frac{H(\mathcal{A}) + H(\mathcal{B})}{2} \qquad (22) \\ &\leq \max\{H(\mathcal{A}), H(\mathcal{B})\} \leq \max\{\log K_\mathcal{A}, \log K_\mathcal{B}\} \leq \log N. \end{aligned}$$

The resulting measures are all known as normalized mutual information (NMI). This measure has been said to exhibit more desirable properties than the Rand index; for example, it is dependent on the relative proportions of the cluster sizes in each clustering rather than the number of elements. However, due to its dependence on the number of clusters in each clustering, it is known to favor comparisons between clusterings with more clusters regardless of any other shared clustering features (White and Liu, 1994; Vinh et al., 2010; Amelio and Pizzuti, 2015).

5.1 Expected Mutual Information, Permutation Model ($M_{\mathbf{perm}}$)

The mutual information between two clusterings has also previously been studied under the assumption that both clusterings were randomly generated from the permutation model (Vinh et al., 2009; Romano et al., 2014; Vinh et al., 2010). Expanding the definition of the mutual information gives

$$\begin{aligned}\mathbb{E}_{\text{perm}}[\text{MI}(\mathcal{A},\mathcal{B})] &= \mathbb{E}_{\text{perm}}[H(\mathcal{A})] + \mathbb{E}_{\text{perm}}[H(\mathcal{B})] - \mathbb{E}_{\text{perm}}[H(\mathcal{A},\mathcal{B})] \\ &= H(\mathcal{A}) + H(\mathcal{B}) - \mathbb{E}_{\text{perm}}[H(\mathcal{A},\mathcal{B})]\end{aligned} \tag{23}$$

where the second line follows from the fact that all cluster sizes (and hence the entropy) are the same for every clustering in M_{perm}.

The expectation of the joint entropy with respect to M_{perm} for the cluster size distributions of clusterings $\mathcal{A}$ and $\mathcal{B}$ is the average over all possible contingency tables $\mathcal{T}$ with entries n

$$\mathbb{E}_{\text{perm}}[H(\mathcal{A},\mathcal{B})] = -\sum_{\mathcal{T}} p(\mathcal{T}|\mathcal{A},\mathcal{B}) \sum_{k=1}^{K_{\mathcal{A}}} \sum_{m=1}^{K_{\mathcal{B}}} \frac{n}{N} \log\left(\frac{n}{N}\right). \tag{24}$$

Rearranging the summations, and recalling that the entries of the contingency tables are hyper-geometrically distributed such that the probability of each entry

$$p(n) = \frac{\binom{b_m}{n}\binom{N-b_m}{a_k-n}}{\binom{N}{a_k}} \tag{25}$$

is only dependent on the row sum a_k and column sum b_m, gives

$$\mathbb{E}_{\text{perm}}[H(\mathcal{A},\mathcal{B})] = -\sum_{k=1}^{K_{\mathcal{A}}} \sum_{m=1}^{K_{\mathcal{B}}} \sum_{n} \frac{n}{N} \log\left(\frac{n}{N}\right) \frac{\binom{b_m}{n}\binom{N-b_m}{a_k-n}}{\binom{N}{a_k}}. \tag{26}$$

According to the hyper-geometric distribution, the summation over table entries n_{km} occurs between the lower bound: $\max\{0, a_k + b_m - N\}$ and the upper bound: $\min\{a_k, b_m\}$. Combining this expression with the individual entropies $H(\mathcal{A})$ and $H(\mathcal{B})$ gives (Vinh et al., 2009)

$$\mathbb{E}_{\text{perm}}[\text{MI}(\mathcal{A},\mathcal{B})] = \sum_{k=1}^{K_{\mathcal{A}}} \sum_{m=1}^{K_{\mathcal{B}}} \sum_{n} \frac{n}{N} \log\left(\frac{Nn}{a_k b_m}\right) \frac{\binom{b_m}{n}\binom{N-b_m}{a_k-n}}{\binom{N}{a_k}}. \tag{27}$$

As shown in Romano et al. (2014), the computational complexity of calculating the expected mutual information assuming the permutation model is of order $\mathcal{O}(\max\{K_{\mathcal{A}}N, K_{\mathcal{B}}N\})$.

The adjusted mutual information (AMI) of Vinh et al. (2009) uses M_{perm} to correct the MI for chance according to equation (1) and selecting an upper bound max[MI] from equation (22) to give

$$\text{AMI}(\mathcal{A},\mathcal{B}) = \frac{\text{MI}(\mathcal{A},\mathcal{B}) - \mathbb{E}_{\text{perm}}[\text{MI}(\mathcal{A},\mathcal{B})]}{\max_{\text{perm}}[\text{MI}] - \mathbb{E}_{\text{perm}}[\text{MI}(\mathcal{A},\mathcal{B})]}. \tag{28}$$

5.2 Expected Mutual Information, Fixed Number of Clusters ($M_{\mathbf{num}}$)

Next, we consider the Mutual Information between two clusterings under the assumptions that both clusterings were independently and uniformly drawn from the ensemble of clusterings with a fixed number of clusters (M_{num}). In this case, the expected mutual information is dependent on both the average partition entropy and the joint partition entropy

$$\mathbb{E}_{\text{num}}[\text{MI}(\mathcal{A},\mathcal{B})] = \mathbb{E}_{\text{num}}[H(\mathcal{A})] + \mathbb{E}_{\text{num}}[H(\mathcal{B})] - \mathbb{E}_{\text{num}}[H(\mathcal{A},\mathcal{B})]. \tag{29}$$

This expectation can be found by considering the average partition entropy and joint partition entropy separately. Recall that in the permutation model $\mathbb{E}_{\text{perm}}[H(\mathcal{A})] = H(\mathcal{A})$ since the cluster sizes remain unchanged; however, the same does not hold in M_{num}. Denoting a random clustering with $K_{\mathcal{A}}$ clusters as $\pi_{K_{\mathcal{A}}}$, and using the notion $\sum_{\sigma_i \in \pi_{K_{\mathcal{A}}}}$ to indicate the summation over all clusters in the clustering $\pi_{K_{\mathcal{A}}}$, where the cardinality of the cluster is $|\sigma_i| = a$, then the expected partition entropy of a random clustering in M_{num} is

$$\mathbb{E}_{\text{num}}[H(\mathcal{A})] = -\sum_{\pi_{K_{\mathcal{A}}}} p_{\text{num}}(\pi_{K_{\mathcal{A}}}) \sum_{\sigma_i \in \pi_{K_{\mathcal{A}}}} \frac{a}{N} \log\left(\frac{a}{N}\right). \tag{30}$$

Note that this expression only depends on the size $a = |\sigma_i|$ for $\sigma_i \in \pi_{K_{\mathcal{A}}}$ of the clusters in the clustering. This means the expected entropy of a random clustering can be rewritten in terms of the expected contribution to the entropy from a random cluster of size a. A counting argument gives the number of clusters of size a which appear in all of the clusterings in the random ensemble. First, choose a of the N elements to form the cluster. Each clustering in M_{num} must have $K_{\mathcal{A}}$ clusters, so the remaining $N - a$ elements have to be arranged into $K_{\mathcal{A}} - 1$ other clusters. There are $S(N-a, K_{\mathcal{A}}-1)$ ways to partition these remaining elements. This gives $\binom{N}{a} S(N-a, K_{\mathcal{A}}-1)$ clusters of size a (Chern et al., 2014). The expected number of clusters $n_{\text{num}}(a)$ in a random clustering drawn from M_{num} is then $\binom{N}{a}\frac{S(N-a,K_{\mathcal{A}}-1)}{S(N,K_{\mathcal{A}})}$. Therefore, the expected clustering entropy in M_{num} is:

$$\mathbb{E}_{\text{num}}[H(\mathcal{A})] = -\sum_{a=1}^{N-(K_{\mathcal{A}}-1)} \binom{N}{a} \frac{S(N-a, K_{\mathcal{A}}-1)}{S(N,K_{\mathcal{A}})} \frac{a}{N} \log\left(\frac{a}{N}\right). \tag{31}$$

where the summation is over all possible cluster sizes $[1, N-(K_{\mathcal{A}}-1)]$ encountered when partitioning N elements into $K_{\mathcal{A}}$ clusters.

Similarly, the expected joint entropy of two random clusterings drawn independently from M_{num} is given by the expected number of clusters of size a from a clustering with

$K_{\mathcal{A}}$ clusters, the expected number of clusters of size b from a clustering with $K_{\mathcal{B}}$ clusters, and then considering the probability of overlap $p(n_{km}) = \frac{\binom{b}{n_{km}}\binom{N-b}{a-n_{km}}}{\binom{N}{a}}$ from the resulting random contingency table

$$\begin{aligned}\mathbb{E}_{\text{num}}[H(\mathcal{A},\mathcal{B})] &= -\sum_{\pi_{K_{\mathcal{A}}}} p_{\text{num}}(\pi_{K_{\mathcal{A}}}) \sum_{\pi_{K_{\mathcal{B}}}} p_{\text{num}}(\pi_{K_{\mathcal{B}}}) \\ &\times \sum_{k=1}^{K_{\mathcal{A}}}\sum_{m=1}^{K_{\mathcal{B}}}\sum_{n} \frac{n}{N}\log\left(\frac{Nn}{a_k b_m}\right)\frac{\binom{b_m}{n}\binom{N-b_m}{a_k-n}}{\binom{N}{a_k}} \\ &= -\sum_{a=1}^{N-(K_{\mathcal{A}}-1)}\sum_{b=1}^{N-(K_{\mathcal{B}}-1)}\sum_{n}\left[\binom{N}{a}\frac{S(N-a,K_{\mathcal{A}}-1)}{S(N,K_{\mathcal{A}})}\right. \\ &\times \left.\binom{N}{b}\frac{S(N-b,K_{\mathcal{B}}-1)}{S(N,K_{\mathcal{B}})}\frac{n}{N}\log\left(\frac{n}{N}\right)\frac{\binom{b}{n}\binom{N-b}{a-n}}{\binom{N}{a}}\right].\end{aligned} \tag{32}$$

Note that, when using equation (1) to adjust the mutual information for chance under the assumption of M_{num}, the maximum value for the measure over the entire ensemble of random clusterings has to be used. When considering clusterings with a fixed number of clusters, we know that $H(\mathcal{A}) \leq \log K_{\mathcal{A}}$. This means that the choices for $\max_{\text{num}}[\text{MI}(\mathcal{A},\mathcal{B})]$ are

$$\min\{\log K_{\mathcal{A}}, \log K_{\mathcal{B}}\} \leq \sqrt{\log K_{\mathcal{A}} \log K_{\mathcal{B}}} \leq \frac{1}{2}\log K_{\mathcal{A}}K_{\mathcal{B}} \leq \max\{\log K_{\mathcal{A}}, \log K_{\mathcal{B}}\}. \tag{33}$$

As is apparent from the summations in equation (32), the computational complexity of exactly calculating the expected mutual information assuming M_{num} is of order $\mathcal{O}(N^3)$.

5.3 Expected Mutual Information, All Clusterings M_{all}

The expected Mutual Information between two clusterings under the assumption that both clusterings were independently and uniformly drawn from the set of all possible clusterings of N elements, M_{all}, has a similar derivation as the previous case of M_{num}. Both the expectations for the entropy of a single clustering and the joint entropy of the two clusterings need to be considered separately and can be rewritten in terms of the contributions from individual clusters of a given size. In M_{all}, the number of clusters of size a is again found by choosing a of the N elements for the cluster and then partitioning the remaining $N-a$ elements; there are now B_{N-a} possible ways to cluster the remaining elements (Chern et al., 2014). This gives

$$\mathbb{E}_{\text{all}}[H(\mathcal{A})] = -\sum_{a=1}^{N}\binom{N}{a}\frac{B_{N-a}}{B_N}\frac{a}{N}\log\left(\frac{a}{N}\right). \tag{34}$$

The expected joint entropy for two clusterings is then

$$\begin{aligned}\mathbb{E}_{\text{all}}[H(\mathcal{A},\mathcal{B})] &= -\sum_{\pi_a} p(\pi_a)\sum_{\pi_b} p(\pi_b)\sum_{i=1}^{N}\sum_{j=1}^{N}\sum_{n}\frac{n}{N}\log\left(\frac{Nn}{a_i b_j}\right)\frac{\binom{b_j}{n}\binom{N-b_j}{a_i-n}}{\binom{N}{a_i}} \\ &= -\sum_{a=1}^{N}\binom{N}{a}\frac{B_{N-a}}{B_N}\sum_{b=1}^{N}\binom{N}{b}\frac{B_{N-b}}{B_N}\sum_{n}\frac{n}{N}\log\left(\frac{n}{N}\right)\frac{\binom{b}{n}\binom{N-b}{a-n}}{\binom{N}{a}} \\ &= -2\sum_{a=1}^{N}\sum_{b=1}^{a-1}\binom{N}{a}\frac{B_{N-a}}{B_N}\binom{N}{b}\frac{B_{N-b}}{B_N}\sum_{n}\frac{n}{N}\log\left(\frac{n}{N}\right)\frac{\binom{b}{n}\binom{N-b}{a-n}}{\binom{N}{a}} \\ &- \sum_{a=1}^{N}\left(\binom{N}{a}\frac{B_{N-a}}{B_N}\right)^2\sum_{n}\frac{n_{ij}}{N}\log\left(\frac{n}{N}\right)\frac{\binom{a}{n}\binom{N-a}{a-n}}{\binom{N}{a}},\end{aligned} \tag{35}$$

with the last simplification resulting from the symmetry of the hyper-geometric term with respect to a and b.

As in the previous case, the maximum bound of the measure must be consider over the entire ensemble of clusterings. Again, we consider the bound $H(\mathcal{A}) \leq \log N$. This reduces to only one choice for $\max_{\text{all}}[\text{MI}(\mathcal{A},\mathcal{B})] = \log N$.

5.4 One-Sided Mutual Information

As was the case for the one-sided expected Rand index, the one-sided expectation of mutual information follows from the fact that the cluster sequence for the reference clustering is fixed. This results in the following one-sided expected joint entropy when the random clustering $\mathcal{A}$ is drawn from the M_{num} model

$$\mathbb{E}^1_{\text{num}}[H(\mathcal{A},\mathcal{G})] = -\sum_{a=1}^{N}\binom{N}{a}\frac{S(N-a,K_{\mathcal{A}}-1)}{S(N,K_{\mathcal{A}})}\sum_{b=1}^{K_{\mathcal{G}}}\sum_{n}\frac{n}{N}\log\left(\frac{n}{N}\right)\frac{\binom{g_b}{n}\binom{N-g_b}{a-n}}{\binom{N}{a}}. \tag{36}$$

The corresponding one-sided expected MI assuming M^1_{num} is

$$\begin{aligned}\mathbb{E}^1_{\text{num}}[\text{MI}(\mathcal{A},\mathcal{G})] &= -\sum_{a=1}^{K_{\mathcal{A}}}\binom{N}{a}\frac{S(N-a,K_{\mathcal{A}}-1)}{S(N,K_{\mathcal{A}})}\frac{a}{N}\log\left(\frac{a}{N}\right) - \sum_{b=1}^{K_{\mathcal{G}}}\frac{g_b}{N}\log\left(\frac{g_b}{N}\right) \\ &+ \sum_{a=1}^{N}\binom{N}{a}\frac{S(N-a,K_{\mathcal{A}}-1)}{S(N,K_{\mathcal{A}})}\sum_{b=1}^{K_{\mathcal{G}}}\sum_{n}\frac{n}{N}\log\left(\frac{n}{N}\right)\frac{\binom{g_b}{n}\binom{N-g_b}{a-n}}{\binom{N}{a}}.\end{aligned} \tag{37}$$

The one-sided expected joint entropy when the random clustering $\mathcal{A}$ is drawn from the M^1_{all} model is

$$\mathbb{E}^1_{\text{all}}[H(\mathcal{A},\mathcal{G})] = -\sum_{a=1}^{N}\binom{N}{a}\frac{B_{N-a}}{B_N}\sum_{b=1}^{K_{\mathcal{G}}}\sum_{n}\frac{n}{N}\log\left(\frac{n}{N}\right)\frac{\binom{g_b}{n}\binom{N-g_b}{a-n}}{\binom{N}{a}}, \tag{38}$$

and the one-sided expectation of the MI when the random clustering $\mathcal{A}$ is drawn from the M_{all}^1 model is

$$\mathbb{E}_{\text{all}}^1[\text{MI}(\mathcal{A},\mathcal{G})] = -\sum_{a=1}^{K_\mathcal{A}} \binom{N}{a} \frac{B_{N-a}}{B_N} \frac{a}{N} \log\left(\frac{a}{N}\right) - \sum_{b=1}^{K_\mathcal{G}} \frac{g_b}{N} \log\left(\frac{g_b}{N}\right) + \sum_{a=1}^{N} \binom{N}{a} \frac{B_{N-a}}{B_N} \sum_{b=1}^{K_\mathcal{G}} \sum_{n} \frac{n}{N} \log\left(\frac{n}{N}\right) \frac{\binom{g_b}{n}\binom{N-g_b}{a-n}}{\binom{N}{a}}. \tag{39}$$

Again, the maximum bound must be chosen with respect to the measure maximum over the clusterings present in the random model.

6. Results

The choice of random model for clusterings and the choice of one-sided comparisons can significantly affect results of clustering comparisons. We first illustrate that the ranking of similar clustering pairs (or, equivalently, finding the most similar clustering pair) depends on the choices of random models in a hypothetical example (Section 6.1) and K-means clustering of a handwritten digits data set (Section 6.2). One of the primary reasons such strong discrepancies occur is that the cluster size sequences are fixed within samples from M_{perm}. This means that adjusted comparisons using M_{perm} are unable to differentiate random clusterings with drastically different cluster size sequences, as we illustrate through our third example in Section 6.3. Second, we demonstrate that the interpretation of adjusted clustering similarity measures with respect to a random baseline also depends on the random model through an evaluation of hierarchical clustering applied to gene expression data in Section 6.4. Crucially, all of these examples illustrate that conclusions based on corrected similarity measures can change depending on the random model for clusterings.

6.1 Clustering Similarity Ranking

Our first example demonstrates how rankings assigned by the similarity score can change depending on the assumed random model. Consider the four hypothetical clusterings of 20 elements presented in Figure 1a. Clustering $\mathcal{W}$ contains four equally sized clusters; clustering $\mathcal{X}$ is generated by shifting the membership of one element from $\mathcal{W}$; clustering $\mathcal{Y}$ groups the elements into 10 equally sized clusters; and clustering $\mathcal{Z}$ groups the elements into 10 heterogeneous clusters. The similarity (from the most similar at the top to the least similar at the bottom) of all 6 clustering pairs is ranked using the Rand index and each of its three adjusted variants in Figure 1b. Note that the adjusted Rand index can be negative. The unadjusted Rand index ranking serves as a reference to illustrate how the random models change rankings.

As one would expect, all four Rand measures identify clusterings $\mathcal{W}$ and $\mathcal{X}$ as the most similar (Figure 1b). However, the ranking of the other five comparisons varies widely as a result of the underlying random models. These changes can be understood by tracking comparisons to clustering $\mathcal{Z}$. The low Rand index for the three comparisons with clustering $\mathcal{Z}$ (≈ 0.76) reflects the fact that clustering $\mathcal{Z}$ has a drastically different number of clusters or cluster size sequence from the other three clusterings. The permutation model retains these

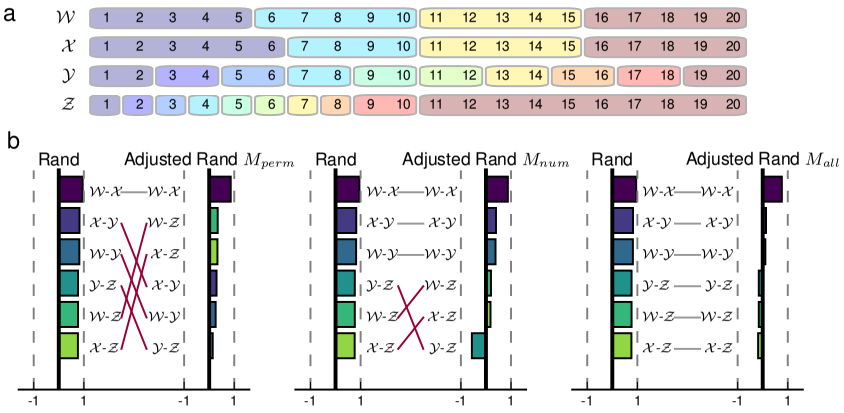

Figure 1: The choice of random model for the Rand index has a significant impact on the rankings of clustering similarity. **a**, Four clusterings of $N = 20$ elements; $\mathcal{W}$ and $\mathcal{X}$ each contain four clusters and differ by the assignment of one element (6), $\mathcal{Y}$ and $\mathcal{Z}$ each contain ten clusters. **b**, Rankings for the similarity of clustering pairs using the Rand index, the Adjusted Rand index assuming M_{perm}, the Adjusted Rand index assuming M_{num}, and the Adjusted Rand index assuming M_{all}. Rankings which change as a function of random model are highlighted in dark red.

differences in all random clusterings; the resulting adjusted index thus treats comparisons between clustering $\mathcal{Z}$ and either $\mathcal{W}$ or $\mathcal{X}$ more favorably than those to clustering $\mathcal{Y}$. On the other hand, the cluster size sequence for clustering $\mathcal{Z}$ is relatively rare in both M_{num} and M_{all}. Since clusterings $\mathcal{Y}$ and $\mathcal{Z}$ have the same number of clusters, the differences in their adjusted scores using M_{num} are a consequence of their cluster size sequences. Finally, all four clusterings are over 20 elements—the only factor that specifies the expected Rand index assuming M_{all}—so they are all adjusted by the same amount when M_{all} is used. Note that in our example, clustering $\mathcal{Z}$ has a negative adjusted Rand score using the M_{all} when compared with all three other clusterings, thus it is less similar to the other three clusterings than one would have expected from comparing two completely random clusterings.

This example illustrates an important property of the M_{all} model. Namely, the ranking provided by the Rand index remains unchanged whenever the M_{all} model is used for adjustment because all clusterings have the same number of elements. However, the corrected baseline now provides a strong interpretation for negative scores: Two randomly selected clusterings are expected to be more similar. This is an important consideration for the evaluation of clustering methods; if the derived clustering is no more similar than would be expected when comparing completely random clusterings, the solution is likely not a meaningful representation of the data.

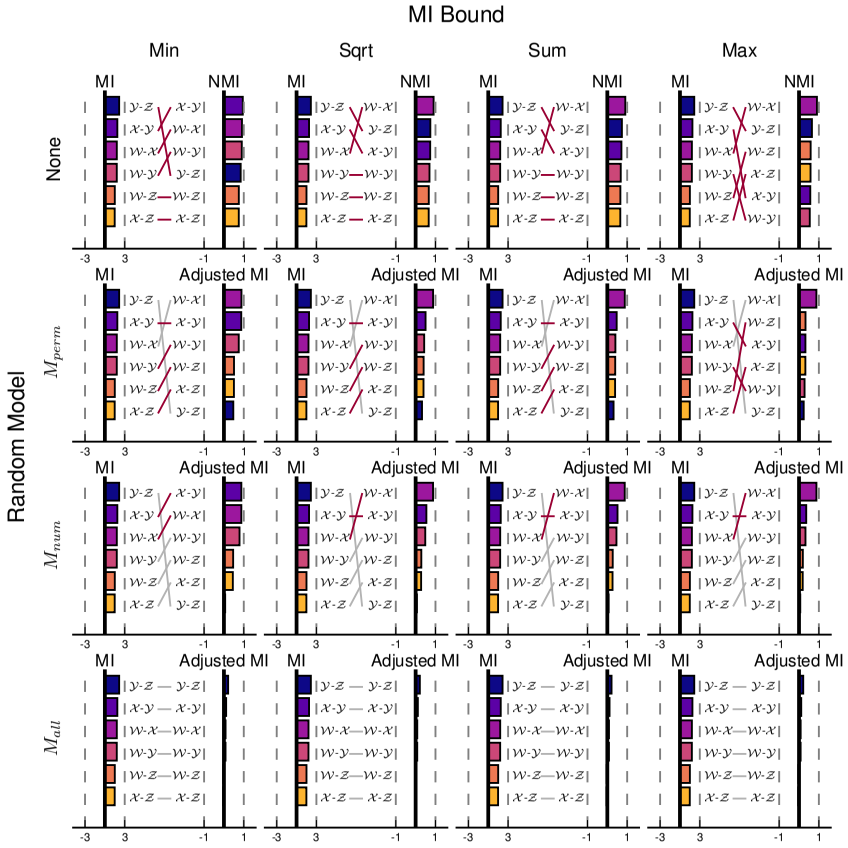

Figure 2: Both the random model and maximum bound have a significant impact on the rankings of clustering similarity using Mutual Information (MI). Rankings for the similarity of clustering pairs from Figure 1a using (vertically) the raw MI, the Adjusted MI assuming M_{perm}, the Adjusted MI assuming M_{num}, and the Adjusted MI assuming M_{all}. MI similarity also depends on the choice of maximum bound (horizontal) as a function of the two clusterings' model entropies; minimum (Min), square-root (Sqrt), average (Sum), and maximum (Max). The MI measures which are normalized but not adjusted by a random model are all members of the common family of normalized MI (NMI). For a given random model, similarity rankings which change as a function of maximum bound are highlighted in dark red.

We then turn our attention to clustering similarity measured by mutual information (MI). Rankings using the adjusted MI depend on two dimensions of variation: the random model and the maximum bound for the measure. This variation is illustrated in Figure 2 using the same 6 comparisons between pairs of clusterings from Figure 1a. We consider four cases for the MI maximum bound: Min, Sqrt, Sum, and Max, corresponding to the minimum of the two model partition entropies, the geometric mean of the two model partition entropies, the average of the two model partition entropies, and the maximum of the two model partition entropies, respectively (see Appendix 5 for details). For the permutation model, the model partition entropies are calculated from the cluster size sequences, while the model partition entropies in M_{num} are bounded by the logarithm of the number of clusters and the model partition entropies in M_{all} are bounded by the logarithm of the number of elements. As a point of reference, all rankings are illustrated in comparison to the raw mutual information score, unnormalized and without a random model adjustment (None). All adjustments of the mutual information without a random model (None, first row) are members of the commonly used family of Normalized Mutual Information (NMI) measures (Danon et al., 2005).

The rankings in Figure 2 demonstrate that both the random model and the maximum bound affect the relative similarity between clusterings when adjusting MI. Firstly, the only random model whose adjustments are independent of MI's maximum bound is M_{all}. This occurs because every choice of the maximum bound reduces to $\log N$ (the entropy of the clustering that places each element into its own cluster). In the other three random model scenarios, the maximum bound depends on the clusterings under comparison. Secondly, MI is highly dependent on the number of clusters in each of the clusterings: When either no normalization and random model adjustment are used, or the M_{all} model is used, MI ranks the similarity of clusterings $\mathcal{Y}$ and $\mathcal{Z}$ above that of $\mathcal{W}$ and $\mathcal{X}$ because of the greater number of clusters in the former case. This bias is mitigated to varying extents by the NMI variations; while NMI using the Sqrt, Sum, and Max normalization terms all produce the intuitive ranking of $\mathcal{W}$ and $\mathcal{X}$ as the most similar pair, NMI using Min for normalization still succumbs to the larger number of clusters in $\mathcal{Y}$, and ranks $\mathcal{X}$ and $\mathcal{Y}$ as the most similar clustering pair. The adjustments provided by both the M_{perm} and M_{num} random models control for the number of clusters; this reduces the impact of the number of clusters when the cluster sizes are regular, but the bias re-occurs when there is a large imbalance between the cluster sizes.

6.2 Appropriate Random Model for Comparing K-means Clusterings

Clustering similarity measures are commonly used to evaluate the results of clustering methods in relation to a known reference clustering. Since the number of clusters can vary between instances, appropriately corrected similarity measures are necessary. However, as we have already seen, the choice of similarity measure and its chance corrected variants can affect the results of the comparisons and suggest drastically different interpretations for the effectiveness of the method.

We demonstrate the importance of the random ensemble assumption through a comparison of the clusterings uncovered by 400 runs of K-means on a collection of hand-written digits (Alimoglu and Alpaydin, 1996, see Appendix B.1 for details). The K-means cluster-

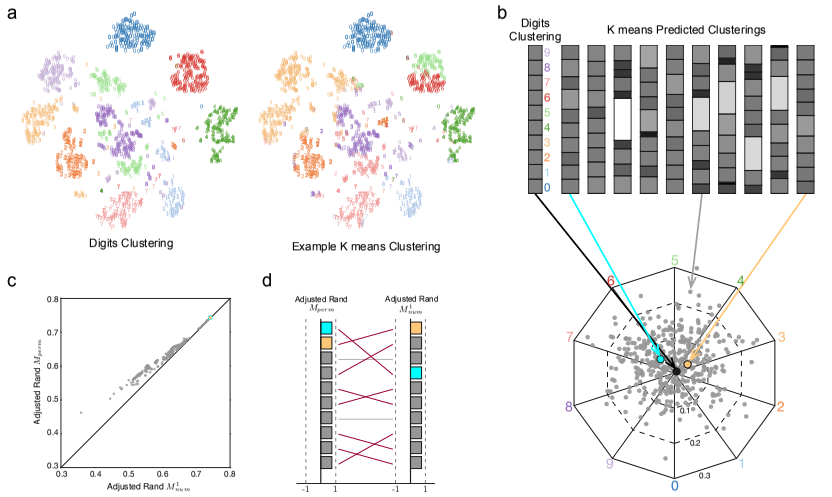

Figure 3: The impact of random model choice on the evaluation of K-means clustering. **a**, The digits data set contains 1,797 points in 64 dimensions (projected to 2 dimensions using t-SNE dimensionality reduction for visualization, Van der Maaten and Hinton, 2008) with a ground truth clustering corresponding to the digit, and an example K-means clustering. **b**, The original cluster size sequence (top left) and 10 cluster size sequences uncovered by K-means clustering with random initialization (top right). Intensity represents cluster sizes that are smaller (darker) or larger (lighter) than the ground truth clusters. (bottom) The cluster size sequence for 400 clusterings uncovered by K-means clustering with random initialization using Barycentric coordinates. The actual clustering size sequence (black) and the most similar clustering determined by the Adjusted Rand index assuming M_{perm} (light blue) and M^1_{num} (light orange). **c**, The similarity between the actual digits clusterings and each of the 400 K-means clusterings as measured by the Adjusted Rand index assuming M_{perm} (y-axis) and M^1_{num} (x-axis). **d**, The ranking of the most similar 10 K-means clusterings as determined by the Adjusted Rand index assuming M_{perm} (left) and M^1_{num} (right).

ing method groups elements so as to minimize the average (Euclidean) distance from the cluster centroid. In most scenarios, it uncovers clusterings with a pre-specified number of clusters (K). For our example, the digits naturally fall into 10 disjoint clusters, shown in Figure 3a, with relative cluster sizes given on the left of Figure 3b. Interestingly, almost all 400 clusterings produced by K-means have a different cluster size sequence (Figure 3b, bottom) and the cluster sizes vary over a wide range (Figure 3b, top). This suggests that both the specific assignment of elements to clusters and the size sequence of the clusters are major factors differentiating the K-means clusterings. Both sources of variation need to be captured by the random model in order to have a meaningful baseline.

Since the number of clusters does not change between runs, but the size sequence of those clusters changes considerably, it is more appropriate to assess similarity within the context of random clusterings with a fixed number of clusters rather than those given by the permutation model. Furthermore, since all of the comparisons are made against the same reference clustering, a one-sided similarity metric better captures the comparison scenario. In Figure 3c, the similarity of the reference clustering compared to each of the 400 uncovered clusterings is shown using the Adjusted Rand index assuming M_{perm} and the Adjusted Rand index assuming M^1_{num}. While the measures are strongly correlated (the black line indicates perfect agreement), the Adjusted Rand index assuming M_{perm} is consistently biased towards higher similarity. Most importantly, the bulk of the uncovered clusterings change their relative ranking when considered in the context of M^1_{num} compared to M_{perm} as demonstrated by the rankings of the top 10 most similar clusterings in Figure 3d.

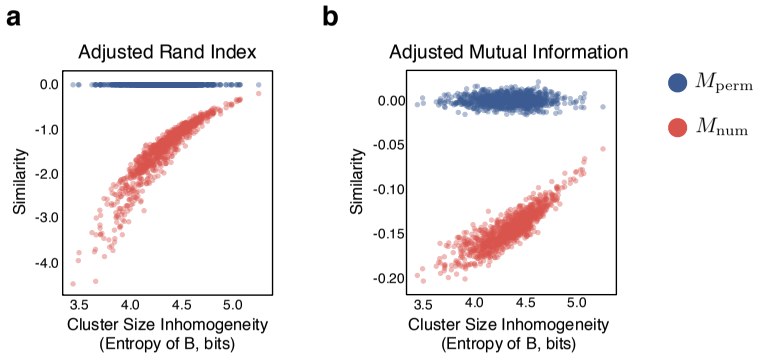
6.3 Random Models and Inhomogeneous Cluster Sizes

For both the Rand index and MI, the permutation model is invariant to differences in the cluster size sequence. This invariance is explicitly demonstrated in our next example by the difference between the adjusted similarity measures assuming M_{perm} and M_{num}. To generate an increasing disparity in cluster sizes, we use a preferential attachment model of element assignment. At each step of the algorithm, a random element is uniformly chosen for reassignment to a new cluster based on the current sizes of those clusters. A move is rejected if it results in an empty cluster.

In Figure 4, we compare a clustering of 1,000 elements grouped into 50 equally sized clusters and a randomized variant of the same clustering throughout 10^6-steps of our preferential attachment algorithm using the Adjusted Rand index (Figure 4a) and Adjusted MI (Figure 4b). Cluster size inhomogeneity is measured by the entropy of the clustering size sequence; equally sized clusters have the maximum entropy ($\log_2 50 \approx 5.64$), while greater inhomogeneity in cluster sizes decreases the entropy of the cluster size sequence. In both cases, the comparisons assuming M_{perm} are invariant to the inhomogeneity of the cluster size sequences. On the other hand, comparisons assuming M_{num} reflect the changes in the cluster size sequence.

6.4 Performing at Random in Tumor Gene Expression Clustering

Finally, recall that adjusted clustering similarity measures have the added interpretation with respect to a random baseline. Such random baselines play an important role when



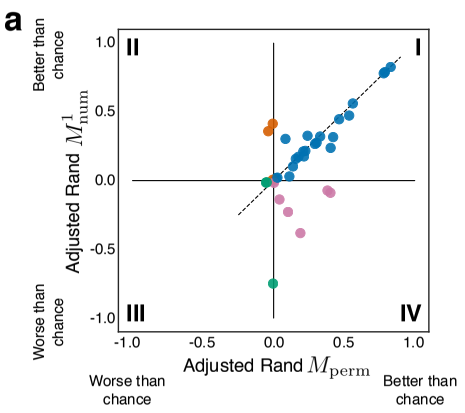


Figure 4: The invariance to inhomogeneous cluster size sequences when assuming M_{perm}. A clustering with 50 equal-sized clusters is compared to a second clustering B generated by a preferential attachment model. The cluster size sequence inhomogenity for clustering B is measured by the cluster size sequence entropy (low entropy is indicative of large cluster size inhomogenity). The similarity is calculated using the adjusted similarity assuming the permutation model M_{perm} and M_{num} for **a**, the Adjusted Rand index, and **b**, the Adjusted Mutual Information. In both cases, the similarity assuming M_{perm} is relatively constant (near 0), while the similarity assuming M_{num} increases with increasing entropy.

evaluating methods in unsupervised learning and classification. In our case, the adjusted similarity measures answer the question: *Is the result of our clustering method more similar to the desired clustering than if we selected a random clustering?* The adjusted similarity measure quantifies an answer to this question: positive scores indicate performance above random, while negative scores indicate a random clustering is more similar.

The interpretation of the adjusted similarity as a random baseline is highly dependent on the assumption of the random model. Critically, if the random model does not reflect the actual ensemble in which the clustering method is searching, the baseline does not accurately reflect the scenario in question. Thus, methods are incorrectly assessed as performing better than randomly generating a clustering.

We illustrate the dependence of adjusted similarity baseline on the choice of random model using a gene expression data set. Specifically, we use a collection of 35 cancer gene expression studies assembled in de Souto et al. (2008). The studies in the collection aim to differentiate the gene expression in cancerous cell tissue samples from those in healthy controls. Each study contains anywhere from 22 to 248 data points (individual tissue samples) for which between 85 and 4,553 features (individual gene expression) were measured after removing the uninformative and missing genes. For details on the individual studies and filtering methodologies, see de Souto et al. (2008) and references therein.

III	3	3	6	1
IV	7	9	28	12

Figure 5: The impact of random model choice on the evaluation of gene expression clustering with respect to the random baseline. The results of agglomerative hierarchical clustering identified from the gene expression in tissue samples from cancerous and healthy cells in 35 studies. **a**, The uncovered clusterings are compared to the reference clustering using the Adjusted Rand index assuming the permutation model M_{perm} (x-axis), and the one-sided Adjusted Rand index assuming a fixed-number of clusters M^1_{num} (y-axis). The dashed grey line indicates numerical agreement between the similarity measures. There are four possibilities when using two measures to assess similarity with respect to the random baseline: both random models conclude better than chance (blue, quadrant I), both random models conclude worse than chance (green, quadrant III), M_{perm} concludes better than chance but M^1_{num} concludes worse than chance (pink, quadrant IV), and visa-versa (orange, quadrant II). **b**, The assumed random model affects the classification of clustering comparisons with respect to the random baseline in all four random models considered here ($M^1_{\text{num}}, M_{\text{num}}, M_{\text{all}}$ and M^1_{all}) vs. M_{perm}.

Clusterings are identified via agglomerative hierarchical clustering using correlation to compute the average linkage between data points, a common clustering methodology in biology. While many other methods could be used (and indeed, were compared in de Souto et al., 2008), we use hierarchical clustering as a representative example to illustrate the consequences of the random model. Since hierarchical clustering produces a clustering with the user specified number of clusters, its similarity should be adjusted using the one-sided Adjusted Rand index assuming M^1_{num}, where the reference clustering is specified for each study individually.

Figure 5 shows the similarity between the derived clustering and the reference clustering for each of the 35 studies. The Adjusted Rand index assuming M_{perm} is shown on the

x-axis; positive scores (blue and pink points) denote the method performed better than the random baseline, while negative scores (orange and green points) denote the method performed worse than the random baseline. When the Adjusted Rand index assuming M^1_{num} is used (y-axis), a different classification of method performance with respect to the random baseline is found. Of particular note are the seven studies for which the method performed better than chance according to M_{perm}, yet, M^1_{num} concludes the method actually performed worse than chance (pink points). *In this case, a random clustering drawn from the model with a fixed number of clusters would actually perform better than agglomerative hierarchical clustering, yet the practitioner using the permutation model would incorrectly conclude the method was performing better than chance.* This discrepancy occurs even when the values of the Adjusted Rand index assuming M_{perm} are relatively high (> 0.4). Similarly interesting are the three studies in which the method performed worse than chance according to M_{perm}, yet, M^1_{num} concludes the method actually performed better than chance (orange points).

7. Discussion

Given the prevalence of clustering methods for analyzing data, clustering comparison is a fundamental problem that is pertinent to numerous areas of science. In particular, the correction of clustering similarity for chance serves to establish a baseline that facilitates comparisons between different clustering solutions. Expanding previous studies on the selection of an appropriate model for random clusterings (Meila, 2005; Vinh et al., 2009; Romano et al., 2016), our work provides an extensive summary of random models and clearly demonstrates the strong impact of the random model on the interpretation of clustering results.

Our results underpin the importance of selecting the appropriate random model for a given context. To that end, we offer the following guidelines:

1. Consider what is fixed by the clustering method: do all clusterings have a user specified number of clusters (use M_{num}), or is the cluster size sequence fixed (use M_{perm})?

2. Is the comparison against a reference clustering (use a one-sided comparison), or are you comparing two derived clusterings (then use a two-sided comparison)?

The specific comparisons studied here are not meant to establish the superiority of a particular clustering identification technique or a specific random clustering model, rather, they illustrate the importance of the *choice* of the random model. Crucially, conclusions based on corrected similarity measures can change depending on the random model for clusterings. Therefore, previous studies which did promote methods based on evidence from corrected similarity measures should be re-evaluated in the context of the appropriate random model for clusterings (Yeung et al., 2001; de Souto et al., 2008; Yeung and Ruzzo, 2001; Thalamuthu et al., 2006; McNicholas and Murphy, 2010).

Throughout this work, we assumed a uniform probability of selecting a partition given a constraint on the types of partitions in the ensemble. However, other probability distributions could be used which better model the clusterings encountered in practice. For example, instead of using a uniform distribution over the number of clusters, one could consider an inferred distribution for the number of clusters actually uncovered by a given

method (e.g. affinity propagation). This is particularly relevant when considering M_{all}, an extreme case for random partitions. Additionally, given that many systems exhibit clusterings with a heavy-tailed cluster size sequence, clusterings with such skewed cluster size distributions could be favored. Changes to the prior probabilities would likely change the expectations of the clustering similarity measures.

The behavior of the Rand index and Mutual Information in the context of the random clustering models discussed here further reveals problems with both measures. Specifically, the expected similarity of random clusterings increases as the number of elements grows. Intuition would suggest the opposite; the similarity of two randomly selected clusterings should decrease as the number of elements increases because it is harder to match the element memberships to clusters between two random clusterings. Instead, both MI and Rand are dominated by the fact that the expected number of clusters and cluster size distribution are converging with increasing N (Mansour, 2012). Our analysis also illustrates the dependency on the normalization term for MI, which, combined with a previously established bias on the number of clusters, suggests more care should be taken when interpreting the results of MI clustering comparisons.

In conclusion, our framework for the correction of clustering similarity for chance allows for more conscious comparisons between clusterings. The practitioner should always provide justification for their choice of random clustering model and treatment of one-sided comparisons.

Appendix A. Stirling and Bell Numbers

The Stirling number of the second kind $S(n,k)$ gives the number of ways to partition a set of n elements into k clusters, where

$$S(n,k) = \frac{1}{k!}\sum_{j=0}^{k}(-1)^{k-j}\binom{k}{j}j^n. \tag{40}$$

There are several recurrence relations which also give $S(n,k)$, one of the most useful is the relation

$$\begin{aligned} S(0,0) &= 1 \qquad S(n,0) = S(0,n) = 0 \\ S(n+1,k) &= kS(n,k) + S(n,k-1). \end{aligned} \tag{41}$$

As $n \to \infty$, an asymptotic approximation to the Stirling numbers of the second kind for a fixed k is given by $S(n,k) \approx \frac{k^n}{k!}$.

The Bell number B_n is the total number of clusterings over a set with n elements. It is related the Stirling numbers of the second kind by the summation over k for a fixed n, $B_n = \sum_{k=0}^{n} S(n,k)$. There is also a useful recurrence relation for Bell numbers: $B_{n+1} = \sum_{k=0}^{n} \binom{n}{k} B_k$. As $n \to \infty$, an asymptotic approximation to the ratio of the n-th and $(n+1)$-th Bell numbers is $\frac{B_n}{B_{n+1}} \approx \frac{\log n}{n}$. See Mansour (2012) for an extended discussion of both the Stirling numbers of the second kind and the Bell numbers.

In practice, calculating the Bell numbers and Stirling numbers of the second kind from their recurrence relations can be computationally expensive. However, many efficient approximations and implementations are available (Temme, 1993; Mansour, 2012). Here, we make use of the mpmath arbitrary precision library for Python developed by Johansson et al. (2013). This library takes advantage of Dobiński's Formula to approximate the Bell numbers (Dobiński, 1877; Chen and Yeh, 1994).

Appendix B. Application Data Sets

B.1 Digits Data Set

The digits data set is bundled with the sci-kit learn source code and consists of $1,797$ images of 8×8 gray level pixels of handwritten digits. The reference clustering contains 10 clusters corresponding to the true digit. The data set was originally assembled in Alimoglu and Alpaydin (1996). To provide a visualization, the data was projected to 2-d using the t-Distributed Stochastic Neighbor Embedding (t-SNE) dimensionality reduction method (Van der Maaten and Hinton, 2008) initialized from the pca decomposition.

B.2 Gene Expression Data Set

The data was assembled in de Souto et al. (2008) and is freely available from `http://bioinformatics.rutgers.edu/Publications/deSouto2008c/index.html`. The studies represent two prominent methods for determining gene expression in cell tissue samples from cancer tumors or healthy controls, Affymetrix microarrays and cDNA microarrays, which, respectively, measure the number of RNA copies found in the cell and the ratio of the number of copies vs a control sample. Each study contains anywhere from 22 to 248 data points (individual tissue samples) for which between 85 and $4,553$ features (individual gene expression) were measured after removing the uninformative and missing genes. Please see de Souto et al. (2008) for details of this selection process.

Abstract

We study the cost function for hierarchical clusterings introduced by (Dasgupta, 2016) where hierarchies are treated as first-class objects rather than deriving their cost from projections into flat clusters. It was also shown in (Dasgupta, 2016) that a top-down algorithm based on the *uniform* Sparsest Cut problem returns a hierarchical clustering of cost at most $O(\alpha_n \log n)$ times the cost of the optimal hierarchical clustering, where α_n is the approximation ratio of the Sparsest Cut subroutine used. Thus using the best known approximation algorithm for Sparsest Cut due to Arora-Rao-Vazirani, the top-down algorithm returns a hierarchical clustering of cost at most $O\left(\log^{3/2} n\right)$ times the cost of the optimal solution. We improve this by giving an $O(\log n)$-approximation algorithm for this problem. Our main technical ingredients are a combinatorial characterization of ultrametrics induced by this cost function, deriving an Integer Linear Programming (ILP) formulation for this family of ultrametrics, and showing how to iteratively round an LP relaxation of this formulation by using the idea of *sphere growing* which has been extensively used in the context of graph partitioning. We also prove that our algorithm returns an $O(\log n)$- approximate hierarchical clustering for a generalization of this cost function also studied in (Dasgupta, 2016). Experiments show that the hierarchies found by using the ILP formulation as well as our rounding algorithm often have better projections into flat clusters than the standard linkage based algorithms. We conclude with constant factor inapproximability results for this problem: 1) no polynomial size LP or SDP can achieve a constant factor approximation for this problem and 2) no polynomial time algorithm can achieve a constant factor approximation under the *Small Set Expansion* hypothesis.

Keywords: Hierarchical clustering, clustering, convex optimization, linear programming, approximation algorithms

1. Introduction

Hierarchical clustering is an important method in cluster analysis where a data set is recursively partitioned into clusters of successively smaller size. They are typically represented by rooted trees where the root corresponds to the entire data set, the leaves correspond to individual data points and the intermediate nodes correspond to a cluster of its descendant leaves. Such a hierarchy represents several possible *flat clusterings* of the data at various levels of granularity; indeed every pruning of this tree returns a possible clustering. Therefore in situations where the number of desired clusters is not known beforehand, a hierarchical clustering scheme is often preferred to flat clustering.

The most popular algorithms for hierarchical clustering are bottom-up agglomerative algorithms like *single linkage*, *average linkage* and *complete linkage*. In terms of theoretical guarantees these algorithms are known to correctly recover a ground truth clustering if the similarity function on the data satisfies corresponding stability properties (see, e.g., (Balcan et al., 2008)). Often, however, one wishes to think of a good clustering as optimizing some kind of cost function rather than recovering a hidden "ground truth", since one can then assign a numerical score to an algorithm's performance on every instance. This is useful for objectively comparing the output of different clustering algorithms. Popular objective functions in the classical clustering setting are k-means, k-median, min-sum and k-center (see Chapter 14, (Friedman et al., 2001)). However as pointed out by (Dasgupta, 2016) for a lot of popular hierarchical clustering algorithms including linkage based algorithms, it is hard to pinpoint explicitly the cost function that these algorithms are optimizing. Moreover, much of the existing cost function based approaches towards hierarchical clustering evaluate a hierarchy based on a cost function for flat clustering, e.g., assigning the k-means or k-median cost to a pruning of this tree. Motivated by this, (Dasgupta, 2016) introduced a cost function for hierarchical clustering where the cost takes into account the entire structure of the tree rather than just the projections into flat clusterings. This cost function is shown to recover the intuitively correct hierarchies on several synthetic examples like planted partitions and cliques. In addition, a top-down graph partitioning algorithm based on the *uniform* Sparsest Cut problem is presented that outputs a tree with cost at most $O(\alpha_n \log n)$ times the cost of the optimal tree and where α_n is the approximation guarantee of the Sparsest Cut subroutine used. Thus using the Leighton-Rao algorithm (Leighton and Rao, 1988, 1999) or the Arora-Rao-Vazirani algorithm (Arora et al., 2009) gives an approximation factor of $O\left(\log^2 n\right)$ and $O\left(\log^{3/2} n\right)$ respectively.

In this work we give a polynomial time algorithm to recover a hierarchical clustering of cost at most $O(\log n)$ times the cost of the optimal clustering according to this cost function. We also analyze a generalization of this cost function studied by (Dasgupta, 2016) and show that our algorithm still gives an $O(\log n)$ approximation in this setting. We do this by viewing the cost function in terms of the ultrametric it induces on the data, writing a convex relaxation for it and concluding by analyzing a popular rounding scheme used in graph partitioning algorithms. We also implement the integer program, its LP relaxation, and the rounding algorithm and test it on some synthetic and real world data sets to compare the cost of the rounded solutions to the true optimum as well as to compare its performance to other hierarchical clustering algorithms used in practice. Our experiments suggest that the hierarchies found by this algorithm are often better than the ones found by linkage based algorithms as well as the k-means algorithm in terms of the error of the best pruning of the tree compared to the ground truth.

1.1 Related Work

The immediate precursor to this work is (Dasgupta, 2016) where the cost function for evaluating a hierarchical clustering was introduced. Prior to this there has been a long line of research on hierarchical clustering in the context of phylogenetics and taxonomy (see, e.g., (Jardine and Sibson, 1971; Sneath et al., 1973; Felsenstein and Felenstein, 2004)). Several authors have also given theoretical justifications for the success of the popular linkage based algorithms for hierarchical clustering (see, e.g. (Jardine and Sibson, 1968; Zadeh and Ben-David, 2009; Ackerman et al., 2010)). In terms of cost functions, one approach has been to evaluate a hierarchy in terms of the k-means or k-median cost that it induces (see (Dasgupta and Long, 2005)). The cost function and the top-down algorithm in (Dasgupta, 2016) can also be seen as a theoretical justification for several graph partitioning heuristics that are used in practice.

Besides this prior work on hierarchical clustering, we are also motivated by the long line of work in the classical clustering setting where a popular strategy is to study convex relaxations of these problems and to round an optimal fractional solution into an integral one with the aim of getting a good approximation to the cost function. A long line of work (see, e.g., (Charikar et al., 1999; Jain and Vazirani, 2001; Jain et al., 2003; Charikar and Li, 2012)) has employed this approach on LP relaxations for the k-median problem, including (Li and Svensson, 2013) which gives the best known approximation factor of $1+\sqrt{3}+\varepsilon$. Similarly, a few authors have studied LP and SDP relaxations for the k-means problem (see, e.g., (Peng and Xia, 2005; Peng and Wei, 2007; Awasthi et al., 2015)), while one of the best known algorithms for kernel k-means and

spectral clustering is due to (Recht et al., 2012) which approximates the nonnegative matrix factorization (NMF) problem by LPs.

LP relaxations for hierarchical clustering have also been studied in (Ailon and Charikar, 2005) where the objective is to fit a tree metric to a data set given pairwise dissimilarities. While the LP relaxation and rounding algorithm in (Ailon and Charikar, 2005) is similar in flavor, the result is incomparable to ours (see Section 8 for a discussion). Another work that is indirectly related to our approach is (Di Summa et al., 2015) where the authors study an ILP to obtain a closest ultrametric to arbitrary functions on a discrete set. Our approach is to give a combinatorial characterization of the ultrametrics induced by the cost function of (Dasgupta, 2016) which allows us to use the tools from (Di Summa et al., 2015) to model the problem as an ILP. The natural LP relaxation of this ILP turns out to be closely related to LP relaxations considered before for several graph partitioning problems (see, e.g., (Leighton and Rao, 1988, 1999; Even et al., 1999; Krauthgamer et al., 2009)) and we use a rounding technique studied in this context to round this LP relaxation.

Recently, we became aware of independent work by (Charikar and Chatziafratis, 2017) obtaining similar results for hierarchical clustering. In particular (Charikar and Chatziafratis, 2017) improve the approximation factor to $O(\alpha_n)$, where α_n is the approximation factor of the uniform Sparsest Cut problem, by showing how to round a spreading metric SDP relaxation. The analysis of this rounding procedure also enabled them to show that the top-down heuristic of (Dasgupta, 2016) actually returns an $O(\alpha_n)$ approximate clustering rather than an $O(\alpha_n \log n)$ approximate clustering. This improves the approximation factor to $O(\sqrt{\log n})$ using (Arora et al., 2009) for solving the uniform Sparsest Cut problem. (Charikar and Chatziafratis, 2017) also analyzed a similar LP relaxation using the *divide-and-conquer approximation algorithms using spreading metrics* paradigm of (Even et al., 2000) together with a result of (Bartal, 2004) to show an $O(\log n)$ approximation. Finally, (Charikar and Chatziafratis, 2017) also gave similar constant factor inapproximability results for this problem.

1.2 Contribution

While studying convex relaxations of optimization problems is fairly natural, for the cost function introduced in (Dasgupta, 2016) however, it is not immediately clear how one would go about writing such a relaxation. Our first contribution is to give a combinatorial characterization of the family of ultrametrics induced by this cost function on hierarchies. Inspired by the approach in (Di Summa et al., 2015) where the authors study an integer linear program for finding the closest ultrametric, we are able to formulate the problem of finding the minimum cost hierarchical clustering as an integer linear program. Interestingly and perhaps unsurprisingly, the specific family of ultrametrics induced by this cost function give rise to linear constraints studied before in the context of finding balanced separators in weighted graphs. We then show how to round an optimal fractional solution using the *sphere growing* technique first introduced in (Leighton and Rao, 1988) (see also (Garg et al., 1996; Even et al., 1999; Charikar et al., 2003)) to recover a tree of cost at most $O(\log n)$ times the optimal tree for this cost function. The generalization of this cost function involves scaling every pairwise distances by an arbitrary strictly increasing function f satisfying $f(0) = 0$. We modify the integer linear program for this general case and show that the rounding algorithm still finds a hierarchical clustering of cost at most $O(\log n)$ times the optimal clustering in this setting. Complementing the algorithms, we also show a constant factor inapproximability result for this problem under two different settings: 1) for any polynomial time algorithm under the *Small Set Expansion* hypothesis and, 2) unconditionally, for any polynomial sized LP and SDP relaxations. We conclude with an experimental study of the integer linear program and the rounding algorithm on some synthetic and real world data sets to show that the approximation algorithm often recovers clusters close to the true optimum (according to this cost function) and that its projections into flat clusters often has a better error rate than the linkage based algorithms and the k-means algorithm.

2. Preliminaries

A similarity based clustering problem consists of a dataset V of n points and a *similarity function* $\kappa : V \times V \to \mathbb{R}_{\geq 0}$ such that $\kappa(i,j)$ is a measure of the similarity between i and j for any $i,j \in V$. We will assume that the similarity function is symmetric i.e., $\kappa(i,j) = \kappa(j,i)$ for every $i,j \in V$. Note that we do not make any assumptions about the points in V coming from an underlying metric space. For a given instance of a clustering problem we have an associated weighted complete graph K_n with vertex set V and weight function given by κ. A *hierarchical clustering* of V is a tree T with a designated root r and with the elements of V as its leaves, i.e., $\text{leaves}(T) = V$. For any set $S \subseteq V$ we denote the *lowest common ancestor* of S in T by $\text{lca}(S)$. For pairs of points $i,j \in V$ we will abuse the notation for the sake of simplicity and denote $\text{lca}(\{i,j\})$ simply by $\text{lca}(i,j)$. For a node v of T we denote the subtree of T rooted at v by $T[v]$. The following cost function was introduced by (Dasgupta, 2016) to measure the quality of the hierarchical clustering T

$$\text{cost}(T) \coloneqq \sum_{\{i,j\} \in E(K_n)} \kappa(i,j) \left|\text{leaves}(T[\text{lca}(i,j)])\right|. \tag{1}$$

The intuition behind this cost function is as follows. Let T be a hierarchical clustering with designated root r so that r represents the whole data set V. Since $\text{leaves}(T) = V$, every internal node $v \in T$ represents a cluster of its descendant leaves, with the leaves themselves representing singleton clusters of V. Starting from r and going down the tree, every distinct pair of points $i,j \in V$ will be eventually separated at the leaves. If $\kappa(i,j)$ is large, i.e., i and j are very similar to each other then we would like them to be separated as far down the tree as possible if T is a good clustering of V. This is enforced in the cost function (1): if $\kappa(i,j)$ is large then the number of leaves of $\text{lca}(i,j)$ should be small i.e., $\text{lca}(i,j)$ should be far from the root r of T. Such a cost function is not unique however; see Section 8 for some other cost functions of a similar flavor.

Note that while requiring κ to be non-negative might seem like an artificial restriction, cost function (1) breaks down when all the $\kappa(i,j) < 0$, since in this case the trivial clustering r, T^* where T^* is the star graph with V as its leaves is always the minimizer. Therefore in the rest of this work we will assume that $\kappa \geq 0$. This is not a restriction compared to (Dasgupta, 2016), since the Sparsest Cut algorithm used as a subroutine also requires this assumption. Let us now briefly recall the notion of an ultrametric.

Definition 1 (Ultrametric) *An* ultrametric *on a set X of points is a distance function $d : X \times X \to \mathbb{R}$ satisfying the following properties for every $x,y,z \in X$*

1. ***Nonnegativity:*** *$d(x,y) \geq 0$ with $d(x,y) = 0$ iff $x = y$,*
2. ***Symmetry:*** *$d(x,y) = d(y,x)$,*
3. ***Strong triangle inequality:*** *$d(x,y) \leq \max\{d(y,z), d(z,x)\}$.*

Note that due to the requirement of strong triangle inequality, ultrametrics only admit *acute isosceles triangles* and *equilaterial triangles*, in contrast to general metric spaces. Under the cost function (1), one can interpret the tree T as inducing an ultrametric d_T on V given by $d_T(i,j) \coloneqq |\text{leaves}(T[\text{lca}(i,j)])| - 1$. This is an ultrametric since $d_T(i,j) = 0$ iff $i = j$ and for any triple $i,j,k \in V$ we have $d_T(i,j) \leq \max\{d_T(i,k), d_T(j,k)\}$. In the following definition we introduce the notion of *non-trivial ultrametrics*, which turn out to be precisely the ultrametrics that are induced by tree decompositions of V corresponding to cost function (1), as we will show in Corollary 8. We use the notation $x \sim y$ to denote an equivalence relation between x and y. Note that if d is an ultrametric, then $x \sim y$ iff $d(x,y) \leq t$ is an equivalence relation for every $t \in \mathbb{R}$.

Definition 2 *An ultrametric d on a set of points V is* non-trivial *if the following conditions hold.*

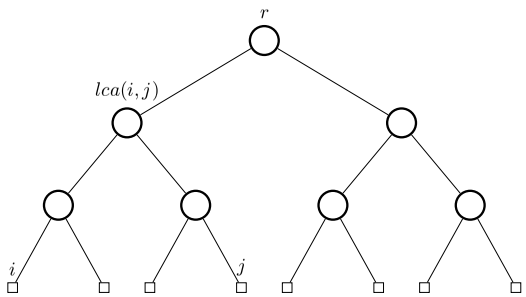

Figure 1: Example hierarchical clustering showing the lca of two data points i and j.

1. *For every non-empty set $S \subseteq V$, there is a pair of points $i, j \in S$ such that $d(i,j) \geq |S| - 1$.*
2. *For any t, if S_t is an equivalence class of V under the relation $i \sim j$ iff $d(i,j) \leq t$, then*

$$\max_{i,j \in S_t} d(i,j) \leq |S_t| - 1.$$

Note that for an equivalence class S_t where $d(i,j) \leq t$ for every $i, j \in S_t$ it follows from Condition 1 that $t \geq |S_t| - 1$. Thus in the case when $t = |S_t| - 1$ the two conditions imply that the maximum distance between any two points in S is t and that there is a pair $i, j \in S$ for which this maximum is attained. The following lemma shows that non-trivial ultrametrics behave well under restrictions to equivalence classes S_t of the form $i \sim j$ iff $d(i,j) \leq t$. All missing proofs from this section can be found in Appendix A.

Lemma 3 *Let d be a non-trivial ultrametric on V and let $S_t \subseteq V$ be an equivalence class under the relation $i \sim j$ iff $d(i,j) \leq t$. Then d restricted to S_t is a non-trivial ultrametric on S_t.*

The intuition behind the two conditions in Definition 2 is as follows. Condition 1 imposes a certain lower bound by ruling out trivial ultrametrics where, e.g., $d(i,j) = 1$ for every distinct pair $i, j \in V$. On the other hand Condition 2 discretizes and imposes an upper bound on d by restricting its range to the set $\{0, 1, \ldots, n-1\}$ (see Lemma 4). This rules out the other spectrum of triviality where for example $d(i,j) = n$ for every distinct pair $i, j \in V$ with $|V| = n$.

Lemma 4 *Let d be a non-trivial ultrametric on the set V as in Definition 2. Then the range of d is contained in the set $\{0, 1, \ldots, n-1\}$ with $|V| = n$.*

3. Ultrametrics and Hierarchical Clusterings

We start with the following easy lemma about the lowest common ancestors of subsets of V in a hierarchical clustering T of V. See Figure 1 for a helpful illustration. All missing proofs from this section can be found in Appendix B.

Lemma 5 *Let $S \subseteq V$ with $|S| \geq 2$. If $r = \mathrm{lca}(S)$ then there is a pair $i, j \in S$ such that $\mathrm{lca}(i,j) = r$.*

We will now show that non-trivial ultrametrics on V as in Definition 2 are exactly those that are induced by hierarchical clusterings on V under cost function (1). The following lemma shows the forward direction: the ultrametric d_T induced by any hierarchical clustering T is non-trivial.

Lemma 6 *Let T be a hierarchical clustering on V and let d_T be the ultrametric on V induced by it. Then d_T is non-trivial.*

The following crucial lemma shows the converse: every non-trivial ultrametric on V is realized by a hierarchical clustering T of V.

Lemma 7 *For every non-trivial ultrametric d on V there is a hierarchical clustering T on V such that for any pair $i, j \in V$ we have*

$$d_T(i,j) = |\mathrm{leaves}(T[\mathrm{lca}\,(i,j)])| - 1 = d(i,j).$$

Moreover this hierarchy can be constructed in time $O\left(n^3\right)$ by Algorithm 1 where $|V| = n$.

Lemmas 6 and 7 together imply the following corollary about the equivalence of hierarchical clusterings and non-trivial ultrametrics.

Corollary 8 *There is a bijection between the set of hierarchical clusterings T on V and the set of non-trivial ultrametrics d on V satisfying the following conditions.*

1. *For every hierarchical clustering T on V, there is a non-trivial ultrametric d_T defined as $d_T(i,j) := |\mathrm{leaves}\, T[\mathrm{lca}(i,j)]| - 1$ for every $i, j \in V$.*
2. *For every non-trivial ultrametric d on V, there is a hierarchical clustering T on V such that for every $i, j \in V$ we have $|\mathrm{leaves}\, T[\mathrm{lca}(i,j)]| - 1 = d(i,j)$.*

Moreover this bijection can be computed in $O(n^3)$ time, where $|V| = n$.

Therefore to find the hierarchical clustering of minimum cost, it suffices to minimize $\langle \kappa, d \rangle$ over non-trivial ultrametrics $d : V \times V \to \{0, \ldots, n-1\}$, where V is the data set. Note that the cost of the ultrametric d_T corresponding to a tree T is an affine offset of $\mathrm{cost}(T)$. In particular, we have $\langle \kappa, d_T \rangle = \mathrm{cost}(T) - \sum_{\{i,j\} \in E(K_n)} \kappa(i,j)$.

A natural approach is to formulate this problem as an Integer Linear Program (ILP) and then study LP or SDP relaxations of it. We consider the following ILP for this problem that is motivated by (Di Summa et al., 2015). We have the variables $x_{ij}^1, \ldots, x_{ij}^{n-1}$ for every distinct pair $i, j \in V$ with $x_{ij}^t = 1$ if and only if $d(i,j) \geq t$. For any positive integer n, let $[n] := \{1, 2, \ldots, n\}$.

$$\min \quad \sum_{t=1}^{n-1} \sum_{\{i,j\} \in E(K_n)} \kappa(i,j) x_{ij}^t \qquad \text{(ILP-ultrametric)}$$

$$\text{s.t.} \quad x_{ij}^t \geq x_{ij}^{t+1} \qquad \forall i, j \in V, t \in [n-2] \tag{2}$$

$$x_{ij}^t + x_{jk}^t \geq x_{ik}^t \qquad \forall i, j, k \in V, t \in [n-1] \tag{3}$$

$$\sum_{i,j \in S} x_{ij}^t \geq 2 \qquad \forall t \in [n-1], S \subseteq V, |S| = t+1 \tag{4}$$

$$\sum_{i,j \in S} x_{ij}^{|S|} \leq |S|^2 \left(\sum_{i,j \in S} x_{ij}^t + \sum_{\substack{i \in S \\ j \notin S}} \left(1 - x_{ij}^t\right) \right) \quad \forall t \in [n-1], S \subseteq V \tag{5}$$

$$x_{ij}^t = x_{ji}^t \qquad \forall i, j \in V, t \in [n-1] \tag{6}$$

$$x_{ii}^t = 0 \qquad \forall i \in V, t \in [n-1] \tag{7}$$

$$x_{ij}^t \in \{0, 1\} \qquad \forall i, j \in V, t \in [n-1] \tag{8}$$

Input: Data set V of n points, non-trivial ultrametric $d : V \times V \to \mathbb{R}_{\geq 0}$
Output: Hierarchical clustering T of V with root r

$r \leftarrow$ arbitrary choice of designated root in V
$X \leftarrow \{r\}$
$E \leftarrow \emptyset$
if $n = 1$ **then**
  $T \leftarrow (X, E)$
  return r, T
else
  Partition V into $\{V_1, \dots V_m\}$ under the equivalence relation $i \sim j$ iff $d(i,j) < n-1$
  for $l \in \{1, \dots, m\}$ **do**
    Let r_l, T_l be output of Algorithm 1 on V_l, $d|_{V_l}$
    $X \leftarrow X \cup V(T_l)$
    $E \leftarrow E \cup \{r, r_l\}$
  end
  $T \leftarrow (X, E)$
  return r, T
end

Algorithm 1: Hierarchical clustering of V from non-trivial ultrametric

Constraints (2) and (7) follow from the interpretation of the variables x_{ij}^t: if $d(i,j) \geq t$, i.e., $x_{ij}^t = 1$ then clearly $d(i,j) \geq t-1$ and so $x_{ij}^{t-1} = 1$. Furthermore, for any $i \in V$ we have $d(i,i) = 0$ and so $x_{ii}^t = 0$ for every $t \in [n-1]$. Note that constraint (3) is the same as the *strong triangle inequality* (Definition 1) since the variables x_{ij}^t are in $\{0,1\}$. Constraint (6) ensures that the ultrametric is symmetric. Constraint (4) ensures the ultrametric satisfies Condition 1 of non-triviality: for every $S \subseteq V$ of size $t+1$ we know that there must be points $i, j \in S$ such that $d(i,j) = d(j,i) \geq t$ or in other words $x_{ij}^t = x_{ji}^t = 1$. Constraint (5) ensures that the ultrametric satisfies Condition 2 of non-triviality. To see this note that the constraint is active only when $\sum_{i,j \in S} x_{ij}^t = 0$ and $\sum_{i \in S, j \notin S}(1 - x_{ij}^t) = 0$. In other words $d(i,j) \leq t-1$ for every $i, j \in S$ and S is a maximal such set since if $i \in S$ and $j \notin S$ then $d(i,j) \geq t$. Thus S is an equivalence class under the relation $i \sim j$ iff $d(i,j) \leq t-1$ and so for every $i, j \in S$ we have $d(i,j) \leq |S| - 1$ or equivalently $x_{ij}^{|S|} = 0$. The ultrametric d represented by a feasible solution x_{ij}^t is given by $d(i,j) = \sum_{t=1}^{n-1} x_{ij}^t$.

Definition 9 *For any* $\left\{x_{ij}^t \mid t \in [n-1], i, j \in V\right\}$ *let* E_t *be defined as* $E_t := \left\{\{i,j\} \mid x_{ij}^t = 0\right\}$. *Note that if* x_{ij}^t *is feasible for ILP-ultrametric then* $E_t \subseteq E_{t+1}$ *for any* t *since* $x_{ij}^t \geq x_{ij}^{t+1}$. *The sets* $\{E_t\}_{t=1}^{n-1}$ *induce a natural sequence of graphs* $\{G_t\}_{t=1}^{n-1}$ *where* $G_t = (V, E_t)$ *with* V *being the data set.*

For a fixed $t \in \{1, \dots, n-1\}$, it is instructive to study the combinatorial properties of the *layer-t problem*, where we restrict ourselves to the constraints corresponding to that particular t and drop constraints (2) and

(5) since they involve different layers in their expression.

$$\min \quad \sum_{\{i,j\} \in E(K_n)} \kappa(i,j) x_{ij}^t \qquad \text{(ILP-layer)}$$

$$\text{s.t.} \quad x_{ij}^t + x_{jk}^t \geq x_{ik}^t \qquad \forall i,j,k \in V \qquad (9)$$

$$\sum_{i,j \in S} x_{ij}^t \geq 2 \qquad \forall S \subseteq V, |S| = t+1 \qquad (10)$$

$$x_{ij}^t = x_{ji}^t \qquad \forall i,j \in V \qquad (11)$$

$$x_{ii}^t = 0 \qquad \forall i \in V \qquad (12)$$

$$x_{ij}^t \in \{0,1\} \qquad \forall i,j \in V \qquad (13)$$

The following lemma provides a combinatorial characterization of feasible solutions to the layer-t problem.

Lemma 10 *Let* $G_t = (V, E_t)$ *be the graph as in Definition 9 corresponding to a solution* x_{ij}^t *to the layer-t problem ILP-layer. Then* G_t *is a disjoint union of cliques of size* $\leq t$. *Moreover this exactly characterizes all feasible solutions of ILP-layer.*

Proof We first note that $G_t = (V, E_t)$ must be a disjoint union of cliques since if $\{i,j\} \in E_t$ and $\{j,k\} \in E_t$ then $\{i,k\} \in E_t$ since $x_{ik}^t \leq x_{ij}^t + x_{jk}^t = 0$ due to constraint (9). Suppose there is a clique in G_t of size $> t$. Choose a subset S of this clique of size $t+1$. Then $\sum_{i,j \in S} x_{ij}^t = 0$ which violates constraint (10). Conversely, let E_t be a subset of edges such that $G_t = (V, E_t)$ is a disjoint union of cliques of size $\leq t$. Let $x_{ij}^t = 0$ if $\{i,j\} \in E_t$ and 1 otherwise. Clearly $x_{ij}^t = x_{ji}^t$ by definition. Suppose x_{ij}^t violates constraint (9), so that there is a pair $i, j, k \in V$ such that $x_{ik}^t = 1$ but $x_{ij}^t = x_{jk}^t = 0$. However this implies that G_t is not a disjoint union of cliques since $\{i,j\}, \{j,k\} \in E_t$ but $\{i,k\} \notin E_t$. Suppose x_{ij}^t violates constraint (10) for some set S of size $t+1$. Therefore for every $i, j \in S$, we have $x_{ij}^t = 0$ since $x_{ij}^t = x_{ji}^t$ for every $i, j \in V$ and so S must be a clique of size $t+1$ in G_t which is a contradiction. ■

By Lemma 10 the layer-t problem is to find a subset $\overline{E}_t \subseteq E(K_n)$ of minimum weight under κ, such that the complement graph $G_t = (V, E_t)$ is a disjoint union of cliques of size $\leq t$. Note that this implies that the number of components in the complement graph is $\geq \lceil n/t \rceil$.The converse however, is not necessarily true: when $t = n-1$ then the layer t-problem is the minimum (weighted) cut problem whose partitions may have size larger than 1. Our algorithmic approach is to solve an LP relaxation of ILP-ultrametric and then round the solution to obtain a feasible solution to ILP-ultrametric. The rounding however proceeds iteratively in a layer-wise manner and so we need to make sure that the rounded solution satisfies the inter-layer constraints (2) and (5). The following lemma gives a combinatorial characterization of solutions that satisfy these two constraints.

Lemma 11 *For every* $t \in [n-1]$, *let* x_{ij}^t *be feasible for the layer-t problem ILP-layer. Let* $G_t = (V, E_t)$ *be the graph as in Definition 9 corresponding to* x_{ij}^t, *so that by Lemma 10,* G_t *is a disjoint union of cliques* $K_1^t, \dots, K_{l_t}^t$ *each of size at most t. Then* x_{ij}^t *is feasible for ILP-ultrametric if and only if the following conditions hold.*

Nested cliques *For any* $s \leq t$ *every clique* K_p^s *for some* $p \in [l_s]$ *in* G_s *is a subclique of some clique* K_q^t *in* G_t *where* $q \in [l_t]$.

Realization *If* $\left|K_p^t\right| = s$ *for some* $s \leq t$, *then* G_s *contains* K_p^t *as a component clique, i.e.,* $K_q^s = K_p^t$ *for some* $q \in [l_s]$.

Proof Since x^t_{ij} is feasible for the layer-t problem ILP-layer it is feasible for ILP-ultrametric if and only if it satisfies constraints (2) and (5). The solution x^t_{ij} satisfies constraint (2) if and only if $E_t \subseteq E_{t+1}$ by definition and so Condition Nested cliques follows.

Let us now assume that x^t_{ij} is feasible for ILP-ultrametric, so that by the above argument Condition Nested cliques is satisfied. Note that every clique K^t_p in the clique decomposition of G_t corresponds to an equivalence class S_t under the relation $i \sim j$ iff $x^t_{ij} = 0$. Moreover, by Lemma 10 we have $|S_t| \leq t$. Constraint (5) implies that $x^{|S_t|}_{ij} = 0$ for every $i, j \in S_t$. In other words, if $|S_t| = s \leq t$, then $x^s_{ij} = 0$ for every $i, j \in S_t$ and so S_t is a subclique of some clique K^s_q in the clique decomposition of G_s. However by Condition Nested cliques, K^s_q must be a subclique of a clique $K^t_{p'}$ in the clique decomposition of G_t, since $s \leq t$. However, as $K^t_p \cap K^t_{p'} = S_t$ and the clique decomposition decomposes G_t into a disjoint union of cliques, it follows that $S_t \subseteq K^s_q \subseteq K^t_{p'} = K^t_p = S_t$ and so $K^s_q = K^t_p$. Therefore Condition Realization is satisfied.

Conversely, suppose that x^t_{ij} satisfies Conditions Nested cliques and Realization, so that by the argument in the paragraph above x^t_{ij} satisfies constraint (2). Let us assume for the sake of contradiction that for a set $S \subseteq V$ and a $t \in [n-1]$ constraint (5) is violated, i.e.,

$$\sum_{i,j \in S} x^{|S|}_{ij} > |S| \left(\sum_{i,j \in S} x^t_{ij} + \sum_{\substack{i \in S \\ j \notin S}} \left(1 - x^t_{ij}\right) \right).$$

Since $x^t_{ij} \in \{0,1\}$ it follows that $x^t_{ij} = 0$ for every $i, j \in S$ and $x^t_{ij} = 1$ for every $i \in S, j \notin S$ so that S is a clique in G_t. Note that $|S| < t$ since $\sum_{i,j \in S} x^{|S|}_{ij} > 0$. This contradicts Condition Realization however, since S is clearly not a clique in $G_{|S|}$. ■

The combinatorial interpretation of the individual layer-t problems allow us to simplify the formulation of ILP-ultrametric by replacing the constraints for sets of a specific size (constraint (4)) by a global constraint about all sets (constraint (14)). These global constraints are also referred to as *spreading constraints*.

Lemma 12 *We may replace constraint* (4) *of ILP-ultrametric by the following equivalent* spreading constraint*:*

$$\sum_{j \in S} x^t_{ij} \geq |S| - t \qquad \forall t \in [n-1], S \subseteq V, i \in S. \tag{14}$$

Proof Let x^t_{ij} be a feasible solution to ILP-ultrametric. Note that if $|S| \leq t$ then the constraints are redundant since $x^t_{ij} \in \{0,1\}$. Thus we may assume that $|S| > t$ and let i be any vertex in S. Let us suppose for the sake of a contradiction that $\sum_{j \in S} x^t_{ij} < |S| - t$. This implies that there is a t sized subset $S' \subseteq S \setminus \{i\}$ such that for every $j \in S'$ we have $x^t_{ij'} = 0$. In other words $\{i, j'\}$ is an edge in $G_t = (V, E_t)$ for every $j' \in S'$ and since G_t is a disjoint union of cliques (constraint (3)), this implies the existence of a clique of size $t+1$. Thus by Lemma 10, x^t_{ij} could not have been a feasible solution to ILP-ultrametric.

Conversely, suppose x^t_{ij} is feasible for the modified ILP where constraint (4) is replaced by constraint (14). Then again $G_t = (V, E_t)$ is a disjoint union of cliques since x^t_{ij} satisfies constraint (3). Assume for contradiction that constraint (4) is violated: there is a set S of size $t+1$ such that $\sum_{i,j \in S} x^t_{ij} < 2$. Note that this implies that $\sum_{i,j} x^t_{ij} = 0$ since $x^t_{ij} = x^t_{ji}$ for every $i, j \in V$ and $t \in [n-1]$. Fix any $i \in S$, then $\sum_{j \in S} x^t_{ij} < 1 = |S| - t$ since $x^t_{ij} = x^t_{ji}$ by constraint (6), a violation of constraint (14). Thus x^t_{ij} is feasible for ILP-ultrametric since it satisfies every other constraint by assumption. ■

4. Rounding an LP relaxation

In this section we consider the following natural LP relaxation for ILP-ultrametric. All missing proofs from this section can be found in Appendix C. We keep the variables x^t_{ij} for every $t \in [n-1]$ and $i, j \in V$ but relax the integrality constraint on the variables as well as drop constraint (5).

$$\min \quad \sum_{t=1}^{n-1} \sum_{\{i,j\} \in E(K_n)} \kappa(i,j) x^t_{ij} \tag{LP-ultrametric}$$

$$\text{s.t.} \quad x^t_{ij} \geq x^{t+1}_{ij} \qquad \forall i, j \in V, t \in [n-2] \tag{15}$$

$$x^t_{ij} + x^t_{jk} \geq x^t_{ik} \qquad \forall i, j, k \in V, t \in [n-1] \tag{16}$$

$$\sum_{j \in S} x^t_{ij} \geq |S| - t \qquad \forall t \in [n-1], S \subseteq V, i \in S \tag{17}$$

$$x^t_{ij} = x^t_{ji} \qquad \forall i, j \in V, t \in [n-1] \tag{18}$$

$$x^t_{ii} = 0 \qquad \forall i, j \in V, t \in [n-1] \tag{19}$$

$$0 \leq x^t_{ij} \leq 1 \qquad \forall i, j \in V, t \in [n-1] \tag{20}$$

A feasible solution x^t_{ij} to LP-ultrametric induces a sequence $\{d_t\}_{t \in [n-1]}$ of distance metrics over V defined as $d_t(i,j) \coloneqq x^t_{ij}$. Constraint (17) enforces an additional structure on this metric: informally points in a "large enough" subset S should be spread apart according to the metric d_t. Metrics of type d_t are called *spreading metrics* and were first studied in (Even et al., 1999, 2000) in relation to graph partitioning problems. The following lemma gives a technical interpretation of spreading metrics (see, e.g., (Even et al., 1999, 2000; Krauthgamer et al., 2009)); we include a proof for completeness.

Lemma 13 *Let x^t_{ij} be feasible for LP-ultrametric and for a fixed $t \in [n-1]$, let d_t be the induced spreading metric. Let $i \in V$ be an arbitrary vertex and let $S \subseteq V$ be a set with $i \in S$ such that $|S| > (1+\varepsilon)t$ for some $\varepsilon > 0$. Then $\max_{j \in S} d_t(i,j) > \frac{\varepsilon}{1+\varepsilon}$.*

Proof For the sake of a contradiction suppose that for every $j \in S$ we have $d_t(i,j) = x^t_{ij} \leq \frac{\varepsilon}{1+\varepsilon}$. This implies that x^t_{ij} violates constraint (17) leading to a contradiction:

$$\sum_{j \in S} x^t_{ij} \leq \frac{\varepsilon}{1+\varepsilon} |S| < |S| - t,$$

where the last inequality follows from $|S| > (1+\varepsilon)t$. ■

Note that there are exponentially many inequalities for constraint (17); however the following lemma shows that we can still optimize over LP-ultrametric in polynomial time using the Ellipsoid method.

Lemma 14 *An optimal solution to LP-ultrametric can be computed in time polynomial in n and* $\log\left(\max_{i,j} \kappa(i,j)\right)$.

Proof We argue in the standard fashion via the application of the Ellipsoid method (see e.g., (Schrijver, 1998)). As such it suffices to verify that the encoding length of the numbers is small (which is indeed the case here) and that the constraints can be separated in polynomial time in the size of the input, i.e., in n and the logarithm of the absolute value of the largest coefficient. Since constraints of type (15), (16), (18), and (19) are polynomially many in n, we only need to check separation for constraints of type (17). Given a claimed solution x^t_{ij} we can check constraint (17) by iterating over all $t \in [n-1]$, vertices $i \in V$, and sizes m of the set S from $t+1$ to n. For a fixed t, i, and set size m sort the vertices in $V \setminus \{i\}$ in increasing order of distance from i (according to the metric d_t) and let $\overline{S}$ be the first m vertices in this ordering. If $\sum_{j \in \overline{S}} x^t_{ij} < m - t$ then

clearly x^t_{ij} is not feasible for LP-ultrametric, so we may assume that $\sum_{j\in\overline{S}} x^t_{ij} \geq m-t$. Moreover this is the only set to check: for any set $S \subseteq V$ containing i such that $|S| = m$, $\sum_{j\in S} x^t_{ij} \geq \sum_{j\in\overline{S}} x^t_{ij} \geq m-t$. Thus for a fixed $t \in [n-1]$, $i \in V$ and set size m, it suffices to check that x^t_{ij} satisfies constraint (17) for this subset $\overline{S}$. ■

From now on we will simply refer to a feasible solution to LP-ultrametric by the sequence of spreading metrics $\{d_t\}_{t\in[n-1]}$ it induces. The following definition introduces the notion of an open ball $\mathcal{B}_U(i,r,t)$ of radius r centered at $i \in V$ according to the metric d_t and restricted to the set $U \subseteq V$.

Definition 15 *Let $\{d_t \mid t \in [n-1]\}$ be the sequence of spreading metrics feasible for LP-ultrametric. Let $U \subseteq V$ be an arbitrary subset of V. For a vertex $i \in U$, $r \in \mathbb{R}$, and $t \in [n-1]$ we define the* open ball *$\mathcal{B}_U(i,r,t)$ of radius r centered at i as*

$$\mathcal{B}_U(i,r,t) \coloneqq \{j \in U \mid d_t(i,j) < r\} \subseteq U.$$

If $U = V$ then we denote $\mathcal{B}_U(i,r,t)$ simply by $\mathcal{B}(i,r,t)$.

Remark 16 *For every pair $i,j \in V$ we have $d_t(i,j) \geq d_{t+1}(i,j)$ by constraint* (15)*. Thus for any subset $U \subseteq V$, $i \in U$, $r \in \mathbb{R}$, and $t \in [n-2]$, it holds $\mathcal{B}_U(i,r,t) \subseteq \mathcal{B}_U(i,r,t+1)$.*

To round LP-ultrametric to get a feasible solution for ILP-ultrametric, we will use the technique of *sphere growing* which was introduced in (Leighton and Rao, 1988) to show an $O(\log n)$ approximation for the maximum multicommodity flow problem. Recall from Lemma 10 that a feasible solution to ILP-layer consists of a decomposition of the graph G_t into a set of disjoint cliques of size at most t. One way to obtain such a decomposition is to choose an arbitrary vertex, grow a ball around this vertex until the expansion of this ball is below a certain threshold, chop off this ball and declare it as a partition and then recurse on the remaining vertices. This is the main idea behind sphere growing, and the parameters are chosen depending on the constraints of the specific problem (see, e.g., (Garg et al., 1996; Even et al., 1999; Charikar et al., 2003) for a few representative applications of this technique). The first step is to associate to every ball $\mathcal{B}_U(i,r,t)$ a volume $\mathrm{vol}(\mathcal{B}_U(i,r,t))$ and a boundary $\partial\mathcal{B}_U(i,r,t)$ so that its expansion is defined. For any $t \in [n-1]$ and $U \subseteq V$ we denote by γ^U_t the value of the layer-t objective for solution d_t restricted to the set U, i.e.,

$$\gamma^U_t \coloneqq \sum_{\substack{i,j\in U\\ i<j}} \kappa(i,j) d_t(i,j).$$

When $U = V$ we refer to γ^U_t simply by γ_t. Since $\kappa : V \times V \to \mathbb{R}_{\geq 0}$, it follows that $\gamma^U_t \leq \gamma_t$ for any $U \subseteq V$. We are now ready to define the volume, boundary, and expansion of a ball $\mathcal{B}_U(i,r,t)$. We use the definition of (Even et al., 1999) modified for restrictions to arbitrary subsets $U \subseteq V$.

Definition 17 *(Even et al., 1999) Let U be an arbitrary subset of V. For a vertex $i \in U$, radius $r \in \mathbb{R}_{\geq 0}$, and $t \in [n-1]$, let $\mathcal{B}_U(i,r,t)$ be the ball of radius r as in Definition 15. Then we define its* volume *as*

$$\mathrm{vol}(\mathcal{B}_U(i,r,t)) \coloneqq \frac{\gamma^U_t}{n\log n} + \sum_{\substack{j,k\in\mathcal{B}_U(i,r,t)\\ j<k}} \kappa(j,k) d_t(j,k) + \sum_{\substack{j\in\mathcal{B}_U(i,r,t)\\ k\notin\mathcal{B}_U(i,r,t)\\ k\in U}} \kappa(j,k)\left(r - d_t(i,j)\right).$$

The boundary *of the ball $\partial\mathcal{B}_U(i,r,t)$ is the partial derivative of volume with respect to the radius:*

$$\partial\mathcal{B}_U(i,r,t) \coloneqq \frac{\partial\,\mathrm{vol}(\mathcal{B}_U(i,r,t))}{\partial r} = \sum_{\substack{j\in\mathcal{B}_U(i,r,t)\\ k\notin\mathcal{B}_U(i,r,t)\\ k\in U}} \kappa(j,k).$$

The expansion *$\phi(\mathcal{B}_U(i,r,t))$ of the ball $\mathcal{B}_U(i,r,t)$ is defined as the ratio of its boundary to its volume, i.e.,*

$$\phi\left(\mathcal{B}_U(i,r,t)\right) \coloneqq \frac{\partial\mathcal{B}_U(i,r,t)}{\mathrm{vol}\left(\mathcal{B}_U(i,r,t)\right)}.$$

The following lemma shows that the volume of a ball $\mathcal{B}_U(i,r,t)$ is differentiable with respect to r in the interval $(0,\Delta]$ except at finitely many points (see e.g., (Even et al., 1999)).

Lemma 18 *Let $\mathcal{B}_U(i,r,t)$ be the ball corresponding to a set $U \subseteq V$, vertex $i \in U$, radius $r \in \mathbb{R}$ and $t \in [n-1]$. Then $\mathrm{vol}(\mathcal{B}_U(i,r,t))$ is differentiable with respect to r in the interval $(0,\Delta]$ except at finitely many points.*

Input: Data set V, $\{d_t\}_{t\in[n-1]} : V \times V$, $\varepsilon > 0$, $\kappa : V \times V \to \mathbb{R}_{\geq 0}$
Output: A solution set of the form $\left\{x^t_{ij} \in \{0,1\} \mid t \in \left[\left\lfloor\frac{n-1}{1+\varepsilon}\right\rfloor\right], i,j \in V\right\}$

1 $m_\varepsilon \leftarrow \left\lfloor\frac{n-1}{1+\varepsilon}\right\rfloor$

17 **end**
18 **end**
19 $x^t_{ij} = 1$ if $i \in U_1 \in \mathcal{C}_t$, $j \in U_2 \in C_t$ and $U_1 \neq U_2$, else $x^t_{ij} = 0$
20 $t \leftarrow t-1$
21 **end**
22 **return** $\left\{x^t_{ij} \mid t \in [m_\varepsilon], i,j \in V\right\}$

Algorithm 2: Iterative rounding algorithm to find a low cost ultrametric

The following theorem establishes that the rounding procedure of Algorithm 2 ensures that the cliques in $\mathcal{C}_t$ are "small" and that the cost of the edges removed to form them, is not too high. It also shows that Algorithm 2 can be implemented to run in time polynomial in n.

Theorem 19 *Let $m_\varepsilon \coloneqq \left\lfloor\frac{n-1}{1+\varepsilon}\right\rfloor$ as in Algorithm 2 and let $\left\{x^t_{ij} \mid t \in [m_\varepsilon], i,j \in V\right\}$ be the output of Algorithm 2 run on a feasible solution $\{d_t\}_{t\in[n-1]}$ of LP-ultrametric and any choice of $\varepsilon \in (0,1)$. For any*

$t \in [m_\varepsilon]$, *we have that* x^t_{ij} *is feasible for the layer-*$\lfloor(1+\varepsilon)\,t\rfloor$ *problem ILP-layer and there is a constant* $c(\varepsilon) > 0$ *depending only on* ε *such that*

$$\sum_{\{i,j\}\in E(K_n)} \kappa(i,j)x^t_{ij} \leq c(\varepsilon)(\log n)\gamma_t.$$

Moreover, Algorithm 2 can be implemented to run in time polynomial in n.

Remark 20 *A discrete version of the volumetric argument for region growing can be found in (Gupta, 2005).*

We are now ready to prove the main theorem showing that we can obtain a low cost non-trivial ultrametric from Algorithm 2.

Theorem 21 *Let* $\left\{x^t_{ij} \mid t \in [m_\varepsilon]\,, i,j \in V\right\}$ *be the output of Algorithm 2 on an optimal solution* $\{d_t\}_{t\in[n-1]}$ *of LP-ultrametric for any choice of* $\varepsilon \in (0,1)$. *Define the sequence* $\left\{y^t_{ij}\right\}$ *for every* $t \in [n-1]$ *and* $i,j \in V$ *as*

$$y^t_{ij} := \begin{cases} x^{\lfloor t/(1+\varepsilon)\rfloor}_{ij} & \text{if } t > 1+\varepsilon \\ 1 & \text{if } t \leq 1+\varepsilon. \end{cases}$$

Then y^t_{ij} *is feasible for ILP-ultrametric and satisfies*

$$\sum_{t=1}^{n-1}\sum_{\{i,j\}\in E(K_n)} \kappa(i,j)y^t_{ij} \leq (2c(\varepsilon)\log n)\,\mathrm{OPT}$$

where OPT *is the optimal solution to ILP-ultrametric and* $c(\varepsilon)$ *is the constant in the statement of Theorem 19.*

Proof Note that by Theorem 19 for every $t \in [m_\varepsilon]$, x^t_{ij} is feasible for the layer-$\lfloor(1+\varepsilon)t\rfloor$ problem ILP-layer and that there is a constant $c(\varepsilon) > 0$ such that for every $t \in [m_\varepsilon]$, we have $\sum_{\{i,j\}\in E(K_n)} \kappa(i,j)x^t_{ij} \leq (c(\varepsilon)\log n)\,\gamma_t$.
Let y^t_{ij} be as in the statement of the theorem. The graph $G_t = (V, E_t)$ as in Definition 9 corresponding to y^t_{ij} for $t \leq 1+\varepsilon$ consists of isolated vertices, i.e., cliques of size 1: By definition y^t_{ij} is feasible for the layer-t problem ILP-layer. The collection $\mathcal{C}_1$ corresponding to x^1_{ij} consists of cliques of size at most $1+\varepsilon$, however since $0 < \varepsilon < 1$ it follows that the cliques in $\mathcal{C}_1$ are isolated vertices and so $x^1_{ij} = 1$ for every $\{i,j\} \in E(K_n)$. Thus $\sum_{i,j}\kappa(i,j)y^t_{ij} = \sum_{i,j}\kappa(i,j)x^1_{ij} \leq (c(\varepsilon)\log n)\,\gamma_1$ for $t \leq 1+\varepsilon$ by Theorem 19. Moreover for every $t > 1+\varepsilon$, we have $\sum_{i,j}\kappa(i,j)y^t_{ij} \leq (c(\varepsilon)\log n)\gamma_{\lfloor t/(1+\varepsilon)\rfloor}$ again by Theorem 19. We claim that y^t_{ij} is feasible for ILP-ultrametric. The solution y^t_{ij} corresponds to the collection $\mathcal{C}_{\lfloor\frac{t}{1+\varepsilon}\rfloor}$ for $t > 1+\varepsilon$ or to the collection $\mathcal{C}_1$ for $t \leq 1+\varepsilon$ from Algorithm 2. For any $t < m_\varepsilon$, every ball $\mathcal{B}_U(i,r,t) \in \mathcal{C}_t$ comes from the refinement of a ball $\mathcal{B}_{U'}(i',r',t')$ for some $i' \in V$, $r' \geq r$, $t' \geq t$ and $U' \supseteq U$. Thus y^t_{ij} satisfies Condition Nested cliques of Lemma 11. On the other hand line 8 ensures that if $|\mathcal{B}_U(i,r,t)| = \lfloor(1+\varepsilon)s\rfloor$ for some $U \subseteq V$ and $s < t$ then $\mathcal{B}_U(i,r,t)$ also appears as a ball in $\mathcal{C}_s$. Therefore y^t_{ij} also satisfies Condition Realization of Lemma 11 and so is feasible for ILP-ultrametric. The cost of y^t_{ij} is at most

$$\begin{aligned}\sum_{t=1}^{n-1}\sum_{\{i,j\}\in E(K_n)} \kappa(i,j)y^t_{ij} &\leq (c(\varepsilon)\log n)\left(\gamma_1 + \sum_{t=2}^{n-1}\gamma_{\lfloor t/(1+\varepsilon)\rfloor}\right) \\ &\leq 2c(\varepsilon)\log n\sum_{t=1}^{n-1}\gamma_t \\ &\leq 2c(\varepsilon)\log n\,\mathrm{OPT},\end{aligned}$$

where we use the fact that $\sum_{t=1}^{n-1}\gamma_t = \mathrm{OPT}(LP) \leq \mathrm{OPT}$ since LP-ultrametric is a relaxation of ILP-ultrametric. ■

Theorem 21 implies the following corollary where we put everything together to obtain a hierarchical clustering of V in time polynomial in n with $|V| = n$. Let $\mathcal{T}$ denote the set of all possible hierarchical clusterings of V.

Input: Data set V of n points, similarity function $\kappa : V \times V \to \mathbb{R}_{\geq 0}$
Output: Hierarchical clustering of V
1 Solve LP-ultrametric to obtain optimal sequence of spreading metrics $\{d_t \mid d_t : V \times V \to [0,1]\}$
2 Fix a choice of $\varepsilon \in (0,1)$
3 $m_\varepsilon \leftarrow \lfloor\frac{n-1}{1+\varepsilon}\rfloor$
4 Let $\left\{x^t_{ij} \mid t \in [m_\varepsilon]\right\}$ be the output of Algorithm 2 on $V, \kappa, \{d_t\}_{t\in[n-1]}$
5 Let $y^t_{ij} := \begin{cases} x^{\lfloor t/(1+\varepsilon)\rfloor}_{ij} & \text{if } t > 1+\varepsilon \\ 1 & \text{if } t \leq 1+\varepsilon \end{cases}$ for every $t \in [n-1], i,j \in E(K_n)$
6 $d(i,j) \leftarrow \sum_{t=1}^{n-1} y^t_{ij}$ for every $i,j \in E(K_n)$
7 $d(i,i) \leftarrow 0$ for every $i \in V$
8 Let r, T be the output of Algorithm 1 on V, d
9 **return** r, T

Algorithm 3: Hierarchical clustering of V for cost function (1)

Corollary 22 *Given a data set* V *of* n *points and a similarity function* $\kappa : V \times V \to \mathbb{R}_{\geq 0}$, *Algorithm 3 returns a hierarchical clustering* T *of* V *satisfying*

$$\mathrm{cost}(T) \leq O(\log n)\min_{T'\in\mathcal{T}}\mathrm{cost}(T').$$

Moreover Algorithm 3 runs in time polynomial in n *and* $\log\left(\max_{i,j\in V}\kappa(i,j)\right)$.

Proof Let $\widehat{T}$ be the optimal hierarchical clustering according to cost function (1). By Corollary 8 and Theorem 21 we can find a hierarchical clustering T satisfying

$$\sum_{\{i,j\}\in E(K_n)}\kappa(i,j)(|\mathrm{leaves}(T[\mathrm{lca}(i,j)])| - 1) \leq O(\log n)\left(\sum_{\{i,j\}\in E(K_n)}\kappa(i,j)\left(\left|\mathrm{leaves}(\widehat{T}[\mathrm{lca}(i,j)])\right| - 1\right)\right).$$

Let $K := \sum_{\{i,j\}\in E(K_n)}\kappa(i,j)$. Then it follows from the above expression that $\mathrm{cost}(T) \leq O(\log n)\,\mathrm{cost}(\widehat{T}) - O(\log n)K + K \leq O(\log n)\,\mathrm{cost}(\widehat{T})$.
We can find an optimal solution to LP-ultrametric due to Lemma 14 using the Ellipsoid algorithm in time polynomial in n and $\log\left(\max_{i,j\in V}\kappa(i,j)\right)$. Algorithm 2 runs in time polynomial in n due to Theorem 19. Finally, Algorithm 1 runs in time $O\left(n^3\right)$ due to Lemma 7. ■

5. Generalized Cost Function

In this section we study the following natural generalization of cost function (1) also introduced by (Dasgupta, 2016) where the distance between the two points is scaled by a function $f : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$, i.e.,

$$\mathrm{cost}_f(T) := \sum_{\{i,j\}\in E(K_n)}\kappa(i,j)f\left(|\mathrm{leaves}\,T[\mathrm{lca}(i,j)]|\right). \tag{21}$$

In order that cost function (21) makes sense, f should be strictly increasing and satisfy $f(0) = 0$. Possible choices for f could be $\{x^2, e^x - 1, \log(1+x)\}$. The top-down heuristic in (Dasgupta, 2016) finds the optimal hierarchical clustering up to an approximation factor of $c_n \log n$ with c_n being defined as

$$c_n \coloneqq 3\alpha_n \max_{1 \le n' \le n} \frac{f(n')}{f\left(\lceil n'/3 \rceil\right)}$$

and where α_n is the approximation factor from the algorithm used for solving uniform Sparsest Cut problem. A naive approach to solving this problem using the ideas of Algorithm 2 would be to replace the objective function of ILP-ultrametric by

$$\sum_{\{i,j\} \in E(K_n)} \kappa(i,j) f\left(\sum_{t=1}^{n-1} x_{ij}^t\right).$$

This makes the corresponding analogue of LP-ultrametric non-linear however, and for a general κ and f it is not clear how to compute an optimum solution in polynomial time. One possible solution is to assume that f is convex and use the Frank-Wolfe algorithm to compute an optimum solution. That still leaves the problem of how to relate $f\left(\sum_{t=1}^{n-1} x_{ij}^t\right)$ to $\sum_{t=1}^{n-1} f\left(x_{ij}^t\right)$ as one would have to do to get a corresponding version of Theorem 21. The following simple observation provides an alternate way of tackling this problem.

Observation 23 *Let $d : V \times V \to \mathbb{R}$ be an ultrametric and $f : \mathbb{R}_{\ge 0} \to \mathbb{R}_{\ge 0}$ be a strictly increasing function such that $f(0) = 0$. Define the function $f(d) : V \times V \to \mathbb{R}$ as $f(d)(i,j) \coloneqq f(d(i,j))$. Then $f(d)$ is also an ultrametric on V.*

Therefore by Corollary 8 to find a minimum cost hierarchical clustering T of V according to the cost function (21), it suffices to minimize $\langle \kappa, d \rangle$ where d is the f-image of a non-trivial ultrametric as in Definition 2. The following lemma lays down the analogue of Conditions 1 and 2 from Definition 2 that the f-image of a non-trivial ultrametric satisfies. As in Definition 2, we will use the notation $x \sim y$ to denote an equivalence relation between x and y.

Lemma 24 *Let $f : \mathbb{R}_{\ge 0} \to \mathbb{R}_{\ge 0}$ be a strictly increasing function satisfying $f(0) = 0$. An ultrametric d on V is the f-image of a non-trivial ultrametric on V iff*

1. *for every non-empty set $S \subseteq V$, there is a pair of points $i, j \in S$ such that $d(i,j) \ge f(|S| - 1)$,*
2. *for any t, if S_t is an equivalence class of V under the relation $i \sim j$ iff $d(i,j) \le t$, then $\max_{i,j \in S_t} d(i,j) \le f(|S_t| - 1)$.*

Proof If d is the f-image of a non-trivial ultrametric d' on V then clearly d satisfies Conditions 1 and 2. Conversely, let d be an ultrametric on V satisfying Conditions 1 and 2. Note that f is strictly increasing and V is a finite set and thus f^{-1} exists and is strictly increasing as well, with $f^{-1}(0) = 0$. Define d' as $d'(i,j) \coloneqq f^{-1}(d(i,j))$ for every $i, j \in V$. By Observation 23 d' is an ultrametric on V satisfying Conditions 1 and 2 of Definition 2 and so d' is a non-trivial ultrametric on V. ■

Lemma 24 allows us to write the analogue of ILP-ultrametric for finding the minimum cost ultrametric that is the f-image of a non-trivial ultrametric on V. Note that by Lemma 4 the range of such an ultrametric is the set $\{f(0), f(1), \ldots, f(n-1)\}$. We have the binary variables x_{ij}^t for every distinct pair $i, j \in V$ and

$t \in [n-1]$, where $x_{ij}^t = 1$ if $d(i,j) \ge f(t)$ and $x_{ij}^t = 0$ if $d(i,j) < f(t)$.

$$\min \quad \sum_{t=1}^{n-1} \sum_{\{i,j\} \in E(K_n)} \kappa(i,j) \left(f(t) - f(t-1)\right) x_{ij}^t \qquad \text{(f-ILP-ultrametric)}$$

$$\text{s.t.} \quad x_{ij}^t \ge x_{ij}^{t+1} \qquad \forall i,j \in V, t \in [n-2] \tag{22}$$

$$x_{ij}^t + x_{jk}^t \ge x_{ik}^t \qquad \forall i,j,k \in V, t \in [n-1] \tag{23}$$

$$\sum_{i,j \in S} x_{ij}^t \ge 2 \qquad \forall t \in [n-1], S \subseteq V, |S| = t+1 \tag{24}$$

$$\sum_{i,j \in S} x_{ij}^{|S|} \le |S|^2 \left(\sum_{i,j \in S} x_{ij}^t + \sum_{\substack{i \in S \\ j \notin S}} \left(1 - x_{ij}^t\right) \right) \quad \forall t \in [n-1], S \subseteq V \tag{25}$$

$$x_{ij}^t = x_{ji}^t \qquad \forall i,j \in V, t \in [n-1] \tag{26}$$

$$x_{ii}^t = 0 \qquad \forall i \in V, t \in [n-1] \tag{27}$$

$$x_{ij}^t \in \{0,1\} \qquad \forall i,j \in V, t \in [n-1] \tag{28}$$

If x_{ij}^t is a feasible solution to f-ILP-ultrametric then the ultrametric represented by it is defined as

$$d(i,j) \coloneqq \sum_{t=1}^{n-1} (f(t) - f(t-1)) x_{ij}^t.$$

Constraint (24) ensures that d satisfies Condition 1 of Lemma 24, since for every $S \subseteq V$ of size $t+1$ we have a pair $i, j \in S$ such that $d(i,j) \ge f(t)$. Similarly constraint (25) ensures that d satisfies Condition 2 of Lemma 24 since it is active if and only if S is an equivalence class of V under the relation $i \sim j$ iff $d(i,j) < f(t)$. In this case Condition 2 of Lemma 24 requires $\max_{i,j \in S} d(i,j) \le f(|S| - 1)$ or in other words $x_{ij}^{|S|} = 0$ for every $i, j \in S$.

Similar to ILP-layer we define an analogous *layer-t problem* where we fix a choice of $t \in [n-1]$ and drop the constraints that relate the different layers to each other.

$$\min \quad \sum_{\{i,j\} \in E(K_n)} \kappa(i,j) \left(f(t) - f(t-1)\right) x_{ij}^t \qquad \text{(f-ILP-layer)}$$

$$\text{s.t.} \quad x_{ij}^t + x_{jk}^t \ge x_{ik}^t \qquad \forall i,j,k \in V \tag{29}$$

$$\sum_{i,j \in S} x_{ij}^t \ge 2 \qquad \forall S \subseteq V, |S| = t+1 \tag{30}$$

$$x_{ij}^t = x_{ji}^t \qquad \forall i,j \in V \tag{31}$$

$$x_{ii}^t = 0 \qquad \forall i \in V \tag{32}$$

$$x_{ij}^t \in \{0,1\} \qquad \forall i,j \in V \tag{33}$$

Note that f-ILP-ultrametric and f-ILP-layer differ from ILP-ultrametric and ILP-layer respectively only in the objective function. Therefore Lemmas 10 and 11 also give a combinatorial characterization of the set of feasible solutions to f-ILP-layer and f-ILP-ultrametric respectively. Similarly, by Lemma 12 we may replace constraint (24) by the following equivalent constraint over all subsets of V

$$\sum_{j \in S} x_{ij}^t \ge |S| - t \qquad \forall t \in [n-1], S \subseteq V, i \in S.$$

This provides the analogue of LP-ultrametric in which we drop constraint (25) and enforce it in the rounding procedure.

$$\min \quad \sum_{t=1}^{n-1} \sum_{\{i,j\}\in E(K_n)} \kappa(i,j)\left(f(t)-f(t-1)\right) x_{ij}^t \qquad \text{(f-LP-ultrametric)}$$

$$\text{s.t.} \quad x_{ij}^t \geq x_{ij}^{t+1} \qquad \forall i,j \in V, t \in [n-2] \tag{34}$$

$$x_{ij}^t + x_{jk}^t \geq x_{ik}^t \qquad \forall i,j,k \in V, t \in [n-1] \tag{35}$$

$$\sum_{j\in S} x_{ij}^t \geq |S| - t \qquad \forall t \in [n-1], S \subseteq V, i \in S \tag{36}$$

$$x_{ij}^t = x_{ji}^t \qquad \forall i,j \in V, t \in [n-1] \tag{37}$$

$$x_{ii}^t = 0 \qquad \forall i \in V, t \in [n-1] \tag{38}$$

$$0 \leq x_{ij}^t \leq 1 \qquad \forall i,j \in V, t \in [n-1] \tag{39}$$

Since f-LP-ultrametric differs from LP-ultrametric only in the objective function, it follows from Lemma 14 that an optimum solution to f-LP-ultrametric can be computed in time polynomial in n. As before, a feasible solution x_{ij}^t of f-LP-ultrametric induces a sequence $\{d_t\}_{t\in[n-1]}$ of spreading metrics on V defined as $d_t(i,j) \coloneqq x_{ij}^t$. Note that in contrast to the ultrametric d, the spreading metrics $\{d_t\}_{t\in[n-1]}$ are independent of the function f.

Let $\mathcal{B}_U(i,r,t)$ be a ball of radius r centered at $i \in U$ for some set $U \subseteq V$ as in Definition 15. For a subset $U \subseteq V$, let γ_t^U be defined as before to be the value of the layer-t objective corresponding to a solution d_t of f-LP-ultrametric restricted to U, i.e.,

$$\gamma_t^U \coloneqq \sum_{\substack{i,j\in U \\ i<j}} \left(f(t)-f(t-1)\right)\kappa(i,j)d_t(i,j).$$

As before, we denote γ_t^V by γ_t. We will associate a volume $\mathrm{vol}\left(\mathcal{B}_U(i,r,t)\right)$ and a boundary $\partial\mathcal{B}_U(i,r,t)$ to the ball $\mathcal{B}_U(i,r,t)$ as in Section 4.

Definition 25 *Let U be an arbitrary subset of V. For a vertex $i \in U$, radius $r \in \mathbb{R}_{\geq 0}$, and $t \in [n-1]$, let $\mathcal{B}_U(i,r,t)$ be the ball of radius r as in Definition 15. Then we define its* volume *as*

$$\mathrm{vol}\left(\mathcal{B}_U(i,r,t)\right) \coloneqq \frac{\gamma_t^U}{n\log n} + \left(f(t)-f(t-1)\right)\left(\sum_{\substack{j,k\in\mathcal{B}_U(i,r,t)\\ j<k}} \kappa(j,k)d_t(j,k) + \sum_{\substack{j\in\mathcal{B}_U(i,r,t)\\ k\notin\mathcal{B}_U(i,r,t)\\ k\in U}} \kappa(j,k)\left(r-d_t(i,j)\right)\right).$$

The boundary *of the ball $\partial\mathcal{B}_U(i,r,t)$ is the partial derivative of volume with respect to the radius:*

$$\partial\mathcal{B}_U(i,r,t) \coloneqq \left(f(t)-f(t-1)\right)\left(\frac{\partial\,\mathrm{vol}\left(\mathcal{B}_U(i,r,t)\right)}{\partial r}\right) = \left(f(t)-f(t-1)\right)\left(\sum_{\substack{j\in\mathcal{B}_U(i,r,t)\\ k\notin\mathcal{B}_U(i,r,t)\\ k\in U}} \kappa(j,k)\right).$$

The expansion *$\phi\left(\mathcal{B}_U(i,r,t)\right)$ of the ball $\mathcal{B}_U(i,r,t)$ is defined as the ratio of its boundary to its volume, i.e.,*

$$\phi\left(\mathcal{B}_U(i,r,t)\right) \coloneqq \frac{\partial\mathcal{B}_U(i,r,t)}{\mathrm{vol}\left(\mathcal{B}_U(i,r,t)\right)}.$$

Note that the expansion $\phi\left(\mathcal{B}_U(i,r,t)\right)$ of Definition 25 is the same as in Definition 17 since the $\left(f(t)-f(t-1)\right)$ term cancels out. Thus one could run Algorithm 2 with the same notion of volume as in Definition 17, however in that case the analogous versions of Theorems 19 and 21 do not follow as naturally. The following is then a simple corollary of Theorem 19.

Corollary 26 *Let $m_\varepsilon \coloneqq \left\lfloor \frac{n-1}{1+\varepsilon} \right\rfloor$ as in Algorithm 2. Let $\left\{x_{ij}^t \mid t \in [n-1], i,j \in V\right\}$ be the output of Algorithm 2 using the notion of volume, boundary and expansion as in Definition 25, on a feasible solution to f-LP-ultrametric and any choice of $\varepsilon \in (0,1)$. For any $t \in [m_\varepsilon]$, we have that x_{ij}^t is feasible for the layer-$\lfloor(1+\varepsilon)t\rfloor$ problem f-ILP-layer and there is a constant $c(\varepsilon) > 0$ depending only on ε such that*

$$\sum_{\{i,j\}\in E(K_n)} \kappa(i,j)\left(f(t)-f(t-1)\right)x_{ij}^t \leq \left(c(\varepsilon)\log n\right)\gamma_t.$$

Corollary 26 allows us to prove the analogue of Theorem 21, i.e., we can use Algorithm 2 to get an ultrametric that is an f-image of a non-trivial ultrametric and whose cost is at most $O(\log n)$ times the cost of an optimal hierarchical clustering according to cost function (21).

Theorem 27 *Let $\{x_{ij}^t \mid t \in [m_\varepsilon], i,j \in V\}$ be the output of Algorithm 2 using the notion of volume, boundary, and expansion as in Definition 25 on an optimal solution $\{d_t\}_{t\in[n-1]}$ of f-LP-ultrametric for any choice of $\varepsilon \in (0,1)$. Define the sequence $\left\{y_{ij}^t\right\}$ for every $t \in [n-1]$ and $i,j \in V$ as*

$$y_{ij}^t \coloneqq \begin{cases} x_{ij}^{\lfloor t/(1+\varepsilon)\rfloor} & \text{if } t > 1+\varepsilon \\ 1 & \text{if } t \leq 1+\varepsilon. \end{cases}$$

Then y_{ij}^t is feasible for f-ILP-ultrametric and there is a constant $c(\varepsilon) > 0$ such that

$$\sum_{t=1}^{n-1} \sum_{\{i,j\}\in E(K_n)} \kappa(i,j)\left(f(t)-f(t-1)\right)y_{ij}^t \leq \left(c(\varepsilon)\log n\right)\mathrm{OPT}$$

where OPT *is the optimal solution to f-ILP-ultrametric.*

Proof Immediate from Corollary 26 and Theorem 21. ■

Finally we put everything together to obtain the corresponding Algorithm 4 that outputs a hierarchical clustering of V of cost at most $O(\log n)$ times the optimal clustering according to cost function (21).

Corollary 28 *Given a data set V of n points and a similarity function $\kappa : V \times V \to \mathbb{R}$, Algorithm 4 returns a hierarchical clustering T of V satisfying*

$$\mathrm{cost}_f(T) \leq O\left(c_n + \log n\right)\min_{T'\in\mathcal{T}} \mathrm{cost}_f(T'),$$

where $c_n \coloneqq \max_{n'\in[n]} f(n') - f(n'-1)$. Moreover Algorithm 4 runs in time polynomial in n, $\log f(n)$ and $\log\left(\max_{i,j\in V}\kappa(i,j)\right)$.

Proof Let $\widehat{T}$ be an optimal hierarchical clustering according to cost function (21). By Corollary 8, Lemma 24 and Theorem 27 it follows that we can find a hierarchical clustering T satisfying

$$\sum_{\{i,j\}\in E(K_n)} \kappa(i,j) f\left(|\mathrm{leaves}(T[\mathrm{lca}(i,j)]|-1\right) \leq O(\log n)\left(\sum_{\{i,j\}\in E(K_n)} \kappa(i,j) f\left(\left|\mathrm{leaves}(\widehat{T}[\mathrm{lca}(i,j)]\right|-1\right)\right).$$

Recall that $\text{cost}_f(T) := \sum_{\{i,j\}\in E(K_n)} \kappa(i,j) f(|\text{leaves}(T[\text{lca}(i,j)]|)$. Let $K := \sum_{\{i,j\}\in E(K_n)} \kappa(i,j)$. Note that for any hierarchical clustering T' we have $K \leq \text{cost}_f(T')$ since f is an increasing function. From the above expression we infer that

$$\text{cost}_f(T) - c_n K \leq \sum_{\{i,j\}\in E(K_n)} \kappa(i,j) f(|\text{leaves}(T[\text{lca}(i,j)]| - 1) \leq O(\log n)\, \text{cost}_f(\widehat{T}),$$

and so $\text{cost}_f(T) \leq O(\log n)\, \text{cost}_f(\widehat{T}) + c_n K \leq O(c_n + \log n)\, \text{cost}_f(\widehat{T})$. We can find an optimal solution to f-LP-ultrametric due to Lemma 14 using the Ellipsoid algorithm in time polynomial in n, $\log f(n)$, and $\log\left(\max_{i,j\in V} \kappa(i,j)\right)$. Note the additional $\log f(n)$ in the running time since now we need to binary search over the interval $\left[0, \max_{i,j\in V} \kappa(i,j) \cdot f(n) \cdot n\right]$. Algorithm 2 runs in time polynomial in n due to Theorem 19. Finally, Algorithm 1 runs in time $O\left(n^3\right)$ due to Lemma 7. ■

Input: Data set V of n points, similarity function $\kappa : V \times V \to \mathbb{R}_{\geq 0}$, $f : \mathbb{R}_{\geq 0} \to \mathbb{R}_{\geq 0}$ strictly increasing with $f(0) = 0$
Output: Hierarchical clustering of V

Solve f-LP-ultrametric to obtain optimal sequence of spreading metrics $\{d_t \mid d_t : V \times V \to [0,1]\}$
Fix a choice of $\varepsilon \in (0,1)$
$m_\varepsilon \leftarrow \left\lfloor \frac{n-1}{1+\varepsilon} \right\rfloor$
Let $\left\{x^t_{ij} \mid t \in [m_\varepsilon]\right\}$ be the output of Algorithm 2 on $V, \kappa, \{d_t\}_{t\in[n-1]}$
Let $y^t_{ij} := \begin{cases} x^{\lfloor t/(1+\varepsilon)\rfloor}_{ij} & \text{if } t > 1+\varepsilon \\ 1 & \text{if } t \leq 1+\varepsilon \end{cases}$ for every $t \in [n-1], i,j \in E(K_n)$
$d(i,j) \leftarrow \sum_{t=1}^{n-1} (f(t) - f(t-1))\, y^t_{ij}$ for every $i,j \in E(K_n)$
$d(i,i) \leftarrow 0$ for every $i \in V$
Let r, T be the output of Algorithm 1 on $V, f^{-1}(d)$
return r, T

Algorithm 4: Hierarchical clustering of V for cost function (21)

6. Experiments

Finally, we describe the experiments we performed. For small data sets ILP-ultrametric and f-ILP-ultrametric describe integer programming formulations that allow us to compute the exact optimal hierarchical clustering for cost functions (1) and (21) respectively. We implement f-ILP-ultrametric where one can plug in any strictly increasing function f satisfying $f(0) = 0$. In particular, setting $f(x) = x$ gives us ILP-ultrametric. We use the Mixed Integer Programming (MIP) solver Gurobi 6.5 (Gurobi Optimization, 2015). Similarly, we also implement Algorithms 1, 2, and 4 using Gurobi as our LP solver. Note that Algorithm 4 needs to fix a parameter choice $\varepsilon \in (0,1)$. In Sections 4 and 5 we did not discuss the effect of the choice of the parameter ε in detail. In particular, we need to choose an ε small enough such that for every $U \subseteq V$ encountered in Algorithm 2, $\text{vol}\left(\mathcal{B}_U(i,\Delta,t)\right)$ is of the same sign as $\text{vol}\left(\mathcal{B}_U(i,0,t)\right)$ for every $t \in [n-1]$, so that $\log\left(\frac{\text{vol}(\mathcal{B}_U(i,\Delta,t))}{\text{vol}(\mathcal{B}_U(i,0,t))}\right)$ is defined. In our experiments we start with a particular value of ε (say 0.5) and halve it till the volumes have the same sign. For the sake of exposition, we limit ourselves to the following choices for the function f

$$\left\{x, x^2, \log(1+x), e^x - 1\right\}.$$

By Lemma 14 we can optimize over f-LP-ultrametric in time polynomial in n using the Ellipsoid method. In practice however, we use the *dual simplex* method where we separate triangle inequality constraints (35) and spreading constraints (36) to obtain fast computations. For the similarity function $\kappa : V \times V \to \mathbb{R}$ we limit ourselves to using *cosine similarity* and the *Gaussian kernel* with $\sigma = 1$. They are defined formally below.

Definition 29 (Cosine similarity) *Given a data set $V \in \mathbb{R}^m$ for some $m \geq 0$, the cosine similarity κ_{cos} is defined as $\kappa_{cos}(x,y) := \frac{\langle x,y\rangle}{\|x\|\,\|y\|}$, for any pair of points $x, y \in V$.*

Since the LP rounding Algorithm 2 assumes that $\kappa \geq 0$ in practice we implement $1 + \kappa_{cos}$ rather than κ_{cos}.

Definition 30 (Gaussian kernel) *Given a data set $V \in \mathbb{R}^m$ for some $m \geq 0$, the Gaussian kernel κ_{gauss} with standard deviation σ is defined as $\kappa_{gauss}(x,y) := \exp\left(-\frac{\|x-y\|^2}{2\sigma^2}\right)$, for any pair of points $x, y \in V$.*

The main aim of our experiments was to answer the following two questions.

1. How good is the hierarchal clustering obtained from Algorithm 4 as opposed to the true optimal output by f-ILP-ultrametric?
2. How good does Algorithm 4 perform compared to other hierarchical clustering methods?

For the first question, we are restricted to working with small data sets since computing an optimum solution to f-ILP-ultrametric is expensive. In this case we consider synthetic data sets of small size and samples of some data sets from the UCI database (Lichman, 2013). The synthetic data sets we consider are mixtures of Gaussians in various small dimensional spaces. Figure 2 shows a comparison of the cost of the hierarchy (according to cost function (21)) returned by solving f-ILP-ultrametric and by Algorithm 4 for various forms of f when the similarity function is κ_{cos} and κ_{gauss}. Note that we normalize the cost of the tree returned by f-ILP-ultrametric and Algorithm 4 by the cost of the trivial clustering r, T^* where T^* is the star graph with V as its leaves and r as the internal node. In other words $d_{T^*}(i,j) = n-1$ for every distinct pair $i,j \in V$ and so the normalized cost of any tree lies in the interval $(0,1]$.
For the study of the second question, we consider some of the popular algorithms for hierarchical clustering such as *single linkage*, *average linkage*, *complete linkage*, and *Ward's method* (Ward Jr, 1963). To get a numerical handle on how good a hierarchical clustering T of V is, we prune the tree to get the *best* k flat clusters and measure its error relative to the target clustering. We use the following notion of error also known as *Classification Error* that is standard in the literature for hierarchical clustering (see, e.g., (Meilă and Heckerman, 2001)). Note that we may think of a flat k-clustering of the data V as a function h mapping elements of V to a label set $\mathcal{L} := \{1, \ldots, k\}$. Let S_k denote the group of permutations on k letters.

Definition 31 (Classification Error) *Given a proposed clustering $h : V \to \mathcal{L}$ its* classification error *relative to a target clustering $g : V \to \mathcal{L}$ is denoted by* $\text{err}(g,h)$ *and is defined as*

$$\text{err}(g,h) := \min_{\sigma\in S_k} \left[\Pr_{x\in V}[h(x) \neq \sigma(g(x))\right].$$

We compare the error of Algorithm 4 with the various linkage based algorithms that are commonly used for hierarchical clustering, as well as Ward's method and the k-means algorithm. We test Algorithm 4 most extensively for $f(x) = x$ while doing a smaller number of tests for $f(x) \in \left\{x^2, \log(1+x), e^x - 1\right\}$. Note that both Ward's method and the k-means algorithm work on the squared Euclidean distance $\|x-y\|_2^2$ between two points $x, y \in V$, i.e., they both require an embedding of the data points into a normed vector space which provides extra information that can be potentially exploited. For the linkage based algorithms we use the same notion of similarity $1 + \kappa_{cos}$ or κ_{gauss} that we use for Algorithm 4. For comparison we use a mix of synthetic data sets as well as the Wine, Iris, Soybean-small, Digits, Glass, and Wdbc data sets from the

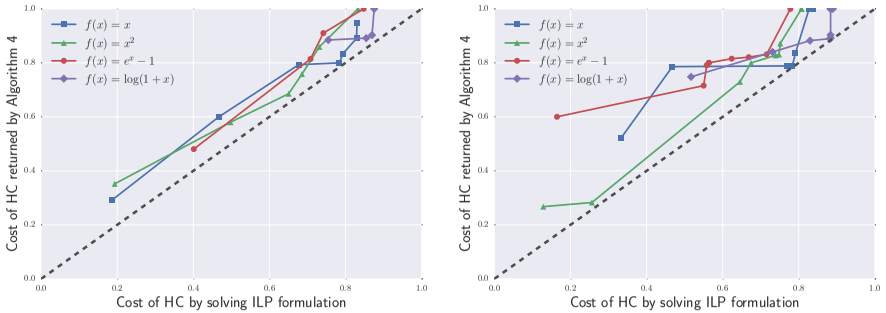

Figure 2: Comparison of f-ILP-ultrametric and Algorithm 4 for $1 + \kappa_{cos}$ (left) and κ_{gauss} (right)

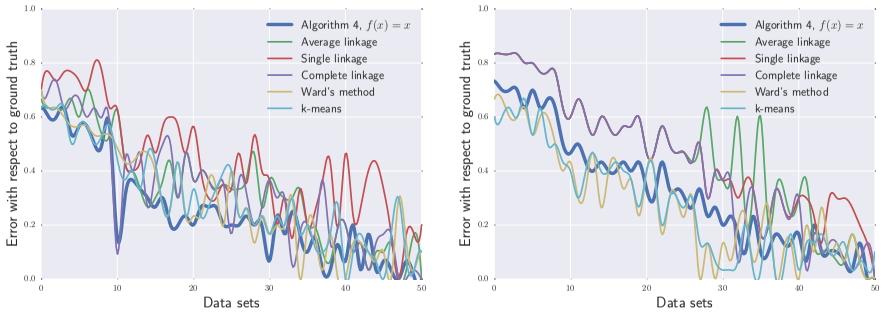

Figure 3: Comparison of Algorithm 4 using $f(x) = x$, with other algorithms for clustering using $1 + \kappa_{cos}$ (left) and κ_{gauss} (right)

UCI repository (Lichman, 2013). For some of the larger data sets, we sample uniformly at random a smaller number of data points and take the average of the error over the different runs. Figures 3, 4, 5, and 6 plot the performance of the various algorithms, with the x-axis representing the data sets (sorted in decreasing order of average classification error) and the y-axis representing the classification error. From the figures, we see that the hierarchical clustering returned by Algorithm 4 with $f(x) \in \{x, x^2, \log(1+x), e^x - 1\}$ often has better projections into flat clusterings than the other algorithms. This is especially true when we compare it to the linkage based algorithms, since they use the same pairwise similarity function as Algorithm 4, as opposed to Ward's method and k-means.

7. Hardness of finding the optimal hierarchical clustering

In this section we study the hardness of finding the optimal hierarchical clustering according to cost function (1). We show that under the assumption of the *Small Set Expansion* (SSE) hypothesis there is no constant factor approximation algorithm for this problem. We also show that no polynomial sized Linear Program

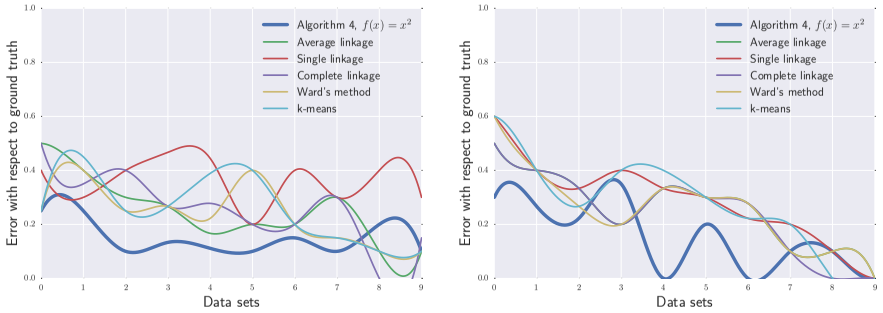

Figure 4: Comparison of Algorithm 4 using $f(x) = x^2$, with other algorithms for clustering using $1 + \kappa_{cos}$ (left) and κ_{gauss} (right)

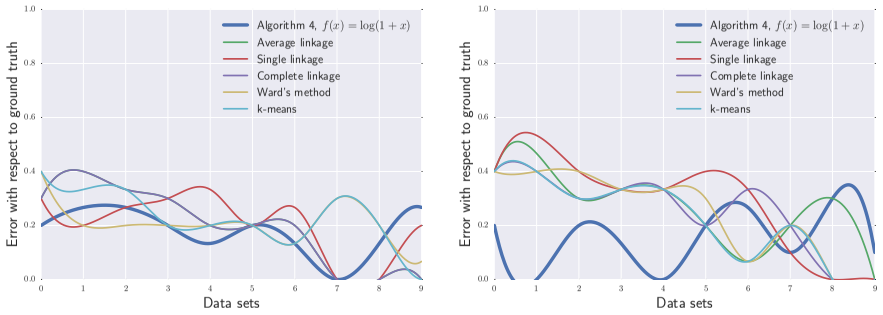

Figure 5: Comparison of Algorithm 4 using $f(x) = \log(1+x)$, with other algorithms for clustering using $1 + \kappa_{cos}$ (left) and κ_{gauss} (right)

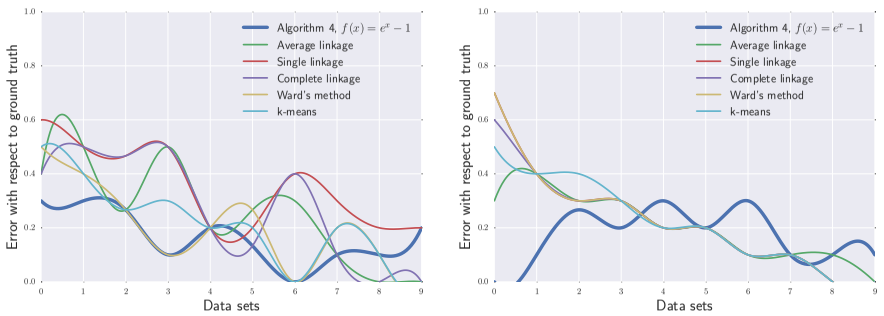

Figure 6: Comparison of Algorithm 4 using $f(x) = e^x - 1$, with other algorithms for clustering using $1 + \kappa_{cos}$ (left) and κ_{gauss} (right)

(LP) or Semidefinite Program (SDP) can give a constant factor approximation for this problem without the need for any complexity theoretic assumptions. Both these results make use of the similarity of this problem with the *minimum linear arrangement* problem. To show hardness under Small Set Expansion, we make use of the result of (Raghavendra et al., 2012) showing that there is no constant factor approximation algorithm for the Minimum Linear Arrangement problem under the assumption of SSE. To show the LP and SDP inapproximability results, we make use of the reduction framework of (Braun et al., 2015) together with the NP-hardness proof for Minimum Linear Arrangement due to (Garey et al., 1976). We also note that both these hardness results hold even for unweighted graphs (i.e., when $\kappa \in \{0,1\}$).
Note that the individual layer-t problem f-ILP-layer for $t = \lfloor n/2 \rfloor$ is equivalent to the *minimum bisection problem* for which the best known approximation is $O(\log n)$ due to (Räcke, 2008), while the best known bi-criteria approximation is $O\left(\sqrt{\log n}\right)$ due to (Arora et al., 2009) and improving these approximation factors is a major open problem. However it is not clear if an improved approximation algorithm for hierarchical clustering under cost function (1) would imply an improved algorithm for every layer-t problem, which is why a constant factor inapproximability result is of interest. We recall the following setup for LP and SDP reductions between optimization problems from (Braun et al., 2015). We denote by $\mathcal{P} = (\mathcal{S}, \mathcal{I}, \mathrm{val})$, a generic optimization problem consisting of *solutions*, *feasible instances* and an *objective function* respectively. The (C,S)-approximate LP and SDP complexity of a problem $\mathcal{P}$ is denoted by $\mathrm{fc}_{\mathrm{LP}}(\mathcal{P},C,S)$ and $\mathrm{fc}_{\mathrm{SDP}}(\mathcal{P},C,S)$ respectively. A reduction from problem $\mathcal{P}_1$ with approximation guarantees (C_1,S_1) to a problem $\mathcal{P}_2$ with approximation guarantees (C_2,S_2) is formally defined as:

Definition 32 (Reduction) *(Braun et al., 2015) Let $\mathcal{P}_1 = (\mathcal{S}_1, \mathcal{I}_1, \mathrm{val})$ and $\mathcal{P}_2 = (\mathcal{S}_2, \mathcal{I}_2, \mathrm{val})$ be optimization problems with guarantees C_1, S_1 and C_2, S_2, respectively. Let $\tau_1 = +1$ if $\mathcal{P}_1$ is a maximization problem, and $\tau_1 = -1$ if $\mathcal{P}_1$ is a minimization problem. Similarly, let $\tau_2 = \pm 1$ depending on whether $\mathcal{P}_2$ is a maximization problem or a minimization problem.*
A reduction *from $\mathcal{P}_1$ to $\mathcal{P}_2$ respecting the guarantees consists of*

1. *two mappings: $*\colon \mathcal{I}_1 \to \mathcal{I}_2$ and $*\colon \mathcal{S}_1 \to \mathcal{S}_2$ translating instances and feasible solutions independently;*

2. *two nonnegative $\mathcal{I}_1 \times \mathcal{S}_1$ matrices M_1, M_2*

subject to the conditions

$$\tau_1 \left[C_1(\mathcal{I}_1) - \mathrm{val}_{\mathcal{I}_1}(s_1)\right] = \tau_2 \left[C_2(\mathcal{I}_1^*) - \mathrm{val}_{\mathcal{I}_1^*}(s_1^*)\right] M_1(\mathcal{I}_1, s_1) + M_2(\mathcal{I}_1, s_1) \qquad \text{(40-complete)}$$

$$\tau_2 \,\mathrm{OPT}\,(\mathcal{I}_1^*) \le \tau_2 S_2(\mathcal{I}_1^*) \qquad \text{if } \tau_1 \,\mathrm{OPT}\,(\mathcal{I}_1) \le \tau_1 S_1(\mathcal{I}_1). \qquad \text{(40-sound)}$$

The matrices M_1 and M_2 control the parameters of the reduction relating the integrality gap of relaxations for $\mathcal{P}_1$ to the integrality gap of corresponding relaxations for $\mathcal{P}_2$. For a matrix A, let $\mathrm{rk}_+ A$ and $\mathrm{rk}_{\mathrm{psd}} A$ denote the nonnegative rank and psd rank of A respectively. The following theorem is a restatement of Theorem 3.2 from (Braun et al., 2015) ignoring constants.

Theorem 33 *(Braun et al., 2015) Let $\mathcal{P}_1$ and $\mathcal{P}_2$ be optimization problems with a reduction from $\mathcal{P}_1$ to $\mathcal{P}_2$ respecting the completeness guarantees C_1, C_2 and soundness guarantees S_1, S_2 of $\mathcal{P}_1$ and $\mathcal{P}_2$, respectively. Then*

$$\mathrm{fc}_{\mathrm{LP}}(\mathcal{P}_1, C_1, S_1) \le \mathrm{rk}_+ M_2 + \mathrm{rk}_+ M_1 + \mathrm{rk}_+ M_1 \cdot \mathrm{fc}_{\mathrm{LP}}(\mathcal{P}_2, C_2, S_2), \qquad (41)$$

$$\mathrm{fc}_{\mathrm{SDP}}(\mathcal{P}_1, C_1, S_1) \le \mathrm{rk}_{\mathrm{psd}} M_2 + \mathrm{rk}_{\mathrm{psd}} M_1 + \mathrm{rk}_{\mathrm{psd}} M_1 \cdot \mathrm{fc}_{\mathrm{SDP}}(\mathcal{P}_2, C_2, S_2), \qquad (42)$$

where M_1 and M_2 are the matrices in the reduction as in Definition 32.

Therefore to obtain a lower bound for problem $\mathcal{P}_2$, it suffices to find a source problem $\mathcal{P}_1$ and matrices M_1 and M_2 of low nonnegative rank and low psd rank, satisfying Definition 32.
Below, we cast the hierarchical clustering problem (HCLUST) as an optimization problem. We also recall a different formulation of cost function (1) due to (Dasgupta, 2016) that will be useful in the analysis of the reduction.

Definition 34 (HCLUST **as optimization problem**) *The minimization problem* HCLUST *of size n consists of*

instances *similarity function $\kappa : E(K_n) \to \mathbb{R}_{\ge 0}$*
feasible solutions *hierarchical clustering r, T of $V(K_n)$*
measure $\mathrm{val}_\kappa(T) = \sum_{\{i,j\} \in E(K_n)} \kappa(i,j)\, |\mathrm{leaves}(T[\mathrm{lca}(i,j)])|$.

We will also make use of the following alternate interpretation of cost function (1) given by (Dasgupta, 2016). Let $\kappa\colon V \times V \to \mathbb{R}_{\ge 0}$ be an instance of HCLUST. For a subset $S \subseteq V$, a split $S_1, \ldots, S_k$ is a partition of S into k disjoint pieces. For a binary split S_1, S_2 we can define $\kappa(S_1, S_2) := \sum_{i \in S_1, j \in S_2} \kappa(i,j)$. This can be extended to k-way splits in the natural way:

$$\kappa(S_1, \ldots, S_k) := \sum_{1 \le i \le j \le k} \kappa(S_i, S_j).$$

Then the cost of a tree T is the sum over all the internal nodes of the splitting costs at the nodes, as follows.

$$\mathrm{cost}(T) = \sum_{\text{splits } S \to (S_1, \ldots, S_k) \text{ in } T} |S|\, \kappa(S_1, \ldots, S_k).$$

We now briefly recall the MAXCUT problem.

Definition 35 (MAXCUT **as optimization problem**) *The maximization problem* MAXCUT *of size n consists of*

instances *all graphs G with $V(G) \subseteq [n]$*
feasible solutions *all subsets X of $[n]$*
measure $\mathrm{val}_G(X) = |\delta_G(X)|$.

Similarly, the Minimum Linear Arrangement problem can be phrased as an optimization problem as follows.

Definition 36 (MLA **as optimization problem**) *The minimization problem* MLA *of size n consists of*

instances *weight function $w : E(K_n) \to \mathbb{R}_{\geq 0}$*
feasible solutions *all permutations $\pi : V(K_n) \to [n]$*
measure $\mathrm{val}_w(\pi) \coloneqq \sum_{\{i,j\} \in E(K_n)} w(i,j)\,|\pi(i) - \pi(j)|$.

We now describe the reduction from MAXCUT to HCLUST which is a modification of the reduction from MAXCUT to MLA due to (Garey et al., 1976). Note that an instance of MAXCUT maps to an unweighted instance of HCLUST, i.e., $\kappa \in \{0,1\}$.

Mapping instances Given an instance $G = (V,E)$ of MAXCUT of size n, let $r = n^4$ and $U = \{u_1, u_2, \ldots, u_r\}$. The instance κ of HCLUST is on the graph with vertex set $V' \coloneqq V \cup U$ and has weights in $\{0,1\}$. For any distinct pair $i,j \in V'$, if $\{i,j\} \in E$ then we define $\kappa(i,j) \coloneqq 0$ and otherwise we set $\kappa(i,j) \coloneqq 1$.

Mapping solutions Given a cut $X \subseteq V$ of MAXCUT we map it to the clustering r, T of V' where the root r has the following children: n^4 leaves corresponding to U, and 2 internal vertices corresponding to X and $\overline{X}$. The internal vertices for X and $\overline{X}$ are split into $|X|$ and $\left|\overline{X}\right|$ leaves respectively at the next level.

The following lemma relates the LP and SDP formulations for MAXCUT and MLA.

Lemma 37 *For any completeness and soundness guarantee (C,S), we have the following*

$$\mathrm{fc}_{\mathrm{LP}}\left(\mathsf{MAXCUT}, C, S\right) \leq \mathrm{fc}_{\mathrm{LP}}\left(\mathsf{HCLUST}, C', S'\right) + O(n^2)$$
$$\mathrm{fc}_{\mathrm{SDP}}\left(\mathsf{MAXCUT}, C, S\right) \leq \mathrm{fc}_{\mathrm{SDP}}\left(\mathsf{HCLUST}, C', S'\right) + O(n^2).$$

where $C' \coloneqq \frac{(n^4+n)^3-(n^4+n)}{3} - C(n^4+n)$ and $S' \coloneqq \binom{n^4+n+1}{3} - Sn^4$.

Proof To show completeness, we analyze the cost of the tree T that a cut X maps to, using the alternate interpretation of the cost function (1) due to (Dasgupta, 2016) (see above). Let H be the graph on vertex set V' induced by κ, i.e. $\{i,j\} \in E(H)$ iff $\kappa(i,j) = 1$. Let $\overline{H}$ denote the complement graph of H and let $\overline{\kappa}$ be the similarity function induced by it, i.e., $\overline{\kappa}(i,j) = 1$ iff $\{i,j\} \notin E(H)$ and $\overline{\kappa}(i,j) = 0$ otherwise. For a hierarchical clustering T of V', we denote by $\mathrm{cost}_H(T)$ and $\mathrm{cost}_{\overline{H}}(T)$ the cost of T induced by κ and $\overline{\kappa}$ respectively, i.e., $\mathrm{cost}_H(T) \coloneqq \sum_{\{i,j\} \in E(H)} |\mathrm{leaves}(T[\mathrm{lca}(i,j)])|$ and $\mathrm{cost}_{\overline{H}}(T) \coloneqq \sum_{\{i,j\} \notin E(H)} |\mathrm{leaves}(T[\mathrm{lca}(i,j)])|$. Let $\overline{X} \coloneqq V' \setminus X$. The cost of the tree T that the cut X maps to, is given by

$$\begin{aligned}
\mathrm{cost}(T) &= \mathrm{cost}_H(T) \\
&= \frac{\left(n+n^4\right)^3 - (n+n^4)}{3} - \mathrm{cost}_{\overline{H}}(T) \\
&= \frac{\left(n+n^4\right)^3 - (n+n^4)}{3} - \sum_{\text{splits } S \to (S_1,\ldots,S_k) \text{ in } T} |S|\,\overline{\kappa}(S_1,\ldots,S_k) \\
&= \frac{\left(n+n^4\right)^3 - (n+n^4)}{3} - \left(n+n^4\right)\mathrm{val}_G(X) - \left(|X|\,|E[X]| + \left|\overline{X}\right|\,\left|E[\overline{X}]\right|\right),
\end{aligned}$$

where $E[X]$ and $E[\overline{X}]$ are the edges of $E(H)$ induced on the set X and $\overline{X}$ respectively. Therefore, we have the following completeness relationship between the two problems

$$C - \mathrm{val}_G(X) = \frac{1}{n+n^4}\left(\mathrm{cost}(T) - \left(\frac{(n+n^4)^3 - (n+n^4)}{3} - C(n+n^4)\right)\right) + \frac{|X|\,|E[X]| + \left|\overline{X}\right|\,\left|E[\overline{X}]\right|}{n^4+n}.$$

We now define the matrices M_1 and M_2 as $M_1(H,X) \coloneqq \frac{1}{n+n^4}$ and $M_2(H,X) \coloneqq |X|\,|E[X]| + \left|\overline{X}\right|\,\left|E[\overline{X}]\right|$. Clearly, M_1 has $O(1)$ nonnegative rank and psd rank. We claim that the nonnegative rank of M_2 is at most $2^{\binom{n}{2}}$. The vectors $v_H \in \mathbb{R}^{2^{\binom{n}{2}}}$ corresponding to the instances H is defined as the concatenation $[u_H, w_H]$ of two vectors $u_H, w_H \in \mathbb{R}^{\binom{n}{2}}$. Both the vectors u_H, w_H encode the edges of H scaled by n^4+n, i.e., $u_H(\{i,j\}) = w_H(\{i,j\}) = 1/(n^4+n)$ iff $\{i,j\} \in E(H)$ and 0 otherwise. The vectors $v_X \in \mathbb{R}^{2^{\binom{n}{2}}}$ corresponding to the solutions are also defined as the concatenation $[u_X, w_X]$ of two vectors $u_X, w_X \in \mathbb{R}^n$. The vector u_X encodes the vertices in X scaled by $|X|$ i.e., $u_X(\{i,j\}) = |X|$ iff $i,j \in X$ and 0 otherwise. The vector w_X encodes the vertices in $\overline{X}$ scaled by $\left|\overline{X}\right|$ i.e., $w_X(\{i,j\}) = \left|\overline{X}\right|$ iff $i,j \in \overline{X}$ and 0 otherwise. Clearly, we have $M_2(H,X) = \langle v_H, v_X \rangle$ and so the nonnegative (and psd) rank of M_2 is at most $2^{\binom{n}{2}}$. Soundness follows due to the analysis in (Garey et al., 1976) and by noting that the cost of a linear arrangement obtained by projecting the leaves of T is a lower bound on $\mathrm{cost}(T)$. By the analysis in (Garey et al., 1976) if the optimal value $\mathrm{OPT}(G)$ of MAXCUT is at most S, then the optimal value of MLA on V', κ is at least $\binom{n^4+n+1}{3} - Sn^4$. Therefore, it follows that the optimal value of HCLUST on V', κ is also at least $\binom{n^4+n+1}{3} - Sn^4$. ■

The constant factor inapproximability result for HCLUST now follows due to the following theorems.

Theorem 38 ((Chan et al., 2013, Theorem 3.2)) *For any $\varepsilon > 0$ there are infinitely many n such that*

$$\mathrm{fc}_{\mathrm{LP}}\left(\mathsf{MAXCUT}, 1-\varepsilon, \frac{1}{2} + \frac{\varepsilon}{6}\right) \geq n^{\Omega(\log n / \log\log n)}.$$

Theorem 39 ((Braun et al., 2015, Theorem 7.1)) *For any $\delta, \varepsilon > 0$ there are infinitely many n such that*

$$\mathrm{fc}_{\mathrm{SDP}}\left(\mathsf{MAXCUT}, \frac{4}{5} - \varepsilon, \frac{3}{4} + \delta\right) = n^{\Omega(\log n / \log\log n)}. \tag{43}$$

Thus we have the following corollary about the LP and SDP inapproximability for the problem HCLUST.

Corollary 40 (LP and SDP hardness for HCLUST**)** *For any constant $c \geq 1$,* HCLUST *is LP-hard and SDP-hard with an inapproximability factor of c.*

Proof Straightforward by using Theorems 38 and 39 together with Lemma 37 and by choosing n large enough. ■

The following lemma shows that a minor modification of the argument in (Raghavendra et al., 2012) also implies a constant factor inapproximability result under the *Small Set Expansion* (SSE) hypothesis. Note that this reduction is also true for unit capacity graphs, i.e., $\kappa \in \{0,1\}$. The SSE hypothesis implies the well-known Unique Games Conjecture (UGC) and it is believed that the two may be equivalent. We briefly recall the formulation of the Small Set Expansion hypothesis. Informally, given a graph $G = (V,E)$ the problem is to decide whether all "small" sets in the graph are expanding. Let $d(i)$ denote the degree of a vertex $i \in V$. For a subset $S \subseteq V$ let $\mu(S) \coloneqq |S| \,/\, |V|$ be the volume of S, and let $\phi(S) \coloneqq E(S,\overline{S}) / \sum_{i \in S} d(i)$ be the expansion of S. Then the SSE problem is defined as follows.

Definition 41 (Small set expansion (SSE) hypothesis (Raghavendra et al., 2012)) *For every constant $\eta > 0$, there exists sufficiently small $\delta > 0$ such that given a graph $G = (V, E)$, it is NP-hard to decide the following cases,*

Completeness *there exists a subset $S \subseteq V$ with volume $\mu(S) = \delta$ and expansion $\phi(S) \leq \eta$,*

Soundness *every subset $S \subseteq V$ of volume $\mu(S) = \delta$ has expansion $\phi(S) \geq 1 - \eta$.*

Under this assumption, (Raghavendra et al., 2012) proved the following amplification result about the expansion of small sets in the graph.

Theorem 42 (Theorem 3.5 (Raghavendra et al., 2012)) *For all $q \in \mathbb{N}$ and $\varepsilon', \gamma > 0$ it is SSE-hard to distinguish the following for a given graph $H = (V_H, E_H)$*

Completeness *There exist disjoint sets $S_1, \ldots, S_q \subseteq V_H$ satisfying $\mu(S_i) = \frac{1}{q}$ and $\phi(S_i) \leq \varepsilon' + o(\varepsilon')$ for all $i \in [n]$,*

Soundness *For all sets $S \subseteq V_H$ we have $\phi(S) \geq \phi_{\mathcal{G}}(1 - \varepsilon'/2)(\mu(S)) - \gamma/\mu(S)$,*

where $\phi_{\mathcal{G}}(1 - \varepsilon'/2)(\mu(S))$ is the expansion of sets of volume $\mu(S)$ in the infinite Gaussian graph $\mathcal{G}(1 - \varepsilon'/2)$.

The following lemma establishes that it is SSE-hard to approximate HCLUST to within any constant factor. The argument closely parallels Corollary A.5 of (Raghavendra et al., 2012) where it was shown that it is SSE-hard to approximate MLA to within any constant factor.

Lemma 43 *Let $G = (V, E)$ be a graph on V with κ induced by the edges E i.e., $\kappa(i, j) = 1$ iff $\{i, j\} \in E$ and 0 otherwise. Then it is SSE-hard to distinguish between the following two cases*

Completeness *There exists a hierarchical clustering T of V with $\text{cost}(T) \leq \varepsilon n |E|$,*

Soundness *Every hierarchical clustering T of V satisfies $\text{cost}(T) \geq c\sqrt{\varepsilon} n |E|$*

for some constant c not depending on n.

Proof Apply Theorem 42 on the graph G with the following choice of parameters: $q = \lceil 2/\varepsilon \rceil$, $\varepsilon' = \varepsilon/3$ and $\gamma = \varepsilon$. Suppose there exist $S_1, \ldots, S_q \subseteq V$ satisfying $\phi(S_i) \leq \varepsilon' + o(\varepsilon')$ and $|S_i| = |V| / q \leq \varepsilon |V| / 2$. Then consider the tree r, T with the root r having q children corresponding to each S_i, and each S_i being further separated into $|S_i|$ leaves at the next level. We claim that $\text{cost}(T) \leq \varepsilon n |E|$. We analyze this using the alternate interpretation of cost function (1) (see above). Every crossing edge between S_i, S_j for distinct $i, j \in [q]$ incurs a cost of n, but by assumption there are at most $\varepsilon |E| / 2$ such edges. Further, any edge in S_i incurs a cost $\frac{n}{q} \leq \varepsilon n/2$ and thus their contribution is upper bounded by $\varepsilon n |E|$.
The analysis for soundness follows by the argument of Corollary A.5 in (Raghavendra et al., 2012). In particular, if for every $S \subseteq V$ we have $\phi(S) \geq \phi_{\mathcal{G}}(1 - \varepsilon'/2)(\mu(S)) - \gamma/\mu(S)$ then the cost of the optimal linear arrangement on G is at most $\sqrt{\varepsilon} n |E|$. Since the cost of any tree (including the optimal tree) is at least the cost of the linear arrangement induced by projecting the leaf vertices, the claim about soundness follows. ■

8. Discussion

In this work we have studied the cost functions (1) and (21) for hierarchical clustering given a pairwise similarity function over the data and shown an $O(\log n)$ approximation algorithm for this problem. As briefly mentioned in Section 2 however, such a cost function is not unique. Further, there is an intimate connection between hierarchical clusterings and ultrametrics over discrete sets which points to other directions for formulating a cost function over hierarchies. In particular we briefly mention the related notion of *hierarchically well-separated trees* (HST) as defined in (Bartal, 1996) (see also (Bartal et al., 2001, 2003)). A k-HST for $k \geq 1$ is a tree T such that each vertex $u \in T$ has a label $\Delta(u) \geq 0$ such that $\Delta(u) = 0$ if and only if u is a leaf of T. Further, if u is a child of v in T then $\Delta(u) \leq \Delta(v)/k$. It is well known that any ultrametric d on a finite set V is equivalent to a 1-HST where V is the set of leaves of T and $d(i, j) = \Delta(\text{lca}(i, j))$ for every $i, j \in V$. Thus in the special case when $\Delta(u) = |\text{leaves } T[u]| - 1$ we get the cost function (1), while if $\Delta(u) = f(|\text{leaves } T[u]| - 1)$ for a strictly increasing function f with $f(0) = 0$ then we get cost function (21). It turns out this assumption on Δ enables us to prove the combinatorial results of Section 3 and give an $O(\log n)$ approximation algorithm to find the optimal cost tree according to these cost functions. It is an interesting problem to investigate cost functions and algorithms for hierarchical clustering induced by other families of Δ that arise from a k-HST on V, i.e., if the cost of T is defined as

$$\text{cost}_{\Delta}(T) \coloneqq \sum_{\{i,j\} \in E(K_n)} \kappa(i, j) \Delta(\text{lca}(i, j)). \tag{44}$$

Note that not all choices of Δ lead to a meaningful cost function. For example, choosing $\Delta(u) = \text{diam}(T[u]) - 1$ gives rise to the following cost function

$$\text{cost}(T) \coloneqq \sum_{\{i,j\} \in E(K_n)} \kappa(i, j) \, \text{dist}_T(i, j) \tag{45}$$

where $\text{dist}_T(i, j)$ is the length of the unique path from i to j in T. In this case, the trivial clustering r, T^* where T^* is the star graph with V as its leaves and r as the root is always a minimizer; in other words, there is no incentive for spreading out the hierarchical clustering. Also worth mentioning is a long line of related work on fitting tree metrics to metric spaces (see e.g., (Ailon and Charikar, 2005; Räcke, 2008; Fakcharoenphol et al., 2003)). In this setting, the data points V are assumed to come from a metric space d_V and the objective is to find a hierarchical clustering T so as to minimize $\|d_V - d_T\|_p$. If the points in V lie on the unit sphere and the similarity function κ is the cosine similarity $\kappa_{cos}(i, j) = 1 - d_V(i, j)/2$, then the problem of fitting a tree metric with $p = 2$ minimizes the same objective as cost function (45). Since $d_V \leq 1$ in this case, the minimizer is the trivial tree r, T^* (as remarked above). In general, when the points in V are not constrained to lie on the unit sphere, the two problems are incomparable.

Appendix A. Missing proofs from Section 2

Lemma 44 (Restatement of Lemma 3.) *Let d be a non-trivial ultrametric on V and let $S_t \subseteq V$ be an equivalence class under the relation $i \sim j$ iff $d(i, j) \leq t$. Then d restricted to S_t is a non-trivial ultrametric on S_t.*

Proof Clearly d restricted to S_t is an ultrametric on S_t and so we need to establish that it satisfies Conditions 1 and 2 of Definition 2. Let $S \subseteq S_t$ be any set. Since d is a non-trivial ultrametric on V it follows that there is a pair $i, j \in S$ with $d(i,j) \geq |S| - 1$, and so d restricted to S_t satisfies Condition 1.
If S'_r is an equivalence class in S_t under the relation $i \sim j$ iff $d(i,j) \leq r$ then clearly $S'_r = S_t$ if $r > t$. Since d is a non-trivial ultrametric on V, it follows that $\max_{i,j \in S'_r} d(i,j) = \max_{i,j \in S_t} d(i,j) \leq |S_t| - 1 = |S'_r| - 1$. Thus we may assume that $r \leq t$. Consider an $i \in S'_r$ and let $j \in V$ be such that $d(i,j) \leq r$. Since $r \leq t$ and $i \in S_t$, it follows that $j \in S_t$ and so $j \in S'_r$. In other words S'_r is an equivalence class in V under the relation $i \sim j$ iff $d(i,j) \leq r$. Since d is an ultrametric on V it follows that $\max_{i,j \in S'_r} d(i,j) \leq |S'_r| - 1$. Thus d restricted to S_t satisfies Condition 2. ■

Lemma 45 (Restatement of Lemma 4.) *Let d be a non-trivial ultrametric on the set V as in Definition 2. Then the range of d is contained in the set $\{0, 1, \ldots, n-1\}$ with $|V| = n$.*

Proof We will prove this by induction on $|V|$. The base case when $|V| = 1$ is trivial. Therefore, we now assume that $|V| > 1$. By Condition 1 there is a pair $i, j \in V$ such that $d(i,j) \geq n-1$. Let $t = \max_{i,j \in V} d(i,j)$, then the only equivalence class under the relation $i \sim j$ iff $d(i,j) \leq t$ is V. By Condition 2 it follows that $\max_{i,j \in V} d(i,j) = t = n-1$. Let $V_1, \ldots V_m$ denote the set of equivalence classes of V under the relation $i \sim j$ iff $d(i,j) \leq n-2$. Note that $m > 1$ as there is a pair $i, j \in V$ with $d(i,j) = n-1$, and therefore each $V_l \subsetneq V$. By Lemma 3, d restricted to each of these V_l's is a non-trivial ultrametric on those sets. The claim then follows immediately: for any $i, j \in V$ either $i, j \in V_l$ for some V_l in which case by the induction hypothesis $d(i,j) \in \{0, 1, \ldots, |V_l| - 1\}$, or $i \in V_l$ and $j \in V_{l'}$ for $l \neq l'$ in which case $d(i,j) = n-1$. ■

Appendix B. Missing proofs from Section 3

Lemma 46 (Restatement of Lemma 5) *Let $S \subseteq V$ with $|S| \geq 2$. If $r = \mathrm{lca}(S)$ then there is a pair $i, j \in S$ such that $\mathrm{lca}(i,j) = r$.*

Proof We will proceed by induction on $|S|$. If $|S| = 2$ then the claim is trivial and so we may assume $|S| > 2$. Let $i \in S$ be an arbitrary point and let $r' = \mathrm{lca}(S \setminus \{i\})$. We claim that $r = \mathrm{lca}(i, r')$. Clearly the subtree rooted at $\mathrm{lca}(i, r')$ contains S and since $T[r]$ is the smallest such tree it follows that $r \in T[\mathrm{lca}(i, r')]$. Conversely, $T[r]$ contains $S \setminus \{i\}$ and so $r' \in T[r]$ and since $i \in T[r]$, it follows that $\mathrm{lca}(i, r') \in T[r]$. Thus we conclude that $r = \mathrm{lca}(i, r')$.
If $\mathrm{lca}(i, r') = r'$, then we are done by the induction hypothesis. Thus we may assume that $i \notin T[r']$. Consider any $j \in S$ such that $j \in T[r']$. Then we have that $\mathrm{lca}(i,j) = r$ as $\mathrm{lca}(i, r') = r$ and $j \in T[r']$ and $i \notin T[r']$. ■

Lemma 47 (Restatement of Lemma 6) *Let T be a hierarchical clustering on V and let d_T be the ultrametric on V induced by it. Then d_T is non-trivial.*

Proof Let $S \subseteq V$ be arbitrary and $r = \mathrm{lca}(S)$, then $T[r]$ has at least $|S|$ leaves. By Lemma 5 there must be a pair $i, j \in S$ such that $r = \mathrm{lca}(i,j)$ and so $d_T(i,j) \geq |S| - 1$. This satisfies Condition 1 of non-triviality.
For any t, let S_t be a non-empty equivalence class under the relation $i \sim j$ iff $d_T(i,j) \leq t$. Since d_T satisfies Condition 1 it follows that $|S_t| - 1 \leq t$. Let us assume for the sake of contradiction that there is a pair $i, j \in S_t$ such that $d_T(i,j) > |S_t| - 1$. Let $r = \mathrm{lca}(S_t)$; using the definition of d_T it follows that $t + 1 \geq |\mathrm{leaves}(T[r])| > |S_t|$ since $i, j \in S_t$. Let $k \in \mathrm{leaves}(T[r]) \setminus S_t$ be an arbitrary point, then for every $l \in S_t$ it follows that $d_T(k,l) \leq |\mathrm{leaves}(T[r])| - 1 \leq t$ since the subtree rooted at r contains both k and l. This is a contradiction to S_t being an equivalence class under $i \sim j$ iff $d_T(i,j) \leq t$ since $k \notin S_t$. Thus d_T also satisfies Condition 2 of Definition 2. ■

Lemma 48 (Restatement of Lemma 7) *For every non-trivial ultrametric d on V there is a hierarchical clustering T on V such that for any pair $i, j \in V$ we have*

$$d_T(i,j) = |\mathrm{leaves}(T[\mathrm{lca}\,(i,j)])| - 1 = d(i,j).$$

Moreover this hierarchy can be constructed in time $O\left(n^3\right)$ by Algorithm 1 where $|V| = n$.

Proof The proof is by induction on n. The base case when $n = 1$ is straightforward. We now suppose that the statement is true for sets of size $< n$. Note that $i \sim j$ iff $d(i,j) \leq n-2$ is an equivalence relation on V and thus partitions V into m equivalence classes $V_1, \ldots, V_m$. We first observe that $m > 1$ since by Condition 1 there is a pair of points $i, j \in V$ such that $d(i,j) \geq n-1$ and in particular $|V|_l < n$ for every $l \in \{1, \ldots, m\}$. By Lemma 3, d restricted to any V_l is a non-trivial ultrametric on V_l and there is a pair of points $i, j \in V_l$ such that $d(i,j) = |V_l| - 1$ by Conditions 1 and 2. Therefore by the induction hypothesis we construct trees $T_1, \ldots, T_m$ such that for every $l \in \{1, \ldots, m\}$ we have $\mathrm{leaves}(T_l) = V_l$. Further for any pair of points $i, j \in V_l$ for some $l \in \{1, \ldots, m\}$, we also have $d(i,j) = d_{T_l}(i,j)$.
We construct the tree T as follows: we first add a root r and then connect the root r_l of T_l to r for every $l \in \{1, \ldots, m\}$. Consider a pair of points $i, j \in V$. If $i, j \in V_l$ for some $l \in \{1, \ldots, m\}$ then we are done since $d_{T_l}(i,j) = d_T(i,j)$ as $\mathrm{lca}(i,j) \in T_l$. If $i \in V_l$ and $j \in V_{l'}$ for some $l \neq l'$ then $d(i,j) = n-1$ since $d(i,j) \geq n-1$ by definition of the equivalence relation and the range of d lies in $\{0, 1, \ldots, n-1\}$ by Lemma 4. Moreover i and j are leaves in T_l and $T_{l'}$ respectively, and thus by construction of T we have $\mathrm{lca}(i,j) = r$, i.e., $d_T(i,j) = n-1$ and so the claim follows. Algorithm 1 simulates this inductive argument can be easily implemented to run in time $O\left(n^3\right)$. ■

Appendix C. Missing proofs from Section 4

Lemma 49 (Restatement of Lemma 18) *Let $\mathcal{B}_U(i,r,t)$ be the ball corresponding to a set $U \subseteq V$, vertex $i \in U$, radius $r \in \mathbb{R}$ and $t \in [n-1]$. Then $\mathrm{vol}\left(\mathcal{B}_U(i,r,t)\right)$ is differentiable with respect to r in the interval $(0, \Delta]$ except at finitely many points.*

Proof Note that for any fixed $U \subseteq V$, $\mathrm{vol}\left(\mathcal{B}_U(i,r,t)\right)$ is a monotone non-decreasing function in r since for a pair $j, k \in U$ such that $j \in \mathcal{B}_U(i,r,t)$ and $k \notin \mathcal{B}_U(i,r,t)$ we have $r - d_t(i,j) \leq d_t(j,k)$ otherwise $r - d_t(i,j) > d_t(j,k)$ so that $r > d_t(i,j) + d_t(j,k) \geq d_t(i,k)$, a contradiction to the fact that $k \notin \mathcal{B}_U(i,r,t)$. Therefore adding the vertex k to the ball centered at i is only going to increase its volume as $r - d_t(i,j) \leq d_t(j,k)$ (see Definition 15). Thus $\mathrm{vol}\left(\mathcal{B}_U(i,r,t)\right)$ is differentiable with respect to r in the interval $(0, \Delta]$ except at finitely many points which correspond to a new vertex from U being added to the ball. ■

Theorem 50 (Restatement of Theorem 19) *Let $m_\varepsilon := \left\lfloor \frac{n-1}{1+\varepsilon} \right\rfloor$ as in Algorithm 2 and let $\left\{ x^t_{ij} \mid t \in [m_\varepsilon], i, j \in V \right\}$ be the output of Algorithm 2 run on a feasible solution $\{d_t\}_{t \in [n-1]}$ of LP-ultrametric and any choice of $\varepsilon \in (0,1)$. For any $t \in [m_\varepsilon]$, we have that x^t_{ij} is feasible for the layer-$\lfloor (1+\varepsilon)\, t \rfloor$ problem ILP-layer and there is a constant $c(\varepsilon) > 0$ depending only on ε such that*

$$\sum_{\{i,j\} \in E(K_n)} \kappa(i,j) x^t_{ij} \leq c(\varepsilon)(\log n)\gamma_t.$$

Moreover, Algorithm 2 can be implemented to run in time polynomial in n.

Proof We first show that for a fixed t, the constructed solution x^t_{ij} is feasible for the layer-$\lfloor(1+\varepsilon)t\rfloor$ problem ILP-layer. Let $\mathcal{C}_t$ be as in Algorithm 2 so that $x^t_{ij}=1$ if i,j belong to different sets in $\mathcal{C}_t$ and $x^t_{ij}=0$ otherwise. Let $G_t=(V,E_t)$ be as in Definition 9 corresponding to x^t_{ij}. Note that for any $t\in[m_\varepsilon]$, every $V_i\in\mathcal{C}_t$ is a clique in G_t by construction (line 19) and for every distinct pair $V_i,V_j\in\mathcal{C}_t$ we have $V_i\cap V_j=\emptyset$ (lines 15 and 16). Therefore by Lemma 10, it suffices to prove that for any $V_i\in\mathcal{C}_t$, it holds $|V_i|\le\lfloor(1+\varepsilon)t\rfloor$. If V_i is added to $\mathcal{C}_t$ in line 9 then there is nothing to prove.

Thus let us assume that V_i is of the form $\mathcal{B}_U(i,r,t)$ for some $U\subseteq V$ as in line 14 so that $\phi(\mathcal{B}_U(i,r,t))\le\frac{1}{\Delta}\log\left(\frac{\mathrm{vol}(\mathcal{B}_U(i,\Delta,t))}{\mathrm{vol}(\mathcal{B}_U(i,0,t))}\right)$. Note that by Lemma 13 it suffices to show that there is such an $r\in(0,\Delta]$. This property follows from the rounding scheme due to (Even et al., 1999) as we will explain now.

By Lemma 18 $\mathrm{vol}(\mathcal{B}_U(i,r,t))$ is differentiable everywhere in the interval $(0,\Delta]$ except at finitely many points X. Let the set of discontinuous points be $X=\{x_1,x_2,\ldots,x_{k-1}\}$ with $x_0=0<x_1<x_2\ldots x_{k-1}<x_k=\Delta$. We claim that there must be an $r\in(0,\Delta]\setminus X$ such that $\phi(\mathcal{B}_U(i,r,t))\le\frac{1}{\Delta}\log\left(\frac{\mathrm{vol}(\mathcal{B}_U(i,\Delta,t))}{\mathrm{vol}(\mathcal{B}_U(i,0,t))}\right)$. Let us assume for the sake of a contradiction that for every $r\in(0,\Delta]\setminus X$ we have $\phi(\mathcal{B}_U(i,r,t))>\frac{1}{\Delta}\log\left(\frac{\mathrm{vol}(\mathcal{B}_U(i,\Delta,t))}{\mathrm{vol}(\mathcal{B}_U(i,0,t))}\right)$. However integrating both sides from 0 to Δ results in a contradiction:

$$\begin{aligned}
\int_{r=0}^{\Delta}\phi(\mathcal{B}_U(i,r,t))\,dr &= \int_{r=0}^{\Delta}\frac{\partial\mathcal{B}_U(i,r,t)}{\mathrm{vol}(\mathcal{B}_U(i,r,t))}dr && (46)\\
&= \sum_{i=1}^{k}\int_{r=x_{i-1}}^{x_i}\frac{\partial\mathcal{B}_U(i,r,t)}{\mathrm{vol}(\mathcal{B}_U(i,r,t))}dr && (47)\\
&= \sum_{i=1}^{k}\int_{r=x_{i-1}}^{x_i}\frac{d(\mathrm{vol}(\mathcal{B}_U(i,r,t)))}{\mathrm{vol}(\mathcal{B}_U(i,r,t))} && (48)\\
&\le \log\mathrm{vol}(\mathcal{B}_U(i,\Delta,t))-\log\mathrm{vol}(\mathcal{B}_U(i,0,t)) && (49)\\
&= \int_{r=0}^{\Delta}\frac{1}{\Delta}\log\left(\frac{\mathrm{vol}(\mathcal{B}_U(i,\Delta,t))}{\mathrm{vol}(\mathcal{B}_U(i,0,t))}\right)dr, && (50)
\end{aligned}$$

where line 49 follows since f is monotonic increasing. For any $t\in[m_\varepsilon]$ the set $\mathcal{C}_t$ is a disjoint partition of V with balls of the form $\mathcal{B}_U(i,r,t')$ for some $t'\ge t$ and $U\subseteq U_l\in\mathcal{C}_{t'+1}$: this is easily seen by induction since $\mathcal{C}_{m_\varepsilon+1}$ is initialized as V. Further, a cluster V_i is added to $\mathcal{C}_t$ either in line 15 in which case it is a ball of the form $\mathcal{B}_U(i,r,t)$ for some $U\in\mathcal{C}_{t+1}$, $i\in U$, and $r\in\mathbb{R}$ or it is added in line 9 in which case it must have been a ball $\mathcal{B}_U(i',r',t')$ for some $t'>t$, $U\subseteq U_l\in\mathcal{C}_{t'+1}$, $i'\in V$, and $r'\in\mathbb{R}$. Note that for any $t'\ge t$ and $U\subseteq V$, it holds $\gamma^U_{t'}\le\gamma^U_t$ since for every pair $i,j\in V$ we have $\kappa(i,j)\ge0$ and $d_t(i,j)\ge d_{t'}(i,j)$ because of constraint (15). Moreover, for any subset $U\subseteq V$ we have $\gamma^U_t\le\gamma_t$ since $\kappa,d_t\ge0$. We claim that for any $t\in[m_\varepsilon]$ the total volume of the balls in $\mathcal{C}_t$ is at most $\left(2+\frac{1}{\log n}\right)\gamma_t$. First note that the affine term $\frac{\gamma^U_{t'}}{n\log n}$ in the volume of a ball $\mathcal{B}_U(i,r,t')$ in $\mathcal{C}_t$ is upper bounded by $\frac{\gamma_t}{n\log n}$ and appears at most n times. Next we claim that the contribution to the total volume from the term involving the edges inside and crossing a ball $\mathcal{B}_U(i,r,t')\in\mathcal{C}_t$ is at most $2\gamma_t$. This is because the balls are disjoint, $r-d_{t'}(i,k)\le d_{t'}(j,k)\le d_t(j,k)$ for the crossing edges of a ball $\mathcal{B}_U(i,r,t')\in\mathcal{C}_t$ and a crossing edge contributes to the volume of at most 2 balls in $\mathcal{C}_t$. Note that for any $U\subseteq V$, $i\in U$, and $r\in\mathbb{R}_{\ge0}$ we have $\mathrm{vol}(\mathcal{B}_U(i,r,t))\in\left[\frac{\gamma^U_t}{n\log n},\left(1+\frac{1}{n\log n}\right)\gamma^U_t\right]$.

Using this observation and the stopping condition of line 14 it follows that

$$\begin{aligned}
\sum_{\{i,j\}\in E(K_n)}\kappa(i,j)x^t_{ij} &= \sum_{\substack{\{i,j\}\in E(K_n):\\ i,j\text{ separated in }\mathcal{C}_t}}\kappa(i,j)\\
&= \frac{1}{2}\underbrace{\sum_{\substack{\mathcal{B}_U(i,r,t')\in\mathcal{C}_t:\\ t'\ge t\\ U\subseteq U_l\in\mathcal{C}_{t'+1}}}\ \sum_{\substack{j\in\mathcal{B}_U(i,r,t')\\ k\notin\mathcal{B}_U(i,r,t')}}\kappa(j,k)}_{\text{Since }\kappa\text{ is symmetric}}\\
&= \frac{1}{2}\sum_{\substack{\mathcal{B}_U(i,r,t')\in\mathcal{C}_t:\\ t'\ge t\\ U\subseteq U_l\in\mathcal{C}_{t'+1}}}\partial\mathcal{B}_U(i,r,t')\\
&= \frac{1}{2}\sum_{\substack{\mathcal{B}_U(i,r,t')\in\mathcal{C}_t:\\ t'\ge t\\ U\subseteq U_l\in\mathcal{C}_{t'+1}}}\phi(\mathcal{B}_U(i,r,t'))\,\mathrm{vol}(\mathcal{B}_U(i,r,t'))\\
&\le \sum_{\substack{\mathcal{B}_U(i,r,t')\in\mathcal{C}_t:\\ t'\ge t\\ U\subseteq U_l\in\mathcal{C}_{t'+1}}}\frac{1}{2\Delta}\log\left(\frac{\mathrm{vol}(\mathcal{B}_U(i,\Delta,t'))}{\mathrm{vol}(\mathcal{B}_U(i,0,t'))}\right)\mathrm{vol}(\mathcal{B}_U(i,r,t'))\\
&\le \frac{1}{2\Delta}\underbrace{(\log(n\log n+1))}_{\text{via interval bounds}}\sum_{\substack{\mathcal{B}_U(i,r,t')\in\mathcal{C}_t:\\ t'\ge t\\ U\subseteq U_l\in\mathcal{C}_{t'+1}}}\mathrm{vol}(\mathcal{B}_U(i,r,t'))\\
&\le \frac{1+\varepsilon}{2\varepsilon}(\log(n\log n+1))\underbrace{\left(2+\frac{1}{\log n}\right)\gamma_t}_{\substack{\text{contribution of affine term}\le\frac{\gamma_t}{\log n}\\ \text{contribution of edge terms}\le2\gamma_t}}\\
&\le c(\varepsilon)(\log n)\gamma_t,
\end{aligned}$$

for some constant $c(\varepsilon)>0$ depending only on ε.

For the run time of Algorithm 2 note that the loop in line 5 runs for at most $n-1$ steps, while the loop in line 7 runs for at most n steps. For a set $U\subseteq V$, to compute the ball $\mathcal{B}_U(i,r,t)$ of least radius r such that $\phi(\mathcal{B}_U(i,r,t))\le\frac{1}{\Delta}\log\left(\frac{\mathrm{vol}(\mathcal{B}_U(i,\Delta,t))}{\mathrm{vol}(\mathcal{B}_U(i,0,t))}\right)$, sort the vertices in $U\setminus\{i\}$ in increasing order of distance from i according to d_t. Let the vertices in $U\setminus\{i\}$ in this sorted order be $\{j_1,\ldots,j_{|U|-1}\}$. Then it suffices to check the expansion of the balls $\{i\}$ and $\{i\}\cup\{j_1,\ldots,j_k\}$ for every $k\in[|U|-1]$. It is straightforward to see that all the other steps in Algorithm 2 run in time polynomial in n. ■

Abstract

This article describes the Multiagent Decision Process (MADP) Toolbox, a software library to support planning and learning for intelligent agents and multiagent systems in uncertain environments. Key features are that it supports partially observable environments and stochastic transition models; has unified support for single- and multiagent systems; provides a large number of models for decision-theoretic decision making, including one-shot and sequential decision making under various assumptions of observability and cooperation, such as Dec-POMDPs and POSGs; provides tools and parsers to quickly prototype new problems; provides an extensive range of planning and learning algorithms for single- and multiagent systems; is released under the GNU GPL v3 license; and is written in C++ and designed to be extensible via the object-oriented paradigm.

Keywords: software, decision-theoretic planning, reinforcement learning, multiagent systems

1. Introduction

Decision making is a core topic of research in the fields of artificial intelligence and machine learning. Especially research on planning and learning in stochastic, partially observable and/or multiagent systems (MASs) has received much attention in the last decade, since these settings hold great promise to deal with challenging decision-making problems encountered in the real world. For instance, *Markov decision processes (MDPs)* can be used for aircraft collision avoidance (Kochenderfer and Chryssanthacopoulos, 2011), *partially observable MDPs (POMDPs)* may enable active perception or certain robotics applications (Kaelbling et al., 1998; Spaan, 2012; Hsu et al., 2008), *decentralized POMDPs (Dec-POMDPs)* (Bernstein et al., 2000; Oliehoek and Amato, 2016) enable reasoning about the behavior of a team of robots or other decision makers acting on local information (Amato et al., 2015), and *partially observable stochastic games (POSGs)* allow for representing situations with self-interested agents (Hansen et al., 2004).

All these models are closely related and instances of what we refer to as *multiagent decision processes (MADPs)* (Oliehoek and Amato, 2016). While many software libraries are available for planning or learning in specific sub-classes of MADPs—e.g., there are many toolboxes focusing on single-agent, fully observable reinforcement learning—no comprehensive libraries are available that support the more complex partially observable multiagent settings. The MADP Toolbox aims to fill this void by providing the building blocks for developing planning and learning algorithms for existing and novel instances of MADPs. Some important features of the toolbox are:

Toolkit and Library. It can be used in two ways: as a toolbox containing a number of planning and learning algorithms and as a software library to develop one's own models and algorithms.

Modular design. It is object oriented, making it easy to extend to new problem classes, and implement new planning and learning algorithms.

Flexible. It was designed for multiagent problems, providing support for mixing different types of agents. It is also suitable for single-agent problems, which are just a special case.

Feature rich. It includes many code-intensive features, such as support for factored models (including variable elimination and max-sum optimization), for basic inference in partially observable settings, and for simulations of MASs under different communication assumptions. Finally, it comes equipped with a large number of state-of-the-art methods particularly for (Dec-)POMDPs.

Connected. It reads a number of problem formats: ProbModelXML (Arias et al., 2012), `.pomdp` file format, `.dpomdp` file format, and exports SPUDD (Hoey et al., 1999) format.

Documented. It comes with fairly extensive user and developer documentation. This is complemented by an API reference, as well as a user email list.

2. Supported Problem Classes and Algorithms

Here we give a concise overview of the different MADP frameworks that are currently supported by the toolbox along with implemented algorithms.[1] The MADP Toolbox is designed to support both *planning*, i.e., settings where the model is given in advance, and reinforcement learning, i.e., settings where no such model is available, but the agents *learn* to interact during simulations.

Decentralized POMDPs. One of the most general models that the toolbox represents is the Dec-POMDP. Formally, a Dec-POMDP is a tuple $\langle \mathcal{D}, \mathcal{S}, \boldsymbol{\mathcal{A}}, T, R, \boldsymbol{\mathcal{O}}, O, h, b^0 \rangle$, where $\mathcal{D} = \{1, \ldots, n\}$ is the set of n agents, $\mathcal{S}$ is a set of states s, $\boldsymbol{\mathcal{A}}$ is the set of joint actions $\boldsymbol{a} = \langle a_1, \ldots a_n \rangle$, T is the transition function that specifies $\Pr(s^{t+1}|s^t, \boldsymbol{a}^t)$, $R(s, \boldsymbol{a})$ is the immediate reward function, $\boldsymbol{\mathcal{O}}$ is the set of joint observations $\boldsymbol{o} = \langle o_1, \ldots, o_n \rangle$, O is the observation function: $\Pr(\boldsymbol{o}^{t+1}|\boldsymbol{a}^t, s^{t+1})$, h is the horizon of the problem, $b^0 \in \triangle(\mathcal{S})$ is the initial state distribution at time $t = 0$. The typical goal of the agents is to optimize the expected (possibly discounted) cumulative reward. The toolbox supports a range of solution methods for Dec-POMDPs, including JESP (Nair et al., 2003), DP-LPC (Boularias and Chaib-draa, 2008), (Generalized) Multiagent A* (GMAA) and variants (Szer et al., 2005; Oliehoek et al., 2013), and direct CE (DICE) policy search (Oliehoek et al., 2008a). In general, GMAA-ICE is the fastest optimal solution method included, while DICE is the most scalable approximate method for Dec-POMDPs in the toolbox. The toolbox also includes methods to deal with 1-step delayed communication (Oliehoek et al., 2008b).

POMDPs. A Dec-POMDP with just a single agent or with instantaneous communication reduces to a POMDP (referred to as a *multiagent POMDP* in the latter case). The MADP Toolbox includes a number of solution methods for these: Perseus (Spaan and Vlassis, 2005), Monahan's algorithm (Monahan, 1982), incremental pruning (Cassandra et al., 1997) with accelerated vector pruning (Walraven and Spaan, 2017).

1. For more details on these frameworks, please see, e.g., Oliehoek and Amato (2016).

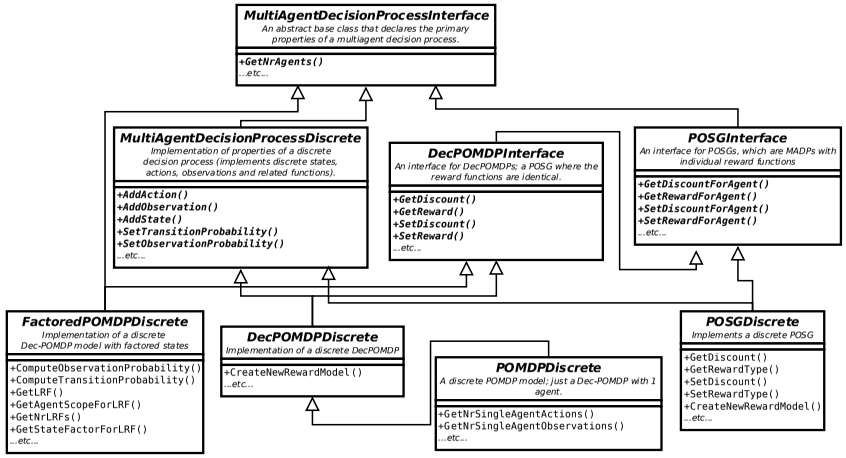

Figure 1: A simplified view of the object-oriented approach to representing problems. Illustrated is how both DecPOMDPDiscrete and POSGDiscrete inherit the implementation of states, actions, observations, etc. from MultiagentDecisionProcessDiscrete. In contrast, FactoredDecPOMDPDiscrete does not inherit this implementation.

MDPs. When the problem additionally is fully observable, the model simplifies further to the standard MDP. For these settings, the toolbox provides algorithms such as value iteration and policy iteration, as well as a GPU accelerated version of the latter. Additionally, there is a Q-learner agent and an agent performing on-line MDP planning.

Factored Models. Since the aforementioned models can be quite large for real problems, compact specification is an important issue. The toolbox includes support for compact *factored* representations (e.g., Oliehoek et al., 2008c, and references therein). For instance, it includes the GMAA-ELSI factored Dec-POMDP solver (Oliehoek et al., 2008c) and exports to SPUDD (Hoey et al., 1999).

Inheritance and Extensibility. The toolbox is designed to be extensible via the object-oriented paradigm. To illustrate this Figure 1 gives a (slightly simplified) illustration of how the discussed problem classes inherit from one another. The figure also shows that the toolbox support POSGs, which generalize Dec-POMDPs to include individual payoff functions.

Additional Functionality. A key functionality that the toolbox provides is the ability to conveniently specify MADPs. Three methods currently exist: 1) using Anthony Cassandra's plain text `.pomdp` file format or a multiagent `.dpomdp` extension, 2) using the graphical OpenMarkov[2] editor for ProbModelXML files, or 3) writing a C++ class that implements the appropriate interface.

The MADP Toolbox also provides a collection of support classes that represent histories, beliefs, value functions, and policies, etc., as well as some algorithms to perform belief updates and approximate inference. Additionally, as part of GMAA, the toolbox also provides classes to represent and solve collaborative (Graphical) Bayesian games (Oliehoek et al., 2008b, 2012).

3. Technical Details

The software can be used in two ways: as a toolbox and as a library. The fact that it can be used as a library provides flexibility to, for instance, support the deployment and real-time execution of decision-theoretic control policies for autonomous agents (such as the markov_decision_making ROS package mentioned below). Since it has been implemented in C++ and is organized according to the object-oriented paradigm, it is easy to extend. Furthermore, as the toolbox aims to support core planning tasks, C++ provides the additional advantage that it is very fast for such computationally expensive routines.

The MADP Toolbox is released under the GNU GPL v3 license and can be downloaded from `https://github.com/MADPToolbox/MADP`. It is developed under Debian GNU/Linux, has been tested under various recent Linux distributions and also supports Mac OS X. In order to provide reliability, the toolbox includes a basic set of tests which cover most of the included functionality. MADP Toolbox 0.4.1 adheres to the C++98 standard and is relatively self-contained: required Boost header files and required libraries are included. It comes with extensive documentation both in form of a user/developer manual as well as API documentation (also available online).

4. Related Software

Many toolboxes exists for decision making, but few deal with MASs or partially observable settings. Closely related software and toolboxes for planning, reinforcement learning (RL) and machine learning (ML) applications are shown in Table 1. The columns 'MAS' and 'PO' indicate whether the respective toolbox includes algorithms for multiagent or partially observable settings, respectively. Closest in scope is BURLAP, which does not support partially observable multiagent settings.

The MADP software distribution uses functionality from and therefore includes boost and libDAI (Mooij, 2010). The MADP Toolbox is the back-end of a number of solution methods on the THINC lab solver page.[3] It is also used in the markov_decision_making ROS package in order to parse model files and query agent policies in real time.[4]

Acknowledgments

We are grateful to Joris Mooij for allowing to include libDAI and to many others that made contributions. The MADP Toolbox has been developed over the course of many years, and has thus been supported by various funding agencies including: The Dutch Ministry of Economic Affairs, AFOSR, NWO, FP7 Marie Curie, FCT. F.O. was also affiliated with the University of Amsterdam, supported by NWO Veni grant #639.021.336, during the writing of this article.

Abstract

We present tools for the analysis of Follow-The-Regularized-Leader (FTRL), Dual Averaging, and Mirror Descent algorithms when the regularizer (equivalently, prox-function or learning rate schedule) is chosen adaptively based on the data. Adaptivity can be used to prove regret bounds that hold on every round, and also allows for data-dependent regret bounds as in AdaGrad-style algorithms (e.g., Online Gradient Descent with adaptive per-coordinate learning rates). We present results from a large number of prior works in a unified manner, using a modular and tight analysis that isolates the key arguments in easily re-usable lemmas. This approach strengthens previously known FTRL analysis techniques to produce bounds as tight as those achieved by potential functions or primal-dual analysis. Further, we prove a general and exact equivalence between adaptive Mirror Descent algorithms and a corresponding FTRL update, which allows us to analyze Mirror Descent algorithms in the same framework. The key to bridging the gap between Dual Averaging and Mirror Descent algorithms lies in an analysis of the FTRL-Proximal algorithm family. Our regret bounds are proved in the most general form, holding for arbitrary norms and non-smooth regularizers with time-varying weight.

Keywords: online learning, online convex optimization, regret analysis, adaptive algorithms, follow-the-regularized-leader, mirror descent, dual averaging

1. Introduction

We consider the problem of online convex optimization over a series of rounds $t \in \{1, 2, \dots\}$. On each round the algorithm selects a point (e.g., a predictor or an action) $x_t \in \mathbb{R}^n$, and then an adversary selects a convex loss function f_t, and the algorithm suffers loss $f_t(x_t)$. The goal is to minimize

$$\text{Regret}_T(x^*, f_t) \equiv \sum_{t=1}^{T} f_t(x_t) - \sum_{t=1}^{T} f_t(x^*), \tag{1}$$

Algorithm 1 General Template for Adaptive FTRL

Parameters: Scheme for selecting convex r_t s.t. $\forall x,\ r_t(x) \geq 0$ for $t = 0, 1, 2, \dots$
$x_1 \leftarrow \arg\min_{x \in \mathbb{R}^n}\ r_0(x)$
for $t = 1, 2, \dots$ **do**
  Observe convex loss function $f_t : \mathbb{R}^n \to \mathbb{R} \cup \{\infty\}$
  Incur loss $f_t(x_t)$
  Choose incremental convex regularizer r_t, possibly based on $f_1, \dots f_t$
  Update

$$x_{t+1} \leftarrow \arg\min_{x \in \mathbb{R}^n} \sum_{s=1}^{t} f_s(x) + \sum_{s=0}^{t} r_s(x)$$

end for

the difference between the algorithm's loss and the loss of a fixed point x^*, potentially chosen with full knowledge of the sequence of f_t up through round T. When the functions f_t and round T are clear from the context we write $\text{Regret}(x^*)$. The "adversary" choosing the f_t need not be malicious, for example the f_t might be drawn from a distribution. The name "online convex optimization" was introduced by Zinkevich (2003), though the setting was introduced earlier by Gordon (1999). When a particular set of comparators $\mathcal{X}$ is fixed in advance, one is often interested in $\text{Regret}(\mathcal{X}) \equiv \sup_{x^* \in \mathcal{X}} \text{Regret}(x^*)$; since $\mathcal{X}$ is often a norm ball, frequently we bound $\text{Regret}(x^*)$ by a function of $\|x^*\|$.

Online algorithms with good regret bounds (that is, bounds that are sublinear in T) can be used for a wide variety of prediction and learning tasks (Cesa-Bianchi and Lugosi, 2006; Shalev-Shwartz, 2012). The case of online logistic regression, where one predicts the probability of a binary outcome, is typical. Here, on each round a feature vector $a_t \in \mathbb{R}^n$ arrives, and we make a prediction $p_t = \sigma(a_t \cdot x_t) \in (0, 1)$ using the current model coefficients $x_t \in \mathbb{R}^n$, where $\sigma(z) = 1/(1 + e^{-z})$. The adversary then reveals the true outcome $y_t \in \{0, 1\}$, and we measure loss with the negative log-likelihood, $\ell(p_t, y_t) = -y_t \log p_t - (1 - y_t) \log(1 - p_t)$. We encode this problem as online convex optimization by taking $f_t(x) = \ell(\sigma(a_t \cdot x), y_t)$; these f_t are in fact convex. Linear Support Vector Machines (SVMs), linear regression, and many other learning problems can be encoded in a similar manner; Shalev-Shwartz (2012) and many of the other works cited here contain more details and examples.

We consider the family of Follow-The-Regularized-Leader (FTRL, or FoReL) algorithms as shown in Algorithm 1 (Shalev-Shwartz, 2007; Shalev-Shwartz and Singer, 2007; Rakhlin, 2008; McMahan and Streeter, 2010; McMahan, 2011). Shalev-Shwartz (2012) and Hazan (2015) provide a comprehensive survey of analysis techniques for non-adaptive members of this algorithm family, where the regularizer is fixed for all rounds and chosen with knowledge of the horizon T. In this survey,

we allow the regularizer to change adaptively. Given a sequence of incremental regularization functions $r_0, r_1, r_2, \ldots$, we consider the algorithm that selects

$$x_1 \in \arg\min_{x \in \mathbb{R}^n} r_0(x)$$
$$x_{t+1} = \arg\min_{x \in \mathbb{R}^n} f_{1:t}(x) + r_{0:t}(x) \qquad \text{for } t = 1, 2, \ldots, \tag{2}$$

where we use the compressed summation notation $f_{1:t}(x) = \sum_{s=1}^{t} f_s(x)$ (we also use this notation for sums of scalars or vectors). The argmin in Eq. (2) is over all $\mathbb{R}^n$, but it is often necessary to constrain the selected points x_t to a convex feasible set $\mathcal{X}$. This can be accomplished in our framework by including the indicator function $I_{\mathcal{X}}$ as a term in r_0 ($I_{\mathcal{X}}$ is a convex function defined by $I_{\mathcal{X}}(x) = 0$ for $x \in \mathcal{X}$ and ∞ otherwise); details are given in Section 2.4. The algorithms we consider are adaptive in that each r_t can be chosen based on $f_1, f_2, \ldots, f_t$. For convenience, we define functions h_t by

$$h_0(x) = r_0(x)$$
$$h_t(x) = f_t(x) + r_t(x) \qquad \text{for } t = 1, 2, \ldots$$

so $x_{t+1} = \arg\min_x h_{0:t}(x)$. Generally we will assume the f_t are convex, and the r_t are chosen so that $r_{0:t}$ (or $h_{0:t}$) is strongly convex for all t, e.g., $r_{0:t}(x) = \frac{1}{2\eta_t}\|x\|_2^2$ (Sections 2.3 and 4.2 review important definitions and results from convex analysis).

FTRL algorithms generalize the Follow-The-Leader (FTL) approach (Hannan, 1957; Kalai and Vempala, 2005), which selects $x_{t+1} = \arg\min_x f_{1:t}(x)$. FTL can provide sublinear regret in the case of strongly convex functions (as we will show), but for general convex functions additional regularization is needed.

Adaptive regularization can be used to construct practical algorithms that provide regret bounds that hold on all rounds T, rather than only on a single round T which is chosen in advance. The framework is also particularly suitable for analyzing AdaGrad-style algorithms that adapt their regularization or norms based on the observed data, for example those of McMahan and Streeter (2010) and Duchi et al. (2010a, 2011). This approach leads to regret bounds that depend on the actual observed sequence of functions f_t (usually via $\nabla f_t(x_t)$), rather than purely worst-case bounds. These tighter bounds translate to much better performance in practice, especially for high-dimensional but sparse problem (e.g., bag-of-words feature vectors). Examples of such algorithms are analyzed in Sections 3.4 and 3.5.

We also study Mirror Descent algorithms, for example updates like

$$x_{t+1} = \arg\min_{x \in \mathcal{X}} \nabla f_t(x_t) \cdot x + \lambda\|x\|_1 + \frac{1}{2\eta_t}\|x - x_t\|_2^2$$

where η_t is an adaptive non-increasing learning rate. This update generalizes Online Gradient Descent with a non-smooth regularization term; Mirror Descent also encompasses the use of an arbitrary Bregman divergence in place of the $\|\cdot\|_2^2$ penalty

above. We will discuss this family of algorithms at length in Section 6. In fact, Mirror Descent algorithms can be expressed as particular members of the FTRL family, though generally not the most natural ones. In particular, since the state maintained by Mirror Descent is essentially only the current feasible point x_t, we will see that Mirror Descent algorithms are forced to linearize penalties like $\lambda\|x\|_1$ from previous rounds, while the more natural FTRL algorithms can keep these terms in closed form, leading to practical advantages such as producing sparser models when L_1 regularization is used.

While we focus on online algorithms and regret bounds, the development of many of the algorithms considered rests heavily on work in general convex optimization and stochastic optimization. As a few starting points, we refer the reader to Nemirovsky and Yudin (1983) and Nesterov (2004, 2007). Going the other way, the algorithms presented here can be applied to batch optimization problems of the form

$$\arg\min_{x \in \mathbb{R}^n} F(x) \qquad \text{where} \qquad F(x) \equiv \sum_{t=1}^{T} f_t(x) \tag{3}$$

by running the online algorithm for one or more passes over the set of f_t and returning a suitable point (usually the last x_t or an average of past x_t). Using online-to-batch conversion techniques (e.g., Cesa-Bianchi et al. (2004), Shalev-Shwartz (2012, Chapter 5)), one can convert the regret bounds given here to convergence bounds for the batch problem. Many state-of-the-art algorithms for batch optimization over very large datasets can be analyzed in this fashion.

Outline In Section 2, we elaborate on the family of algorithms encompassed by the update of Eq. (2). We then state two regret bounds, Theorems 1 and 2, which are flexible enough to cover many known results for general and strongly convex functions; in Section 3 we use them to derive concrete bounds for many standard online algorithms.

In Section 4 we break the analysis of adaptive FTRL algorithms into three main components, which helps to modularize the arguments. In Section 4.1 we prove the *Strong FTRL Lemma* which lets us express the regret through round T as a regularization term on the comparator x^*, namely $r_{0:T}(x^*)$, plus a sum of per-round stability terms. This reduces the problem of bounding regret to that of bounding these per-round terms. In Section 4.2 we review some standard results from convex analysis, and prove lemmas that make bounding the per-round terms relatively straightforward. The general regret bounds are then proved in Section 4.3 as corollaries of these results.

Section 5 considers the special case of a composite objective, where for example $f_t(x) = \ell_t(x) + \Psi(x)$ with ℓ_t is a smooth loss on the t'th training example and Ψ is a possibly non-smooth regularizer (e.g., $\Psi(x) = \|x\|_1$). Finally, Section 6 proves the

Algorithm 2 General Template for Adaptive Linearized FTRL

Parameters: Scheme for selecting convex r_t s.t. $\forall x,\ r_t(x) \geq 0$ for $t = 0, 1, 2, \ldots$
$z \leftarrow \mathbf{0} \in \mathbb{R}^n$ *//Maintains* $g_{1:t}$
$x_1 \leftarrow \arg\min_{x \in \mathbb{R}^n}\ z \cdot x + r_0(x)$
for $t = 1, 2, \ldots$ **do**
  Select x_t, observe loss function f_t, incur loss $f_t(x_t)$
  Compute a subgradient $g_t \in \partial f_t(x_t)$
  Choose incremental convex regularizer r_t, possibly based on $g_1, \ldots, g_t$
  $z \leftarrow z + g_t$
  $x_{t+1} \leftarrow \arg\min_{x \in \mathbb{R}^n}\ z \cdot x + r_{0:t}(x)$ *//Often solved in closed form*
end for

equivalence of an arbitrary adaptive Mirror Descent algorithm and a certain FTRL algorithm, and uses this to prove regret bounds for Mirror Descent.

New Contributions The principal goal of this work is to provide a useful survey of central results in the analysis of adaptive algorithms for online convex optimization; whenever possible we provide precise references to earlier results that we re-prove or strengthen. Achieving this goal in a concise fashion requires some new results, which we summarize here.

The FTRL style of analysis is both modular and intuitive, but in previous work resulted in regret bounds that are not the tightest possible; we remedy this by introducing the Strong FTRL Lemma in Section 4.1. This also relates the FTRL analysis technique to the primal-dual style of analysis.

By analyzing both FTRL-Proximal algorithms (introduced in the next section) and Dual Averaging algorithms in a unified manner, it is much easier to contrast the strengths and weaknesses of each approach. This highlights a technical but important "off-by-one" difference between the two families in the adaptive setting, as well as an important difference when the algorithm is unconstrained (any $x_t \in \mathbb{R}^n$ is feasible).

Perhaps the most significant new contribution is given in Section 6, where we show that Mirror Descent algorithms (including adaptive algorithms for composite objectives) are in fact particular instances of the FTRL-Proximal algorithm schema, and can be analyzed using the general tools developed for the analysis of FTRL.

2. The FTRL Algorithm Family and General Regret Bounds

We begin by considering two important dimensions in the space of FTRL algorithms. First, the algorithm designer has significant flexibility in deciding whether the sum of previous loss functions is optimized exactly as $f_{1:t}(x)$ in Eq. (2), or if the true losses should be replaced by appropriate lower bounds, $\bar{f}_{1:t}(x)$, for computational efficiency.

Second, we consider whether the incremental regularizers r_t are all minimized at a fixed stationary point x_1, or are chosen so they are minimized at the current x_t. After discussing these options, we state general regret bounds.

2.1 Linearization and the Optimization of Lower Bounds

In practice, it may be infeasible to solve the optimization problem of Eq. (2), or even represent it as t becomes sufficiently large. A key point is that we can derive a wide variety of first-order algorithms by linearizing the f_t, and running the algorithm on these linear functions. Algorithm 2 gives the general scheme. For convex f_t, let x_t be defined as above, and let $g_t \in \partial f_t(x_t)$ be a subgradient (e.g., $g_t = \nabla f_t(x_t)$ for differentiable f_t). Convexity implies for any comparator x^*, $f_t(x_t) - f_t(x^*) \leq g_t \cdot (x_t - x^*)$. A key observation of Zinkevich (2003) is that if we let $\bar{f}_t(x) = g_t \cdot x$, then for any algorithm the regret against the functions $\bar{f}_t$ upper bounds the regret against the original f_t:

$$\text{Regret}(x^*, f_t) \leq \text{Regret}(x^*, \bar{f}_t).$$

Note we can construct the functions $\bar{f}_t$ on the fly (after observing x_t and f_t) and then present them to the algorithm.

Thus, rather than solving $x_{t+1} = \arg\min_x f_{1:t}(x) + r_{0:t}(x)$ on each round t, we now solve $x_{t+1} = \arg\min_x g_{1:t} \cdot x + r_{0:t}(x)$. Note that $g_{1:t} \in \mathbb{R}^n$, and we will generally choose the r_t so that $r_{0:t}(x)$ can also be represented in constant space. Thus, we have at least ensured our storage requirements stay constant even as $t \to \infty$. Further, we will usually be able to choose r_t so the optimization with $g_{1:t}$ can be solved in closed form. For example, if we take $r_{0:t}(x) = \frac{1}{2\eta}\|x\|_2^2$ then we can solve $x_{t+1} = \arg\min_x g_{1:t} \cdot x + r_{0:t}(x)$ in closed form, yielding $x_{t+1} = -\eta g_{1:t}$ (that is, this FTRL algorithm is exactly constant learning rate Online Gradient Descent).

However, we will usually state our results in terms of general f_t, since one can always simply take $f_t = \bar{f}_t$ when appropriate. In fact, an important aspect of our analysis is that it does not depend on linearization; our regret bounds hold for the the general update of Eq. (2) as well as applying to linearized variants.

More generally, we can run the algorithm on any $\bar{f}_t$ that satisfy $\bar{f}_t(x_t) - \bar{f}_t(x^*) \geq f_t(x_t) - f_t(x^*)$ for all x^* and have the regret bound achieved for the $\bar{f}$ also apply to the original f. This is generally accomplished by constructing a lower bound $\bar{f}_t$ that is tight at x_t, that is $\bar{f}_t(x) \leq f_t(x)$ for all x and further $\bar{f}_t(x_t) = f_t(x_t)$. A tight linear lower bound is always possible for convex functions, but for example if the f_t are all strongly convex, better algorithms are possible by taking $\bar{f}_t$ to be an appropriate quadratic lower bound.

A more in-depth introduction to the linearization of convex function can be found in Shalev-Shwartz (2012, Sec 2.4). We also note that the idea of replacing the loss function on each round with an appropriate lower bound ("linearization of

convex functions") is distinct from the modeling decision to replace a non-convex loss function (e.g., the zero-one loss for classification) with a convex upper bound (e.g., the hinge loss). This "convexification by surrogate loss" approach is described in detail by (Shalev-Shwartz, 2012, Sec 2.1).

2.2 Regularization in FTRL Algorithms

The term "regularization" can have multiple meanings, and so in this section we clarify the different roles regularization plays in the present work.

We refer to the functions $r_{0:t}$ as regularization functions, with r_t the incremental increase in regularization on round t (we assume $r_t(x) \geq 0$). This is the regularization in the name Follow-The-Regularized-Leader, and these r_t terms should be viewed as part of the algorithm itself—analogous (and in some cases exactly equivalent) to the learning rate schedule in an Online Gradient Descent algorithm, for example. The adaptive choice of these regularizers is the principle topic of the current work. We study two main classes of regularizers:

- In *FTRL-Centered* algorithms, each r_t (and hence $r_{0:t}$) is minimized at a fixed point, $x_1 = \arg\min_x r_0(x)$. An example is Dual Averaging (which also linearizes the losses), where $r_{0:t}$ is called the *prox-function* (Nesterov, 2009).

- In *FTRL-Proximal* algorithms, each incremental regularization function r_t is minimized by x_t, and we call such r_t incremental proximal regularizers.

When we make neither a proximal nor centered assumption on the r_t, we refer to general FTRL algorithms. Theorem 1 (below) allows us to analyze regularization choices that do not fall into either of these two categories, but the Centered and Proximal cases cover the algorithms of practical interest.

There are a number of reasons we might wish to add additional regularization terms to the objective function in the FTRL update. In many cases this is handled immediately by our general theory by grouping the additional regularization terms with either the f_t or the r_t. However, in some cases it will be advantageous to handle this additional regularization more explicitly. We study this situation in detail in Section 5.

2.3 General Regret Bounds

In this section we introduce two general regret bounds that can be used to analyze many different adaptive online algorithms. First, we introduce some additional notation and definitions.

Notation and Definitions An extended-value convex function $\psi : \mathbb{R}^n \to \mathbb{R} \cup \{\infty\}$ satisfies

$$\psi(\theta x + (1-\theta)y) \leq \theta\psi(x) + (1-\theta)\psi(y),$$

for $\theta \in (0,1)$, and the domain of ψ is the convex set $\operatorname{dom}\psi \equiv \{x : \psi(x) < \infty\}$ (e.g., Boyd and Vandenberghe (2004, Sec. 3.1.2)); ψ is proper if $\exists x \in \mathbb{R}^n$ s.t. $\psi(x) < +\infty$ and $\forall x \in \mathbb{R}^n, \psi(x) > -\infty$. We refer to extended-value proper convex functions as simply "convex functions."

We write $\partial\psi(x)$ for the subdifferential of ψ at x; a subgradient $g \in \partial\psi(x)$ satisfies

$$\forall y \in \mathbb{R}^n,\ \psi(y) \geq \psi(x) + g \cdot (y - x).$$

The subdifferential $\partial\psi(x)$ for a convex ψ is always non-empty for $x \in \operatorname{int}(\operatorname{dom}\psi)$, and typically non-empty for any $x \in \operatorname{dom}\psi$ for the functions ψ considered in this work; $\partial\psi(x)$ is empty for $x \notin \operatorname{dom}\psi$ (Rockafellar, 1970, Thm. 23.2).

Working with extended convex functions lets us encode constraints seamlessly by using $I_{\mathcal{X}}$, the indicator function on a convex set $\mathcal{X} \subseteq \mathbb{R}^n$ given by

$$I_{\mathcal{X}}(x) = \begin{cases} 0 & x \in \mathcal{X} \\ \infty & \text{otherwise}\ , \end{cases} \tag{4}$$

since $I_{\mathcal{X}}$ is itself an extended convex function. Generally we assume $\mathcal{X}$ is a closed convex set. This approach makes it convenient to write $\arg\min_x$ as shorthand for $\arg\min_{x \in \mathbb{R}^n}$.

A function $\psi : \mathbb{R}^n \to \mathbb{R} \cup \{\infty\}$ is *σ-strongly convex* w.r.t. a norm $\|\cdot\|$ if for all $x, y \in \mathbb{R}^n$,

$$\forall g \in \partial\psi(x), \quad \psi(y) \geq \psi(x) + g \cdot (y - x) + \tfrac{\sigma}{2}\|y - x\|^2. \tag{5}$$

If some ψ only satisfies Eq. (5) for $x, y \in \mathcal{X}$ for a convex set $\mathcal{X}$, then the function $\psi' = \psi + I_{\mathcal{X}}$ satisfies Eq. (5) for all $x, y \in \mathbb{R}^n$, and so is strongly convex by our definition. Thus, we can work with ψ' without any need to explicitly refer to $\mathcal{X}$.

The *convex conjugate* (or Fenchel conjugate) of an arbitrary function $\psi : \mathbb{R}^n \to \mathbb{R} \cup \{\infty\}$ is

$$\psi^\star(g) \equiv \sup_x\ g \cdot x - \psi(x). \tag{6}$$

For a norm $\|\cdot\|$, the dual norm is given by

$$\|x\|_\star \equiv \sup_{y : \|y\| \leq 1}\ x \cdot y.$$

It follows from this definition that for any $x, y \in \mathbb{R}^n$, $x \cdot y \leq \|x\|\|y\|_\star$, a generalization of Hölder's inequality. We make heavy use of norms $\|\cdot\|_{(t)}$ that change as a function of the round t; the dual norm of $\|\cdot\|_{(t)}$ is $\|\cdot\|_{(t),\star}$.

Our basic assumptions correspond to the framework of Algorithm 1, which we summarize together with a few technical conditions as follows:

Setting 1 *We consider the algorithm that selects points according to Eq.* (2) *based on convex r_t that satisfy $r_t(x) \geq 0$ for $t \in \{0, 1, 2, \dots\}$, against a sequence of convex*

loss functions $f_t : \mathbb{R}^n \to \mathbb{R} \cup \{\infty\}$. Further, letting $h_{0:t} = r_{0:t} + f_{1:t}$ we assume $\operatorname{dom} h_{0:t}$ is non-empty. Recalling $x_t = \arg\min_x h_{0:t-1}(x)$, we further assume $\partial f_t(x_t)$ is non-empty.

The minor technical assumptions made here do not rule out any practical applications. We can now introduce the theorems which will be our main focus. The first will typically be applied to FTRL-Centered algorithms such as Dual Averaging:

Theorem 1 General FTRL Bound *Consider Setting 1, and suppose the r_t are chosen such that $h_{0:t} + f_{t+1} = r_{0:t} + f_{1:t+1}$ is 1-strongly-convex w.r.t. some norm $\|\cdot\|_{(t)}$. Then, for any $x^* \in \mathbb{R}^n$ and for any $T > 0$,*

$$\text{Regret}_T(x^*) \leq r_{0:T-1}(x^*) + \frac{1}{2}\sum_{t=1}^{T} \|g_t\|^2_{(t-1),\star}.$$

Our second theorem handles proximal regularizers:

Theorem 2 FTRL-Proximal Bound *Consider Setting 1, and further suppose the r_t are chosen such that $h_{0:t} = r_{0:t} + f_{1:t}$ is 1-strongly-convex w.r.t. some norm $\|\cdot\|_{(t)}$, and further the r_t are proximal, that is x_t is a minimizer of r_t. Then, choosing any $g_t \in \partial f_t(x_t)$ on each round, for any $x^* \in \mathbb{R}^n$ and for any $T > 0$,*

$$\text{Regret}_T(x^*) \leq r_{0:T}(x^*) + \frac{1}{2}\sum_{t=1}^{T} \|g_t\|^2_{(t),\star}.$$

We state these bounds in terms of strong convexity conditions on $h_{0:t}$ in order to also cover the case where the f_t are themselves strongly convex. In fact, if each f_t is strongly convex, then we can choose $r_t(x) = 0$ for all t, and Theorems 1 and 2 produce *identical* bounds (and algorithms).[1] When it is not known a priori whether the loss functions f_t are strongly convex, the r_t can be chosen adaptively to add only as much strong convexity as needed, following Bartlett et al. (2007). On the other hand, when the f_t are not strongly convex (e.g., linear), a sufficient condition for both theorems is choosing the r_t such that $r_{0:t}$ is 1-strongly-convex w.r.t. $\|\cdot\|_{(t)}$.

It is worth emphasizing the "off-by-one" difference between Theorems 1 and 2 in this case: we can choose r_t based on g_t, and when using proximal regularizers, this lets us influence the norm we use to measure g_t in the final bound (namely the $\|g_t\|^2_{(t),\star}$ term); this is not possible using Theorem 1, since we have $\|g_t\|^2_{(t-1),\star}$. This makes constructing AdaGrad-style adaptive learning rate algorithms for FTRL-Proximal easier (McMahan and Streeter, 2010), whereas with FTRL-Centered algorithms one must start with slightly more regularization. We will see this in more detail in Section 3.

1. To see this, note in Theorem 1 the norm in $\|g_t\|_{(t-1),\star}$ is determined by the strong convexity of $f_{1:t}$, and in Theorem 2 the norm in $\|g_t\|_{(t),\star}$ is again determined by the strong convexity of $f_{1:t}$.

Theorem 1 leads immediately to a bound for Dual Averaging algorithms (Nesterov, 2009), including the Regularized Dual Averaging (RDA) algorithm of Xiao (2009), and its AdaGrad variant (Duchi et al., 2011) (in fact, this statement is equivalent to Duchi et al. (2011, Prop. 2) when we assume the f_t are not strongly convex). As in these cases, Theorem 1 is usually applied to FTRL-Centered algorithms where x_1 (often the origin) is a global minimizer of $r_{0:t}$ for each t. The theorem does not require this; however, such a condition is usually necessary to bound $r_{0:T-1}(x^*)$ and hence $\text{Regret}(x^*)$ in terms of $\|x^*\|$.

Less general versions of these theorems often assume that each $r_{0:t}$ is α_t-strongly-convex with respect to a fixed norm $\|\cdot\|$. Our results include this as a special case, see Section 3 and Lemma 3 in particular.

Non-Adaptive Algorithms These theorems can also be used to analyze non-adaptive algorithms. If we choose $r_0(x)$ to be a fixed non-adaptive regularizer (perhaps chosen with knowledge of T) that is 1-strongly convex w.r.t. $\|\cdot\|$, and all $r_t(x) = 0$ for $t \geq 1$, then we have $\|x\|_{(t),\star} = \|x\|_\star$ for all t, and so both theorems provide the identical statement

$$\text{Regret}(x^*) \leq r_0(x^*) + \frac{1}{2}\sum_{t=1}^{T} \|g_t\|^2_\star. \tag{7}$$

This matches Shalev-Shwartz (2012, Theorem 2.11), though we improve by a constant factor due to the use of the Strong FTRL Lemma.

2.4 Incorporating a Feasible Set

We have introduced the FTRL update as an unconstrained optimization over $x \in \mathbb{R}^n$. For many learning problems, where x_t is a vector of model parameters, this may be fine, but in other applications we need to enforce constraints. These could correspond to budget constraints, structural constraints like $\|x_t\|_2 \leq R$ or $\|x_t\|_1 \leq R_1$, a constraint that x_t is a flow on a graph, or that x_t is a probability distribution. In all of these cases, this amounts to the constraint that $x_t \in \mathcal{X}$ where $\mathcal{X}$ is a suitable convex feasible set. Further, for FTRL-Proximal algorithms a constraint like $\|x_t\|_2 \leq R$ is generally needed in order to bound $r_{0:T}(x^*)$; see Section 3.3.

Such constraints can be addressed immediately in our setting by adding the additional regularizer $I_{\mathcal{X}}$ to r_0, based on the equivalence

$$\arg\min_{x \in \mathbb{R}^n} f_{1:t}(x) + r_{0:t}(x) + I_{\mathcal{X}}(x) \quad = \quad \arg\min_{x \in \mathcal{X}} f_{1:t}(x) + r_{0:t}(x).$$

Further, if $r_{0:t}$ satisfies the conditions of Theorem 1, then so does $r_{0:t} + I_{\mathcal{X}}$. Similarly, for Theorem 2, adding $I_{\mathcal{X}}$ to r_0 will generally still produce a scheme where r_t has x_t as a minimizer, and so the theorem will still apply. We apply this technique to specific algorithms in Section 3.

Note that while the theorems still apply, the regret bounds change in an important way, since $I_{\mathcal{X}}(x^*)$ now appears in the regret bound: that is, if Theorem 1 on functions $r_0, r_1, \ldots,$ gives a bound $\text{Regret}(x^*) \leq r_{0:T-1}(x^*) + \frac{1}{2}\sum_{t=1}^T \|g_t\|^2_{(t-1),\star}$, then the version constrained to select from $\mathcal{X}$ by adding $I_{\mathcal{X}}$ to r_0 has regret bound

$$\text{Regret}_T(x^*) \leq I_{\mathcal{X}}(x^*) + r_{0:T-1}(x^*) + \frac{1}{2}\sum_{t=1}^T \|g_t\|^2_{(t-1),\star}.$$

This bound is *vacuous* for $x^* \notin \mathcal{X}$, but identical to the unconstrained bound for $x^* \in \mathcal{X}$. This makes sense: one can show that any online algorithm constrained to select $x_t \in \mathcal{X}$ cannot in general hope to have sublinear regret against some $x^* \notin \mathcal{X}$. Thus, if we believe some $x^* \notin \mathcal{X}$ could perform very well, incorporating the constraint $x_t \in \mathcal{X}$ is a significant sacrifice that should only be made if external considerations really require it.

3. Application to Specific Algorithms and Settings

Before proving these theorems, we apply them to a variety of specific algorithms. We will use the following lemma, which collects some facts for the sequence of incremental regularizers r_t. These claims are immediate consequences of the relevant definitions.

Lemma 3 *Consider a sequence of r_t as in Setting 1. Then, since $r_t(x) \geq 0$, we have $r_{0:t}(x) \geq r_{0:t-1}(x)$, and so $r^\star_{0:t}(x) \leq r^\star_{0:t-1}(x)$, where $r^\star_{0:t}$ is the convex-conjugate of $r_{0:t}$. If each r_t is σ_t-strongly convex w.r.t. a norm $\|\cdot\|$ for $\sigma_t \geq 0$, then, $r_{0:t}$ is $\sigma_{0:t}$-strongly convex w.r.t. $\|\cdot\|$, or equivalently, is 1-strongly-convex w.r.t. $\|x\|_{(t)} = \sqrt{\sigma_{0:t}}\|x\|$, which has dual norm $\|x\|_{(t),\star} = \frac{1}{\sqrt{\sigma_{0:t}}}\|x\|$.*

For reasons that will become clear, it is natural to define a learning rate schedule η_t to be the inverse of the cumulative strong convexity,

$$\eta_t = \frac{1}{\sigma_{0:t}}.$$

In fact, in many cases it will be more natural to define the learning rate schedule, and infer the sequence of σ_t,

$$\sigma_t = \frac{1}{\eta_t} - \frac{1}{\eta_{t-1}},$$

with $\sigma_0 = \frac{1}{\eta_0}$.

For simplicity, in this section we assume the loss functions have already been linearized, that is, $f_t(x) = g_t \cdot x$, unless otherwise stated. Figure 1 summarizes most of the FTRL algorithms analyzed in this section.

3.1 Constant Learning Rate Online Gradient Descent

As a warm-up, we first consider a non-adaptive algorithm, unconstrained constant learning rate Online Gradient Descent, which selects $x_1 = 0$ and thereafter

$$x_{t+1} = x_t - \eta g_t, \tag{8}$$

where the parameter $\eta > 0$ is the learning rate. Iterating this update, we see $x_{t+1} = -\eta g_{1:t}$. There is a close connection between Online Gradient Descent and FTRL, which we will use to analyze this algorithm. If we take FTRL with $r_0(x) = \frac{1}{2\eta}\|x\|_2^2$ and $r_t(x) = 0$ for $t \geq 1$, we have the update

$$x_{t+1} = \arg\min_x g_{1:t} \cdot x + \frac{1}{2\eta}\|x\|_2^2, \tag{9}$$

which we can solve in closed form to see $x_{t+1} = -\eta g_{1:t}$ as well. Applying either Theorem 1 or 2 (recall they are equivalent when the regularizer is fixed) gives the bound of Eq. (7), in this case

$$\text{Regret}_T(x^*) \leq \frac{1}{2\eta}\|x^*\|_2^2 + \frac{1}{2}\sum_{t=1}^T \eta\|g_t\|_2^2, \tag{10}$$

using Lemma 3 for $\|x\|_{(t),\star} = \sqrt{\eta}\|x\|_2$. Suppose we are concerned with x^* where $\|x^*\|_2 \leq R$, the g_t satisfy $\|g_t\|_2 \leq G$, and we want to minimize regret after T' rounds. Then, choosing $\eta = \frac{R}{G\sqrt{T'}}$ minimizes Eq. (10) when $T = T'$, and we have

$$\text{Regret}_T(x^*) \leq \frac{RG}{2}\sqrt{T'} + \frac{RG}{2}\frac{T}{\sqrt{T'}},$$

or $\text{Regret}(x^*) \leq RG\sqrt{T}$ when $T = T'$. However, this bound is only $\mathcal{O}(\sqrt{T})$ when $T = \mathcal{O}(T')$. For $T \ll T'$, or $T \gg T'$ the bound is no longer interesting, and in fact the algorithm will likely perform poorly. This deficiency can be addressed via the "doubling trick", where we double T' and restart the algorithm each time T grows larger than T' (c.f., Shalev-Shwartz (2012, 2.3.1)). However, adaptively choosing the learning rate without restarting will allow us to achieve better bounds than the doubling trick (by a constant factor) with a more practically useful algorithm. We do this in Sections 3.2 and 3.3 below.

Constant Learning Rate Online Gradient Descent with a Feasible Set Above we assumed $\|x^*\|_2 \leq R$, but there is no a priori bound on the magnitude of the x_t selected by the algorithm. Following the approach of Section 2.4, we can incorporate a feasible set by taking $r_0(x) = \frac{1}{2\eta}\|x\|_2^2 + I_{\mathcal{X}}(x)$, so the update becomes

$$x_{t+1} = \arg\min_{x\in\mathbb{R}^n} g_{1:t} \cdot x + \frac{1}{2\eta}\|x\|_2^2 + I_{\mathcal{X}}(x) = \arg\min_{x\in\mathcal{X}} g_{1:t} \cdot x + \frac{1}{2\eta}\|x\|_2^2. \tag{11}$$

Following Shalev-Shwartz (2012, Sec. 2.6), this update is equivalent to the two-step update where we first solve the unconstrained problem and then project onto the feasible set, namely

$$u_{t+1} = \arg\min_{x\in\mathbb{R}^n} g_{1:t}\cdot x + \frac{1}{2\eta}\|x\|_2^2$$
$$x_{t+1} = \Pi_{\mathcal{X}}(u_{t+1}) \qquad \text{where} \qquad \Pi_{\mathcal{X}}(u) \equiv \arg\min_{x\in\mathcal{X}} \|x-u\|_2.$$

Many FTRL algorithms on feasible sets can in this way be interpreted as lazy-projection algorithms, where we find (or maintain) the solution to the unconstrained problem, and then project onto the feasible set when needed.

Theorem 1 can be used to analyze the constrained algorithm of Eq. (11) in exactly the same way we analyzed Eq. (9): adding $I_{\mathcal{X}}$ does not change the strong convexity of the $\|x\|_2^2$ terms in the regularizer, and so the only difference is in the $r_{0:T}(x^*)$ term. Instead of Eq. (10), we have

$$\forall x^*\in\mathcal{X},\ \text{Regret}_T(x^*) \le \frac{1}{2\eta}\|x^*\|_2^2 + \frac{1}{2}\sum_{t=1}^T \eta\|g_t\|_2^2,$$

where we have chosen to use the explicit $\forall x^*\in\mathcal{X}$ rather than the equivalent choice of including $I_{\mathcal{X}}(x^*)$ on the right-hand side.

Interestingly, the update of Eq. (11) is no longer equivalent to the standard projected Online Gradient Descent update $x_{t+1} = \Pi_{\mathcal{X}}(x_t - \eta g_t)$; this issue is discussed in the context of more general Mirror Descent updates in Appendix C.2. We will be able to analyze this algorithm using techniques from Section 6.

3.2 Dual Averaging

Dual Averaging is an adaptive FTRL-Centered algorithm with linearized loss functions; the adaptivity allows us to prove regret bounds that are $\mathcal{O}(\sqrt{T})$ for all T. We choose $r_t(x) = \frac{\sigma_t}{2}\|x\|_2^2$ for constants $\sigma_t \ge 0$, so $r_{0:t}$ is 1-strongly-convex w.r.t. the norm $\|x\|_{(t)} = \sqrt{\sigma_{0:t}}\|x\|_2$, which has dual norm $\|x\|_{(t),\star} = \frac{1}{\sqrt{\sigma_{0:t}}}\|x\|_2 = \sqrt{\eta_t}\|x\|_2$, using Lemma 3. Plugging into Theorem 1 then gives

$$\forall T,\ \text{Regret}_T(x^*) \le \frac{1}{2\eta_{T-1}}\|x^*\|_2^2 + \frac{1}{2}\sum_{t=1}^T \eta_{t-1}\|g_t\|_2^2.$$

Suppose we know $\|g_t\|_2 \le G$, and we consider x^* where $\|x^*\|_2 \le R$. Then, with the choice $\eta_t = \frac{R}{\sqrt{2}G\sqrt{t+1}}$, using the inequality $\sum_{t=1}^T \frac{1}{\sqrt{t}} \le 2\sqrt{T}$, we arrive at

$$\forall T,\ \text{Regret}_T(x^*) \le \frac{\sqrt{2}}{2}\left(R + \frac{\|x^*\|_2^2}{R}\right)G\sqrt{T}. \tag{12}$$

When in fact $\|x^*\| \le R$, we have Regret $\le \sqrt{2}RG\sqrt{T}$, but the bound of Eq. (12) is valid (and meaningful) for arbitrary $x^* \in \mathbb{R}^n$. Observe that on a particular round T, this bound is a factor $\sqrt{2}$ worse than the bound of $RG\sqrt{T}$ shown in Section 3.1 when the learning rate is tuned for exactly round T; this is the (small) price we pay for a bound that holds uniformly for all T.

As in the previous example, Dual Averaging can also be restricted to select from a feasible set $\mathcal{X}$ by including $I_{\mathcal{X}}$ in r_0. Additional non-smooth regularization can also be applied by adding the appropriate terms to r_0 (or any of the r_t); for example, we can add an L_1 and L_2 penalty by adding the terms $\lambda_1\|x\|_1 + \lambda_2\|x\|_2^2$. When in addition the f_t are linearized, this produces the Regularized Dual Averaging algorithm of Xiao (2009). Note that our result of $\sqrt{2}RG\sqrt{T}$ improves on the bound of $2RG\sqrt{T}$ achieved by Xiao (2009, Cor. 2(a)). We consider the case of such additional regularization terms in more detail in Section 5.

3.3 FTRL-Proximal

Suppose $\mathcal{X} \subseteq \{x \mid \|x\|_2 \le R\}$, and we choose $r_0(x) = I_{\mathcal{X}}(x)$ and for $t > 1$, $r_t(x) = \frac{\sigma_t}{2}\|x - x_t\|_2^2$. It is worth emphasizing that unlike in the previous examples, for FTRL-Proximal the inclusion of the feasible set $\mathcal{X}$ is essential to proving regret bounds. With this constraint we have $r_{0:t}(x^*) \le \frac{\sigma_{1:t}}{2}(2R)^2$ for any $x^* \in \mathcal{X}$, since each $x_t \in \mathcal{X}$. Without forcing $x_t \in \mathcal{X}$, however, the terms $\|x^* - x_t\|_2^2$ in $r_{0:t}(x^*)$ cannot be usefully bounded.

With these choices, $r_{0:t}$ is 1-strongly-convex w.r.t. the norm $\|x\|_{(t)} = \sqrt{\sigma_{1:t}}\|x\|_2$, which has dual norm $\|x\|_{(t),\star} = \frac{1}{\sqrt{\sigma_{1:t}}}\|x\|_2$. Thus, applying Theorem 2, we have

$$\forall x^*\in\mathcal{X},\quad \text{Regret}(x^*) \le \frac{1}{2\eta_T}(2R)^2 + \frac{1}{2}\sum_{t=1}^T \eta_t\|g_t\|^2, \tag{13}$$

where again $\eta_t = \frac{1}{\sigma_{1:t}}$. Choosing $\eta_t = \frac{\sqrt{2}R}{G\sqrt{t}}$ and assuming $\|x^*\| \le R$ and $\|g_t\|_2 \le G$,

$$\text{Regret}(x^*) \le 2\sqrt{2}RG\sqrt{T}. \tag{14}$$

Note that we are a factor of 2 worse than the corresponding bound for Dual Averaging. However, this is essentially an artifact of loosely bounding $\|x^* - x_t\|_2^2$ by $(2R)^2$, whereas for Dual Averaging we can bound $\|x^* - 0\|_2^2$ with R^2. In practice one would hope x_t is closer to x^* than 0, and so it is reasonable to believe that the FTRL-Proximal bound will actually be tighter post-hoc in many cases. Empirical evidence also suggests FTRL-Proximal can work better in practice (McMahan, 2011).

3.4 FTRL-Proximal with Diagonal Matrix Learning Rates

We now consider an AdaGrad FTRL-Proximal algorithm which is adaptive to the observed sequence of gradients g_t, improving on the previous result. For simplicity,

first consider a one-dimensional problem. Let $r_0 = I_{\mathcal{X}}$ with $\mathcal{X} = [-R, R]$, and fix a learning rate schedule for FTRL-Proximal where

$$\eta_t = \frac{\sqrt{2}R}{\sqrt{\sum_{s=1}^t g_s^2}}$$

for use in Eq. (13). This gives

$$\text{Regret}(x^*) \leq 2\sqrt{2}R\sqrt{\sum_{t=1}^T g_t^2}, \tag{15}$$

where we have used the following lemma, which generalizes $\sum_{t=1}^T 1/\sqrt{t} \leq 2\sqrt{T}$:

Lemma 4 *For any non-negative real numbers $a_1, a_2, \ldots, a_n$,*

$$\sum_{i=1}^n \frac{a_i}{\sqrt{\sum_{j=1}^i a_j}} \leq 2\sqrt{\sum_{i=1}^n a_i}\ .$$

For a proof see Auer et al. (2002) or Streeter and McMahan (2010, Lemma 1). The bound of Eq. (15) gives us a fully adaptive version of Eq. (14): not only do we not need to know T in advance, we also do not need to know a bound on the norms of the gradients G. Rather, the bound is fully adaptive and we see, for example, that the bound only depends on rounds t where the gradient is nonzero (as one would hope). We do, however, require that R is chosen in advance; for algorithms that avoid this, see Streeter and McMahan (2012); Orabona (2013); McMahan and Abernethy (2013), and McMahan and Orabona (2014).

To arrive at an AdaGrad-style algorithm for n-dimensions we need only apply the above technique on a per-coordinate basis, namely using learning rate

$$\eta_{t,i} = \frac{\sqrt{2}R_\infty}{\sqrt{\sum_{s=1}^t g_{s,i}^2}}$$

for coordinate i, where we assume $\mathcal{X} \subseteq [-R_\infty, R_\infty]^n$. Streeter and McMahan (2010) take the per-coordinate approach directly; the more general approach here allows us to handle arbitrary feasible sets and L_1 or other non-smooth regularization.

We take $r_0 = I_{\mathcal{X}}$, and for $t \geq 1$ define $r_t(x) = \frac{1}{2}\|Q_t^{\frac{1}{2}}(x - x_t)\|_2^2$ where $Q_t = \text{diag}\left(\sigma_{t,i}\right)$, the diagonal matrix with entries $\sigma_{t,i} = \eta_{t,i}^{-1} - \eta_{t-1,i}^{-1}$. This Q_t is positive semi-definite, and for any such Q_t, we have that $r_{0:t}$ is 1-strongly-convex w.r.t. the norm $\|x\|_{(t)} = \|(Q_{1:t})^{\frac{1}{2}}x\|_2$, which has dual norm $\|g\|_{(t),\star} = \|(Q_{1:t})^{-\frac{1}{2}}g\|_2$. Then, plugging into Theorem 2 gives

$$\text{Regret}(x^*) \leq r_{0:T}(x^*) + \frac{1}{2}\sum_{t=1}^T \|(Q_{1:t})^{-\frac{1}{2}}g_t\|_2.$$

which improves on McMahan and Streeter (2010, Theorem 2) by a constant factor.

Essentially, this bound amounts to summing Eq. (15) across all n dimensions; McMahan and Streeter (2010, Cor. 9) show this bound is at least as good (and often better) than that of Eq. (14). Full matrix learning rates can be derived using a matrix generalization of Lemma 4, e.g., Duchi et al. (2011, Lemma 10); however, since this requires $\mathcal{O}(n^2)$ space and potentially $\mathcal{O}(n^2)$ time per round, in practice these algorithms are often less useful than the diagonal varieties.

It is perhaps not immediately clear that the diagonal FTRL-Proximal algorithm is easy and efficient to implement. However, taking the linear approximation to f_t, one can see $h_{1:t}(x) = g_{1:t} \cdot x + r_{1:t}(x)$ is itself just a quadratic which can be represented using two length n vectors, one to maintain the linear terms ($g_{1:t}$ plus adjustment terms) and one to maintain $\sum_{s=1}^t g_{s,i}^2$, from which the diagonal entries of $Q_{1:t}$ can be constructed. That is, the update simplifies to

$$x_{t+1} = \operatorname*{arg\,min}_{x \in \mathcal{X}} \ (g_{1:t} - a_{1:t}) \cdot x + \sum_{i=1}^n \frac{1}{2\eta_{t,i}} x_i^2 \qquad \text{where} \qquad a_t = \sigma_t x_t.$$

This update can be solved in closed-form on a per-coordinate basis when $\mathcal{X} = [-R_\infty, R_\infty]^n$. For a general feasible set, it is equivalent to a lazy-projection algorithm that first solves for the unconstrained solution and then projects it onto $\mathcal{X}$ using norm $\|(Q_{1:t})^{\frac{1}{2}} \cdot \|$ (see McMahan and Streeter (2010, Eq. 7)). Pseudo-code which also incorporates L_1 and L_2 regularization is given in McMahan et al. (2013).

3.5 AdaGrad Dual Averaging

Similar ideas can be applied to Dual Averaging (where we center each r_t at x_1), but one must use some care due to the "off-by-one" difference in the bounds. For example, for the diagonal algorithm, it is necessary to choose per-coordinate learning rates

$$\eta_t \approx \frac{R}{\sqrt{G^2 + \sum_{s=1}^t g_s^2}},$$

where $|g_t| \leq G$. Thus, we arrive at an algorithm that is almost (but not quite) fully adaptive in the gradients, since a modest dependence on the initial guess G of the maximum per-coordinate gradient remains in the bound. This offset appears, for example, as the δI terms added to the learning rate matrix H_t in Figure 1 of Duchi et al. (2011). We will see this issue again in Section 3.7.

3.6 Strongly Convex Functions

Suppose each loss function f_t is 1-strongly-convex w.r.t. a norm $\|\cdot\|$, and let $r_t(x) = 0$ for all t (that is, we use the Follow-The-Leader (FTL) algorithm). Define $\|x\|_{(t)} =$

Non-Adaptive FTRL Algorithms (fixed regularizer r_0, with $r_t(x) = 0$ for $t \geq 1$)

Constant Learning Rate Unprojected Online Gradient Descent

$$\begin{aligned} x_{t+1} &= x_t - \eta g_t \\ &= \arg\min_x g_{1:t} \cdot x_t + \frac{1}{2\eta}\|x\|_2^2 \\ &= -\eta g_{1:t} \end{aligned}$$

Follow-The-Leader where the f_t are 1-strongly-convex w.r.t. $\|\cdot\|$

$$x_{t+1} = \arg\min_x f_{1:t}(x)$$

Online Gradient Descent for strongly-convex functions

$$\begin{aligned} x_{t+1} &= \arg\min_x g_{1:t} \cdot x + \frac{1}{2}\sum_{s=1}^t \|x - x_s\|^2 \qquad \text{where } g_t \in \partial f_t(x_t) \\ &= x_t - \eta_t g_t \qquad \text{where } \eta_t = \frac{1}{t} \end{aligned}$$

Adaptive FTRL-Centered Algorithms (r_t chosen adaptively and minimized at x_1)

Unconstrained Dual Averaging (adaptive to t)

$$\begin{aligned} x_{t+1} &= \arg\min_x g_{1:t} \cdot x + \frac{1}{2\eta_t}\|x\|_2^2 \qquad \text{where } \eta_t = \frac{R}{\sqrt{2}G\sqrt{t+1}} \\ &= -\eta_t g_{1:t} \end{aligned}$$

FTRL with the entropic regularizer over the probability simplex Δ (adaptive to g_t)

$$x_{t+1} = \arg\min_{x\in\Delta} g_{1:t} \cdot x + \frac{1}{2\eta_t}\sum_{i=1}^n x_i \log x_i \qquad \text{where } \eta_t = \frac{\sqrt{\log n}}{\sqrt{G_\infty^2 + \sum_{s=1}^t \|g_s\|_\infty^2}}, \text{ or}$$

$$x_{t+1,i} = \frac{\exp(-\eta_t g_{1:t,i})}{\sum_{i=1}^n \exp(-\eta_t g_{1:t,i})} \qquad \text{in closed form}$$

Adaptive FTRL-Proximal Algorithms (r_t chosen adaptively and minimized at x_t)

FTRL-Proximal (adaptive to t) with $\sigma_s = \eta_s^{-1} - \eta_{s-1}^{-1}$

$$x_{t+1} = \arg\min_{x\in\mathcal{X}} g_{1:t} \cdot x + \sum_{s=1}^t \frac{\sigma_s}{2}\|x - x_s\|_2^2 \qquad \text{where } \eta_t = \frac{\sqrt{2}R}{G\sqrt{t}}$$

AdaGrad FTRL-Proximal (adaptive to g_t) with $\sigma_{s,i} = \eta_{s,i}^{-1} - \eta_{s-1,i}^{-1}$.

$$x_{t+1} = \arg\min_{x\in\mathcal{X}} g_{1:t} \cdot x + \sum_{s=1}^t \frac{1}{2}\left\| \operatorname{diag}\left(\sigma_{s,i}^{\frac{1}{2}}\right)(x - x_s)\right\|_2^2 \qquad \text{where } \eta_{t,i} = \frac{\sqrt{2}R}{\sqrt{\sum_{s=1}^t g_{s,i}^2}}$$

Figure 1: Example updates for algorithms in different branches of the FTRL family.

$\sqrt{t}\|x\|$, and observe $h_{0:t}(x)$ is 1-strongly-convex w.r.t. $\|\cdot\|_{(t)}$ (by Lemma 3). Then, applying either Theorem 1 or 2 (recalling they coincide when all $r_t(x) = 0$),

$$\text{Regret}(x^*) \leq \frac{1}{2}\sum_{t=1}^T \|g_t\|_{(t),\star}^2 = \frac{1}{2}\sum_{t=1}^T \frac{1}{t}\|g_t\|^2 \leq \frac{G^2}{2}(1 + \log T),$$

where we have used the inequality $\sum_{t=1}^T 1/t \leq 1 + \log T$ and assumed $\|g_t\| \leq G$. This recovers, e.g., Kakade and Shalev-Shwartz (2008, Cor. 1) for the the exact FTL algorithm. This algorithm requires optimizing over $f_{1:t}$ exactly, which may be computationally prohibitive.

For a 1-strongly-convex f_t with $g_t \in \partial f_t(x_t)$ we have by definition

$$f_t(x) \geq \underbrace{f_t(x_t) + g_t \cdot (x - x_t) + \frac{1}{2}\|x - x_t\|^2}_{=\bar{f}_t}.$$

Thus, we can define a $\bar{f}_t$ equal to the right-hand-side of the above inequality, so $\bar{f}_t(x) \leq f_t(x)$ and $\bar{f}_t(x_t) = f_t(x_t)$. The $\bar{f}_t$ are also 1-strongly-convex w.r.t. $\|\cdot\|$, and so running FTL on these functions produces an identical regret bound. Theorem 11 will show that the update $x_{t+1} = \arg\min_x \bar{f}_{1:t}(x)$ is equivalent to the Online Gradient Descent update

$$x_{t+1} = x_t - \frac{1}{t}g_t,$$

showing this update is essentially the Online Gradient Descent algorithm for strongly convex functions given by Hazan et al. (2007).[2]

3.7 Adaptive Dual Averaging with the Entropic Regularizer

We consider problems where the algorithm selects a probability distribution (e.g., in order to sample an action from a discrete set of n choices), that is $x_t \in \Delta_n$ with

$$\Delta_n = \left\{ x \;\middle|\; \sum_{i=1}^n x_i = 1 \text{ and } x_i \geq 0 \right\}.$$

We assume gradients are bounded so that $\|g_t\|_\infty \leq G_\infty$, which is natural for example if each action has a cost in the range $[-G_\infty, G_\infty]$, so $g_t \cdot x$ gives the expected cost of choosing an action from the distribution x. This is the classic problem of prediction from expert advice (Vovk, 1990; Littlestone and Warmuth, 1994; Freund and Schapire, 1995; Cesa-Bianchi and Lugosi, 2006).

2. Again, the constraint to select from a fixed feasible set $\mathcal{X}$ can be added easily in either case; however, the natural way to add the constraint to the FTRL expression produces a "lazy-projection" algorithm, whereas adding the constraint to the Online Gradient Descent update produces a "greedy-projection" algorithm. This issue is discussed in some depth in Appendix C.2.

The previously introduced algorithms can be applied by enforcing the constraint $x \in \Delta_n$ by adding I_{Δ_n} to r_0, but to instantiate their bounds we can only bound $\|g_t\|_2$ by $\sqrt{n}G_\infty$ in this case, leading to bounds like $\mathcal{O}(G_\infty\sqrt{nT})$. By using a more appropriate regularizer, we can reduce the dependence on the dimension from $\sqrt{n}$ to $\sqrt{\log n}$. In particular, we use the entropic regularizer,

$$H(x) = I_\Delta(x) + \log n + \sum_{i=1}^n x_i \log x_i,$$

from which we define the following adaptive regularization schedule:

$$r_{0:t}(x) = \frac{1}{\eta_t} H(x) \qquad \text{where} \qquad \eta_t = \frac{\sqrt{\log n}}{\sqrt{G_\infty^2 + \sum_{s=1}^t \|g_s\|_\infty^2}}$$

for $t \geq 0$. Note that as in AdaGrad Dual Averaging, we make the learning rate schedule η_t a function of the observed g_t. The function H (and hence each $r_{0:t}$) is minimized by the uniform distribution $x_1 = (1/n, \dots, 1/n)$ where $H(x) = 0$, and so these regularizers are centered at x_1. Note also that h is maximized at the corners of Δ_n (e.g., $x = (1, 0, \dots, 0)$) where it has value $\log n$.

The entropic regularizer H is 1-strongly-convex with respect to the L_1 norm over the probability simplex $\mathcal{X}$ (e.g., Shalev-Shwartz (2012, Ex 2.5)), and it follows that $r_{0:t}$ is 1-strongly convex with respect to the norm $\|x\|_{(t)} = \frac{1}{\sqrt{\eta_t}}\|x\|_1$, and $\|g\|_{(t),\star}^2 = \eta_t\|g\|_\infty^2$. Then, applying Theorem 1, we have

$$\begin{aligned}
\text{Regret}(x^*) &\leq r_{0:T-1}(x^*) + \frac{1}{2}\sum_{t=1}^T \|g_t\|_{(t-1),\star}^2 \\
&\leq \frac{\log n}{\eta_{T-1}} + \frac{1}{2}\sum_{t=1}^T \eta_{t-1}\|g_t\|_\infty^2 \\
&\leq \frac{\log n}{\eta_{T-1}} + \frac{\sqrt{\log n}}{2}\sum_{t=1}^T \frac{\|g_t\|_\infty^2}{\sqrt{\sum_{s=1}^t \|g_s\|_\infty^2}} \qquad \text{since } \forall t,\ \|g_t\|_\infty \leq G_\infty \\
&\leq 2\sqrt{\left(G_\infty^2 + \sum_{t=1}^{T-1}\|g_t\|_\infty^2\right)\log n} \qquad \text{Lemma 4 and } \|g_T\|_\infty \leq G_\infty \\
&\leq 2G_\infty\sqrt{T\log n}.
\end{aligned}$$

The last line gives an adaptive ($\forall T$) version of Shalev-Shwartz (2012, Cor. 2.14 and Cor 2.16), but the version of the bound in terms of $\|g_t\|_\infty$ may be much tighter if there are many rounds where the maximum magnitude cost is much less than G_∞. For similar adaptive algorithms, see Stoltz (2005, Thm 2.3) and Stoltz (2011, Thm 1.4, Eq. (1.22)).

4. A General Analysis Technique

In this section, we prove Theorems 1 and 2; the analysis techniques developed will also be used in subsequent sections to analyze composite objectives and Mirror Descent algorithms.

4.1 Inductive Lemmas

In this section we prove the following lemma that lets us analyze arbitrary FTRL-style algorithms:

Lemma 5 (Strong FTRL Lemma) *Let f_t be a sequence of arbitrary (possibly non-convex) loss functions, and let r_t be arbitrary non-negative regularization functions, such that $x_{t+1} = \arg\min_x h_{0:t}(x)$ is well defined, where $h_{0:t}(x) \equiv f_{1:t}(x) + r_{0:t}(x)$. Then, the algorithm that selects these x_t achieves*

$$\text{Regret}(x^*) \leq r_{0:T}(x^*) + \sum_{t=1}^T h_{0:t}(x_t) - h_{0:t}(x_{t+1}) - r_t(x_t). \tag{16}$$

This lemma can be viewed as a stronger form of the more well-known standard FTRL Lemma (see Kalai and Vempala (2005); Hazan (2008), Hazan (2010, Lemma 1), McMahan and Streeter (2010, Lemma 3), and Shalev-Shwartz (2012, Lemma 2.3)). The strong version has three main advantages over the standard version: 1) it is essentially tight, which improves the final bounds by a constant factor, 2) it can be used to analyze adaptive FTRL-Centered algorithms in addition to FTRL-Proximal, and 3) it relates directly to the primal-dual style of analysis. For completeness, in Appendix A we present the standard version of the lemma, along with the proof of a bound analogous to Theorem 2 (but weaker by a constant factor).

The Strong FTRL Lemma bounds regret by the sum of two factors:

- **Stability** The terms in the sum over t measure how much better x_{t+1} is for the cumulative objective function $h_{0:t}$ than the point actually selected, x_t: namely $h_{0:t}(x_t) - h_{0:t}(x_{t+1})$. These per-round terms can be seen as measuring the stability of the algorithm, an online analog to the role of stability in the stochastic setting (Bousquet and Elisseeff, 2002; Rakhlin et al., 2005; Shalev-Shwartz et al., 2010).
- **Regularization** The term $r_{0:T}(x^*)$ quantifies how much regularization we have added, measured at the comparator point x^*. This captures the intuitive fact that if we could center our regularization at x^* it should not increase regret.

Adding strongly convex regularizers will increase stability (and hence decrease the cost of the stability terms), at the expense of paying a larger regularization penalty

$r_{0:T}(x^*)$. At the heart of the adaptive algorithms we study is the ability to dynamically balance these two competing goals.

The following corollary relates the above statement to the primal-dual style of analysis:

Corollary 6 *Consider the same conditions as Lemma 5, and further suppose the loss functions are linear, $f_t(x) = g_t \cdot x_t$. Then,*

$$h_{0:t}(x_t) - h_{0:t}(x_{t+1}) - r_t(x_t) = r^\star_{0:t}(-g_{1:t}) - r^\star_{0:t-1}(-g_{1:t-1}) + g_t \cdot x_t, \tag{17}$$

which implies

$$\text{Regret}(x^*) \leq r_{0:T}(x^*) + \sum_{t=1}^T r^\star_{0:t}(-g_{1:t}) - r^\star_{0:t-1}(-g_{1:t-1}) + g_t \cdot x_t.$$

We make a few remarks before proving these results at the end of this section. Corollary 6 can easily be proved directly using the Fenchel-Young inequality. Our statement directly matches the first claim of Orabona (2013, Lemma 1), and in the non-adaptive case re-arrangement shows equivalence to Shalev-Shwartz (2007, Lemma 1) and Shalev-Shwartz (2012, Lemma 2.20); see also Kakade et al. (2012, Corollary 4). McMahan and Orabona (2014, Thm. 1) give a closely related duality result for regret and reward, and discuss several interpretations for this result, including the potential function view, the connection to Bregman divergences, and an interpretation of $r^\star$ as a benchmark target for reward.

Note, however, that Lemma 5 is strictly stronger than Corollary 6: it applies to non-convex f_t and r_t. Further, even for convex f_t, it can be more useful: for example, we can directly analyze strongly convex f_t with all $r_t(x) = 0$ using the first statement. Lemma 5 is also arguably simpler, in that it does not require the introduction of convexity or the Fenchel conjugate. We now prove the Strong FTRL Lemma:

Proof of Lemma 5 First, we bound a quantity that is essentially our regret if we had used the FTL algorithm against the functions $h_1, \dots h_T$ (for convenience, we include a $-h_0(x^*)$ term as well):

$$\begin{aligned}
&\sum_{t=1}^T h_t(x_t) - h_{0:T}(x^*) \\
&\quad = \sum_{t=1}^T (h_{0:t}(x_t) - h_{0:t-1}(x_t)) - h_{0:T}(x^*) \\
&\quad \leq \sum_{t=1}^T (h_{0:t}(x_t) - h_{0:t-1}(x_t)) - h_{0:T}(x_{T+1}) \quad \text{Since } x_{T+1} \text{ minimizes } h_{0:T} \\
&\quad \leq \sum_{t=1}^T (h_{0:t}(x_t) - h_{0:t}(x_{t+1})),
\end{aligned}$$

where the last line follows by simply re-indexing the $-h_{0:t}$ terms and dropping the the non-positive term $-h_0(x_1) = -r_0(x_1) \leq 0$. Expanding the definition of h on the left-hand-side of the above inequality gives

$$\sum_{t=1}^T (f_t(x_t) + r_t(x_t)) - f_{1:T}(x^*) - r_{0:T}(x^*) \leq \sum_{t=1}^T (h_{0:t}(x_t) - h_{0:t}(x_{t+1})).$$

Re-arranging the inequality proves the lemma. ■

We remark it is possible to make Lemma 5 an *equality* if we include the term $h_{0:T}(x_{T+1}) - h_{0:T}(x^*)$ on the RHS, since we can assume $r_0(x_1) = 0$ without loss of generality. In this case, we do not need the assumption that $x_{t+1} = \arg\min_x h_{0:t}(x)$, and so the lemma applies to an arbitrary sequence of points $x_1, \dots, x_T$. On the other hand, if one is actually interested in the performance of the Follow-The-Leader (FTL) algorithm against the h_t (e.g., if all the r_t are uniformly zero), then running the FTL algorithm and choosing $x^* = x_{T+1}$ is particularly natural.

Proof of Corollary 6 Using the definition of the Fenchel conjugate and of x_{t+1},

$$r^\star_{0:t}(-g_{1:t}) = \max_x \; -g_{1:t} \cdot x - r_{0:t}(x) = -\big(\min_x \; g_{1:t} \cdot x + r_{0:t}(x)\big) = -h_{0:t}(x_{t+1}). \tag{18}$$

Now, observe that

$$\begin{aligned}
h_{0:t}(x_t) - r_t(x_t) &= g_{1:t} \cdot x_t + r_{0:t}(x_t) - r_t(x_t) \\
&= g_{1:t-1} \cdot x_t + r_{0:t-1}(x_t) + g_t \cdot x_t \\
&= h_{0:t-1}(x_t) + g_t \cdot x_t \\
&= -r^\star_{0:t-1}(-g_{1:t-1}) + g_t \cdot x_t,
\end{aligned}$$

where the last line uses Eq. (18) with $t \to t-1$. Combining this with Eq. (18) again $(-h_{0:t}(x_{t+1}) = r^\star_{0:t}(-g_{1:t}))$ proves Eq. (17). ■

4.2 Tools from Convex Analysis

Here we highlight a few key tools from convex analysis that will be used to bound the per-round stability terms that appear in the Strong FTRL Lemma. For more background on convex analysis, see Rockafellar (1970) and Shalev-Shwartz (2007, 2012). The next result generalizes arguments found in earlier proofs for FTRL algorithms:

Lemma 7 *Let $\phi_1 : \mathbb{R}^n \to \mathbb{R} \cup \{\infty\}$ be a convex function such that $x_1 = \arg\min_x \phi_1(x)$ exists. Let ψ be a convex function such that $\phi_2(x) = \phi_1(x) + \psi(x)$ is strongly convex w.r.t. norm $\|\cdot\|$. Let $x_2 = \arg\min_x \phi_2(x)$. Then, for any $b \in \partial\psi(x_1)$, we have*

$$\|x_1 - x_2\| \leq \|b\|_\star, \tag{19}$$

and for any x',

$$\phi_2(x_1) - \phi_2(x') \leq \frac{1}{2}\|b\|_\star^2.$$

We defer the proofs of the results in this section to Appendix B. When ϕ_1 and ψ are quadratics (with ψ possibly linear) and the norm is the corresponding L_2 norm, both statements in the above lemma hold with equality. For the analysis of composite updates (Section 5), it will be useful to split the change ψ in the objective function ϕ into two components:

Corollary 8 *Let $\phi_1 : \mathbb{R}^n \to \mathbb{R} \cup \{\infty\}$ be a convex function such that $x_1 = \arg\min_x \phi_1(x)$ exists. Let ψ and Ψ be convex functions such that $\phi_2(x) = \phi_1(x) + \psi(x) + \Psi(x)$ is strongly convex w.r.t. norm $\|\cdot\|$. Let $x_2 = \arg\min_x \phi_2(x)$. Then, for any $b \in \partial\psi(x_1)$ and any x',*

$$\phi_2(x_1) - \phi_2(x') \leq \frac{1}{2}\|b\|_\star^2 + \Psi(x_1) - \Psi(x_2).$$

The concept of strong smoothness plays a key role in the proof of the above lemma, and can also be used directly in the application of Corollary 6. A function ψ is *σ-strongly-smooth* with respect to a norm $\|\cdot\|$ if it is differentiable and for all x, y we have

$$\psi(y) \leq \psi(x) + \nabla\psi(x) \cdot (y - x) + \tfrac{\sigma}{2}\|y - x\|^2. \tag{20}$$

There is a fundamental duality between strongly convex and strongly smooth functions:

Lemma 9 *Let ψ be closed and convex. Then ψ is σ-strongly convex with respect to the norm $\|\cdot\|$ if and only if $\psi^\star$ is $\frac{1}{\sigma}$-strongly smooth with respect to the dual norm $\|\cdot\|_\star$.*

For the strong convexity implies strongly smooth direction see Shalev-Shwartz (2007, Lemma 15), and for the other direction see Kakade et al. (2012, Theorem 3).

4.3 Regret Bound Proofs

In this section, we prove Theorems 1 and 2 using Lemma 5. Stating these two analyses in a common framework makes clear exactly where the "off-by-one" issue arises for FTRL-Centered, and how assuming proximal r_t resolves this issue. The key tool is Lemma 7, though for comparison we also provide a proof of Theorem 1 for linearized functions from Corollary 6 directly using strong smoothness.

General FTRL including FTRL-Centered (Proof of Theorem 1) In order to apply Lemma 5, we work to bound the stability terms in the sum in Eq. (16). Fix a particular round t. For Lemma 7 take $\phi_1(x) = h_{0:t-1}(x)$ and $\phi_2(x) = h_{0:t-1}(x) + f_t(x)$, so $x_t = \arg\min_x \phi_1(x)$, and by assumption ϕ_2 is 1-strongly-convex w.r.t. $\|\cdot\|_{(t-1)}$. Then, applying Lemma 7 to ϕ_2 (with $x' = x_{t+1}$), we have $\phi_2(x_t) - \phi_2(x_{t+1}) \leq \frac{1}{2}\|g_t\|_{(t-1),\star}^2$ for $g_t \in \partial f_t(x_t)$, and so

$$\begin{aligned} h_{0:t}(x_t) - h_{0:t}(x_{t+1}) - r_t(x_t) &= \phi_2(x_t) + r_t(x_t) - \phi_2(x_{t+1}) - r_t(x_{t+1}) - r_t(x_t) \\ &\leq \frac{1}{2}\|g_t\|_{(t-1),\star}^2 \end{aligned}$$

where we have used the assumption that $r_t(x) \geq 0$ to drop the $-r_t(x_{t+1})$ term. We can now plug this bound into Lemma 5. However, we need to make one additional observation: the choice of r_T only impacts the bound by increasing $r_{0:T}(x^*)$. Further, r_T does not influence any of the points $x_1, \ldots, x_T$ selected by the algorithm. Thus, for analysis purposes, we can take $r_T(x) = 0$ without loss of generality, and hence replace $r_{0:T}(x^*)$ with $r_{0:T-1}(x^*)$ in the final bound. ■

FTRL-Proximal (Proof of Theorem 2) The key is again to bound the stability terms in the sum in Eq. (16). Fix a particular round t, and take $\phi_1(x) = f_{1:t-1}(x) + r_{0:t}(x) = h_{0:t}(x) - f_t(x)$. Since the r_t are proximal (so x_t is a global minimizer of r_t) we have $x_t = \arg\min_x \phi_1(x)$, and $x_{t+1} = \arg\min_x \phi_1(x) + f_t(x)$. Thus,

$$\begin{aligned} h_{0:t}(x_t) - h_{0:t}(x_{t+1}) - r_t(x_t) &\leq h_{0:t}(x_t) - h_{0:t}(x_{t+1}) && \text{Since } r_t(x) \geq 0 \\ &= \phi_1(x_t) + f_t(x_t) - \phi_1(x_{t+1}) - f_t(x_{t+1}) \\ &\leq \frac{1}{2}\|g_t\|_{(t),\star}^2, && (21) \end{aligned}$$

where the last line follows by applying Lemma 7 to ϕ_1 and $\phi_2(x) = \phi_1(x) + f_t(x) = h_{0:t}(x)$. Plugging into Lemma 5 completes the proof. ■

Primal-dual Analysis of General FTRL on Linearized Functions We give an alternative proof of Theorem 1 for linear functions, $f_t(x) = g_t \cdot x$, using Eq. (17). We remark that in this case $x_t = \nabla r_{1:t-1}^\star(-g_{1:t-1})$ (see Lemma 15 in Appendix B).

By Lemma 9, $r^\star_{1:t-1}$ is 1-strongly-smooth with respect to $\|\cdot\|_{(t-1),\star}$, and so

$$r^\star_{1:t-1}(-g_{1:t}) \le r^\star_{1:t-1}(-g_{1:t-1}) - x_t \cdot g_t + \frac{1}{2}\|g_t\|^2_{(t-1),\star}, \tag{22}$$

and we can bound the per-round terms in Eq. (17) by

$$\begin{aligned} r^\star_{1:t}(-g_{1:t}) - r^\star_{1:t-1}(-g_{1:t-1}) + x_t \cdot g_t &\le r^\star_{1:t}(-g_{1:t}) - r^\star_{1:t-1}(-g_{1:t}) + \frac{1}{2}\|g_t\|^2_{(t-1),\star} \\ &\le \frac{1}{2}\|g_t\|^2_{(t-1),\star}, \end{aligned}$$

where we use Eq. (22) to bound $-r^\star_{1:t-1}(-g_{1:t-1}) + x_t \cdot g_t$, and then used the fact that $r^\star_{1:t-1}(-g_{1:t}) \ge r^\star_{1:t}(-g_{1:t})$ from Lemma 3. ■

5. Additional Regularization Terms and Composite Objectives

In this section, we consider generalized FTRL algorithms where we introduce an additional regularization term $\alpha_t\Psi(x)$ on each round, where Ψ is a convex function taking on only non-negative values, and the weights $\alpha_t \ge 0$ for $t \ge 1$ are non-increasing in t. We further assume Ψ and r_0 are both minimized at x_1, and w.l.o.g. $\Psi(x_1) = 0$ (as usual, additive constant terms do not impact regret). We generalize our definition of h_t to $h_0(x) = r_0(x)$ and

$$h_t(x) = g_t \cdot x + \alpha_t\Psi(x) + r_t(x), \tag{23}$$

so the FTRL update is

$$x_{t+1} = \arg\min_x h_{0:t}(x) = \arg\min_x g_{1:t} \cdot x + \alpha_{1:t}\Psi(x) + r_{0:t}(x). \tag{24}$$

In applications, generally the $g_t \cdot x_t$ terms come from the linearization of a loss ℓ_t, that is $g_t = \partial\ell_t(x_t)$. Here ℓ_t is for example a loss function measuring the prediction error on the tth training example for a model parameterized by x_t. (It is straightforward to replace $g_t \cdot x$ with $\ell_t(x)$ in this section, but for simplicity we assume linearization has been applied).

The Ψ terms often encode a non-smooth regularizer, and might be added for a variety of reasons. For example, the actual convex optimization problem we are solving may itself contain regularization terms. This is perhaps most clear in the case of applying an online algorithm to a batch problem as in Eq. (3). For example:

- An L_2 penalty $\Psi(x) = \|x\|_2^2$ might be added in order to promote generalization in a statistical setting, as in regularized empirical risk minimization.

- An L_1 penalty $\Psi(x) = \|x\|_1$ (as in the LASSO method) might be added to encourage sparse solutions and improve generalization in the high-dimensional setting ($n \gg T$).
- An indicator function might be added by taking $\Psi(x) = I_{\mathcal{X}}(x)$ to force $x \in \mathcal{X}$ where $\mathcal{X}$ is a convex set of feasible solutions.

As discussed in Section 2.4, the case of $\Psi = I_{\mathcal{X}}$ can be handled by our existing results. However, for other choices of Ψ it is generally preferable to only apply the linearization to the part of the objective where it is necessary computationally; in the L_1 case, given loss functions $\ell_t(x) + \lambda_1\|x\|_1$, we might partially linearize by taking $\bar{f}_t(x) = g_t \cdot x + \lambda_1\|x\|_1$, where $g_t \in \partial\ell_t(x_t)$. Recall that the primary motivation for linearization was to reduce the computation and storage requirements of the algorithm. Storing and optimizing over $\ell_{1:t}$ might be prohibitive; however, for common choices of Ψ and r_t, the optimization of Eq. (24) can be represented and solved efficiently (often in closed form). Thus, it is advantageous to consider such a composite representation.

Further, even in the case of a feasible set $\Psi = I_{\mathcal{X}}$, a careful consideration of if and when Ψ is linearized is critical to understanding the connection between Mirror Descent and FTRL. We will see that Mirror Descent *always* linearizes the past penalties $\alpha_{1:t-1}\Psi$, while with FTRL it is possible to avoid this additional linearization as in Eq. (24)—to make this distinction more clear, we will refer to the direct application of Eq. (24) as the Native FTRL algorithm. For $\Psi = I_{\mathcal{X}}$ this gives rise to the distinction between "lazy-projection" and "greedy-projection" algorithms, as discussed in Appendix C.2. And for $\Psi(x) = \|x\|_1$, this distinction makes Native FTRL algorithms preferable to composite-objective Mirror Descent for generating sparse models using L_1 regularization (see Section 6.2).

There are two types of regret bounds we may wish to prove in this setting, depending on whether we group the Ψ terms with the objective g_t, or with the regularizer r_t. We discuss these below.

In the objective We may view the $\alpha_t\Psi(x)$ terms as part of the objective, in that we desire a bound on regret against the functions $f^\Psi_t(x) \equiv g_t \cdot x + \alpha_t\Psi(x)$, that is

$$\text{Regret}(x^*, f^\Psi) \equiv \sum_{t=1}^T f^\Psi_t(x_t) - f^\Psi_t(x^*).$$

This setting is studied by Xiao (2009) and Duchi et al. (2010b, 2011), though in the less general setting where all $\alpha_t = 1$. We can directly apply Theorem 1 or Theorem 2 to the f^Ψ in this case, but this gives us bounds that depend on terms like $\|g_t + g_t^{(\Psi)}\|^2_{(t),\star}$ where $g_t^{(\Psi)} \in \partial(\alpha_t\Psi)(x_t)$; this is fine for $\Psi = I_{\mathcal{X}}$ since we can then always take $g_t^{(\Psi)} = 0$ since $x_t \in \mathcal{X}$, but for general Ψ this bound may be harder

to interpret. Further, adding a fixed known penalty like Ψ should intuitively make the problem no harder, and we would like to demonstrate this in our bounds.

In the regularizer We may wish to measure loss only against the functions $f_t(x) = g_t \cdot x$, that is,

$$\text{Regret}(x^*, g_t) \equiv \sum_{t=1}^{T} g_t \cdot x_t - g_t \cdot x^*,$$

even though we include the terms $\alpha_t \Psi$ in the update of Eq. (24). This approach is natural when we are only concerned with regret on the learning problem, $f_t(x) = \ell_t(x)$, but wish to add (for example) additional L_1 regularization in order to produce sparse models, as in McMahan et al. (2013).

In this case we can apply Theorem 1 to $f_t(x) \leftarrow g_t \cdot x$ and $r_t(x) \leftarrow r_t(x) + \alpha_t \Psi(x)$, noting that if the original $r_{0:t}$ is strongly convex w.r.t. $\|\cdot\|_{(t)}$, then $r_{0:t} + \alpha_{1:t}\Psi$ is as well, since Ψ is convex. However, if r_t is proximal, $r_t + \alpha_t \Psi$ generally will not be, and so a modified result is needed in place of Theorem 2. The following theorem provides this as well as a bound on $\text{Regret}(x^*, f^\Psi)$.

Theorem 10 FTRL-Proximal Bounds for Composite Objectives *Let Ψ be a non-negative convex function minimized at x_1 with $\Psi(x_1) = 0$. Let $\alpha_t \geq 0$ be a non-increasing sequence of constants. Consider Setting 1, and define h_t as in Eq.* (23)*. Suppose the r_t are chosen such that $h_{0:t}$ is 1-strongly-convex w.r.t. some norm $\|\cdot\|_{(t)}$, and further the r_t are proximal, that is x_t is a global minimizer of r_t.*

When we consider regret against $f_t^\Psi(x) = g_t \cdot x + \alpha_t \Psi(x)$, we have

$$\text{Regret}(x^*, f^\Psi) \leq r_{0:T}(x^*) + \frac{1}{2}\sum_{t=1}^{T} \|g_t\|_{(t),\star}^2. \tag{25}$$

When we consider regret against only the functions $f_t(x) = g_t \cdot x$, we have

$$\text{Regret}(x^*, g_t) \leq r_{0:T}(x^*) + \alpha_{1:T}\Psi(x^*) + \frac{1}{2}\sum_{t=1}^{T} \|g_t\|_{(t),\star}^2. \tag{26}$$

Proof The proof closely follows the proof of Theorem 2 in Section 4.3, with the key difference that we use Corollary 8 in place of Lemma 7. We will use Lemma 5 to prove both claims. First, observe that the stability terms $h_{0:t}(x_t) - h_{0:t}(x_{t+1})$ depend only on h, and so we can bound them in the same way in both cases.

Take $\phi_1(x) = h_{0:t-1}(x) + r_t(x)$. Since the r_t are proximal (so x_t is a global minimizer of r_t) we have $x_t = \arg\min_x \phi_1(x)$, and $x_{t+1} = \arg\min_x \phi_2(x)$ where

$\phi_2(x) = \phi_1(x) + g_t \cdot x + \alpha_t \Psi(x) = h_{0:t}(x)$. Then, using Corollary 8 lets us replace Eq. (21) with

$$h_{0:t}(x_t) - h_{0:t}(x_{t+1}) - r_t(x_t) \leq \frac{1}{2}\|g_t\|_{(t),\star}^2 + \alpha_t \Psi(x_t) - \alpha_t \Psi(x_{t+1}).$$

To apply Lemma 5 we sum over t. Considering only the Ψ terms, we have

$$\sum_{t=1}^{T} \alpha_t \Psi(x_t) - \alpha_t \Psi(x_{t+1}) = \alpha_1 \Psi(x_1) - \alpha_T \Psi(x_{T+1}) + \sum_{t=2}^{T} \alpha_t \Psi(x_t) - \alpha_{t-1}\Psi(x_t) \leq 0,$$

since $\Psi(x) \geq 0$, $\alpha_t \leq \alpha_{t-1}$, and $\Psi(x_1) = 0$. Thus,

$$\sum_{t=1}^{T} h_{0:t}(x_t) - h_{0:t}(x_{t+1}) - r_t(x_t) \leq \frac{1}{2}\sum_{t=1}^{T} \|g_t\|_{(t),\star}^2.$$

Using this with Lemma 5 applied to $f_t(x) \leftarrow g_t \cdot x + \alpha_t \Psi(x)$ and $r_t \leftarrow r_t$ proves Eq. (25). For Eq. (26), we apply Lemma 5 taking $f_t(x) \leftarrow g_t \cdot x$ and $r_t(x) \leftarrow \alpha_t \Psi(x) + r_t(x)$. ■

For FTRL-Centered algorithms, Theorem 1 immediately gives a bound for $\text{Regret}(x^*, g_t)$. For the $\text{Regret}(x^*, f^\Psi)$ case, we can prove a bound matching Theorem 1 using arguments analogous to the above.

6. Mirror Descent, FTRL-Proximal, and Implicit Updates

Recall Section 3.1 showed the equivalence between constant learning rate Online Gradient Descent and a fixed-regularizer FTRL algorithm. This equivalence is well-known in the case where $r_t(x) = 0$ for $t \geq 1$, that is, there is a fixed stabilizing regularizer r_0 independent of t, and further we take $\mathcal{X} = \mathbb{R}^n$ (e.g., Rakhlin (2008); Hazan (2010); Shalev-Shwartz (2012)). Observe that in this case FTRL-Centered and FTRL-Proximal coincide. In this section, we show how this equivalence extends to adaptive regularizers (equivalently, adaptive learning rates) and composite objectives. This builds on the work of McMahan (2011), but we make some crucial improvements in order to obtain an exact equivalence result for a much broader class of Mirror Descent algorithms and then use this result to derive regret bounds.[3]

3. Subsequent to this work, Sra et al. (2016) analyzed AdaDelay, an adaptive stochastic gradient descent algorithm that allows for potentially increasing learning rates, and Joulani et al. (2016) provided a more general analysis of Mirror Descent algorithms with non-monotonic regularizers in the online setting. Extending the FTRL view presented here to handle such algorithms is an interesting direction for future work.

Adaptive Mirror Descent Even in the non-adaptive case, Mirror Descent can be expressed as a variety of different updates, some of which are equivalent but some of which are not;[4] in particular, the inclusion of the feasible set constraint $I_{\mathcal{X}}$ gives rise to distinct "lazy projection" vs "greedy projection" algorithms—this issue is discussed in detail in Appendix C. To define the adaptive Mirror Descent family of algorithms we first define the Bregman divergence with respect to a convex differentiable function[5] ϕ:

$$\mathcal{B}_\phi(u, v) = \phi(u) - \big(\phi(v) + \nabla\phi(v) \cdot (u - v)\big).$$

The Bregman divergence is the difference at u between ϕ and ϕ's first-order Taylor expansion taken at v. For example, if we take $\phi(u) = \|u\|^2$, then $\mathcal{B}_\phi(u, v) = \|u-v\|^2$.

An adaptive Mirror Descent algorithm is defined by a sequence of continuously differentiable incremental regularizers $r_0, r_1, \ldots,$ chosen so $r_{0:t}$ is strongly convex. From this, we define the time-indexed Bregman divergence $\mathcal{B}_{r_{0:t}}$,

$$\mathcal{B}_{r_{0:t}}(u, v) = r_{0:t}(u) - \big(r_{0:t}(v) + \nabla r_{0:t}(v) \cdot (u - v)\big).$$

The adaptive Mirror Descent update is then given by

$$\begin{aligned} \hat{x}_1 &= \arg\min_x r_0(x) \\ \hat{x}_{t+1} &= \arg\min_x \; g_t \cdot x + \alpha_t \Psi(x) + \mathcal{B}_{r_{0:t}}(x, \hat{x}_t). \end{aligned} \tag{27}$$

We use $\hat{x}$ to distinguish this update from an FTRL update we will introduce shortly. Building on the previous section, we allow the update to include an additional regularization term $\alpha_t\Psi(x)$. As before, typically $g_t \cdot x$ should be viewed as a subgradient approximation to a loss function ℓ_t; it will become clear that a key question is to what extent Ψ is also linearized.

Mirror Descent algorithms were introduced in Nemirovsky and Yudin (1983) for the optimization of a fixed non-smooth convex function, and generalized to Bregman divergences by Beck and Teboulle (2003). Bounds for the online case appeared in Warmuth and Jagota (1997); a general treatment in the online case for composite objectives (with a non-adaptive learning rate) is given by Duchi et al. (2010b). Following this existing literature, we might term the update of Eq. (27) Adaptive Composite-Objective Online Mirror Descent; for simplicity we simply refer to Mirror Descent in this work.

4. In particular, it is common to see updates written in terms of $\nabla r^\star(\theta)$ for a strongly convex regularizer r, based on the fact that $\nabla r^\star(-\theta) = \arg\min_x \theta \cdot x + r(x)$ (see Lemma 15 in Appendix B).
5. Certain properties of Bregman divergences require ϕ to be strictly convex, but it provides a convenient notation to define $\mathcal{B}_\phi(u, v)$ for any differentiable convex ϕ.

Implicit updates For the moment, we neglect the Ψ terms and consider convex per-round losses ℓ_t. While standard Online Gradient Descent (or Mirror Descent) linearizes the ℓ_t to arrive at the update $\hat{x}_{t+1} = \arg\min_x \; g_t \cdot x_t + \mathcal{B}_{r_{0:t}}(x, \hat{x}_t)$, we can define the alternative update

$$\hat{x}_{t+1} = \arg\min_x \; \ell_t(x) + \mathcal{B}_{r_{0:t}}(x, \hat{x}_t), \tag{28}$$

where we avoid linearizing the loss ℓ_t. This is often referred to as an implicit update, since for general convex ℓ_t it is no longer possible to solve for $\hat{x}_{t+1}$ in closed form. The implicit update was introduced by Kivinen and Warmuth (1997), and has more recently been studied by Kulis and Bartlett (2010).

Again considering the Ψ terms, the Mirror Descent update of Eq. (27) can be viewed as a partial implicit update: if the real loss per round is $\ell_t(x) + \alpha_t\Psi(x)$, we linearize the $\ell_t(x)$ term but not the $\Psi(x)$ term, taking $f_t(x) = g_t \cdot x + \alpha_t\Psi(x)$. Generally this is done for computational reasons, as for common choices of Ψ such as $\Psi(x) = \|x\|_1$ or $\Psi(x) = I_{\mathcal{X}}(x)$, the update can still be solved in closed form (or at least in a computationally efficient manner, e.g., by projection). However, while $\alpha_t\Psi$ is handled without linearization, we shall see that echoes of the past $\alpha_{1:t-1}\Psi$ are encoded in a linearized fashion in the current state $\hat{x}_t$.

On terminology In the unprojected and non-adaptive case, the Mirror Descent update $\hat{x}_{t+1} = \arg\min_x g_t \cdot x + \mathcal{B}_r(x, \hat{x}_t)$ is equivalent to the FTRL update $x_{t+1} = \arg\min_x g_{1:t} \cdot x + r(x)$ (see Appendix C). In fact, Shalev-Shwartz (2012, Sec. 2.6) refers to this update (with linearized losses) explicitly as Mirror Descent.

In our view, the key property that distinguishes Mirror Descent from FTRL is that for Mirror Descent, the state of the algorithm is exactly $\hat{x}_t \in \mathbb{R}^n$, the current feasible point. For FTRL on the other hand, the state is a different vector in $\mathbb{R}^n$, for example $g_{1:t}$ for Dual Averaging. The indirectness of the FTRL representation makes it more flexible, since for example multiple values of $g_{1:t}$ can all map to the same coefficient value x_t.

6.1 Mirror Descent is an FTRL-Proximal Algorithm

We will show that the Mirror Descent update of Eq. (27) can be expressed as the FTRL-Proximal update given in Figure 2. In particular, consider a Mirror Descent algorithm defined by the choice of r_t for $t \geq 0$. Then, we define the FTRL-Proximal update

$$x_{t+1} = \arg\min_x g_{1:t} \cdot x + g^{(\Psi)}_{1:t-1} \cdot x + \alpha_t\Psi(x) + r^{\mathcal{B}}_{0:t}(x) \tag{29}$$

Mirror Descent

$$\hat{x}_{t+1} = \arg\min_x g_t \cdot x + \alpha_t \Psi(x) + \mathcal{B}_{r_{0:t}}(x, \hat{x}_t) \tag{27}$$

Mirror Descent as FTRL-Proximal

$$\hat{x}_{t+1} = \arg\min_x g_{1:t} \cdot x + g_{1:t-1}^{(\Psi)} \cdot x + \alpha_t \Psi(x) + r_0(x) + \sum_{s=1}^{t} \mathcal{B}_{r_s}(x, x_s)$$

$$= \arg\min_x g_{1:t} \cdot x + g_{1:t}^{(\Psi)} \cdot x + r_0(x) + \sum_{s=1}^{t} \mathcal{B}_{r_s}(x, x_s)$$

where $g_s^{(\Psi)}$ is a suitable subgradient from $\partial(\alpha_s \Psi)(x_{s+1})$

Figure 2: Mirror Descent as normally presented, and expressed as an equivalent FTRL-Proximal update.

for an appropriate choice $g_t^{(\Psi)} \in \partial(\alpha_t \Psi)(x_{t+1})$ (given below), where $r_t^{\mathcal{B}}$ is an incremental proximal regularizer defined in terms of r_t, namely

$$r_0^{\mathcal{B}}(x) \equiv r_0(x)$$
$$r_t^{\mathcal{B}}(x) \equiv \mathcal{B}_{r_t}(x, x_t) = r_t(x) - \big(r_t(x_t) + \nabla r_t(x_t) \cdot (x - x_t)\big) \qquad \text{for } t \geq 1.$$

Note that $r_t^{\mathcal{B}}$ is indeed minimized by x_t and $r_t^{\mathcal{B}}(x_t) = 0$. We require $g_t^{(\Psi)} \in \partial(\alpha_t \Psi)(x_{t+1})$ such that

$$g_{1:t} + g_{1:t}^{(\Psi)} + \nabla r_{0:t}^{\mathcal{B}}(x_{t+1}) = 0. \tag{30}$$

The dependence of $g_t^{(\Psi)}$ on x_{t+1} is not problematic, as $g_t^{(\Psi)}$ is not necessary to compute x_{t+1} using Eq. (29). To see (inductively) that we can always find a a $g_t^{(\Psi)}$ satisfying Eq. (30), note the subdifferential of the objective of Eq. (29) at x is

$$g_{1:t} + g_{1:t-1}^{(\Psi)} + \partial(\alpha_t \Psi)(x) + \nabla r_{0:t}^{\mathcal{B}}(x). \tag{31}$$

Since x_{t+1} is a minimizer, we know 0 is a subgradient, which implies there must be a subgradient $g_t^{(\Psi)} \in \partial(\alpha_t \Psi)(x_{t+1})$ that satisfies Eq. (30). The fact we use a subgradient of Ψ at x_{t+1} rather than x_t is a consequence of the fact we are replicating the behavior of a (partial) implicit update algorithm.

Finally, note the update

$$x_{t+1} = \arg\min_x g_{1:t} \cdot x + g_{1:t}^{(\Psi)} \cdot x + r_{0:t}^{\mathcal{B}}(x) \tag{32}$$

is equivalent to Eq. (29), since Equations (30) and (31) imply 0 is in the subgradient of the objective Eq. (29) at the x_{t+1} given by Eq. (32). This update is exactly an FTRL-Proximal update on the functions $f_t(x) = (g_t + g_t^{(\Psi)}) \cdot x$.

With these definitions in place, we can now state and prove the main result of this section, namely the equivalence of the two updates given in Figure 2:

Theorem 11 *The Mirror Descent update of Eq.* (27) *and the FTRL-Proximal update of Eq.* (29) *select identical points.*

Proof The proof is by induction on the hypothesis that $\hat{x}_t = x_t$. This holds trivially for $t = 1$, so we proceed by assuming it holds for t.

First we consider the x_t selected by the FTRL-Proximal algorithm of Eq. (29). Since x_t minimizes this objective, zero must be a subgradient at x_t. Letting $g_s^{(r)} = \nabla r_s(x_s)$ and noting $\nabla r_t^{\mathcal{B}}(x) = \nabla r_t(x) - \nabla r_t(x_t)$, we have $g_{1:t-1} + g_{1:t-1}^{(\Psi)} + \nabla r_{0:t-1}(x_t) - g_{0:t-1}^{(r)} = 0$ following Eq. (31). Since $x_t = \hat{x}_t$ by induction hypothesis, we can rearrange and conclude

$$-\nabla r_{0:t-1}(\hat{x}_t) = g_{1:t-1} + g_{1:t-1}^{(\Psi)} - g_{0:t-1}^{(r)}. \tag{33}$$

For Mirror Descent, the gradient of the objective in Eq. (27) must be zero for $\hat{x}_{t+1}$, and so there exists a $\hat{g}_t^{(\Psi)} \in \partial(\alpha_t \Psi)(\hat{x}_{t+1})$ such that

$$\begin{aligned}
0 &= g_t + \hat{g}_t^{(\Psi)} + \nabla r_{0:t}(\hat{x}_{t+1}) - \nabla r_{0:t}(\hat{x}_t) \\
&= g_t + \hat{g}_t^{(\Psi)} + \nabla r_{0:t}(\hat{x}_{t+1}) - \nabla r_{0:t-1}(\hat{x}_t) - g_t^{(r)} && \text{IH and } \nabla r_t(x_t) = g_t^{(r)} \\
&= g_t + \hat{g}_t^{(\Psi)} + \nabla r_{0:t}(\hat{x}_{t+1}) + g_{1:t-1} + g_{1:t-1}^{(\Psi)} - g_{0:t-1}^{(r)} - g_t^{(r)} && \text{Using Eq. (33)} \\
&= g_{1:t} + g_{1:t-1}^{(\Psi)} + \hat{g}_t^{(\Psi)} + \nabla r_{0:t}(\hat{x}_{t+1}) - g_{0:t}^{(r)} \\
&= g_{1:t} + g_{1:t-1}^{(\Psi)} + \hat{g}_t^{(\Psi)} + \nabla r_{0:t}^{\mathcal{B}}(\hat{x}_{t+1}).
\end{aligned}$$

The last line implies zero is a subgradient of the objective of Eq. (29) at $\hat{x}_{t+1}$, and so $\hat{x}_{t+1}$ is a minimizer. Since $r_{0:t}$ is strongly convex, this solution is unique and so $\hat{x}_{t+1} = x_{t+1}$. ■

6.2 Comparing Mirror Descent to the Native FTRL-Proximal Algorithm, and the Application to L_1 Regularization

Since we can write Mirror Descent as a particular FTRL update, we can now do a careful comparison to the direct application of Section 5 which gives the Native FTRL-Proximal algorithm. These two algorithms are given in Figure 3, expressed in a way that facilitates comparison.

Mirror Descent

$$\hat{x}_{t+1} = \arg\min_x \quad g_{1:t} \cdot x \quad + \quad g^{(\Psi)}_{1:t-1} \cdot x + \alpha_t \Psi(x) \quad + r^{\mathcal{B}}_{0:t}(x)$$

Native FTRL-Proximal

$$x_{t+1} = \arg\min_x \quad g_{1:t} \cdot x \quad + \quad \alpha_{1:t} \Psi(x) \quad + r^{\mathcal{B}}_{0:t}(x)$$

$$(A) \qquad (B) \qquad (C)$$

Figure 3: Mirror Descent expressed as an FTRL-Proximal algorithm compared to the Native FTRL-Proximal algorithm.

Both algorithms use a linear approximation to the loss functions ℓ_t, as seen in column (A) of Figure 3, and the same proximal regularization terms (C). The key difference is in how the non-smooth terms Ψ are handled: Mirror Descent approximates the past $\alpha_s \Psi(x)$ terms for $s < t$ using a subgradient approximation $g^{(\Psi)}_s \cdot x$, keeping only the current $\alpha_t \Psi(x)$ term explicitly. In Native FTRL-Proximal, on the other hand, we represent the full weight of the Ψ terms exactly as $\alpha_{1:t}\Psi(x)$. That is, Mirror Descent is applying significantly more linearization than Native FTRL-Proximal.

Why does this matter? As we will see in Section 6.3, there is no difference in the regret bounds, even though intuitively avoiding unnecessary linearization should be preferable. However, there can be a substantial practical differences for some choices of Ψ. In particular, we focus on the common and practically important case of L_1 regularization, where we take $\Psi(x) = \|x\|_1$. Such regularization terms are often used to produce sparse solutions (x_t where many $x_{t,i} = 0$). Models with few non-zeros can be stored, transmitted, and evaluated much more cheaply than the corresponding dense models.

As discussed in McMahan (2011), it is precisely the explicit representation of the full $\alpha_{1:t}\|x\|_1$ terms that lets Native FTRL produce much sparser solutions when compared with the composite-objective Mirror Descent update with L_1 regularization (equivalent to the FOBOS algorithm of Duchi and Singer (2009)). This argument also applies to Regularized Dual Averaging (RDA, a Native FTRL-Centered algorithm); Xiao (2009) presents experiments showing the advantages of RDA for producing sparse solutions. In the remainder of this section, we explore the application to L_1 regularization in more detail, in order to illustrate the effect of the additional linearization of the $\|x\|_1$ terms used by Mirror Descent as compared to the Native FTRL-Proximal algorithm.

Another way to understand this distinction is the previously mentioned difference in how the two algorithms maintain state. Mirror Descent has exactly one way to

represent a zero coefficient in the ith coordinate, namely $\hat{x}_{t,i} = 0$. The FTRL representation is significantly more flexible, since many state values, say any $g_{1:t,i} \in [-\lambda, \lambda]$, can all correspond to a zero coefficient. This means that FTRL can represent both "we have lots of evidence that $x_{t,i}$ should be zero" (as $g_{1:t,i} = 0$ for example), as well as "we think $x_{t,i}$ is zero right now, but the evidence is very weak" (as $g_{1:t,i} = \lambda$ for example). This means there may be a memory cost for training FTRL, as $g_{1:t,i} \neq 0$ still needs to be stored when $x_{t,i} = 0$, but the obtained models typically provide much better sparsity-accuracy tradeoffs (McMahan, 2011; McMahan et al., 2013).

This distinction is critical even in the non-adaptive case, and so we consider the simplest possible setting: a fixed regularizer $r_0(x) = \frac{1}{2\eta}\|x\|_2^2$ (with $r_t(x) = 0$ for $t \geq 1$), and $\alpha_t \Psi(x) = \lambda \|x\|_1$ for all t. The updates of Figure 3 then simplify to:

Mirror Descent

$$x_{t+1} = \arg\min_x \quad g_{1:t} \cdot x \quad + g^{(\Psi)}_{1:t-1} \cdot x + \lambda\|x\|_1 \quad + \frac{1}{2\eta}\|x\|_2^2 \tag{34}$$

Native FTRL

$$x_{t+1} = \arg\min_x \quad g_{1:t} \cdot x \quad + t\lambda\|x\|_1 \quad + \frac{1}{2\eta}\|x\|_2^2. \tag{35}$$

The key point is the Native FTRL algorithm uses a much stronger explicit L_1 penalty, $\alpha_{1:t} = t\lambda$ instead of just $\alpha_t = \lambda$.

The closed-form update We can write the update of Eq. (34) as a standard Mirror Descent update (that is, as an optimization over f_t and a regularizer centered at the current x_t):

$$\begin{aligned} x_{t+1} &= \arg\min_x g_t \cdot x + \lambda\|x\|_1 + \frac{1}{2\eta}\|x - x_t\|_2^2 \\ &= \arg\min_x \left(g_t - \frac{x_t}{\eta}\right) \cdot x + \lambda\|x\|_1 + \frac{1}{2\eta}\|x\|_2^2. \end{aligned} \tag{36}$$

The above update decomposes on a per-coordinate basis. Subgradient calculations show that for constants $a > 0$, $b \in \mathbb{R}$, and $\lambda \geq 0$, we have

$$\arg\min_{x \in \mathbb{R}} b \cdot x + \lambda|x| + \frac{a}{2}|x|^2 = \begin{cases} 0 & \text{when } |b| \leq \lambda \\ -\frac{1}{a}(b - \text{sign}(b)\lambda) & \text{otherwise.} \end{cases} \tag{37}$$

Thus, we can simplify Eq. (36) to

$$x_{t+1} = \begin{cases} 0 & \text{when } |g_t - \frac{x_t}{\eta}| \leq \lambda \\ x_t - \eta(g_t - \lambda) & \text{when } g_t - \frac{x_t}{\eta} > \lambda \quad (\text{implying } x_{t+1} < 0) \\ x_t - \eta(g_t + \lambda) & \text{otherwise} \quad (\text{i.e., } g_t - \frac{x_t}{\eta} < -\lambda \text{ and } x_{t+1} > 0). \end{cases}$$

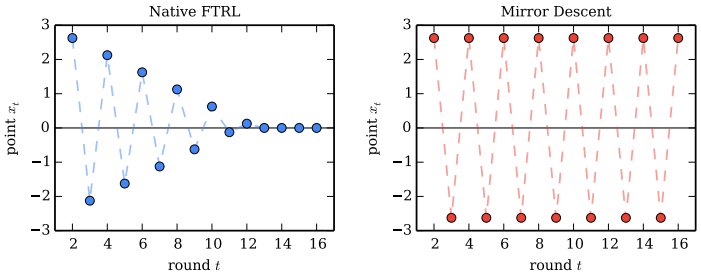

Figure 4: The points selected by Native FTRL and Mirror Descent on the one-dimensional example, using $\alpha_t\Psi(x) = \frac{1}{2}\|x\|_1$. Native FTRL quickly converges to $x^* = 0$, but Mirror Descent oscillates indefinitely.

If we choose $g_t^{(\Psi)} \in \partial\lambda\|x_{t+1}\|_1$ as

$$g_t^{(\Psi)} = \begin{cases} -\lambda & \text{when } x_{t+1} < 0 \\ \lambda & \text{when } x_{t+1} > 0\,, \\ x_t/\eta - g_t & \text{when } x_{t+1} = 0 \end{cases}$$

then Eq. (30) is satisfied, and the update becomes

$$x_{t+1} = x_t - \eta\big(g_t + g_t^{(\Psi)}\big)$$

in all cases, showing how the implicit update can be re-written in terms of a subgradient update using an appropriate subgradient approximation at the *next* point.

A One-Dimensional Example To illustrate the practical significance of the stronger explicit L_1 penalty used by Native FTRL, we compare the updates of Eq. (34) and Eq. (35) on a simple one-dimensional example. The gradients g_t satisfy $\|g_t\|_2 \le G$, and we use a feasible set of radius $R = 2G$. Both algorithms use the theory-recommended fixed learning rate $\eta = \frac{R}{G\sqrt{T}} = \frac{2}{\sqrt{T}}$ (see Section 3), against an adaptive adversary that selects gradients g_t as a function of x_t:

$$g_t = \begin{cases} -\frac{1}{2}(G+\lambda) & \text{when } t = 1 \\ -G & \text{when } t > 1 \text{ and } x_t \le 0 \\ G & \text{when } t > 1 \text{ and } x_t > 0\,. \end{cases}$$

Both algorithms select $x_1 = 0$, and since $g_1 = -\frac{1}{2}(G+\lambda)$ both algorithms select $x_2 = (G-\lambda)/\sqrt{T}$. After this, however, their behavior diverges: Mirror Descent will indefinitely oscillate between x_2 and $-x_2$ for any $\lambda < G$. On the other hand, FTRL learns that $x^* = 0$ is the optimal solution after a constant number of rounds, selecting $x_{t+1} = 0$ for any $t > \frac{G}{2\lambda} + \frac{1}{2}$. The details of this example are worked out in Appendix D

Figure 4 plots the points selected by the algorithms as a function of t, taking $G = 11$, $T = 16$, and $\lambda = 0.5$. This example clearly demonstrates that, though Mirror Descent and Native FTRL have the same regret bounds, Native FTRL is much more likely to produce sparse solutions and can also incur less actual regret.

6.3 Analysis of Mirror Descent as FTRL-Proximal

Having established the equivalence between Mirror Descent and a particular FTRL-Proximal update as given in Figure 2, we now use the general analysis techniques for FTRL developed in this work to prove regret bounds for Mirror Descent algorithm. This is accomplished by applying the Strong FTRL lemma to the FTRL-Proximal expression for Mirror Descent.

First, we observe that in the non-composite case (i.e., all $\alpha_t = 0$), then all $g_t^{(\Psi)} = 0$, and we can apply Theorem 2 directly to Eq. (29) for the loss functions $f_t(x) = g_t \cdot x$, which gives us

$$\text{Regret}(x^*, g_t) \le r^{\mathcal{B}}_{0:T}(x^*) + \frac{1}{2}\sum_{t=1}^T \|g_t\|^2_{(t),\star} = \sum_{t=1}^T \mathcal{B}_{r_t}(x^*, x_t) + \frac{1}{2}\sum_{t=1}^T \|g_t\|^2_{(t),\star}.$$

In the case of a composite-objective (nontrivial Ψ terms, including feasible set constraints such as $I_{\mathcal{X}}$), we will arrive at the same bound, but must refine our analysis somewhat to encompass the partial implicit update of Eq. (29). This is accomplished in the following theorem:

Theorem 12 *We consider the Mirror Descent update of Eq.* (27) *under the same conditions as Theorem 10. When we consider regret against* $f_t^{\Psi}(x) = g_t \cdot x + \alpha_t\Psi(x)$*, we have*

$$\text{Regret}(x^*, f^{\Psi}) \le r^{\mathcal{B}}_{0:T}(x^*) + \frac{1}{2}\sum_{t=1}^T \|g_t\|^2_{(t),\star}. \tag{38}$$

When we consider regret against only the functions $f_t(x) = g_t \cdot x$*, we have*

$$\text{Regret}(x^*, g_t) \le r^{\mathcal{B}}_{0:T}(x^*) + \alpha_{1:T}\Psi(x^*) + \frac{1}{2}\sum_{t=1}^T \|g_t\|^2_{(t),\star}. \tag{39}$$

The bound of Eq. (38) matches Duchi et al. (2011, Prop. 3),[6] and also encompasses Theorem 2 of Duchi et al. (2010b).[7]

Proof First, by Theorem 11, this algorithm can equivalently be expressed as in Eq. (32). To simplify bookkeeping, we define

$$\bar{f}_t(x) = g_t \cdot x + \bar{\Psi}_t(x) \qquad \text{where} \qquad \bar{\Psi}_t(x) = \alpha_t \Psi(x_{t+1}) + g_t^{(\Psi)} \cdot (x - x_{t+1}),$$

Then, the update

$$x_{t+1} = \arg\min_x \bar{f}_{1:t}(x) + r^{\mathcal{B}}_{0:t}(x) \tag{40}$$

is equivalent to Eq. (32), since the objectives differ only in constant terms. Note

$$\bar{\Psi}_t(x_{t+1}) = \alpha_t \Psi(x_{t+1}) \qquad \text{and} \qquad \forall x,\ \alpha_t \Psi(x) \geq \bar{\Psi}_t(x), \tag{41}$$

where the second claim uses the convexity of $\alpha_t \Psi$.

Observe that Eq. (40) defines an FTRL-Proximal algorithm—we can imagine the $\bar{f}_t$ are computed by a black-box given f_t which solves the optimization problem of Eq. (29) in order to compute $g_t^{(\Psi)}$. Thus, we can apply the Strong FTRL Lemma (Lemma 5). Again, the key is bounding the stability terms. Using $h_t(x) = \bar{f}_t(x) + r_t^{\mathcal{B}}(x)$, we have

$$\sum_{t=1}^T h_{1:t}(x_t) - h_{1:t}(x_{t+1}) - r_t(x_t) \leq \sum_{t=1}^T \frac{1}{2}\|g_t\|^2_{(t),\star} + \bar{\Psi}_t(x_t) - \bar{\Psi}_t(x_{t+1}),$$

using Corollary 8 as in Theorem 10.

We first consider regret against the functions $f_t^{\Psi}(x) = g_t \cdot x + \alpha_t \Psi(x)$. We can apply Lemma 5 to the functions $\bar{f}_t$, yielding

$$\text{Regret}(x^*, \bar{f}_t) \leq r^{\mathcal{B}}_{0:T}(x^*) + \sum_{t=1}^T \frac{1}{2}\|g_t\|^2_{(t),\star} + \bar{\Psi}_t(x_t) - \bar{\Psi}_t(x_{t+1}).$$

6. Mapping our notation to their notation, we have $f_t(x) = \ell_t(x) + \alpha_t \Psi(x) \Rightarrow \phi_t(x) = f_t(x) + \varphi(x)$ and $r_{1:t}(x) \Rightarrow \frac{1}{\eta}\psi_t(x)$. Dividing their Update (4) by η and using our notation, we arrive at exactly the update of Eq. (27). We can take $\eta = 1$ in their bound w.l.o.g.. Then, using the fact that ψ_t in their notation is $r_{1:t}$ in our notation, we have

$$\begin{aligned}
\mathcal{B}_{\psi_{t+1}}(x^*, x_{t+1}) - \mathcal{B}_{\psi_t}(x^*, x_{t+1}) &= \psi_{t+1}(x^*) - (\psi_{t+1}(x_{t+1}) + \nabla\psi_{t+1}(x_{t+1}) \cdot (x - x_{t+1})) \\
&\quad - \big(\psi_t(x^*) - (\psi_t(x_{t+1}) + \nabla\psi_t(x_{t+1}) \cdot (x - x_{t+1}))\big) \\
&= r_{t+1}(x^*) - \big(r_{t+1}(x_{t+1}) + \nabla r_{t+1}(x_{t+1}) \cdot (x - x_{t+1})\big) \\
&= \mathcal{B}_{r_{t+1}}(x^*, x_{t+1}).
\end{aligned}$$

7. We can take their $\alpha = 1$ and $\eta = 1$ w.l.o.g., and also assume our $\Psi(x_1) = 0$. Their r is our Ψ, and the implicitly take our $\alpha_t = 1$; their ψ is our r_0 (with our $r_1, \ldots, r_T$ all uniformly zero). Thus, their bound amounts (in our notation) to: Regret $\leq \mathcal{B}_{r_0}(x^*, x_1) + \frac{1}{2}\sum_{t=1}^T \|g_t\|^2_\star$, matching exactly the bound of our Theorem 12 (noting $r^{\mathcal{B}}_{0:t}(x^*) = \mathcal{B}_{r_0}(x^*, x_1)$ in this case).

However, this does not immediately yield a bound on regret against the f_t^{Ψ}. While $\bar{f}_t(x^*) \leq f_t^{\Psi}(x^*)$, our actual loss $f_t^{\Psi}(x_t)$ could be larger than $\bar{f}_t(x_t)$. Thus, in order to bound regret against f_t^{Ψ}, we must add terms $f_t^{\Psi}(x_t) - \bar{f}_t(x_t) = \alpha_t \Psi(x_t) - \bar{\Psi}_t(x_t)$. This gives

$$\begin{aligned}
\text{Regret}(x^*, f_t^{\Psi}) &\leq \text{Regret}(x^*, \bar{f}_t) + \sum_{t=1}^T \alpha_t \Psi(x_t) - \bar{\Psi}_t(x_t) \\
&\leq r^{\mathcal{B}}_{0:T}(x^*) + \sum_{t=1}^T \frac{1}{2}\|g_t\|^2_{(t),\star} + \bar{\Psi}_t(x_t) - \bar{\Psi}_t(x_{t+1}) + \alpha_t \Psi(x_t) - \bar{\Psi}_t(x_t) \\
&= r^{\mathcal{B}}_{0:T}(x^*) + \sum_{t=1}^T \frac{1}{2}\|g_t\|^2_{(t),\star} + \alpha_t \Psi(x_t) - \alpha_t \Psi(x_{t+1}),
\end{aligned}$$

where the equality uses $\bar{\Psi}_t(x_{t+1}) = \alpha_t \Psi(x_{t+1})$. Recalling $\sum_{t=1}^T \alpha_t \Psi(x_t) - \alpha_t \Psi(x_{t+1}) \leq 0$ from the proof of Theorem 10 completes the proof of Eq. (38).

For Eq. (39), applying Lemma 5 with $r_t \leftarrow \bar{\Psi}_t + r_t^{\mathcal{B}}$ and $f_t(x) \leftarrow g_t \cdot x$ yields

$$\text{Regret}(x^*, g_t) \leq r^{\mathcal{B}}_{0:T}(x^*) + \bar{\Psi}_{1:t}(x^*) + \sum_{t=1}^T \frac{1}{2}\|g_t\|^2_{(t),\star} + \bar{\Psi}_t(x_t) - \bar{\Psi}_t(x_{t+1}).$$

Eq. (41) implies $\bar{\Psi}_t(x_t) - \bar{\Psi}_t(x_{t+1}) \leq \alpha_t \Psi(x_t) - \alpha_t \Psi(x_{t+1})$, and so the sum of these terms again vanishes. Finally, observing $\bar{\Psi}_{1:t}(x^*) \leq \alpha_{1:t} \Psi(x^*)$ completes the proof. ■

7. Conclusions

Using a general and modular analysis, we have presented a unified view of a wide family of algorithms for online convex optimization that includes Dual Averaging, Mirror Descent, FTRL, and FTRL-Proximal, recovering and sometimes improving regret bounds from many earlier works. Our emphasis has been on the case of adaptive regularizers, but the results recover those for a fixed learning rate or regularizer as well.

Acknowledgments

The author thanks Daniel Golovin, Francesco Orabona, and the anonymous reviewers for useful feedback on this work.

Appendix A. The Standard FTRL Lemma

The following lemma is a well-known tool for the analysis of FTRL algorithms (see Kalai and Vempala (2005); Hazan (2008), Hazan (2010, Lemma 1), and Shalev-Shwartz (2012, Lemma 2.3)):

Lemma 13 (Standard FTRL Lemma) *Let f_t be a sequence of arbitrary (possibly non-convex) loss functions, and let r_t be arbitrary non-negative regularization functions, such that $x_{t+1} = \arg\min_x h_{0:t}(x)$ is well defined (recall $h_{0:t}(x) = f_{1:t}(x) + r_{0:t}(x)$). Then, the algorithm that selects these x_t achieves*

$$\text{Regret}(x^*) \leq r_{0:T}(x^*) + \sum_{t=1}^{T} f_t(x_t) - f_t(x_{t+1}).$$

The proof of this lemma (e.g., McMahan and Streeter (2010, Lemma 3)) relies on showing that if one could run the Be-The-Leader algorithm by selecting $x_t = \arg\min_x f_{1:t}(x)$ (which requires peaking ahead at f_t to choose x_t), then the algorithm's regret is bounded above by zero.

However, as we see by comparing Theorem 2 and 14 (stated below), this analysis loses a factor of $1/2$ on one of the terms. The key is that being the leader is actually *strictly better* than always using the post-hoc optimal point, a fact that is not captured by the Standard FTRL Lemma. To prove the Strong FTRL Lemma, rather than first analyzing the Be-The-Leader algorithm and showing it has no regret, the key is to directly analyze the FTL algorithm (using a similar inductive argument). The proofs are also similar in that in both the basic bound is proved first for regret against the functions h_t (equivalently, the regret for FTL without regularization), and this bound is then applied to the regularized functions and re-arranged to bound regret against the f_t.

Using Lemma 13, we can prove the following weaker version of Theorem 2:

Theorem 14 Weak FTRL-Proximal Bound *Consider Setting 1, and further suppose the r_t are chosen such that $h_{0:t} = r_{0:t} + f_{1:t}$ is 1-strongly-convex w.r.t. some norm $\|\cdot\|_{(t)}$, and further the r_t are proximal, that is x_t is a global minimizer of r_t. Then, choosing any $g_t \in \partial f_t(x_t)$ on each round, for any $x^* \in \mathbb{R}^n$,*

$$\text{Regret}(x^*) \leq r_{0:T}(x^*) + \sum_{t=1}^{T} \|g_t\|^2_{(t),\star}.$$

We prove Theorem 14 using strong smoothness via Lemma 7. An alternative proof that uses strong convexity directly is also possible, closely following Shalev-Shwartz (2012, Sec. 2.5.2).

Proof of Theorem 14 Applying Lemma 13, it is sufficient to consider a fixed t and upper bound $f_t(x_t) - f_t(x_{t+1})$. For this fixed t, define a helper function $\phi_1(x) = f_{1:t-1}(x) + r_{0:t}(x)$. Observe $x_t = \arg\min_x \phi_1(x)$ since x_t is a minimizer of $r_t(x)$, and by definition of the update x_t is a minimizer of $f_{1:t-1}(x) + r_{0:t-1}(x)$. Let $\phi_2(x) = \phi_1(x) + f_t(x) = h_{0:t}(x)$, so ϕ_2 is 1-strongly convex with respect to $\|\cdot\|_{(t)}$ by assumption, and $x_{t+1} = \arg\min_x \phi_2(x)$. Then, we have

$$\begin{aligned}
f_t(x_t) - f_t(x_{t+1}) &\leq g_t \cdot (x_t - x_{t+1}) && \text{Convexity of } f_t \text{ and } g_t \in \partial f_t(x_t) \\
&\leq \|g_t\|_{(t),\star} \|x_t - x_{t+1}\|_{(t)} && \text{Property of dual norms} \\
&\leq \|g_t\|_{(t),\star} \|g_t\|_{(t),\star} = \|g_t\|^2_{(t),\star}. && \text{Using Eq. (19) from Lemma 7}
\end{aligned}$$

■

Interestingly, it appears difficult to achieve a tight (up to constant factors) analysis of non-proximal FTRL algorithms (e.g., FTRL-Centered algorithms like Dual Averaging) using Lemma 13. The Strong FTRL Lemma, however, allowed us to accomplish this.

Appendix B. Proofs For Section 4.2

We first state a standard technical result (see Shalev-Shwartz (2007, Lemma 15)):

Lemma 15 *Let ψ be 1-strongly convex w.r.t. $\|\cdot\|$, so $\psi^\star$ is 1-strongly smooth with respect to $\|\cdot\|_\star$. Then,*

$$\|\nabla\psi^\star(z) - \nabla\psi^\star(z')\| \leq \|z - z'\|_\star, \tag{42}$$

and

$$\arg\min_x g \cdot x + \psi(x) = \nabla\psi^\star(-g). \tag{43}$$

In order to prove Lemma 7, we first prove a somewhat easier result:

Lemma 16 *Let $\phi_1 : \mathbb{R}^n \to \mathbb{R}$ be strongly convex w.r.t. norm $\|\cdot\|$, and let $x_1 = \arg\min_x \phi_1(x)$, and define $\phi_2(x) = \phi_1(x) + b \cdot x$ for $b \in \mathbb{R}^n$. Letting $x_2 = \arg\min_x \phi_2(x)$, we have*

$$\phi_2(x_1) - \phi_2(x_2) \leq \frac{1}{2}\|b\|^2_\star, \qquad \text{and} \qquad \|x_1 - x_2\| \leq \|b\|_\star.$$

Proof We have

$$-\phi_1^\star(0) = -\max_x 0 \cdot x - \phi_1(x) = \min_x \phi_1(x) = \phi_1(x_1).$$

and similarly,

$$-\phi_1^\star(-b) = -\max_x -b \cdot x - \phi_1(x) = \min_x b \cdot x + \phi_1(x) = b \cdot x_2 + \phi_1(x_2).$$

Since $x_1 = \nabla\phi_1^\star(0)$ and $\phi_1^\star$ is strongly-smooth (Lemma 9), Eq. (20) gives

$$\phi_1^\star(-b) \le \phi_1^\star(0) + x_1 \cdot (-b - 0) + \frac{1}{2}\|b\|_\star^2.$$

Combining these facts, we have

$$\begin{aligned}\phi_1(x_1) + b \cdot x_1 - \phi_1(x_2) - b \cdot x_2 &= -\phi_1^\star(0) + b \cdot x_1 + \phi_1^\star(-b) \\ &\le -\phi_1^\star(0) + b \cdot x_1 + \phi_1^\star(0) + x_1 \cdot (-b) + \frac{1}{2}\|b\|_\star^2 \\ &= \frac{1}{2}\|b\|_\star^2.\end{aligned}$$

For the second part, observe $\nabla\phi_1^\star(0) = x_1$, and $\nabla\phi_1^\star(-b) = x_2$ and so $\|x_1 - x_2\| \le \|b\|_\star$, using both parts of Lemma 15. ■

Proof of Lemma 7 We are given that $\phi_2(x) = \phi_1(x) + \psi(x)$ is 1-strongly convex w.r.t. $\|\cdot\|$. The key trick is to construct an alternative ϕ_1' that is also 1-strongly convex with respect to this same norm, but has x_1 as a minimizer. Fortunately, this is easily possible: define $\phi_1'(x) = \phi_1(x) + \psi(x) - b \cdot x$, and note ϕ_1 is 1-strongly convex w.r.t. $\|\cdot\|$ since it differs from ϕ_2 only by a linear function. Since $b \in \partial\psi(x_1)$ it follows that 0 is in $\partial(\psi(x) - b \cdot x)$ at $x = x_1$, and so $x_1 = \arg\min \phi_1'(x)$. Note $\phi_2(x) = \phi_1'(x) + b \cdot x$. Applying Lemma 16 to ϕ_1' and ϕ_2 completes the proof, noting for any x' we have $\phi_2(x_1) - \phi_2(x') \le \phi_2(x_1) - \phi_2(x_2)$. ■

Proof of Corollary 8 Let $x_2' = \arg\min_x \phi_1(x) + \psi(x)$, so by Lemma 7, we have

$$\phi_1(x_1) + \psi(x_1) - \phi_1(x_2') - \psi(x_2') \le \frac{1}{2}\|b\|_\star^2, \tag{44}$$

Then, noting $\phi_1(x_2') + \psi(x_2') \le \phi_1(x_2) + \psi(x_2)$ by definition, we have

$$\begin{aligned}\phi_2(x_1) - \phi_2(x_2) &= \phi_1(x_1) + \psi(x_1) + \Psi(x_1) - \phi_1(x_2) - \psi(x_2) - \Psi(x_2) \\ &\le \phi_1(x_1) + \psi(x_1) + \Psi(x_1) - \phi_1(x_2') - \psi(x_2') - \Psi(x_2) \\ &\le \frac{1}{2}\|b\|_\star^2 + \Psi(x_1) - \Psi(x_2). && \text{Using Eq. (44).}\end{aligned}$$

Noting that $\phi_2(x_1) - \phi_2(x') \le \phi_2(x_1) - \phi_2(x_2)$ for any x' completes the proof. ■

Appendix C. Non-Adaptive Mirror Descent and Projection

Non-adaptive Mirror Descent algorithms have appeared in the literature in a variety of forms, some equivalent and some not. In this section we briefly review these connections. We first consider the unconstrained case, where the domain of the convex functions is taken to be $\mathbb{R}^n$, and there is no constraint that $x_t \in \mathcal{X}$.

Explicit	$\theta_{t+1} = \theta_t - g_t$ $x_{t+1} = \nabla R^\star(\theta_{t+1})$	$\theta_{t+1} = \nabla R(x_t) - g_t$ $x_{t+1} = \nabla R^\star(\theta_{t+1})$
Implicit	$x_{t+1} = \arg\min_x g_t \cdot x + \mathcal{B}_R(x, x_t)$	
FTRL	$x_{t+1} = \arg\min_x g_{1:t} \cdot x + R(x)$	

Figure 5: Four equivalent expressions for unconstrained Mirror Descent defined by a strongly convex regularizer R. The top-right expression is from by Beck and Teboulle (2003), while the top-left expression matches the presentation of Shalev-Shwartz (2012, Sec 2.6).

C.1 The Unconstrained Case

Figure 5 summarizes a set of equivalent expressions for the unconstrained non-adaptive Mirror Descent algorithm. Here we assume R is a strongly-convex regularizer which is differentiable on $\mathbb{R}^n$ so that the corresponding Bregman divergence $\mathcal{B}_R$ is defined. Recall from Lemma 15,

$$\nabla R^\star(-g) = \arg\min_x g \cdot x + R(x). \tag{45}$$

We now prove that these updates are equivalent:

Theorem 17 *The four updates in Figure 5 are equivalent.*

Proof It is sufficient to prove three equivalences:

- The two explicit formulations are equivalent. For the right-hand version, we have $x_t = \nabla R^\star(\theta_t) = \arg\min_x -\theta_t \cdot x + R(x)$ using Eq. (45). The optimality of x_t for this minimization implies $0 = -\theta_t + \nabla R(x_t)$, or $\nabla R(x_t) = \theta_t$.
- Explicit $\Leftrightarrow$ FTRL: Immediate from Eq. (45) and the fact that $\theta_{t+1} = -g_{1:t}$.
- Implicit $\Leftrightarrow$ FTRL: That is,

$$\hat{x}_{t+1} = \arg\min_x g_t \cdot x + \mathcal{B}_R(x, \hat{x}_t) \qquad \text{and} \tag{46}$$

$$x_{t+1} = \arg\min_x g_{1:t} \cdot x + R(x) \tag{47}$$

are equivalent. The proof is by induction on the hypothesis $x_t = \hat{x}_t$. We must have from Eq. (46) and the IH that $g_t + \nabla R(\hat{x}_{t+1}) - \nabla R(x_t) = 0$, and from Eq. (47) applied to $t-1$ we must have $\nabla R(x_t) = -g_{1:t-1}$, and so $\nabla R(\hat{x}_{t+1}) = -g_{1:t}$. Then, we have the gradient of the objective of Eq. (47) at $\hat{x}_{t+1}$ is $g_{1:t} + \nabla R(\hat{x}_{t+1}) = 0$, and since the optimum of Eq. (47) is unique, we must have $\hat{x}_{t+1} = x_{t+1}$. The same general technique is used to prove the more general result for adaptive composite Mirror Descent in Theorem 11.

■

C.2 The Constrained Case: Projection onto $\mathcal{X}$

Even in the non-adaptive case (fixed R), the story is already more complicated when we constrain the algorithm to select from a convex set $\mathcal{X}$. For this section we take $R(x) = r(x) + I_{\mathcal{X}}(x)$ where r is continuously differentiable on $\operatorname{dom} I_{\mathcal{X}} = \mathcal{X}$.

In this setting, the two explicit algorithms given in the previous table are no longer equivalent. Figure 6 gives the two resulting families of updates. The classic Mirror Descent algorithm corresponds to the right-hand column, and follows the presentation of Beck and Teboulle (2003). This algorithm can be expressed as a greedy projection, and when $r(x) = \frac{1}{2\eta}\|x\|_2^2$ gives a constant learning rate version of the projected Online Gradient Descent algorithm of Zinkevich (2003). The Lazy column corresponds for example to the "Online Gradient Descent with lazy projections" algorithm (Shalev-Shwartz, 2012, Cor. 2.16).

The relationship to these projection algorithms is made explicit by the last row in the table. We define the projection operator onto $\mathcal{X}$ with respect to Bregman divergence $\mathcal{B}_r$ by

$$\Pi^r_{\mathcal{X}}(u) \equiv \operatorname*{arg\,min}_{x \in \mathcal{X}} \mathcal{B}_r(x, u).$$

Expanding the definition of the Bregman divergence, dropping terms independent of x since they do not influence the arg min, and replacing the explicit $x \in \mathcal{X}$ constraint with an $I_{\mathcal{X}}$ term in the objective, we have the equivalent expression

$$\Pi^r_{\mathcal{X}}(u) = \operatorname*{arg\,min}_x r(x) - \nabla r(u) \cdot x + I_{\mathcal{X}}(x). \tag{48}$$

The names Lazy and Greedy come from the manner in which the projection is used. For Lazy-Projection, the state of the algorithm is simply $g_{1:t}$ which can be updated without any need for projection; projection is applied lazily when we need to calculate x_{t+1}. For the Greedy-Projection algorithm on the other, the state of the algorithm is essentially x_t, and in particular u_{t+1} cannot be calculated without knowledge of x_t, the result of greedily applying projection on the previous round. If the g_t are really linear approximations to some f_t, however, a projection is needed on each round for both algorithms to produce x_t so $g_t \in \partial f_t(x_t)$ can be computed.

Both the Lazy and Greedy families can be analyzed (including in the more general adaptive case) using the techniques introduced in this paper. The Lazy family corresponds to the Native FTRL update of Section 5, namely

$$x_{t+1} = \operatorname*{arg\,min}_x g_{1:t} \cdot x + I_{\mathcal{X}}(x) + r_{0:t}(x),$$

which we encode as a single fixed non-smooth penalty $\Psi = I_{\mathcal{X}}$ which arrives on the first round: $\alpha_1 = 1$ and $\alpha_t = 0$ for $t > 1$.

	Lazy	Greedy
Explicit	$\theta_{t+1} = \theta_t - g_t$ $x_{t+1} = \nabla R^\star(\theta_{t+1})$	$\theta_{t+1} = \nabla r(x_t) - g_t$ $x_{t+1} = \nabla R^\star(\theta_{t+1})$
Implicit		$x_{t+1} =$ $\operatorname*{arg\,min}_x g_t \cdot x + \mathcal{B}_r(x, x_t) + I_{\mathcal{X}}(x)$
FTRL	$x_{t+1} = \operatorname*{arg\,min}_x g_{1:t} \cdot x + R(x)$	$x_{t+1} =$ $\operatorname*{arg\,min}_x \left(g_{1:t} + g^{(\Psi)}_{1:t-1}\right) \cdot x + R(x)$
Projection	$u_{t+1} = \operatorname*{arg\,min}_x g_{1:t} \cdot x + r(x)$ $x_{t+1} = \Pi^r_{\mathcal{X}}(u_{t+1})$	$u_{t+1} = \operatorname*{arg\,min}_u g_t \cdot u + \mathcal{B}_r(u, x_t)$ $= \nabla r^\star(\nabla r(x_t) - g_t)$ $x_{t+1} = \Pi^r_{\mathcal{X}}(u_{t+1})$

Figure 6: The Lazy and Greedy families of Mirror Descent algorithms, defined via $R(x) = r(x) + I_{\mathcal{X}}(x)$, where r is a differentiable strongly-convex regularizer. These families are not equivalent, but the different updates in each column are equivalent.

The Greedy-Projection Mirror Descent algorithms, on the other hand, can be thought of us receiving loss functions $g_t \cdot x + I_{\mathcal{X}}(x)$ on each round: that is, we have $\alpha_t = 1$ for all t. This family is analyzed using the techniques from Section 6. In this setting, embedding $I_{\mathcal{X}}(x)$ inside R can be seen as a convenience for defining $\nabla R^\star$,

$$\nabla R^\star(-g) = \operatorname*{arg\,min}_x g \cdot x + r(x) + I_{\mathcal{X}}(x). \tag{49}$$

We have the following equivalence results:

Theorem 18 *The Lazy-Explicit, Lazy-FTRL, and Lazy-Projection updates from the left column of Figure 6 are equivalent.*

Proof First, we show Lazy-Explicit is equivalent to Lazy-FTRL. Iterating the definition of θ_{t+1} in the explicit version gives $\theta_{t+1} = -g_{1:t}$, and so the second line in the update becomes exactly $x_{t+1} = \arg\min_x g_{1:t} \cdot x + R(x)$.

Next, we show that Lazy-Projection is equivalent to the Lazy-Explicit update. Optimality conditions for the minimization that defines u_{t+1} imply $\nabla r(u_{t+1}) = -g_{1:t}$. Then, the second equation in the Lazy-Projection update becomes

$$\begin{aligned} x_{t+1} = \Pi^r_{\mathcal{X}}(u_{t+1}) &= \operatorname*{arg\,min}_x r(x) - \nabla r(u_{t+1}) \cdot x + I_{\mathcal{X}}(x) && \text{Using Eq. (48).} \\ &= \operatorname*{arg\,min}_x g_{1:t} \cdot x + r(x) + I_{\mathcal{X}}(x), && \text{Since } \nabla r(u_{t+1}) = -g_{1:t}. \end{aligned}$$

which is exactly the Lazy-FTRL update (recalling $R(x) = r(x) + I_{\mathcal{X}}(x)$). ■

Theorem 19 *The Explicit, Implicit, FTRL, and Projected updates in the "Greedy" column of Figure 6 are equivalent.*

Proof We prove the result via the following chain of equivalences:

- Greedy-Explicit ⇔ Greedy-Implicit (c.f. Beck and Teboulle (2003, Prop 3.2)). We again use $\hat{x}$ for the points selected by the implicit version,

$$\begin{aligned}\hat{x}_{t+1} &= \arg\min_x g_t \cdot x + \mathcal{B}_r(x, x_t) + I_{\mathcal{X}}(x) \\ &= \arg\min_x g_t \cdot x + r(x) - \nabla r(x_t) \cdot x + I_{\mathcal{X}}(x),\end{aligned}$$

  where we have dropped terms independent of x in the arg min. On the other hand, plugging in the definition of θ_{t+1}, the explicit update is

$$x_{t+1} = \arg\min_x -(\nabla r(x_t) - g_t) \cdot x + r(x) + I_{\mathcal{X}}(x), \tag{50}$$

  which is equivalent.

- Greedy-Implicit ⇔ Greedy-FTRL: This is a special case of Theorem 11, taking $r_0 \leftarrow r + I_{\mathcal{X}}$, $r_t(x) = r_t^{\mathcal{B}}(x) = 0$ for $t \geq 1$, and $\alpha_t \Psi(x) = I_{\mathcal{X}}(x)$ for $t \geq 1$.

- When $I_{\mathcal{X}} = I_{\mathcal{X}}$, Projection is equivalent to the Greedy-Explicit expression. First, note we can re-write the Greedy-Projection update as

$$\begin{aligned}u_{t+1} &= \arg\min_u -(\nabla r(x_t) - g_t) \cdot u + r(u) \\ x_{t+1} &= \arg\min_{x \in \mathcal{X}} \mathcal{B}_r(x, u_{t+1}).\end{aligned}$$

  Optimality conditions for the first expression imply $\nabla r(u_{t+1}) = \nabla r(x_t) - g_t$. Then, the second update becomes

$$\begin{aligned}x_{t+1} &= \Pi_{\mathcal{X}}^r(u_{t+1}) \\ &= \arg\min_x r(x) - \nabla r(u_{t+1}) \cdot x + I_{\mathcal{X}}(x) && \text{Using Eq. (48).} \\ &= \arg\min_x r(x) - (\nabla r(x_t) - g_t) \cdot x + I_{\mathcal{X}}(x), && \text{Since } \nabla r(u_{t+1}) = \nabla r(x_t) - g_t.\end{aligned}$$

  which is equivalent to the Greedy-Explicit update, e.g., Eq. (50). ■

Appendix D. Details for the One-Dimensional L_1 Example

In this section we provide details for the one-dimensional example presented in Section 6.2. Suppose gradients g_t satisfy $\|g_t\|_2 \leq G$, and we use a feasible set of radius $R = 2G$, so the theory-recommended fixed learning rate is $\eta = \frac{R}{G\sqrt{T}} = \frac{2}{\sqrt{T}}$ (see Section 3).

We first consider the behavior of Mirror Descent: we construct the example so that the algorithm oscillates between two points, $\hat{x}$ and $-\hat{x}$ (allowing the possibility that $\hat{x} = -\hat{x} = 0$). Given alternating gradients of $+G$ and $-G$, in such an oscillation the distance one update takes us must be $\eta(G - \lambda)$, assuming $\lambda < G$. Thus, we can cause the algorithm to oscillate between $\hat{x} = (G - \lambda)/\sqrt{T}$ and $-\hat{x}$. We assume an initial $g_1 = -\frac{1}{2}(G + \lambda)$, which gives us $x_2 = \hat{x}$ for both Mirror Descent and FTRL when $x_1 = 0$.

This construction implies that for any constant L_1 penalty $\lambda < G$, Mirror Descent will never learn the optimal solution $x^* = 0$ (note that after the first round, we can view the g_t as being for example the subgradients of $f_t(x) = G\|x\|_1$). The points x_t selected by Mirror Descent, the gradients, and the subgradients of the L_1 penalty are given by the following table:

t	1	2	3	4	5	$\cdots$
g_t	g_1	G	$-G$	G	$-G$	$\cdots$
x_t	0	$\hat{x}$	$-\hat{x}$	$\hat{x}$	$-\hat{x}$	$\cdots$
$g_t^{(\Psi)}$	λ	$-\lambda$	λ	$-\lambda$	λ	$\cdots$

While we have worked from the standard Mirror Descent update, Eq. (36), it is instructive to verify the FTRL-Proximal representation is indeed equivalent. For example, using the values from the table, for x_5 we have

$$\begin{aligned}x_5 &= \arg\min_x g_{1:4} \cdot x + g_{1:3}^{(\Psi)} \cdot x + \lambda\|x\|_1 + \frac{1}{2\eta}\|x\|_2^2 \\ &= \arg\min_x (g_1 + G) \cdot x + \lambda \cdot x + \lambda\|x\|_1 + \frac{1}{2\eta}\|x\|_2^2 = -\frac{G - \lambda}{\sqrt{T}} = -\hat{x},\end{aligned}$$

where we solve the argmin by applying Eq. (37) with $b = g_1 + G + \lambda$.

Now, contrast this with the FTRL update of Eq. (35); we can solve this update in closed form using Eq. (37). First, note that FTRL will not oscillate in the same way, unless $\lambda = 0$. We have that $x_{t+1} = 0$ whenever $|g_{1:t}| < t\lambda$. Note that $g_{1:t}$ oscillates between $g_{1:t} = g_1 = -\frac{1}{2}(G + \lambda)$ on odd rounds t, and $g_{1:t} = g_1 + G = \frac{1}{2}G - \frac{1}{2}\lambda$ on even rounds. Since the magnitude of $g_{1:t}$ is larger on odd rounds, if we have $\frac{1}{2}(G+\lambda) \leq t\lambda$ then x_{t+1} will always be zero; re-arranging, this amounts to $\lambda \geq \frac{G}{2t-1}$. Thus, as with Mirror Descent, we need $\lambda \geq G$ to have $x_2 = 0$ (plugging in $t = 1$) but on subsequent rounds a *much* smaller λ is sufficient to produce sparsity. In the extreme case, taking $\lambda = G/(2T-1)$ is sufficient to ensure $x_T = 0$, whereas we need a λ value almost $2T$ times larger in order to get $x_T = 0$ from Mirror Descent.

Abstract

Distributed training of l_1 regularized classifiers has received great attention recently. Most existing methods approach this problem by taking steps obtained from approximating the objective by a quadratic approximation that is decoupled at the individual variable level. These methods are designed for multicore systems where communication costs are low. They are inefficient on systems such as Hadoop running on a cluster of commodity machines where communication costs are substantial. In this paper we design a distributed algorithm for l_1 regularization that is much better suited for such systems than existing algorithms. A careful cost analysis is used to support these points and motivate our method. The main idea of our algorithm is to do block optimization of many variables on the actual objective function within each computing node; this increases the computational cost per step that is matched with the communication cost, and decreases the number of outer iterations, thus yielding a faster overall method. Distributed Gauss-Seidel and Gauss-Southwell greedy schemes are used for choosing variables to update in each step. We establish global convergence theory for our algorithm, including Q-linear rate of convergence. Experiments on two benchmark problems show our method to be much faster than existing methods.

Keywords: Distributed learning, l_1 regularization

1. Introduction

The design of sparse linear classifiers using l_1 regularization is an important problem that has received great attention in recent years. This is due to its value in scenarios where the number of features is large and the classifier representation needs to be kept compact. Big data is becoming common nowadays. For example, in online advertising one comes across datasets with about a billion examples and a billion features. A substantial fraction of the features is usually irrelevant; and, l_1 regularization offers a systematic way to choose the small fraction of relevant features and form the classifier using them. In the future, one can foresee even bigger sized datasets to arise in this and other applications. For such big data, distributed storage of data over a cluster of commodity machines becomes necessary. Thus, fast training of l_1 regularized classifiers over distributed data is an important problem.

A number of algorithms have been recently proposed for parallel and distributed training of l_1 regularized classifiers; see section 3 for a review.[1] Most of these algorithms are based on coordinate-descent and they assume the data to be feature-partitioned. They are designed for multicore systems in which data communication costs are negligible. Recently, distributed systems with Hadoop running on a cluster of commodity machines have become popular. In such systems, communication costs are generally high; current methods for l_1 regularization are not optimally designed for such systems. Recently there has been been increased attention given to designing communication-efficient algorithms (Jaggi et al., 2014; Ma et al., 2015). *In this paper we develop a distributed block coordinate descent (DBCD) method that is efficient on distributed platforms in which communication costs are high.*

Following are the main contributions of this paper.

1. Most methods for the parallel training of l_1 regularized classifiers (including the ones proposed in this paper) fall into a generic algorithm format (see algorithm 1 in section 2). We make careful choices for the three key steps of this algorithm, leading to the development of a distributed block coordinate descent (DBCD) method that is very efficient on distributed platforms with high communication cost.

2. We provide a detailed cost analysis (section 5) that brings out the computation and communication costs of the generic algorithm clearly for different methods. In the process we motivate the need for new efficient methods such as DBCD that are suited to communication heavy settings.

3. We establish convergence theory (subsection 4.4) for our method using the results of Tseng and Yun (2009) and Yun et al. (2011). It is worth noting the following: (a) though Tseng and Yun (2009) and Yun et al. (2011) cover algorithms using quadratic approximations for the total loss, we use a simple trick to apply them to general nonlinear approximations, thus bringing more power to their results; and (b) even these two works use only per-feature decoupled quadratic models in their implementations whereas we work with more powerful approximations that couple features.

4. We give an experimental evaluation (section 6) that shows the strong performance of DBCD against key current methods in scenarios where communication cost is significant. Based on the experiments we make a final recommendation for the best method to employ for such scenarios.

The paper is organized as follows. The generic algorithm format is described in section 2. This gives a clear view of existing methods and allows us to motivate the new method. In section 3 we discuss the key related work in some detail. In section 4 we describe the DBCD method in detail and prove its convergence. The analysis of computation and communication costs in section 5 gives a firmer motivation of our DBCD method. Experiments

1. In this paper we only consider synchronous distributed training algorithms in which various computing nodes share their information and complete one update. Asynchronous methods (Li et al., 2014) form another important class of methods that needs a separate study.

comparing our method with several existing methods on a few large scale datasets are given in section 6. These experiments strongly demonstrate the efficiency of one version of our method that chooses update variables greedily. This best version of the DBCD method is described in section 7. Section 8 contains some concluding comments.

2. A generic algorithm

Various distributed solvers of the l_1 regularization problem can be put in a generic algorithm format. We begin this section by describing the problem formulation. Then we state the generic algorithm format. We follow this by discussing the choices various methods make for the steps and point out how new choices for the steps can lead to a better design.

2.1 Problem formulation

Let w be the weight vector with m variables, w_j, $j = 1, \ldots, m$, and $x_i \in R^m$ denote the i-th example. Let there be n training examples and let X denote the $n \times m$ data matrix, whose i-th row is x_i^T. Note that we have denoted vector components by subscripts, e.g., w_j is the j-th component of w; we have also used subscripts for indexing examples, e.g., x_i is the i-th example, which itself is a vector. But this will not cause confusion anywhere. A linear classifier produces the output $y_i = w^T x_i$. The loss is a nonlinear convex function applied on the output. For binary class label $c_i \in \{1, -1\}$, the loss is given by $\ell(y_i; c_i)$. Let us simply view $\ell(y_i; c_i)$ as a function of y_i with c_i acting as a parameter. We will assume that ℓ is non-negative and convex, $\ell \in \mathcal{C}^1$, the class of continuously differentiable functions, and that ℓ' is Lipschitz continuous[2]. Loss functions such as least squares loss, logistic loss, SVM squared hinge loss and Huber loss satisfy these assumptions. All experiments reported in this paper use the squared hinge loss, $\ell(y_i; c_i) = \max\{0, 1 - c_i y_i\}^2$. The total loss function, $f : R^m \to R$ is $f(w) = \frac{1}{n} \sum_i \ell(y_i; c_i)$. Let u be the l_1 regularizer given by $u(w) = \lambda \sum_j |w_j|$, where $\lambda > 0$ is the regularization constant. Our aim is to solve the problem

$$\min_{w \in R^m} F(w) = f(w) + u(w). \tag{1}$$

Let $g = \nabla f$. The optimality conditions for (1) are:

$$\forall j: \quad g_j + \lambda \,\mathrm{sign}(w_j) = 0 \text{ if } |w_j| > 0; \quad |g_j| \leq \lambda \text{ if } w_j = 0. \tag{2}$$

For problems with a large number of features, it is natural to randomly partition the columns of X and place the parts in P computing nodes. Let $\{B_p\}_{p=1}^P$ denote this partition of $\mathcal{M} = \{1, \ldots, m\}$, i.e., $B_p \subset \mathcal{M}$ $\forall p$ and $\cup_p B_p = \mathcal{M}$. *We will assume that this feature partitioning is given and that all algorithms operate within that constraint.* The variables associated with a particular partition get placed in one node. Given a subset of variables S, let X_S be the submatrix of X containing the columns corresponding to S. For a vector $z \in R^m$, z_S will denote the vector containing the components of z corresponding to S.

2. A function h is Lipschitz continuous if there exists a (Lipschitz) constant $L \geq 0$ such that $\|h(a) - h(b)\| \leq L\|a - b\|$ $\forall\, a, b$.

2.2 Generic algorithm

Algorithm 1 gives the generic algorithm. In each iteration t, the following steps happen, in parallel, in each node (p): (a) a subset of variables, S_p^t is chosen; (b) a suitable approximating function, f_p^t is formed and the chosen variables are optimized so as to define a direction; (c) a step size is chosen along that direction to update the weight vector on the chosen variables. The outputs of all examples are then computed using an *AllReduce* operation (step (d)) and the algorithm is terminated if optimality conditions are satisfied (step (e)).

Items such as B_p, S_p^t, w_{B_p}, $d_{B_p}^t$, X_{B_p} stay local in node p and do not need to be communicated. Step (d) can be carried out using an *AllReduce* operation (Agarwal et al., 2013) over the nodes and then y becomes available in all the nodes. The gradient subvector $g_{B_p}^t$ (which is needed for solving (3)) can then be computed locally as $g_{B_p}^t = X_{B_p}^T b$ where $b \in R^n$ is a vector with $\{\ell'(y_i)\}$ as its components.

Algorithm 1: A generic distributed algorithm

Choose w^0 and compute $y^0 = Xw^0$;
for $t = 0, 1 \ldots$ **do**
  for $p = 1, \ldots, P$ **do**
    (a) Select a working subset of variables[3], $S_p^t \subset B_p$;
    (b) Form $f_p^t(w_{B_p})$, an approximation of f and minimize, exactly or approximately, $f_p^t + u$ over only the weights corresponding to S_p^t:

$$\min f_p^t(w_{B_p}) + u(w_{B_p}) \quad \text{s.t.} \quad w_j = w_j^t \;\forall\, j \in B_p \setminus S_p^t \tag{3}$$

    to get $\bar{w}_{B_p}^t$ and set direction: $d_{B_p}^t = \bar{w}_{B_p}^t - w_{B_p}^t$;
    (c) Choose α^t and update: $w_{B_p}^{t+1} = w_{B_p}^t + \alpha^t d_{B_p}^t$;
  end
  (d) Update $y^{t+1} = y^t + \alpha^t \sum_p X_{B_p} d_{B_p}^t$;
  (e) Terminate if optimality conditions hold;
end

Steps (d) and (e) of Algorithm 1 are quite straight-forward. But the first three steps, (a)-variable sampling, (b)-function approximation, and (c)-step size determination, can be implemented in various ways and require a detailed discussion.

Step (a) - variable sampling. Some choices are:

- **(a.1)** random selection (Bradley et al., 2011; Richtárik and Takáč, 2014);
- **(a.2)** random cyclic: over a set of consecutive iterations (t) all variables are touched once (Bian et al., 2013);
- **(a.3)** greedy: always choose a set of variables that, in some sense violate (2) the most at the current iterate (Peng et al., 2013; Facchinei et al., 2014); and,
- **(a.4)** greedy selection using the Gauss-Southwell rule (Tseng and Yun, 2009; Yun et al., 2011).

Step (b) - function approximation. It would be ideal to choose f_p^t to be f itself. However, to make the solution simple and efficient, most methods choose a quadratic approximation that is decoupled at the individual variable level:

$$f_p^t(w_{B_p}^t) = \sum_{j \in B_p} g_j(w^t)(w_j - w_j^t) + \frac{L_j}{2}(w_j - w_j^t)^2 \tag{4}$$

The main advantages of (4) are its simplicity and closed-form minimization when used in (3). Choices for L^j that have been tried are:

- **(b.1)** L_j = a Lipschitz constant for g_j (Bradley et al., 2011; Peng et al., 2013);
- **(b.2)** L_j = a large enough bound on the Lipschitz constant for g_j to suit the sampling in step (a) (Richtárik and Takáč, 2014);
- **(b.3)** adaptive adjustment of L_j (Facchinei et al., 2014); and
- **(b.4)** $L_j = H_{jj}^t$, the j-th diagonal term of the Hessian at w^t (Bian et al., 2013).

Step (c) - step size. The choices are:

- **(c.1)** always fix $\alpha^t = 1$ (Bradley et al., 2011; Richtárik and Takáč, 2014; Peng et al., 2013);
- **(c.2)** use stochastic approximation ideas to choose $\{\alpha^t\}$ so that $\sum_t (\alpha^t)^2 < \infty$ and $\sum_t |\alpha^t| = \infty$ (Facchinei et al., 2014); and
- **(c.3)** choose α^t by line search that is directly tied to the optimization of F in (1) (Bian et al., 2013).

2.3 Discussion of choices for steps (a)-(c)

To understand the role of the various choices better, let us first focus on the use of (4) for f_p^t. Algorithm 1 may not converge to the optimal solution due to one of the following decisions: (i) choosing too many variables ($|S_p^t|$ large) for parallel updating in step (a); (ii) choosing small values for the proximal coefficient L_j in step (b); and (iii) not controlling α^t to be sufficiently small in step (c). This is because each of the above has the potential to cause large step sizes leading to increases in F value and, if this happens uncontrolled at all iterations then convergence to the minimum cannot occur. Different methods control against these by making suitable choices in the steps.

The choice made for step (c) gives a nice delineation of methods. With **(c.1)**, one has to do a suitable mix of large enough L_j and small enough $|S_p^t|$. Choice **(c.2)** is better since the proper control of $\{\alpha^t\} \to 0$ takes care of convergence; however, for good practical performance, L_j and α^t need to be carefully adapted, which is usually messy. Choice **(c.3)** is good in many ways: it leads to monotone decrease in F; it is good theoretically and practically; and, it allows both, small L_j as well as large $|S_p^t|$ without hindering convergence.

3. We will refer to the working subset size, i.e., $|S_p^t|$, as WSS.

Except for Bian et al. (2013), Tseng and Yun (2009) and Yun et al. (2011)[4], **(c.3)** has been unused in other methods because it is considered as 'not-in-line' with a proper parallel approach as it requires a separate α^t determination step requiring distributed computations and also needing F computations for several α^t values within one t. With line search, the actual implementation of Algorithm 1 merges steps **(c)** and **(d)** and so it deviates slightly from the flow of Algorithm 1. Specifically, we compute $\delta y = \sum_p X_{B_p} d_{B_p}^t$ before line search using AllReduce. Then each node can compute f at any α locally using $y + \alpha\,\delta y$. Only a scalar corresponding to the l_1 regularization term needs to be communicated for each α. This means that the communication cost associated with line search is minimal.[5] But truly, the slightly increased computation and communication costs is amply made up by a reduction in the number of iterations to reach sufficient optimality. So we go with the choice **(c.3)** in our method.

The choice of (4) for f_p^t in step (b) (in particular, **(b.4)**) is pretty much unanimously used in all previous works. This is done to make the optimization simple. While this is fine for communication friendly systems such as multicore, it is not the right choice when communication costs are high. Such a setting permits more per-node computation time, and there is much to be gained by using a more complex f_p^t. We propose the use of a function f_p^t that couples the variables in S_p^t. We also advocate an approximate solution of (3) (e.g., a few rounds of coordinate descent within each node) in order to control the computation time.

Crucial gains are also possible via resorting to the greedy choices, **(a.3)** and **(a.4)** for choosing S_p^t. On the other hand, with methods based on **(c.1)**, one has to be careful in using **(a.3)**: apart from difficulties in establishing convergence, practical performance can also be bad, as we show in section 6.

3. Related Work

Our interest is mainly in parallel/distributed computing methods. There are many parallel algorithms targeting a single machine having multi-cores with shared memory (Bradley et al., 2011; Richtárik and Takáč, 2015; Bian et al., 2013; Peng et al., 2013). In contrast, there exist only a few efficient algorithms to solve (1) when the data is distributed (Richtárik and Takáč, 2016; Ravazzi et al., 2013) and communication is an important aspect to consider. In this setting, the problem (1) can be solved in several ways depending on how the data is distributed across machines (Peng et al., 2013; Boyd et al., 2011): (A) example (horizontal) split, (B) feature (vertical) split and (C) combined example and feature split (a block of examples/features per node). While methods such as distributed FISTA (Peng et al., 2013) or ADMM (Boyd et al., 2011) are useful for (A), the block splitting method (Parikh and Boyd, 2013) is useful for (C). We are interested in (B), and the most relevant and important class of methods is parallel/distributed coordinate descent methods, as abstracted in algorithm 1. Most of these methods set f_p^t in step (b) of algorithm 1 to be a quadratic

4. Among these three works, Tseng and Yun (2009) and Yun et al. (2011) mainly focus on general theory and little on distributed implementation.
5. Later, in section 5 when we write costs, we write it to be consistent with Algorithm 1. The total cost of all the steps is the same for the implementation described here for line search. For genericity sake, we keep Algorithm 1 as it is even for the line search case. The actual details of the implementation for the line search case will become clear when we layout the final algorithm in section 7.

approximation that is decoupled at the individual variable level. Table 3 compares these methods along various dimensions.[6]

Most dimensions arise naturally from the steps of algorithm 1, as explained in section 2. Two important points to note are: (i) except Richtárik and Takáč (2016) and our method, none of these methods target and sufficiently discuss distributed setting involving communication and, (ii) from a practical view point, it is difficult to ensure stability and get good speed-up with no line search and non-monotone methods. For example, methods such as Bradley et al. (2011); Richtárik and Takáč (2014, 2015); Peng et al. (2013) that do not do line search are shown to have the monotone property only in expectation and that too only under certain conditions. Furthermore, variable selection rules, proximal coefficients and other method-specific parameter settings play important roles in achieving monotone convergence and improved efficiency. As we show in section 6, our method and the parallel coordinate descent Newton method (Bian et al., 2013) (see below for a discussion) enjoy robustness to various settings and come out as clear winners.

It is beyond the scope of this paper to give a more detailed discussion, beyond Table 3, of the methods from a theoretical convergence perspective on various assumptions and conditions under which results hold. We only briefly describe and comment on them below.

Generic Coordinate Descent Method (Scherrer et al., 2012a,b) Scherrer et al. (2012a) and Scherrer et al. (2012b) presented an abstract framework for coordinate descent methods (GenCD) suitable for parallel computing environments. Several coordinate descent algorithms such as stochastic coordinate descent (Shalev-Shwartz and Tewari, 2011), Shotgun (Bradley et al., 2011) and GROCK (Peng et al., 2013) are covered by GenCD. GROCK is a thread greedy algorithm (Scherrer et al., 2012a) in which the variables are selected greedily using gradient information. One important issue is that algorithms such as Shotgun and GROCK may not converge in practice due to their non-monotone nature with no line search; we faced convergence issues on some datasets in our experiments with GROCK (see section 6). Therefore, the practical utility of such algorithms is limited without ensuring necessary descent property through certain spectral radius conditions on the data matrix.

Distributed Coordinate Descent Method (Richtárik and Takáč, 2016) The multicore parallel coordinate descent method of Richtárik and Takáč (2014) is a much refined version of GenCD with careful choices for steps (a)-(c) of algorithm 1 and a supporting stochastic convergence theory. Richtárik and Takáč (2016) extended this to the distributed setting; so, this method is more relevant to this paper. With no line search, their algorithm HYDRA (Hybrid coordinate descent) has (expected) descent property only for certain sampling types of selecting variables and L_j values. One key issue is setting the right L_j values for good performance. Doing this accurately is a costly operation; on the other hand, inaccurate setting using cheaper computations (e.g., using the number of non-zero elements as suggested in their work) results in slower convergence (see section 6).

Necoara and Clipici (2014) suggest another variant of parallel coordinate descent in which all the variables are updated in each iteration. HYDRA and GROCK can be

6. Although our method will be presented only in section 4, we include our method's properties in the last row of Table 3. This helps to easily compare our method against the rest.

considered as two key, distinct methods that represent the set of methods discussed above. So, in our analysis as well as experimental comparisons in the rest of the paper, we do not consider the methods in this set other than these two.

Flexible Parallel Algorithm (FPA) (Facchinei et al., 2014) This method has some similarities with our method in terms of the approximate function optimized at the nodes. Though Facchinei et al. (2014) suggest several approximations, they use only (4) in its final implementation. More importantly, FPA is a non-monotone method using a stochastic approximation step size rule. Tuning this step size rule along with the proximal parameter L_j to ensure convergence and speed-up is hard. (In section 6 we conduct experiments to show this.) Unlike our method, FPA's inner optimization stopping criterion is unverifiable (for e.g., with (6)); also, FPA does not address the communication cost issue.

Parallel Coordinate Descent Newton (PCD) (Bian et al., 2013) One key difference between other methods discussed above and our DBCD method is the use of line search. Note that the PCD method can be seen as a special case of DBCD (see subsection 5.1). In DBCD, we optimize per-node block variables jointly, and perform line search across the blocks of variables; as shown later in our experimental results, this has the advantage of reducing the number of outer iterations, and overall wall clock time due to reduced communication time (compared to PCD).

Synchronized Parallel Algorithm (Patriksson, 1998b) Patriksson (1998b) proposed a Jacobi type synchronous parallel algorithm with line search using a generic cost approximation (CA) framework for differentiable objective functions (Patriksson, 1998a). Its local linear rate of convergence results hold only for a class of strong monotone CA functions. If we view the approximation function, f_p^t as a mapping that is dependent on w^t, Patriksson (1998b) requires this mapping to be continuous, which is unnecessarily restrictive.

ADMM Methods Alternating direction method of multipliers is a generic and popular distributed computing method. It does not fit into the format of Algorithm 1. This method can be used to solve (1) in different data splitting scenarios (Boyd et al., 2011; Parikh and Boyd, 2013). Several variants of global convergence and rate of convergence (e.g., $O(\frac{1}{k})$) results exist under different weak/strong convexity assumptions on the two terms of the objective function (Deng and Yin, 2016; Deng et al., 2013). Recently, an accelerated version of ADMM (Goldstein et al., 2014) derived using the ideas of Nesterov's accelerated gradient method (Nesterov, 2012) has been proposed; this method has dual objective function convergence rate of $O(\frac{1}{k^2})$ under a strong convexity assumption. ADMM performance is quite good when the augmented Lagrangian parameter is set to the right value; however, getting a reasonably good value comes with computational cost. In section 6 we evaluate our method and find it to be much faster.

Based on the above study of related work, we choose HYDRA, GROCK, PCD and FPA as the main methods for analysis and comparison with our method.[7] Thus, Table 3 gives various dimensions only for these methods.

7. In the experiments of section 6, we also include ADMM.

Method	Is $\mathbf{F}(w^t)$ monotone?	Are limits forced on $\lvert S_p^t \rvert$?	How is $\mathbf{S}_p^t$ chosen?	Basis for choosing $\mathbf{L}_j$	How is α^t chosen	Convergence type	Convergence rate
Existing methods							
HYDRA	No	No, if L_j is varied suitably	Random	Lipschitz bound for g_j suited to S_p^t choice	Fixed	Stochastic	Linear
GROCK	No	Yes	Greedy	Lipschitz bound for g_j	Fixed	Deterministic	Sub-linear
FPA	No	No	Random	Lipschitz bound for g_j	Adaptive	Deterministic	None
PCD	Yes	No	Random	Hessian diagonal	Armijo line search	Stochastic	Sub-linear
Our method							
DBCD	Yes	No	Random/Greedy	Free	Armijo line search	Deterministic	Locally linear

Table 1: Properties of selected methods that fit into the format of Algorithm 1. Methods: HYDRA (Richtárik and Takáč, 2016), GROCK (Peng et al., 2013), FPA (Facchinei et al., 2014), PCD (Bian et al., 2013).

4. DBCD method

The DBCD method that we propose fits into the general format of Algorithm 1. It is actually *a class of algorithms* that allows various possibilities for steps (a), (b) and (c). Below we lay out these possibilities and establish a general convergence theory for the class of algorithms that fall under DBCD. We recommend three specific instantiations of DBCD, analyze their costs in section 5, empirically study them in section 6 and make one final best recommendation in section 7. In this section, we also show the relations of DBCD to other methods on aspects such as variable selection, function approximation, line search, etc. As this section is traversed, it is also useful to re-visit table 3 and compare DBCD against other key methods.

Our goal is to develop an efficient distributed learning method that jointly optimizes the costs involved in the various steps of the algorithm. We observed in the previous section that the methods discussed there lack this careful optimization in one or more steps, resulting in inferior performance. This can be understood better via a cost analysis. To avoid too much deviation, we give the gist of this cost analysis here and postpone the full details to section 5. The cost of Algorithm 1 can be written as $T^P(C^P_{\text{comp}} + C^P_{\text{comm}})$ where P denotes the number of nodes, T^P is the number of outer iterations[8], and, C^P_{comp} and C^P_{comm} respectively denote the computation and communication costs per-iteration. In communication heavy situations, existing algorithms have $C^P_{\text{comp}} \ll C^P_{\text{comm}}$. Our method aims to improve overall efficiency by making each iteration more complex (C^P_{comp} is increased) and, in the process, making T^P much smaller.

4.1 Variable selection

Let us now turn to step (a) of Algorithm 1. We propose two schemes for variable selection, i.e., choosing $S_p^t \subset B_p$.

Gauss-Seidel scheme. In this scheme, we form cycles - each cycle consists of a set of consecutive iterations - while making sure that every variable is touched once in each cycle. We implement a cycle as follows. Let τ denote the iteration where a cycle starts. Choose a positive integer T (T may change with each cycle). For each p, randomly partition B_p into T equal parts: $\{S_p^t\}_{t=\tau}^{\tau+T-1}$. Use these variable selections to do T iterations. *Henceforth, we refer to this scheme as the R-scheme.*

Distributed greedy scheme. This is a greedy scheme which is purely distributed and so more specific than the Gauss-Southwell schemes in Tseng and Yun (2009).[9] In each iteration, our scheme chooses variables based on how badly (2) is violated for various j. For one j, an expression of this violation is as follows. Let g^t and H^t denote, respectively, the gradient and Hessian at w^t. Form the following one variable quadratic approximation:

$$q_j(w_j) = g_j^t(w_j - w_j^t) + \frac{1}{2}(H_{jj}^t + \nu)(w_j - w_j^t)^2 + \lambda|w_j| - \lambda|w_j^t| \quad (5)$$

8. For practical purposes, one can view T^P as the number of outer iterations needed to reach a specified closeness to the optimal objective function value. We will say this more precisely in section 6.
9. Yet, our distributed greedy scheme can be shown to imply the Gauss-Southwell-q rule for a certain parameter setting. See the appendix for details.

where ν is a small positive constant. Let $\bar{q}_j$ denote the optimal objective function value obtained by minimizing $q_j(w_j)$ over all w_j. Since $q_j(w_j^t) = 0$, clearly $\bar{q}_j \leq 0$. The more negative $\bar{q}_j$ is, the better it is to choose j.

Our distributed greedy scheme first chooses a working set size, WSS (the size of S_p^t) and then, in each node p, it chooses the top WSS variables from B_p according to smallness of $\bar{q}_j$, to form S_p^t. *Hereafter, we refer to this scheme as the S-scheme.*

It is worth pointing out that, our distributed greedy scheme requires more computation than the Gauss-Seidel scheme. However, since the increased computation is local, non-heavy and communication is the real bottleneck, it is not a worrisome factor.

4.2 Function approximation

Let us begin with step (b). There are three key items involved: (i) what are some of the choices of approximate functions possible, used by our methods and others? (ii) what is the stopping criterion for the inner optimization (i.e., local problem), and, (iii) what is the method used to solve the inner optimization? We discuss all these details below. We stress the main point that, unlike previous methods, we allow f_p^t to be non-quadratic and also to be a joint function of the variables in w_{B_p}. We first describe a general set of properties that f_p^t must satisfy, and then discuss specific instantiations that satisfy these properties.

Condition 1. $f_p^t \in \mathcal{C}^1$; $g_p^t = \nabla f_p^t$ is Lipschitz continuous, with the Lipschitz constant uniformly bounded over all t; f_p^t is strongly convex (uniformly in t), i.e., $\exists\ \mu > 0$ such that $f_p^t - \frac{\mu}{2}\|w_{B_p}\|^2$ is convex; and, f_p^t is gradient consistent with f at $w_{B_p}^t$, i.e., $g_p^t(w_{B_p}^t) = g_{B_p}(w^t)$.

This assumption is not restrictive. Gradient consistency is essential because it is the property that connects f_p^t to f and ensures that a solution of (3) will make $d_{B_p}^t$ a descent direction for F at $w_{B_p}^t$, thus paving the way for a decrease in F at step (c). Strong convexity is a technical requirement that is needed for establishing sufficient decrease in F in each step of Algorithm 1. Our experiments indicate that it is sufficient to set μ to be a very small positive value. Lipschitz continuity is another technical condition that is needed for ensuring boundedness of various quantities; also, it is easily satisfied by most loss functions.

Choice of f_p^t. Let us now discuss some good ways of choosing f_p^t. *For all these instantiations, a proximal term is added to get the strong convexity required by* Condition 1.

- **Proximal-Jacobi.** We can follow the classical Jacobi method in choosing f_p^t to be the restriction of f to $w_{S_p^t}^t$, with the remaining variables fixed at their values in w^t. Let $\bar{B}_p$ denote the complement of B_p, i.e., the set of variables associated with nodes other than p. Thus we set

$$f_p^t(w_{B_p}) = f(w_{B_p}, w_{\bar{B}_p}^t) + \frac{\mu}{2}\|w_{B_p} - w_{B_p}^t\|^2 \tag{6}$$

  where $\mu > 0$ is the proximal constant. It is worth pointing out that, since each node p keeps a copy of the full classifier output vector y aggregated over all the nodes, the computation of f_p^t and g_p^t due to changes in w_{B_p} can be locally computed in node p. Thus the solution of (3) is local to node p and so step (b) of Algorithm 1 can be executed in parallel for all p.

- **Block GLMNET.** GLMNET (Yuan et al., 2012; Friedman et al., 2010) is a sequential coordinate descent method that has been demonstrated to be very promising for the sequential solution of l_1 regularized problems with logistic loss. At each iteration, GLMNET minimizes the second order Taylor series of f at w^t, followed by line search along the direction generated by this minimizer. We can make a distributed version by choosing f_p^t to be the second order Taylor series approximation of $f(w_{B_p}, w_{\bar{B}_p}^t)$ with respect to w_{B_p} while keeping $w_{\bar{B}_p}$ fixed at $w_{\bar{B}_p}^t$. In other words, we can choose f_p^t as

$$f_p^t(w_{B_p}) = Q^t(w_{B_p}) + \frac{\mu}{2}\|w_{B_p} - w_{B_p}^t\|^2 \tag{7}$$

  where Q^t is the quadratic approximation of $f(w_{B_p}, w_{\bar{B}_p}^t)$ with respect to w_{B_p} at $w_{B_p}^t$ with $w_{\bar{B}_p}^t$ fixed.

- **Block L-BFGS.** One can keep a limited history of $w_{B_p}^t$ and $g_{B_p}^t$ and use an $L-BFGS$ approach to build a second order approximation of f in each iteration to form f_p^t:

$$f_p^t(w_{B_p}) = (g_{B_p}^t)^T(w_{B_p} - w_{B_p}^t) + \frac{1}{2}(w_{B_p} - w_{B_p}^t)^T H_{BFGS}(w_{B_p} - w_{B_p}^t) + \frac{\mu}{2}\|w_{B_p} - w_{B_p}^t\|^2 \tag{8}$$

  where H_{BFGS} is a limited memory BFGS approximation of the Hessian of $f(w_{B_p}, w_{\bar{B}_p}^t)$ with respect to w_{B_p} with $w_{\bar{B}_p}^t$ fixed, formed using $\{g_{B_p}^\tau\}_{\tau \leq t}$.

- **Decoupled quadratic.** Like in existing methods we can also form a quadratic approximation of f that decouples at the variable level - see (4). (An additional proximal term can be added.) If the second order term is based on the diagonal elements of the Hessian at w^t, then the PCDN algorithm given in Bian et al. (2013) can be viewed as a special case of our DBCD method. PCDN (Bian et al., 2013) is based on Gauss-Seidel variable selection. But it can also be used in combination with the distributed greedy scheme that we propose in subsection 4.1 below.

Approximate stopping. In step (b) of Algorithm 1 we mentioned the possibility of approximately solving (3). This is irrelevant for previous methods which solve individual variable level quadratic optimization in closed form, but very relevant to our method. Here we propose an approximate relative stopping criterion and later, in subsection 4.4, also give convergence theory to support it.

Let ∂u_j be the set of subgradients of the regularizer term $u_j = \lambda|w_j|$, i.e.,

$$\partial u_j = [-\lambda, \lambda] \ \text{ if } w_j = 0; \ \ \lambda\,\text{sign}(w_j) \ \text{ if } w_j \neq 0. \tag{9}$$

A point $\bar{w}_{B_p}^t$ is optimal for (3) if, at that point,

$$(g_p^t)_j + \xi_j = 0, \ \ \text{for some } \ \xi_j \in \partial u_j \ \ \forall\ j \in S_p^t. \tag{10}$$

An approximate stopping condition can be derived by choosing a tolerance $\epsilon > 0$ and requiring that, for each $j \in S_p^t$ there exists $\xi_j \in \partial u_j$ such that

$$\delta^j = (g_p^t)_j + \xi_j, \ \ |\delta_j| \leq \epsilon |d_j^t| \ \ \forall\ j \in S_p^t \tag{11}$$

A practical alternative is to replace the stopping condition (11) by simply using a fixed number of cycles of coordinate descent to minimize f_p^t.

Method used for solving (3). Now (3) is an l_1 regularized problem restricted to $w_{S_p^t}$. It has to be solved within node p using a suitable sequential method. Going by the state of the art for sequential solution of such problems (Yuan et al., 2010) we use the coordinate-descent method described in Yuan et al. (2010) for solving (3). For logistic regression loss, it is appropriate to use the new-GLMNET method (Yuan et al., 2012).

4.3 Line search

Line search (step (c) of Algorithm 1) forms an important component for making good decrease in F at each iteration. For non-differentiable optimization, there are several ways of doing line search. For our context, Tseng and Yun (2009) and Patriksson (1998a) give two good ways of doing line search based on Armijo backtracking rule. In this paper we use ideas from the former. Let β and σ be real parameters in the interval $(0, 1)$. (We use the standard choices, $\beta = 0.5$ and $\sigma = 0.01$.) We choose α^t to be the largest element of $\{\beta^k\}_{k=0,1,\ldots}$ satisfying

$$F(w^t + \alpha^t d^t) \leq F(w^t) + \alpha^t \sigma \Delta^t, \tag{12}$$

$$\Delta^t \stackrel{\text{def}}{=} (g^t)^T d^t + \lambda u(w^t + d^t) - \lambda u(w^t). \tag{13}$$

4.4 Convergence

We now establish convergence for the class of algorithmic choices discussed in subsections 4.2-4.3. To do this, we make use of the results of Tseng and Yun (2009). An interesting aspect of this use is that, while the results of Tseng and Yun (2009) are stated only for f_p^t being quadratic, we employ a simple trick that lets us apply the results to our algorithm which involves non-quadratic approximations.

Apart from the conditions in Condition 1 (see subsection 4.2) we need one other technical assumption.

Condition 2. For any given t, w_{B_p} and $\hat{w}_{B_p}$, $\exists$ a positive definite matrix $\hat{H} \geq \mu I$ (note: $\hat{H}$ can depend on t, w_{B_p} and $\hat{w}_{B_p}$) such that

$$\hat{g}^t_{B_p}(w_{B_p}) - \hat{g}^t_{B_p}(\hat{w}_{B_p}) = \hat{H}(w_{B_p} - \hat{w}_{B_p}) \tag{14}$$

In the above, $\hat{g}^t_{B_p}$ is the gradient with respect to w_{B_p} of the approximate function f_p^t formed in step (b) of algorithm 1. Note that $\hat{g}^t_{B_p}(w^t_{B_p}) = g^t_{B_p}$.

Except *Proximal-Jacobi*, the other instantiations of f_p^t mentioned in subsection 4.2 are quadratic functions; for these, g_p^t is a linear function and so (14) holds trivially. Let us turn to *Proximal-Jacobi*. If $f_p^t \in \mathcal{C}^2$, the class of twice continuously differentiable functions, then Condition 2 follows directly from mean value theorem; note that, since $f_p^t - \frac{\mu}{2}\|w\|^2$ is convex, $H_p \geq \mu I$ at any point, where H_p is the Hessian of f_p^t. Thus Condition 2 easily holds for least squares loss and logistic loss. Now consider the SVM squared hinge loss, $\ell(y_i; c_i) = 0.5(\max\{0, 1 - y_i c_i\})^2$, which is not in $\mathcal{C}^2$. Condition 2 holds for it because $g = \sum_i \ell'(y_i; c_i) x_i$ and, for any two real numbers z_1, z_2, $\ell'(z_1; c_i) - \ell'(z_2; c_i) = \kappa(z_1, z_2, c_i)(z_1 - z_2)$ where $0 \leq \kappa(z_1, z_2, c_i) \leq 1$.

The main convergence theorem can now be stated. Its proof is given in the appendix.

Theorem 1. Suppose, in Algorithm 1, the following hold:

(i) step (a) is done via the Gauss-Seidel or distributed greedy schemes of subection 5.2;

(ii) f_p^t in step (b) satisfies Condition 1 and Condition 2;

(iii) (11) is used to terminate (3) with $\epsilon = \mu/2$ (where μ is as in Condition 1); and,

(iv) in step (c), α^t is chosen via Armijo backtracking of subection 5.3.

Then Algorithm 1 is well defined and produces a sequence, $\{w^t\}$ such that any accumulation point of $\{w^t\}$ is a solution of (1). If, in addition, the total loss, f is strongly convex, then $\{F(w^t)\}$ converges Q-linearly and $\{w^t\}$ converges at least R-linearly.[10]

4.5 Specific instantiations of DBCD

For function approximation we found the proximal-Jacobi choice, (6) to be powerful. This choice, combined with variable selection done using the R-scheme and S-scheme leads to the two specific instantiations, DBCD-R and DBCD-S. As we explained in subsection 4.2, the PCDN algorithm given by Bian et al. (2013) (referred to as PCD) is a special case of DBCD using a decoupled quadratic function approximation and the R-scheme for variable selection. We also recommend the use of S-scheme with this method and call that instantiation as PCD-S.

5. DBCD method: Cost analysis

As pointed out earlier, the DBCD method is motivated by an analysis of the costs of various steps of algorithm 1. In this section, we present a detailed cost analysis that explains this more clearly. Based on section 3, we select the following five methods for our study: (1) HYDRA (Richtárik and Takáč, 2016), (2) GROCK (Greedy coordinate-block) (Peng et al., 2013), (3) FPA (Flexible Parallel Algorithm) (Facchinei et al., 2014), (4) PCD (Parallel Coordinate Descent Newton method) (Bian et al., 2013), and (5) DBCD. We will use the above mentioned abbreviations for the methods in the rest of the paper.

Let nz and $|S| = \sum_p |S_p^t|$ denote the number of non-zero entries in the data matrix X and the number of variables updated in each iteration respectively. To keep the analysis simple, we make the homogeneity assumption that the number of non-zero data elements in each node is nz/P. Let $\beta(\gg 1)$ be the relative computation to communication speed in the given distributed system; more precisely, it is the ratio of the times associated with communicating a floating point number and performing one floating point operation. On a cluster with 10 Gbps communication bandwidth where we did our experiments, we found the value of β to be in the range $30 - 100$. Recall that n, m and P denote the number of examples, features and nodes respectively. Table 5 gives cost expressions for different steps of the algorithm in one outer iteration. Here c_1, c_2, c_3, c_4 and c_5 are method dependent parameters. Table 5 gives the cost constants for various methods.We briefly discuss different costs below.

10. See chapter 9 of Ortega and Rheinboldt (1970) for definitions of Q-linear and R-linear convergence.

Cost	Steps of Algorithm 1			
	Step (a) Variable selection	Step (b) Inner optimization	Step (c) Choosing step size	Step (d) Updating output
Computation	$c_1\frac{nz}{P}$	$c_2\frac{nz}{P}\frac{\lvert S\rvert}{m}$	$c_3\lvert S\rvert + c_4 n$	$c_5\frac{nz}{P}\frac{\lvert S\rvert}{m}$
Communication	-	-	≈ 0	$\approx \beta n$[11]

Table 2: Cost of various steps of Algorithm 1. C^P_{comp} and C^P_{comm} are respectively, the sums of costs in the computation and communication rows.

Method	c_1	c_2	c_3	c_4	c_5	Computation cost per iteration	Communication cost per iteration
Existing methods							
HYDRA	0	1	1	0	1	$2\frac{nz}{P}\frac{\lvert S\rvert}{m} + \lvert S\rvert$	βn
GROCK	1	q	1	0	q	$\frac{nz}{P} + 2q\frac{nz}{P}\frac{\lvert S\rvert}{m} + \lvert S\rvert$	βn
FPA	1	q	1	1	q	$\frac{nz}{P} + 2q\frac{nz}{P}\frac{\lvert S\rvert}{m} + \lvert S\rvert + n$	βn
PCD	0	1	τ_{ls}	τ_{ls}	1	$2\frac{nz}{P}\frac{\lvert S\rvert}{m} + \tau_{ls}\lvert S\rvert + \tau_{ls} n$	βn
Variations of our method							
PCD-S	1	q	τ_{ls}	τ_{ls}	q	$\frac{nz}{P} + 2q\frac{nz}{P}\frac{\lvert S\rvert}{m} + \tau_{ls}\lvert S\rvert + \tau_{ls} n$	βn
DBCD-R	0	k	τ_{ls}	τ_{ls}	1	$(k+1)\frac{nz}{P}\frac{\lvert S\rvert}{m} + \tau_{ls}\lvert S\rvert + \tau_{ls} n$	βn
DBCD-S	1	kq	τ_{ls}	τ_{ls}	q	$\frac{nz}{P} + q(k+1)\frac{nz}{P}\frac{\lvert S\rvert}{m} + \tau_{ls}\lvert S\rvert + \tau_{ls} n$	βn

Table 3: Cost parameter values and costs for different methods. q lies in the range: $1 \le q \le \frac{m}{\lvert S\rvert}$. R and S refer to variable selection schemes for step (a); see subsection 4.1. PCD uses the R scheme and so it can also be referred to as PCD-R. Typically τ_{ls}, the number of α values tried in line search, is very small; in our experiments we found that on average it is not more than 10. Therefore all methods have pretty much the same communication cost per iteration.

Step a: Methods like our DBCD-S[12], GROCK, FPA and PCD-S need to calculate the gradient and model update to determine which variables to update. Hence, they need to go through the whole data once ($c_1 = 1$). On the other hand HYDRA, PCD and DBCD-R select variables randomly or in a cyclic order. As a result variable subset selection cost is negligible for them ($c_1 = 0$).

11. Note that the communication latency cost (the time taken to communicate zero bytes) is ignored in the communication cost expressions because it is dominated by the throughput cost for large n. Moreover, as in Agarwal et al. (2013), the broadcast and reduce operators are pipelined over the vector entries. This means that communication cost increases sub-linearly wrt. $logP$. If n is assumed to be large (as in our case), it is almost independent of $logP$ and can be written approximately as βn.
12. The DBCD and PCD methods have two variants, R and S corresponding to different ways of implementing step a; see subsection 4.1.

Step b: All the methods except DBCD-S and DBCD-R use the decoupled quadratic approximation (4). For DBCD-R and DBCD-S, an additional factor of k comes in c_2 since we do k inner cycles of CDN in each iteration. HYDRA, PCD and DBCD-R do a random or cyclic selection of variables. Hence, a factor of $\frac{\lvert S\rvert}{m}$ comes in the cost since only a subset $\lvert S\rvert$ of variables is updated in each iteration. However, methods that do selection of variables based on the magnitude of update or expected objective function decrease (DBCD-S, GROCK, FPA and PCD-S) favour variables with low sparsity. As a result, c_2 for these methods has an additional factor q where $1 \le q \le \frac{m}{\lvert S\rvert}$.

Step c: For methods that do not use line-search, $c_3 = 1$ and $c_4 = 0$[13]. The overall cost is $\lvert S\rvert$ to update the variables. For methods like DBCD-S, DBCD-R, PCD and PCD-S that do line-search, $c_3 = c_4 = \tau_{ls}$ where τ_{ls} is the average number of steps (α values tried) in one line search. For each line search step, we need to recompute the loss function which involves going over n examples once. Moreover, *AllReduce* step needs to be performed to sum over the distributed l_1 regularizer term. Since only one scalar needs to be communicated per line search step, the communication cost is dominated by the communication latency, i.e. the time taken to communicate zero bytes. As pointed out in Bian et al. (2013), τ_{ls} can increase with P; but it is still negligible compared to n. Combined with the fact that n is large in step (d), we will ignore this cost in the subsequent analysis.

Step d: This step involves computing and doing *AllReduce* on updated local predictions to get the global prediction vector for the next iteration and is common for all the methods. Note that because we are dealing with linear models, the updated predictions need to be communicated only once in each iteration even for the methods like ours that require line search, i.e., there is no need to communicate the updated predictions again and again for every line search step in each iteration.

The analysis given above is only for C^P_{comp} and C^P_{comm}, the computation and communication costs in one iteration. If T^P is the number of iterations to reach a certain optimality tolerance, then the total cost of Algorithm 1 is: $C^P = T^P(C^P_{\text{comp}} + C^P_{\text{comm}})$. For P nodes, speed-up is given by C^1/C^P. To illustrate the ill-effects of communication cost, let us take the method of Richtárik and Takáč (2015). For illustration, take the case of $\lvert S\rvert = P$, i.e., one variable is updated per node per iteration. For large P, $C^P \approx T^P C^P_{\text{comm}} = T^P\ \beta n$; both β and n are large in the distributed setting. On the other hand, for $P = 1$, $C^P_{\text{comm}} = 0$ and $C^P = C^P_{\text{comp}} \approx \frac{nz}{m}$. Thus $speedup = \frac{T^1}{T^P}\frac{C^1}{C^P} = \frac{T^1}{T^P}\frac{\frac{nz}{m}}{\beta n}$. Richtárik and Takáč (2015) show that T^1/T^P increases nicely with P. But, the term βn in the denominator of C^1/C^P has a severe detrimental effect. Unless a special distributed system with efficient communication is used, speed up has to necessarily suffer. When the training data is huge and so the data is forced to reside in distributed nodes, *the right question to ask is not whether we get great speed up, but to ask which method is the fastest.* Given this, we ask how various choices in the steps of Algorithm 1 can be made to decrease C^P. Suppose we devise choices such that (a) C^P_{comp} is increased while still remaining in the zone where $C^P_{\text{comp}} \ll C^P_{\text{comm}}$, and (b) in the process, T^P is decreased greatly, then C^P can be decreased. The basic idea of our method is to use a more complex f^t_p than the simple quadratic in (4), due to which, T^P becomes much smaller. The use of line search, **(c.3)** for step **c** aids this further. We see

13. For FPA, $c_4 = 1$ since objective function needs to be computed to automatically set the proximal term parameter.

in table 5 that, DBCD-R and DBCD-S have the maximum computational cost. On the other hand, communication cost is more or less the same for all the methods (except for few scalars in the line search step) and dominates the cost. In section 6, we will see on various datasets how, by doing more computation, our methods reduce T^P substantially over the other methods while incurring a small computation overhead (relative to communication) per iteration. These will become amply clear in section 6; see, for example, table 6.3 in that section.

6. Experimental Evaluation

In this section, we present experimental results on real-world datasets for the training of l_1 regularized linear classifiers using the squared hinge loss. Here training refers to the minimization of the function F in (1). We compare our methods with several state of the art methods, in particular, those analyzed in section 5 (see the methods in the first column of table 5) together with ADMM, the accelerated alternating direction method of multipliers (Goldstein et al., 2014). To the best of our knowledge, such a detailed study has not been done for parallel and distributed l_1 regularized solutions in terms of (a) accuracy and solution optimality performance, (b) variable selection schemes, (c) computation versus communication time and (d) solution sparsity. The results demonstrate the effectiveness of our methods in terms of total (computation + communication) time on both accuracy and objective function measures.

6.1 Experimental Setup

Datasets: We conducted our experiments on four datasets: KDD, URL, ADS and WEBSPAM[14]. The key properties of these datasets are given in table 6.1. These datasets have a large number of features and l_1 regularization is important. The number of examples is large for KDD, URL and ADS. WEBSPAM has a much smaller number of examples and hence communication costs are low for this dataset.

Dataset	n	m	nz	$s = nz/m$
KDD	8.41×10^6	20.21×10^6	0.31×10^9	15.34
URL	2.00×10^6	3.23×10^6	0.22×10^9	68.11
ADS	18.56×10^6	0.20×10^6	5.88×10^9	29966.83
WEBSPAM	0.26×10^6	16.60×10^6	0.98×10^9	58.91

Table 4: Properties of datasets. n is the number of examples, m is the number of features, nz is the number of non-zero elements in the data matrix, and s is the average number of non-zero elements per feature.

Methods and Metrics: We evaluate the performance of all the methods using (a) Area Under Precision-Recall Curve (AUPRC) (Sonnenburg and Franc, 2010; Agarwal et al., 2013)[15] and (b) Relative Function Value Difference (RFVD) as a function of time taken. RFVD is computed as $\frac{F(w^t)-F^*}{F^*}$ where F^* is taken as the best value obtained across the methods after a long duration. We also report per node computation time statistics and sparsity pattern behavior of all the methods.

14. KDD, URL and WEBSPAM are popular benchmark datasets taken from `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/`. ADS is a proprietary dataset from Microsoft.

Parameter Settings: For each dataset we used cross validation to find the optimal λ value that gave the best AUPRC values. For each dataset we experimented with a range of λ values centred around the optimal value that have good sparsity variations over the optimal solution. Since the relative performance between methods was quite consistent across different λ values, we give details of the performance only for the optimal λ value. With respect to algorithm 1, the working set size (WSS) per node and the number of nodes (P) are common across all the methods. We set WSS in terms of the fraction (r) of the number of features per node, i.e., WSS=rm/P. Note that WSS will change with P for a given fraction r. For all datasets we give results for two r values $(0.01, 0.1)$. Note that r does not play a role in ADMM since all variables are optimized in each node. We experimented with $P = 25, 100$. Only for *ADS* dataset we used $P = 100, 200$ because it has many more examples than others.

Platform: We ran all our experiments on a Hadoop cluster with 379 nodes and 10 Gbit interconnect speed. Each node has Intel (R) Xeon (R) E5-2450L (2 processors) running at 1.8 GHz and 192 GB RAM. (Though the datasets can fit in this memory configuration, our intention is to test the performance in a distributed setting.) All our implementations were done in *C#* including our binary tree *AllReduce* support (Agarwal et al., 2013) on Hadoop. We implemented the pipelined *AllReduce* operation described in Agarwal et al. (2013) that reduces the communication cost from $\beta nlogP$ to βn for large n.

6.2 Method Specific Parameter Settings

We discuss method specific parameter setting used in our experiments and associated practical implications.

Choice of μ and k for DBCD: To get a practical implementation that gives good performance in our method, we deviate slightly from the conditions of Theorem 1. First, we find that the proximal term does not contribute usefully to the progress of the algorithm (see the left side plot in figure 1). So we choose to set μ to a small value, e.g., $\mu = 10^{-12}$. Second, we replace the stopping condition (11) by simply using a fixed number of cycles of coordinate descent to minimize f_p^t. The right side plot in figure 1 shows the effect of number of cycles, k. We found that $k = 5, 10$ are good choices. Since computations are heavier for DBCD-S, we used $k = 5$ for it and used $k = 10$ for DBCD-R.

Let us begin with ADMM. We use the feature partitioning formulation of ADMM described in subsection 8.3 of Boyd et al. (2011). ADMM does not fit into the format of algorithm 1, but the communication cost per outer iteration is comparable to the other methods that fit into algorithm 1. In ADMM, the augmented Lagrangian parameter (ρ) plays an important role in getting good performance. In particular, the number of iterations required by ADMM for convergence is very sensitive with respect to ρ. While many schemes have been discussed in the literature (Boyd et al., 2011) we found that selecting ρ using the objective function value gave a good estimate; we selected ρ^* from a handful of ρ

15. We employed AUPRC instead of AUC because it differentiates methods more finely.

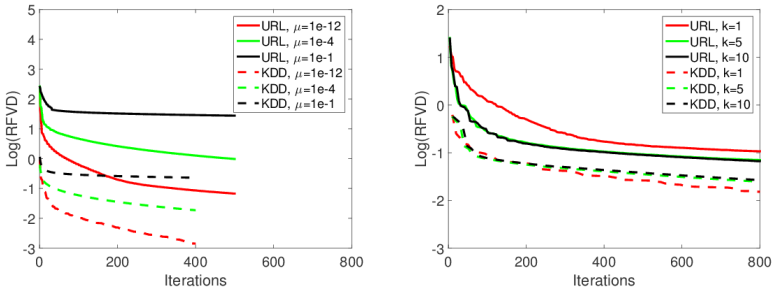

Figure 1: Study of μ and k on *KDD* and *URL*. Left: the effect of μ. Right: the effect of k, the number of cycles to minimize f_p^t. $\mu = 10^{-12}$ and $k = 10$ are good choices. $P = 100$.

values with ADMM run for 10 iterations (i.e., not full training) for each ρ value tried.[16] However, this step incurred some computational/communication time. Note that each ADMM iteration optimizes all variables and involves many inner iterations, thus causing even the ten iterations each for several ρ values to be significantly large. In our time plots shown later, the late start of ADMM results is due to this cost. Note that this minimal number of ten iterations was essential to get a decent ρ^*.

Now consider GROCK, FPA and HYDRA which are based on using Lipschitz constants (L_j). We found GROCK to be either unstable and diverging or extremely slow. The left side plot in figure 2 depicts these behaviors. The solid red line shows the divergence case. FPA requires an additional parameter (γ) setting for the stochastic approximation step size rule. Our experience is that setting right values for these parameters to get good performance can be tricky and highly dataset dependent. The right side plot in figure 2 shows the extremely slow convergence behavior of FPA; its objective function also shows a non-monotone behavior. Therefore, we do not include GROCK and FPA further in our study.

For HYDRA we tuned L_j as follows. We set the first value of L_j to the theoretical default value proposed in Richtárik and Takáč (2016) and decreased it by a factor of $\beta = 2$ each time to create five values for L_j. Then we ran 25 iterations of HYDRA for each of those five values to chose the best value for L_j and then used that value for all remaining iterations. We found that this simple procedure was sufficient to arrive at a near-best single value for L_j. Unlike ADMM, the cost of this tuning step is negligible compared to the overall cost. Richtárik, and Takáč (Richtárik and Takáč, 2016) also showed results with the asynchronous implementation. For fair comparison with other synchronous approaches, we show results with the synchronous implementation only. Extending our work to the asynchronous setting and comparing with the asynchronous variants of other algorithms is an interesting future work.

16. These initial "tuning" iterations are not counted against the limit of 800 we set for the number of iterations. Thus, for ADMM, the total number of iterations can go higher than 800.

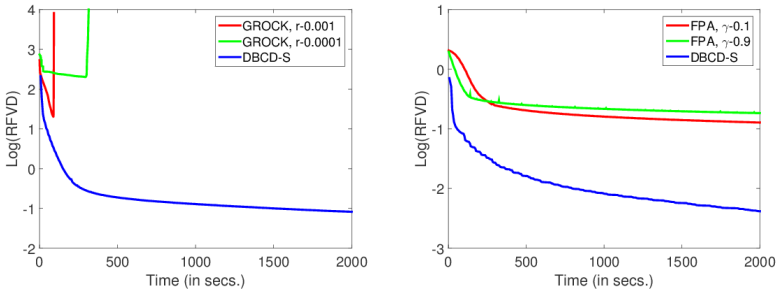

Figure 2: Left: Divergence and slow convergence of GROCK on the URL dataset ($\lambda = 2.4 \times 10^{-6}$ and $P = 25$). Right: Extremely slow convergence of FPA on the KDD dataset ($\lambda = 4.6 \times 10^{-7}$ and $P = 100$).

6.3 Performance Evaluation

We begin by comparing the efficiency of various methods and demonstrating the superiority of the new methods that were developed in section 4 and motivated in section 5. After this we analyze and explain the reasons for the superiority.

Study on AUPRC and RFVD: We have compared the performance of all methods by studying the variation of AUPRC and RFVD as a function of time, for various choices of λ, r (note that r defines the working set size, WSS=rm/P) and the number of nodes (P). To avoid cluttering with too many plots, we provide only representative ones - for each dataset, we choose one value for λ and two values each, for r and P.

Figures 3-6 show the RFVD versus time plots for the four datasets; note the use of log scale for RFVD in those plots. Figures 7-10 show the AUPRC versus time plots. The following observations can be made from these plots.

Superior performance of DBCD-S. In most cases DBCD-S is the best performer. In several of these cases, DBCD-S beats other methods very clearly; for example, on URL with $P = 100$ and $r = 0.01$ (see the bottom left plot of figure 4), the time needed to reach log RFVD=-0.5 is many times smaller than any other method. As another example, with KDD and $r = 0.01$ (see the left side plots in figure 3), if we set the log RFVD value to -2 as the stopping criterion, DBCD-S and PCD-S are faster than all other methods by an order of magnitude. Even in cases where DBCD-S is not the best (e.g., the case in the bottom left plot of figure 5), DBCD-S performs quite close to the best method.

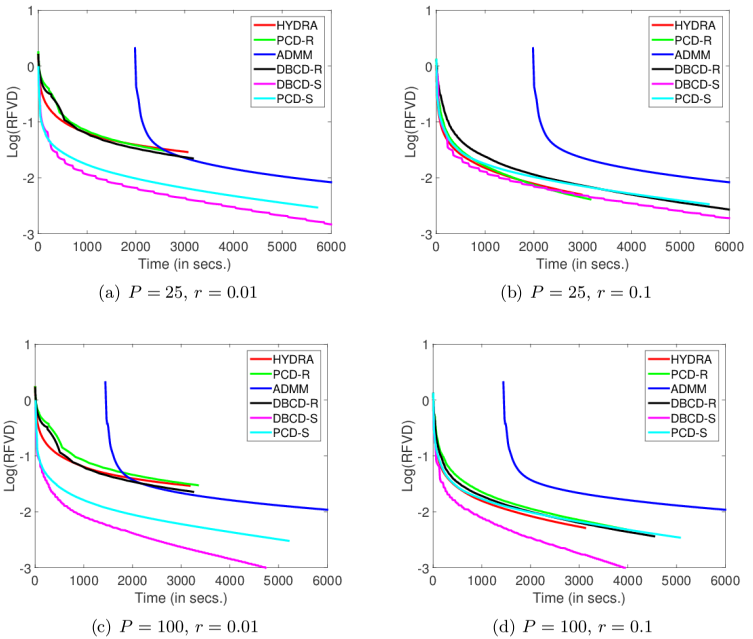
How good is PCD-S? Recall from subsection 4.5 that PCD-S is the variation of the PCDN method Bian et al. (2013) using the S-scheme for variable selection. In some cases such as the last one pointed out in the previous paragraph, PCD-S gives an excellent performance. However, in many other cases, PCD-S does not perform well. This shows that working with quadratic approximations (like PCD-S does) can be quite inferior compared to using the actual nonlinear objective like DBCD-S does.

S-scheme versus R-scheme. In general, the S-scheme of selecting variables (namely, DBCD-S and PCD-S) performs much better than the R-scheme (namely, DBCD-R and

PCD-R), Only on WEBSPAM, PCD-R does slightly better than PCD-S in some cases. One possible reason for this is that WEBSPAM has a small number of examples, causing the communication cost to be much lower than the computation cost; note that the S-scheme requires more computation than the R-scheme.

Effect of r. The choice of r has an effect on the speed of various methods. But the sensitivity is not great. For DBCD-S, a reasonable choice is $r = 0.1$.

Performance of HYDRA. Though HYDRA has a good rate of descent in the objective function during the very early stages, it becomes quite slow soon after, leading to inferior performance. This shows up clearly even in the AUPRC plots.



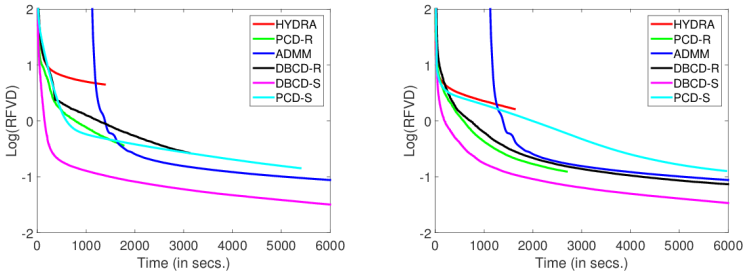
Performance of ADMM. First note that ADMM is independent of r since all the variables are updated. ADMM has a late start due to the time needed for tuning the augmented lagrangian parameter, ρ. (In some cases - see the top two plots in figure 6 - the ADMM curves are not even visible due to the initial tuning cost being relatively large.) Unfortunately, this tuning step is unavoidable; without it, ADMM's performance will be adversely affected. In many cases, DBCD-S reaches excellent solution accuracies even before ADMM begins making any progress.

Consistency between RFVD and AUPRC plots. On KDD, URL and ADS datasets there is good consistency between the two sets of plots. For example, the clear superiority of DBCD-S seen in the top left RFVD plot of figure 4 is also seen in the top left AUPRC plot of figure 8. Only on WEBSPAM (see figure 6 and figure 10) the two sets of plots have some inconsistency; in particular, note that, in figure 6, the initial decrease of the objective function is faster for HYDRA than DBCD-S, while, in figure 10, DBCD-S shows better initial increase in AUPRC than HYDRA. This happens because DBCD-S makes many more variables non-zero and touches many more examples than HYDRA in the initial steps.

Overall, the results point to the choice of DBCD-S as the preferred method as it is highly effective with an order of magnitude improvement over existing methods in many cases. Let us now analyze the reason behind the superior performance of DBCD-S. It is very much along the motivational ideas laid out in section 5: since communication cost dominates computation cost in each outer iteration, DBCD-S reduces overall time by decreasing the number of outer iterations.

Study on the number of outer iterations: We study T^P, the number of outer iterations needed to reach log RFVD$\leq \tau$. Table 6.3 gives T^P values for various methods in various settings. DBCD-S clearly outperforms other methods in terms of having much smaller values for T^P. PCD-S is the second best method, followed by ADMM. The solid reduction of T^P by DBCD-S validates the design that was motivated in section 5. The increased computation associated with DBCD-S is immaterial; because communication cost overshadows computation cost in each iteration for all methods, DBCD-S is also the best in terms of the overall computing time. The next set of results gives the details.

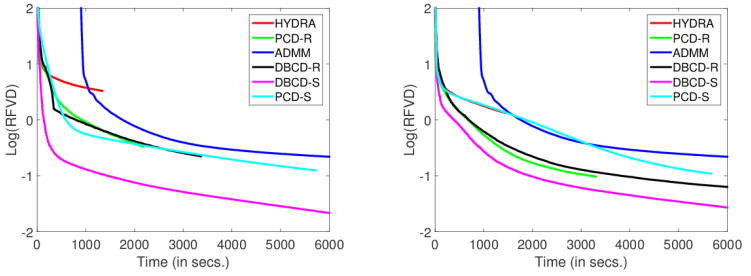
Computation and Communication Time: As emphasized earlier, communication plays an important role in the distributed setting. To study this effect, we measured the computation and communication time separately at each node. Figure 11 shows the computation time per node on the *KDD* dataset. In both cases, ADMM incurs significant computation time compared to other methods. This is because it optimizes over all variables in each node. DBCD-S and DBCD-R come next because our method involves both line search



(a) $P = 25$, $r = 0.01$ (b) $P = 25$, $r = 0.1$

(c) $P = 100$, $r = 0.01$ (d) $P = 100$, $r = 0.1$

Figure 3: KDD dataset. Relative function value difference in log scale. $\lambda = 4.6 \times 10^{-7}$



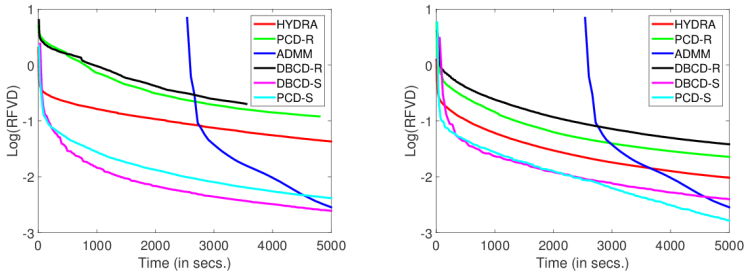
and 10 inner iterations. PCD-R and PCD-S take a little more time than HYDRA because of the line search. As seen in both DBCD and PCD cases, a marginal increase in time is incurred due to the variable selection cost with the S-scheme compared to the R-scheme.

We measured the computation and communication time taken per iteration by each method for different P and r settings. From table 6.3 (which gives representative results for one situation, KDD and $P = 25$), we see that the communication time dominates the cost in HYDRA and PCD-R. DBCD-R takes more computation time than PCD-R and HYDRA since we run through 10 cycles of inner optimization. Note that the methods with S-scheme take more time; however, the increase is not significant compared to the communication cost. DBCD-S takes the maximum computation time and is quite comparable to the communication time. Recall our earlier observation of DBCD-S giving order of magnitude speed-up in the overall time compared to methods such as HYDRA and PCD-R (see figures 3-10). Though the computation times taken by HYDRA, PCD-R and PCD-S are lesser, they need significantly more number of iterations to reach some specified objective function optimality criterion. As a result, these methods become quite inefficient due to extremely large communication cost compared to DBCD. All these observations point to the fact our DBCD method nicely trades-off the computation versus communication cost,

(a) $P = 25$, $r = 0.01$

(b) $P = 25$, $r = 0.1$

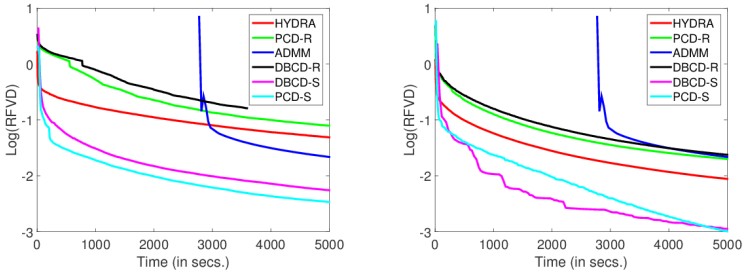
(c) $P = 100$, $r = 0.01$



(d) $P = 100$, $r = 0.1$

Figure 4: URL dataset. Relative function value difference in log scale. $\lambda = 9.0 \times 10^{-8}$

and gives an excellent order of magnitude improvement in overall time. With the additional benefit provided by the S-scheme, DBCD-S clearly turns out to be the method of choice for the distributed setting.



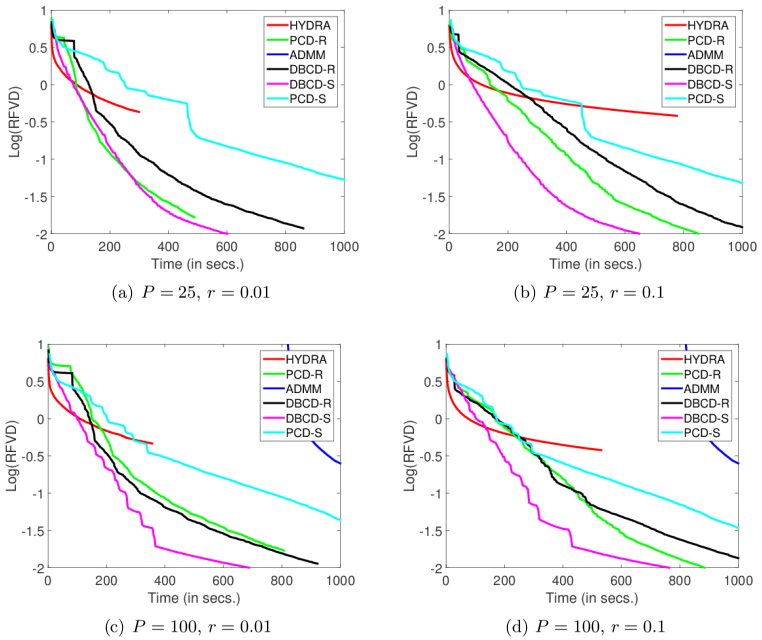
The methods considered in this paper are all synchronous methods. Also, as l_1-regularization gives sparse solutions, load balancing can be prominent and lead to the "curse of last reducer" issue. The increase in waiting time (in our measurement, waiting time is counted as a part of the communication time) is higher for methods that involve greater computation; this is clear from table 6.3 where, roughly, communication time per iteration is higher for methods with higher computation time per iteration. In spite of this, our DBCD-S method, which has the largest computation and communication times per iteration, wins because of the drastically reduced number of iterations compared to other methods.

Sparsity Pattern: To study variable sparsity behaviors of various methods during optimization, we computed the percentage of non-zero variables (ρ) as a function of outer iterations. We set the initial values of the variables to zero. Figure 12 shows similar behaviors for all the random (variable) selection methods. After a few iterations of rise they fall exponentially and remain at the same level. For methods with the S-scheme, many variables remain non-zero for some initial period of time and then ρ falls a lot more sharply.

(a) $P = 100$, $r = 0.01$

(b) $P = 100$, $r = 0.1$

(c) $P = 200$, $r = 0.01$



(d) $P = 200$, $r = 0.1$

Figure 5: ADS dataset. Relative function value difference in log scale. $\lambda = 2.65 \times 10^{-6}$.

It is interesting to note that such an initial behavior seems necessary to make good progress in terms of both function value and AUPRC. In all the cases, many variables stay at zero after initial iterations; therefore, shrinking ideas (i.e., do not consider for selection those variables that tend to remain at zero) can be used to improve efficiency.

Remark on Speed up: Let us consider the RFVD plots corresponding to DBCD-S in figures 3 and 4. It can be observed that the times associated with $P = 25$ and $P = 100$ for reaching a certain tolerance, say log RFVD=-2, are close to each other. This means that using 100 nodes gives almost no speed up over 25 nodes, which may prompt the question: *Is a distributed solution really necessary?* There are two answers to this question. First, as we already mentioned, when the training data is huge[17] and so *the data is generated and forced to reside in distributed nodes*, the right question to ask is not whether we get great speed up, but to ask which method is the fastest. Second, for a given dataset, if the time taken to reach a certain optimality tolerance is plotted as a function of P, it may have a minimum at a value different from $P = 1$. In such a case, it is appropriate to choose a P (as well as r) optimally to minimize training time. Many applications involve

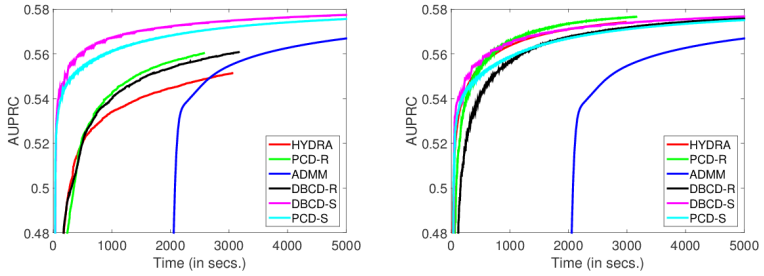
17. The KDD and URL datasets are really not huge in the *Big data* sense. In this paper we used them only because of lack of availability of much bigger public datasets.

(a) $P = 25$, $r = 0.01$ (b) $P = 25$, $r = 0.1$

(c) $P = 100$, $r = 0.01$ (d) $P = 100$, $r = 0.1$

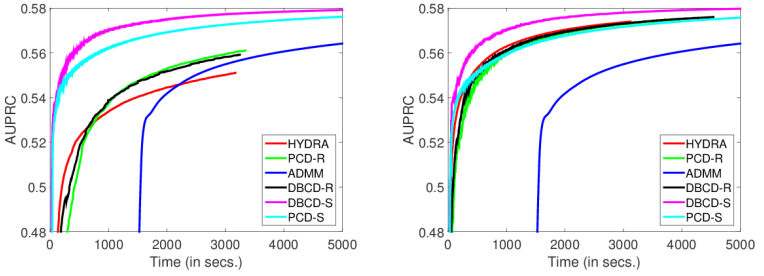
Figure 6: WEBSPAM dataset. Relative function value difference in log scale. $\lambda = 3.92 \times 10^{-5}$

periodically repeated model training. For example, in Advertising, logistic regression based click probability models are retrained on a daily basis on incrementally varying datasets. In such scenarios it is worthwhile to spend time to tune parameters such as P and r in an early deployment phase to minimize time, and then use these parameter values for future runs.



It is also important to point out that the above discussion is relevant to distributed settings in which communication causes a bottleneck. If communication cost is not heavy, e.g., when the number of examples is not large and/or communication is inexpensive such as in multicore solution, then good speed ups are possible; see, for example, the results in Richtárik and Takáč (2015).

7. Recommended DBCD algorithm



In section 4 we explored various options for the steps of Algorithm 1 looking beyond those considered by existing methods and proposing new ones, and empirically analyzing the various resulting methods in section 6. The experiments clearly show that DBCD-S is the best method. We collect full implementation details of this method in Algorithm 2.

Algorithm 2: Recommended DBCD algorithm

Parameters: Proximal constant $\mu > 0$ (Default: $\mu = 10^{-12}$);
WSS = # variables to choose for updating per node (Default: WSS=$r\,m/P$, $r = 0.1$);
k = # CD iterations to use for solving (3) (Default: $k = 10$);
Line search constants: $\beta, \sigma \in (0, 1)$ (Default: $\beta = 0.5$, $\sigma = 0.01$);
Choose w^0 and compute $y^0 = Xw^0$;
for $t = 0, 1 \ldots$ **do**
  for $p = 1, \ldots, P$ *(in parallel)* **do**
    (a) For each $j \in B_p$, solve (5) to get q_j. Sort $\{q_j : j \in B_p\}$ and choose WSS indices with least q_j values to form S_p^t;
    (b) Form $f_p^t(w_{B_p})$ using (6) and solve (3) using k CD iterations to get $\bar{w}_{B_p}^t$ and set direction: $d_{B_p}^t = \bar{w}_{B_p}^t - w_{B_p}^t$;
    (c) Compute $\delta y^t = \sum_p X_{B_p} d_{B_p}^t$ using AllReduce;
    (d) $\alpha = 1$;
    while *(12-13) are not satisfied* **do**
      $\alpha \leftarrow \alpha\beta$;
      Check (12)-(13) using $y + \alpha\,\delta y$ and aggregating the l_1 regularization value via AllReduce;
    end e
    Set $\alpha^t = \alpha$, $w_{B_p}^{t+1} = w_{B_p}^t + \alpha^t d_{B_p}^t$ and $y^{t+1} = y^t + \alpha^t\,\delta y^t$;
  end f
  Terminate if the optimality conditions (2) hold to the desired approximate level;
end

(a) $P = 25$, $r = 0.01$ (b) $P = 25$, $r = 0.1$

(c) $P = 100$, $r = 0.01$ (d) $P = 100$, $r = 0.1$

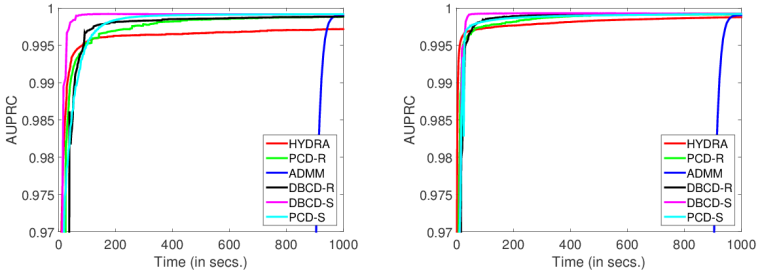
8. Conclusion



In this paper we have proposed a class of efficient block coordinate methods for the distributed training of l_1 regularized linear classifiers. In particular, the proximal-Jacobi approximation together with a distributed greedy scheme for variable selection came out as a strong performer. There are several useful directions for the future. It would be useful to explore other approximations such as block GLMNET and block L-BFGS suggested in subsection 4.2. Like Richtárik and Takáč (2015), developing a complexity theory for our method that sheds insight on the effect of various parameters (e.g., P) on the number of iterations to reach a specified optimality tolerance is worthwhile. It is possible to extend our method to non-convex problems, e.g., deep net training, which has great value.

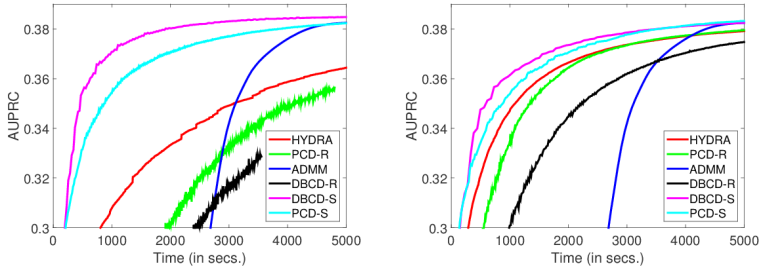
Proof of Theorem 1

First let us write δ_j in (11) as $\delta_j = E_{jj} d_j^t$ where $E_{jj} = \delta_j / (d_{B_p}^t)^j$. Note that $|E_{jj}| \leq \mu/2$. Use the condition (14) in Condition 2 with $w_{B_p} = \bar{w}_{B_p}^t$ and $\hat{w}_{B_p} = w_{B_p}$ in (11) together

(a) $P = 25$, $r = 0.01$ (b) $P = 25$, $r = 0.1$

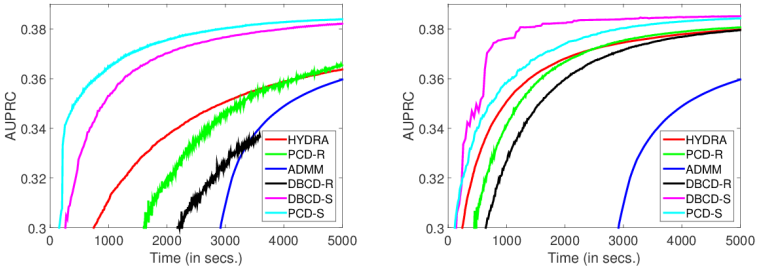
(c) $P = 100$, $r = 0.01$ (d) $P = 100$, $r = 0.1$

Figure 8: URL dataset. AUPRC plots. $\lambda = 9.0 \times 10^{-8}$



with the gradient consistency property of Condition 1 to get

$$g_{S_p^t}^t + H_{S_p^t}^t d_{S_p^t}^t + \xi_{S_p^t} = 0, \tag{15}$$



where $H_{S_p^t}^t = \hat{H}_{S_p^t} - E_{S_p^t}$ and $\hat{H}_{S_p^t}$ is the diagonal submatrix of $\hat{H}$ corresponding to S_p^t. Since $\hat{H} \geq \mu I$ and $|E_{jj}| \leq \mu/2$, we get $H_{S_p^t}^t \geq \frac{\mu}{2} I$. Let us extend the diagonal matrix $E_{S_p^t}^t$ to E_{B_p} by defining $E_{jj} = 0 \, \forall j \in B_p \setminus S_p^t$. This lets us extend $H_{S_p^t}^t$ to H_{B_p} via $H_{B_p}^t = \hat{H}_{B_p} - E_{B_p}$.

Now (15) is the optimality condition for the quadratic minimization,

$$d_{B_p}^t = \arg\min_{d_{B_p}} \; (g_{B_p}^t)^T d_{B_p} + \frac{1}{2} (d_{B_p})^T H_{B_p} d_{B_p} + \sum_{j \in B_p} \lambda \, |w_j^t + d_j| \;\; \text{s.t.} \;\; d_j = 0 \; \forall \, j \in B_p \setminus S_p^t \tag{16}$$

(a) $P = 100$, $r = 0.01$ (b) $P = 100$, $r = 0.1$

(c) $P = 200$, $r = 0.01$ (d) $P = 200$, $r = 0.1$

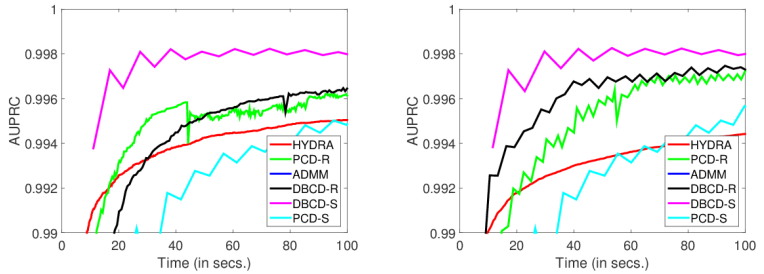


Figure 9: ADS dataset. AUPRC Plots. $\lambda = 2.65 \times 10^{-6}$

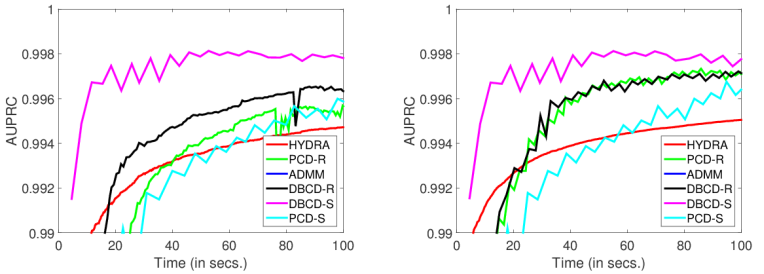
Combined over all p,



$$d^t = \arg\min_d \ (g^t)^T d + \frac{1}{2} d^T H d + u(w^t + d)$$
$$\text{s.t. } d_j = 0 \ \forall \ j \in \cup_p (B_p \setminus S_p^t) \tag{17}$$

where H is a block diagonal matrix with blocks, $\{H_{B_p}\}$. Thus d^t corresponds to the minimization of a positive definite quadratic form, exactly the type covered by the Tseng-Yun theory (Tseng and Yun, 2009).

The line search condition (12)-(13) is a special case of the line search condition in Tseng and Yun (2009). The Gauss-Seidel scheme of subsection 4.1 is an instance of the Gauss-Seidel scheme of Tseng and Yun (2009). Now consider the distributed greedy scheme in subsection 4.1. Let $j_{\max} = \arg\max_{1 \le j \le m} \bar{q}_j$. By the way the S_p^t are chosen, $j_{\max} \in \cup_p S_p^t$. Therefore, $\sum_{j \in \cup_p S_p^t} \bar{q}_j \le \frac{1}{m} \sum_{j=1}^m \bar{q}_j$, thus satisfying the Gauss-Southwell-q rule condition of Tseng and Yun (2009). Now Theorems 1-4 of Tseng and Yun (2009) can be directly applied to prove our Theorem 1. Note that Theorem 4 of Tseng and Yun (2009) ensures that Assumption 2(a) of that paper holds; Assumption 2(b) of that paper trivially holds because, in our case F is convex.

(a) $P = 25$, $r = 0.01$ (b) $P = 25$, $r = 0.1$

(c) $P = 100$, $r = 0.01$ (d) $P = 100$, $r = 0.1$

Figure 10: WEBSPAM dataset. AUPRC Plots. $\lambda = 3.92 \times 10^{-5}$. Because the initial ρ tuning time for ADMM is large, its curves are not seen in the shown time window of 0-100 secs.

Table 5: T^P, the number of outer iterations needed to reach log RFVD$\leq \tau$, for various P and τ values. We set $r = 0.01$. Best values are indicated in boldface. For each dataset, the τ values were chosen to cover the region where AUPRC values are in the process of reaching the steady state value. The methods were terminated when the number of iterations exceeded a maximum; this maximum was set differently for different datasets.

Abstract

We study distributed learning with the least squares regularization scheme in a reproducing kernel Hilbert space (RKHS). By a divide-and-conquer approach, the algorithm partitions a data set into disjoint data subsets, applies the least squares regularization scheme to each data subset to produce an output function, and then takes an average of the individual output functions as a final global estimator or predictor. We show with error bounds and learning rates in expectation in both the L^2-metric and RKHS-metric that the global output function of this distributed learning is a good approximation to the algorithm processing the whole data in one single machine. Our derived learning rates in expectation are optimal and stated in a general setting without any eigenfunction assumption. The analysis is achieved by a novel second order decomposition of operator differences in our integral operator approach. Even for the classical least squares regularization scheme in the RKHS associated with a general kernel, we give the best learning rate in expectation in the literature.

Keywords: Distributed learning, divide-and-conquer, error analysis, integral operator, second order decomposition.

1. Introduction and Distributed Learning Algorithms
