The first step is to augment the parameter space with a set of slice variables. Given the feature allocation matrices Z_t at times $t = t_0, \dots, t_T$, draw a slice variable $S_t \sim \text{Uniform}[0, x^{min}(Z_t)]$ for each time t, where $x^{min}(Z_t)$ is the minimum among the probabilities of the features seen in the feature matrix Z_t. In this way, when conditioning on the value s_t of the slice variable, we have a truncation level s_t and only need to sample the finite number of features whose probability is above this threshold (Teh et al., 2007). In other words, for all $t = t_0, \dots, t_T$, we only need to update the columns of Z_t whose corresponding feature probability $x_k(t)$ is greater than or equal to the slice variable s_t (note that these include both seen and currently unseen features). Observe that we defined a different slice variable for each time point, while an alternative choice could have been drawing a single slice from a uniform between 0 and the minimum feature probability across all times. Having multiple slice variables makes it possible to simulate fewer feature trajectories while keeping inference exact, reducing the computational cost of simulating features with small probabilities of being active. Although this comes at the cost of a larger number of parameters, in experiments we find that having multiple slices does not compromise mixing nor predictive performance.

Accounting for the slice variables, the full conditional probability of the entry Z_{ikt} being active is directly proportional to

$$P(Z_{ikt} = 1 \mid Z_{-(ik)t}, X_k(t), D_{it}, \rho) P(S_t \mid Z_{ikt} = 1, Z_{-(ik)t}) \propto$$
$$x_k(t) P(D_{it} \mid Z_{i-kt}, Z_{ikt} = 1, \rho) \frac{1[0 \le s_t \le x^{min}(Z_{-(ik)t}, Z_{ikt} = 1)]}{x^{min}(Z_{-(ik)t}, Z_{ikt} = 1)}, \tag{9}$$

while the full conditional probability of the entry Z_{ikt} being inactive is directly proportional to

$$P(Z_{ikt} = 0 \mid Z_{-(ik)t}, X_k(t), D_{it}, \rho) P(S_t \mid Z_{ikt} = 0, Z_{-(ik)t}) \propto$$
$$(1 - x_k(t)) P(D_{it} \mid Z_{i-kt}, Z_{ikt} = 0, \rho) \frac{1[0 \le s_t \le x^{min}(Z_{-(ik)t}, Z_{ikt} = 0)]}{x^{min}(Z_{-(ik)t}, Z_{ikt} = 0)}. \tag{10}$$

The term $P(S_t \mid Z_t)$ is not constant as updating Z_{ikt} for a currently unseen feature may modify the value of the minimum probability of the active features.

5.2 Particle Gibbs and thinning

Assume that the feature allocation matrices Z_t are given at the time points $t = t_0, \dots, t_T$ and we are interested in inferring the probabilities X of the underlying features. This section gives the details of inference for each of the following subpartitions of seen and unseen features: features seen for the first time at a given time t_j (for $j = 0, \dots, T$), unseen features alive at time t_0 and unseen features born between any two consecutive times t_j and t_{j+1} (for $j = 0, \dots, T-1$).

5.2.1 Seen features

As already mentioned, we can apply PG to sample from the posterior trajectories of the seen features. In particular, for features that are seen at time t_0 we can simply apply Algorithm 1 as in the fixed-K approximation by replacing the term $\frac{\alpha\beta}{K}$ with 0. This is possible as observing a feature allocation matrix Z_t updates the prior probability of features as in the posterior beta process (Thibaux and Jordan, 2007), meaning that we can draw each seen feature k from a Beta$(n_{kt},\, \beta + N_t - n_{kt})$ (recall that n_{kt} is the number of objects in which feature k is active at time t).

More generally, consider features that are seen for the first time at a given time t_j. As they cannot be identified individually based on any feature matrix Z_{t_k} for $k < j$, these features need to be drawn from the posterior beta process at time t_j and propagated both forward and backwards. Note that simulating from the W-F diffusion backwards in time is not a problem as each W-F$(0, \beta)$ diffusion is time-reversible with respect to the speed density of the PRF (Griffiths, 2003). The additional backward propagation requires adjusting Algorithm 1, already modified by replacing $\frac{\alpha\beta}{K}$ with 0, by further replacing the steps before the while loop with Algorithm 2, where for simplicity we describe the particular case of features seen for the first time at time t_1. This description can be easily generalized to features that are seen for the first time at a generic time point $t \in \{t_0, \dots, t_T\}$.

5.2.2 Unseen features

We now describe a thinning scheme to simulate the unseen features alive at time t_0. Denote the slice variable values at each time by $s_{t_0}, \dots, s_{t_T}$ and note that sampling the set of unseen features from the truncated posterior beta process at time t means drawing samples from a Poisson process on $[s_t, 1)$ with rate measure $x^{-1}(1-x)^{\beta+N_t-1}dx$ (Thibaux and Jordan, 2007), which yields only a finite number of features whose probability is larger than s_t. First, draw the unseen features from the truncated posterior beta process at time t_0. Then, propagate them forward to time t_1 according to the W-F diffusion and accept them with probability $(1-x(t_1))^{N(t_1)}$, namely the binomial likelihood of not seeing them in any object at time t_1. Finally, iterate this propagation and rejection steps up to time t_T. The details of this thinning scheme are given in Algorithm 3.

Notice that simulating the trajectories of the unseen features born between time t_0 and t_1 is equivalent to Algorithm 3 from time t_1 onwards. The only difference is that these features, drawn at time t_1, need to be simulated backwards to time t_0 as well, hence the

Algorithm 2: PG: features seen for the first time at time t_1.

Input: Reference trajectory $x^r_{t_0:t_T}$; M.
Set $x^M_{t_1} = x^r_{t_1}$;
Draw $x^i_{t_1} \sim \text{Beta}(n_{t_1},\, \beta + N_{t_1} - n_{t_1})$ for $i = 1, \dots, M-1$;
Set $x^M_{t_0} = x^r_{t_0}$;
Simulate $x^i_t | x^i_{t_1} \sim \text{WF}(0, \beta)$ backwards for $t \in [t_1, t_0]$ for $i = 1, \dots, M-1$;
Set $x^M_{t_2} = x^r_{t_2}$;
Simulate $x^i_t | x^i_{t_1} \sim \text{WF}(0, \beta)$ for $t \in [t_1, t_2]$ for $i = 1, \dots, M-1$;
Compute $w^i_{t_0} = (1 - x^i_{t_0})^{N_{t_0}}$ for $i = 1, \dots, M$;
Compute $w^i_{t_2} = (x^i_{t_2})^{n_{t_2}} (1 - x^i_{t_2})^{N_{t_2} - n_{t_2}} w^i_{t_0}$ for $i = 1, \dots, M$;
Draw $\bar{x}^i_{t_2}$ with $P(\bar{x}^i_{t_2} = x^i_{t_2}) \propto w^i_{t_2}$ for $i = 1, \dots, M-1$;
Set $\bar{x}^M_{t_2} = x^r_{t_2}$;
Simulate $x^i_t | x^i_{t_2} \sim \text{WF}(0, \beta)$ for $t \in [t_2, t_3]$ for $i = 1, \dots, M-1$;
Set $j \leftarrow 3$;

Algorithm 3: Thinning: unseen features alive at time t_0

Draw from a Poisson process on $[s_{t_0}, 1)$ with rate measure $\alpha x^{-1}(1-x)^{\beta+N_{t_0}-1}dx$ and denote by $\{x^i_{t_0}\}_{i \in A}$ the resulting candidate particles;
Set $j \leftarrow 1$;
while $t_j < t_T$ **do**
  Simulate $x^i_l | x^i_{t_j} \sim \text{WF}(0, \beta)$ for $t \in [t_j, t_{j+1}]$ for all $i \in A$;
  Accept $x^i_{t_{j+1}}$ with probability $(1 - x^i_{t_{j+1}})^{N_{t_{j+1}}}$ for all $i \in A$;
  Remove from A the indices of the rejected particles;
  Set $j \leftarrow j + 1$;
end
Output: Trajectories $\{x^i_{t_0:t_T}\}_{i \in A}$ of the unseen features alive at time t_0 from the truncated PRF(α, β).

Algorithm 4: Thinning: unseen features born between time t_0 and t_1

Draw from a Poisson process on $[s_{t_1}, 1)$ with rate measure $\alpha x^{-1}(1-x)^{\beta+N_{t_1}-1}dx$ and denote by $\{x^i_{t_1}\}_{i\in A}$ the resulting candidate particles;
Simulate $x^i_t | x^i_{t_0} \sim \mathrm{WF}(0,\beta)$ for $t \in [t_0, t_1]$ for all $i \in A$;
for *all* $i \in A$ **do**
  if $x^i_{t_0} > s_{t_0}$ **then**
    Reject $x^i_{t_0}$;
    Set $A \leftarrow A \setminus \{i\}$;
  else
    Accept $x^i_{t_0}$ with probability $(1 - x^i_{t_0})^{N_{t_0}}$;
  end
end
Set $j \leftarrow 1$;
while $t_j < t_T$ **do**
  Simulate $x^i_t | x^i_{t_j} \sim \mathrm{WF}(0,\beta)$ for $t \in [t_j, t_{j+1}]$ for all $i \in A$;
  Accept $x^i_{t_{j+1}}$ with probability $(1 - x^i_{t_{j+1}})^{N_{t_{j+1}}}$ for all $i \in A$;
  Remove from A the indices of the rejected particles;
  Set $j \leftarrow j + 1$;
end
Output: Trajectories $\{x^i_{t_0:t_T}\}_{i\in A}$ of the unseen features born between time t_0 and t_1 from the truncated $\mathrm{PRF}(\alpha, \beta)$.

additional backward simulation followed by the rejection step in the for loop of Algorithm 4. If a feature that is simulated backwards from time t_1 to t_0 has probability 0 by time t_0, then it is a newborn feature and is accepted with probability 1. On the other hand, if its probability at time t_0 is between 0 and s_{t_0}, the particle belongs to the category of features that were alive and unseen at time t_0. Accepting them with probability $(1 - x(t_0))^{N_{t_0}}$ compensates for the features that were below the truncation level s_{t_0} in Algorithm 3 and were thus not simulated at time t_0. In this way, only the features whose mass is below the slice variables s_t at all times $t \in \{t_0, \ldots, t_T\}$ are not simulated. The exactness of the overall MCMC scheme is preserved by the fact that those features are inactive in all the feature allocation matrices by the definition of slice variable.

Finally note that, for simplicity's sake, Algorithm 4 describes only how to simulate the unseen features that were born between times t_0 and t_1, but the procedure needs to be generalized to account for the features born between any two consecutive time points t_j and t_{j+1}, where $j = 0, \ldots, T-1$. In order to do this, it is sufficient to draw the candidate particles at every time t_{j+1}, with $j = 0, \ldots, T-1$, propagate them backwards until time t_0 and thin them as follows: if their mass exceeds s_t at any $t \in \{t_0, \ldots, t_T\}$, then they are rejected; otherwise, at each backward propagation to time $t \in \{t_0, \ldots, t_{T-1}\}$ they are accepted with probability $(1 - x(t))^{N_t}$.

6. Application: linear-Gaussian likelihood model

The WF-IBP we have described defines a prior over latent feature allocation matrices Z and the corresponding feature probabilities X exhibiting a dependency structure over time. The next step is to relate Z to the observed data by means of a given likelihood model. The first model we explore is the linear-Gaussian likelihood, a very common choice in latent feature models (e.g., Doshi-Velez and Ghahramani, 2009; Griffiths and Ghahramani, 2011; Gershman et al., 2015).

Assume that the collection of observations O_t at time $t = t_0, \ldots, t_T$ is in the form of an $N \times D$ matrix generated by the matrix product $O_t = Z_t \times A + \epsilon_t$. Z_t is the $N \times K$ binary matrix of feature assignments at time t and A is a $K \times D$ factor matrix whose rows represent the feature parameters ρ. The matrix product is the way Z_t determines which features are active in each observation, and ϵ_t is a $N \times D$ Gaussian noise matrix, whose entries are assumed to be distributed as independent $\mathcal{N}(0, \sigma^2_X)$. A typical inference problem is to infer both the feature allocation matrices Z and the factor matrix A. In order to achieve this, we place on each element of A an independent prior $\mathcal{N}(0, \sigma^2_A)$ and on the hyper-parameter σ^2_A an inverse-gamma prior $\Gamma^{-1}(1,1)$. This choice of priors is convenient as it is easy to obtain the posterior distributions of σ^2_A and A (for the case $T = 1$, see Doshi-Velez and Ghahramani, 2009).

For simplicity of notation, consider a fixed number of features K. Denote by $\bar{Z}$ the $TN \times K$ matrix obtained by concatenating the feature matrices Z vertically, and by $\bar{O}$ the $TN \times D$ matrix obtained by combining the observations $\{O_t\}_{t=t_0}^{t_T}$ in the same way. The posterior of A is matrix Gaussian with the following mean μ^A (a $K \times D$ matrix) and, for each column of A, the following covariance matrix Σ^A (a $K \times K$ matrix).

$$\mu^A = \left(\bar{Z}^T\bar{Z} + \frac{\sigma^2_X}{\sigma^2_A} I\right)^{-1} \bar{Z}^T\bar{O}$$
$$\Sigma^A = \sigma^2_X \left(\bar{Z}^T\bar{Z} + \frac{\sigma^2_X}{\sigma^2_A} I\right)^{-1}.$$

By conjugacy, the posterior distribution for σ^2_A is still inverse gamma with updated parameters, namely

$$\sigma^2_A \sim \Gamma^{-1}\left(1 + \frac{1}{2}KD, 1 + \frac{1}{2}\sum_k \sum_d A^2_{kd}\right).$$

6.1 Simulations and results

We tested the WF-IBP combined with a linear-Gaussian likelihood on a variety of synthetic data sets. Starting from the fixed-K approximation, we generated $N = 50$ observations at each of 40 equally-spaced time points as in the linear-Gaussian model. The true factor matrix A contained $K = 3$ latent features in the form of binary vectors of length $D = 30$. Their probability of being active was determined continuously over time by three independent W-F$(1,1)$ diffusions, simulated for 0.01 diffusion time-units between every two consecutive time points. The resulting observations were corrupted by a large amount of noise ($\sigma_X = 0.5$). 1000 iterations of the overall algorithm were performed, choosing a

burn-in period of 100 iterations and setting the time-units and drift parameters of the W-F diffusion equal to the true ones in the PG update. As ground truth was available, we were able to test the ability of the algorithm to recover the true feature allocation matrices, the latent feature parameters and their probabilities over time.

Figure 4-top-left compares the true underlying feature matrices at times $t = \{1, 14, 27, 40\}$ in terms of the most frequently active features in the posterior mean matrices, where a feature is set to be active if that is the case in more than half of the samples of the Markov chain. The resulting mean matrices almost perfectly match the true underlying feature matrices. Figure 4-top-right compares the trajectories over time of the true feature probabilities with the inferred ones. The latter tend to be less than two standard deviations away from the former, meaning that the true feature trajectories are closely tracked. Figure 4-bottom-left compares the three features represented by the true factor matrix A and the ones in the posterior mean matrix $\hat{A}$, showing that the algorithm was able to recover accurately the hidden features underlying the noisy observations. Figure 4-bottom-right plots the log-likelihood at each iteration, showing that the algorithm converged quickly, namely in fewer than 50 iterations.

Then, we tested the ability of the slice sampler-based algorithm to recover the correct number of latent features when given a similar set of synthetic data, this time consisting of 4 latent features evolving over 6 time points. The algorithm was initialized with one feature and run for 3300 iterations with a burn-in period of 1000 iterations. As in the finite case, the true underlying feature allocation matrices and feature probabilities were closely recovered as illustrated by the top row of Figure 5. The bottom row of Figure 5 shows that the features were reconstructed accurately and their correct number detected in about 700 iterations.

Finally, we focused on the ability of Particle Gibbs to track the feature trajectories in a wider variety of settings and under model misspecification. We generated a set of feature allocation matrices obtained by letting three feature probabilities evolve over time, first by simulating standard W-F diffusions and then by introducing jumps and spikes. Figure 6 confirms the robustness of the algorithm in the presence of mismatches between the W-F diffusion and the true process determining the feature trajectories. We simulated a set of 20 feature allocation matrices under an increasing amount of mismatch, first by introducing a jump of increasing size from time 10 to 11, and then by adding a spike of increasing sharpness at time 10. Figure 6-left shows that, although larger jump sizes lead to larger discrepancies between the true and inferred trajectories around the jump, the former are always less than two standard deviations away from the latter. Figure 6-right shows that in all three cases the algorithm is able to detect the presence of the spike at time 10. Figure 7 illustrates the performance of the algorithm on a decreasing number of observations. The results show that the posterior mean of the target distribution closely corresponds to the true feature probabilities and, given a sufficient number of observations, always fall within the interval given by two standard deviations about the posterior mean.

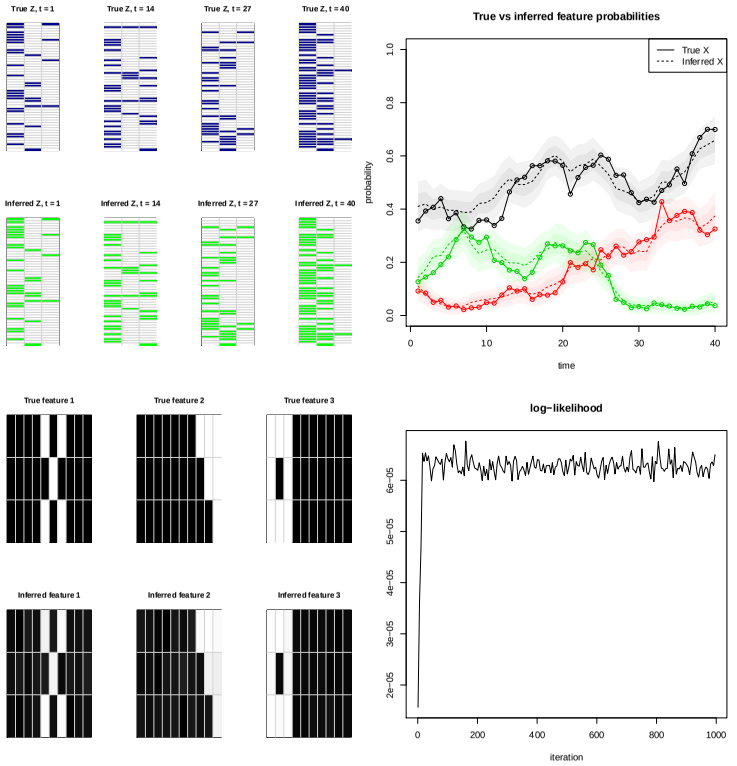

Figure 4: Fixed-K approximation. Top-Left: Subset of true feature allocation matrices vs inferred ones. Top-Right: True vs inferred feature probabilities over time (the dark and the light shaded areas respectively indicate one and two standard deviations about the posterior mean). Bottom-Left: True vs inferred features (black and white entries respectively correspond to 0 and 1, while the shades of grey to the values in between). Bottom-Right: Convergence of the log-likelihood of the observed data.

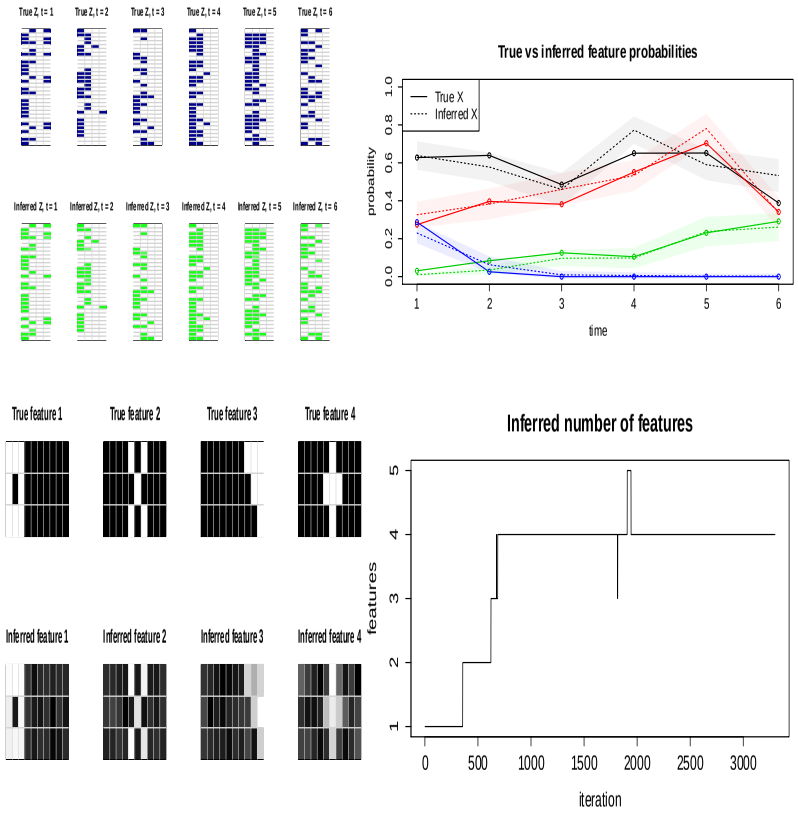

Figure 5: WF-IBP. Top-Left: True vs inferred feature allocation matrices. Top-Right: True vs posterior mean feature trajectories (the shaded areas represent one standard deviation). Bottom-Left: Comparison between true and inferred features. Bottom-Right: Convergence to the true number of features.

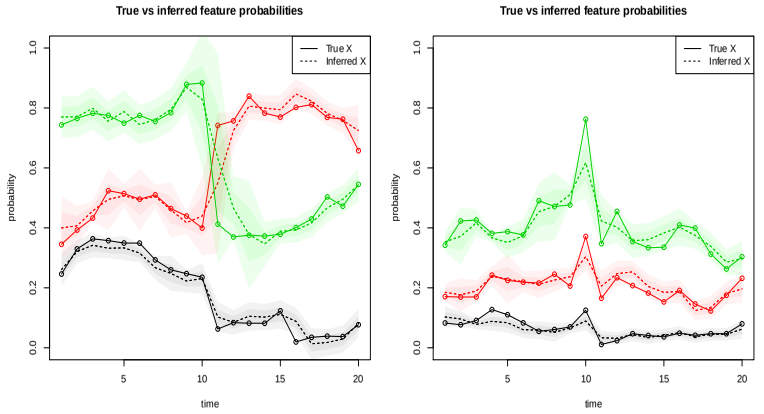

Figure 6: Comparison between the posterior means and the true feature probabilities under an increasing amount of model misspecification. The dark and light shaded areas respectively correspond to 1 and 2 standard deviations about the posterior mean. Left: Jump of increasing size between times 10 and 11. Right: Spike of increasing sharpness at time 10.

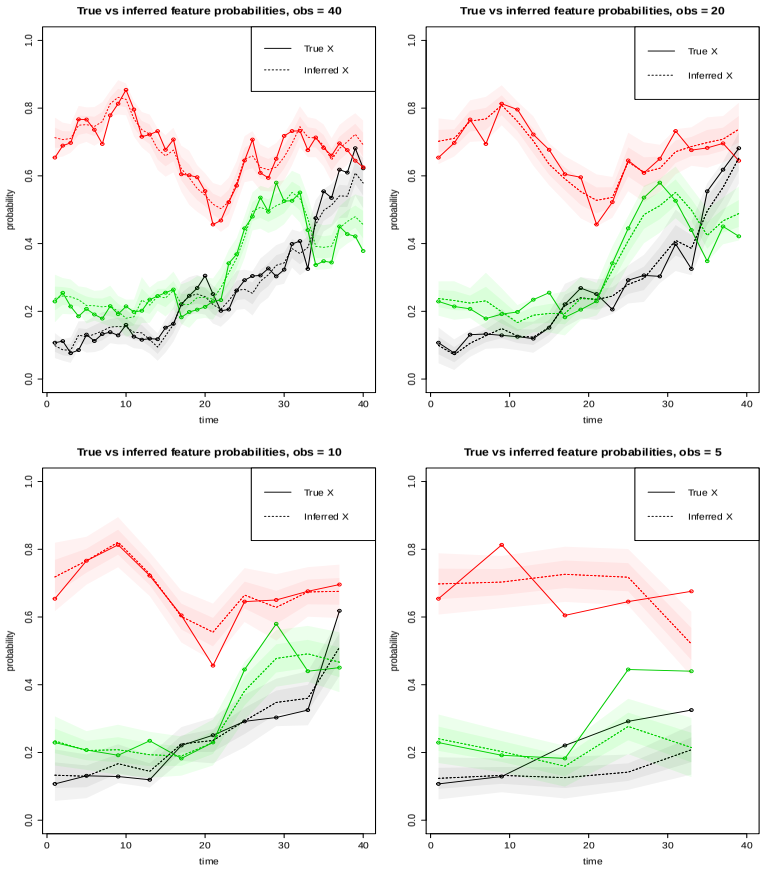

Figure 7: Comparison between true feature probabilities and posterior means obtained via Particle Gibbs for a varying number of observations. The dark and light shaded areas respectively correspond to 1 and 2 standard deviations about the posterior mean.

7. Topic modeling application

In this section we apply the WF-IBP to the modeling of corpora of time-stamped text documents. This is a natural application as documents can be seen as arising from an unknown number of latent topics whose popularity is evolving over time. A related model to achieve this goal is described in Blei and Lafferty (2006), where a Gaussian state space model captures the evolution of topics in such a way that both the content of topics and their proportions evolve over time. This work has had a great impact in the topic modeling community, and anticipates a number of directions for future work that we address here. Specifically their model is parametric, in that the number of topics K is fixed and needs to be pre-specified. The authors claim that it would desirable to drop this assumption to have a more flexible model and, in particular, foresee a process involving births and deaths of topics. The WF-IBP topic model elegantly achieves these goals. Unlike Blei and Lafferty (2006) we focus on the evolution of topic probabilities rather than topic contents, noting that the modeling of time-varying topic contents is orthogonal to our work and could be incorporated into the WF-IBP in future developments. Another class of models called Dirichlet processes aim at modeling the evolution of topics in a time-dependent and nonparametric way. Some of these models, however, assume the evolution of topic probabilities to be unimodal (e.g., Rao and Teh, 2009), while others are HDP-based (Ahmed and Xing, 2012; Dubey et al., 2013) and implicitly assume a positive correlation between the probability of a topic being active and the proportion of that topic within each document. Coupling topic proportions and topic probabilities is undesirable as rare topics may account for a large proportion of words in the few documents in which they appear. Our nonparametric topic model decouples the probability of a topic and its proportion within documents and offers a flexible way to model topic evolutions over time. We achieve this by incorporating time-dependency into the focused topic model presented in Williamson et al. (2010b), which makes use of the IBP to select the finite number of topics that each document treats.

7.1 The WF-IBP topic model

First consider the case in which the number of topics K underlying the corpus of seen documents is known. Define topics as probability distributions over a dictionary of D words and model them as $(\rho_k)_{k=1}^K \overset{iid}{\sim} \text{Dirichlet}(\bar{\eta})$, given a vector $\bar{\eta}$ of length D. Let ρ be the resulting vector and assume the components of $\bar{\eta}$ to be all equal to a constant $\eta > 0$. Consider the usual setting in which the time-dependent popularity of topic (feature) k is denoted by X_k and the binary variables Z_{ikt} indicate whether document i contains topic k at time t. Then, for all $t = t_0, \dots, t_T$ and $k = 1, \dots, K$, sample

$$\begin{aligned}
\theta_{it} \mid \{Z_{it} = z_{it}, \phi_t = \phi'_t\} &\sim \text{Dirichlet}(z_{it} \circ \phi'_t), \quad \forall i = 1, \dots, N_t, \\
\phi_{kt} &\sim \text{Gamma}(\gamma, 1), \\
(Z_{ikt})_{i=1}^{N_t} \mid \{X_k = x_k(t)\} &\overset{iid}{\sim} \text{Bernoulli}(x_k(t)), \\
X_k &\sim \text{WF}\left(\frac{\alpha\beta}{K}, \beta\right),
\end{aligned}$$

where ϕ_{kt} is the kth component of ϕ_t, a K-long vector of topic proportions, and θ_{it} the ith row of θ_t, a $N_t \times K$ matrix with the distributions over topics for each document at

time t. The operation $z_{it} \circ \phi_t$ stands for the Hadamard product between z_{it} and ϕ_t and the Dirichlet is defined over the positive components of the resulting vector. While the topic allocation matrix Z_t encodes which subset of the K topics appears in each document at time t, the variables ϕ_{kt} are related to the proportion of words that topic k explains within each document. Unlike HDP-based models, these two quantities are here modeled independently.

For every document $i = 1, \dots, N_t$, draw the total number of words from a negative-binomial $W_{it} \sim \text{NB}(\sum_k z_{ikt}\phi_{kt}, 1/2)$ and, for each word w_{ilt}, $l = 1, \dots, W_{it}$, sample first the topic assignment

$$a_{ilt} \mid \{\theta_{it} = \theta'_{it}\} \sim \text{Categorical}(\theta'_{it})$$

and then the word

$$w_{ilt} \mid \{a_{ilt} = a'_{ilt}, \rho = \rho'\} \sim \text{Categorical}(\rho'_{a'_{ilt}}).$$

Assume now that the number of potential topics K needs to be learned from the data. The nonparametric extension of this model is easily obtained by replacing the process generating the topic allocation matrices with the WF-IBP, so that topics arise as in the PRF and evolve as independent WF$(0, \beta)$. The feature allocation matrices can be drawn as described in Section 8. In this way, we obtain a time-dependent extension of the IBP compound Dirichlet process presented in Williamson et al. (2010b).

7.2 Posterior inference

In order to infer the latent variables of the model, it is convenient to integrate out the parameters ρ and θ. This can be done easily thanks to the conjugacy between the Dirichlet and the Categorical distribution. In this way, we can run a Gibbs sampler for posterior inference only over the remaining latent variables and are able to follow the derivation of conditionals given by Williamson et al. (2010a). Note that, in our case, we have introduced the slice variable and do not integrate out the topic allocation matrix. Denote by W the complete set of words and by A the complete set of topic assignments a_{ilt} for all times $t = t_0, \dots, t_T$, documents $i = 1, \dots, N_t$ and words $l = 1, \dots, W_{it}$. Denote by S_t the slice variable and by W_t the complete set of words at time t. The conditional distributions that we need to sample from for all times $t = t_0, \dots, t_T$ are

$$\begin{aligned}
&p(A_t \mid Z_t, w, \phi_t),\\
&p(\phi_t, \gamma \mid A_t, W_t, Z_t),\\
&p(S_t \mid Z_t, X(t)),\\
&p(Z_t \mid A_t, X(t), \phi_t, S_t).
\end{aligned}$$

Conditioning on all the other topic assignments a_{-il}, each topic assignment a_{ilt} can be sampled from

$$p(a_{ilt} = k \mid a_{-il}, Z_t, W, \phi_t) \propto (n_k^{w_{il}} + \eta)\frac{n_{kt}^i + \phi_{kt} z_{ikt}}{n_k + \eta D - 1},$$

where $n_k^{w_{il}}$ denotes the number of times that word w_{il} has been assigned to topic k excluding assignment a_{il}, n_{kt}^i the number of words assigned to topic k in document i excluding assignment a_{il} and n_k the total number of words assigned to topic k.

After placing a hyper-prior on $p(\gamma)$, we can sample ϕ and γ via a Metropolis-Hastings step. Indeed, we know that

$$p(\phi_{kt}, \gamma \mid A, Z_t) \propto \frac{\phi_{kt}^{\gamma-1} e^{-\phi_{kt}}}{\Gamma(\gamma)} p(\gamma) \prod_{i=1}^{N_t} \frac{\Gamma(\phi_{kt} z_{ikt} + n_{kt}^i)}{\Gamma(\phi_{kt} z_{ikt}) n_{kt}^i! 2^{\phi_{kt} z_{ikt} + n_{kt}^i}}.$$

Conditioning on Z_t, the slice variable is sampled according to its definition:

$$p(S_t \mid Z_t, X(t)) = \frac{1}{x^{min}(t)} 1_{s_t}([0, x^{min}(t)]),$$

where $x^{min}(t)$ is the minimum among the probabilities of the active topics at time t. As for the feature allocation matrices Z, we sample only the finite number of its components whose topic probability $x_k(t)$ is greater than the slice variable S_t. Assume we are sampling each entry Z_{ikt} sequentially and denote respectively by $x_1^{min}(t)$ and $x_0^{min}(t)$ the minimum active topic probability in the cases $Z_{ikt} = 1$ and $Z_{ikt} = 0$. Let n_{ikt} denote the total number of words assigned to topic k in document i at time t. Then we have that

$$p(Z_{ikt} = 1 \mid A, x_k(t), \phi_{kt}) = \begin{cases} 1, & \text{if } n_{ikt} > 0 \\ \frac{x_k(t) x_0^{min}(t)}{x_k(t) x_0^{min}(t) + 2^{\phi_{kt}}(1 - x_k(t)) x_1^{min}(t)}, & \text{if } n_{ikt} = 0. \end{cases}$$

$$p(Z_{ikt} = 0 \mid A, x_k(t), \phi_{kt}) = \begin{cases} 0, & \text{if } n_{ikt} > 0 \\ \frac{2^{\phi_{kt}}(1 - x_k(t)) x_1^{min}(t)}{x_k(t) x_0^{min}(t) + 2^{\phi_{kt}}(1 - x_k(t)) x_1^{min}(t)}, & \text{if } n_{ikt} = 0. \end{cases}$$

The full conditional distributions presented so far are derived in Appendix C. As in the linear-Gaussian case, when considering the probability of setting $Z_{ikt} = 1$ for a feature that is currently inactive across all observations at time t, it is necessary to jointly propose a new value ϕ_{kt} by drawing it from its prior distribution Gamma$(\gamma, 1)$. Finally, inference on the trajectories of the topic probabilities is a direct application of the Particle Gibbs and thinning scheme outlined for the general case.

7.3 Topic model: simulation and results

At each of 4 time points, a small corpus of $N = 30$ documents was simulated by selecting up to $K = 4$ latent topics for each document and picking words from a dictionary of $D = 100$ words. The hyper-parameter of the Dirichlet prior over words was chosen to be a vector with components equal to $\eta = 0.1$, a Gamma(5,1) hyper-prior was placed on γ and we let topic probabilities evolve as independent W-F$(1, 1)$ diffusions with 0.1 diffusion time-units between each observation. Assume K is known and focus on inference over the remaining parameters. Fix the time-units and drift parameters of the W-F diffusion to their true values in the PG update. We ran the Gibbs sampler for 3000 iterations with a burn-in period of 300 iterations. The log-likelihood converged in about 500 iterations (Figure 8)

and the algorithm was able to infer closely the latent topic allocation matrices (Figure 9-left). The percentage of words assigned to the correct topics were 81% at t_1, 82% at t_2, 83% at t_3 and 85% at t_4.

A Monte Carlo estimate for the probability of word $w = 1, \ldots, D$ under topic k is

$$\hat{\rho}_{kw} = \frac{n_k^w + \eta}{n_k + D\eta},$$

where n_k^w is the number of times word w has been assigned to topic k, n_k is the total number of words assigned to topic k and D is the number of words in the dictionary. A Monte Carlo estimate for the probability of topic k in document i is

$$\hat{\theta}_{ikt} = \frac{n_{ikt} + z_{ikt}\phi_{kt}}{\sum_k (n_{ikt} + z_{ikt}\phi_{kt})}. \tag{11}$$

These two quantities are given by the posterior mean of the Dirichlet distribution under a categorical likelihood. $\hat{\rho}_{kw}$ has been used to plot the posterior distribution over words in Figure 9-right. These results confirm the ability of the algorithm to recover ground truth and provide useful information both at word and topic level.

Finally, we tested the ability of the algorithm to reconstruct topics when presented with a decreasing number of observed documents. 100 documents were simulated at each of two time points as described above. Figure 10 shows how well the probability of the 10 most likely words of the first topic was reconstructed for $N = 60$, 40, 20 and 10 observed documents per time point. As expected, the more documents are observed the more accurate the reconstruction of topics is, with a drop in performance when only 10 documents per time point are observed.

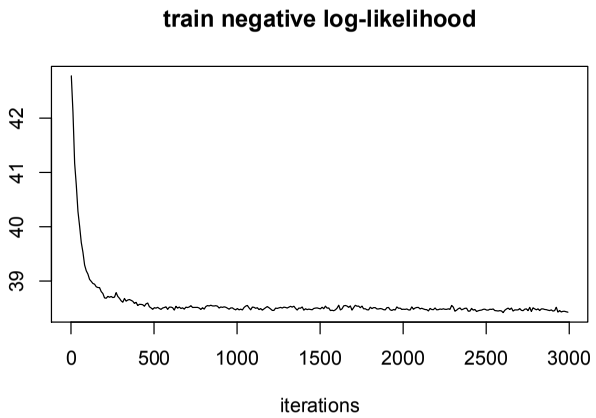

Figure 8: Convergence of the train negative log-likelihood.

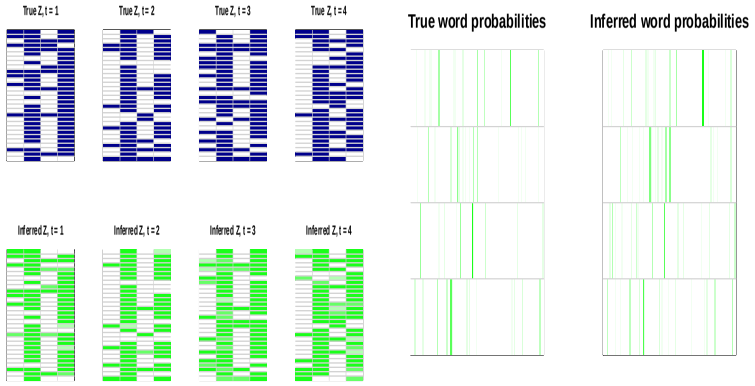

Figure 9: Left: Comparison between the true and the posterior mean topic allocation matrices at each time. Right: True vs inferred distributions over words for each topic. Each row is a topic ($K = 4$) and each column is a word from the dictionary ($D = 100$) (the darker the green, the larger the probability of the corresponding word).

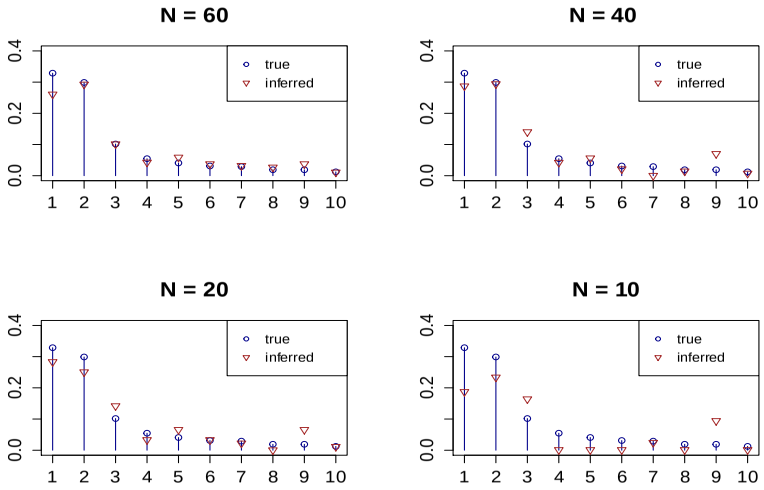

Figure 10: Comparison, given different numbers N of observed documents, between the true probabilities of the 10 most likely words within a given topic and the inferred probabilities of those words for that topic. The more documents are observed, the better the reconstruction of the topic is.

7.3.1 Comparison: static model and hierarchical model

We now demonstrate the advantages of modeling time-dependency by comparing our model with two alternative versions. First, we consider a static counterpart where time is not modeled and thus information about the time-stamp of documents is not exploited. Second, we consider a hierarchical model where feature probabilities at each time point are distributed as conditionally independent beta processes given a lower-layer beta process (Thibaux and Jordan, 2007); note that in this model observations at different time points are modeled separately, but information on the order of the time points is ignored.

In particular, we investigate whether incorporating time into the model improves upon test-set perplexity, a measure widely used in topic modeling settings that assesses the ability of topic models to generalize to unseen data. Given the model parameters Φ, perplexity on documents $D_{test} := \{d_i\}_{i=1}^{M}$ is defined as

$$\text{perplexity}(D_{test} \mid \Phi) = \exp\left(-\frac{\sum_{i=1}^{M} \log p(d_i \mid \Phi)}{\sum_{i=1}^{M} W_i}\right),$$

where W_i denotes the number of words in document d_i. As we assume that words within each document are drawn independently given the model parameters Φ, the probability of document d_i can be computed as

$$p(d_i \mid \Phi) = \prod_{l=1}^{W_i} p(w_{il} \mid \Phi),$$

where

$$p(w_{il} \mid \Phi) = \sum_{k=1}^{K} \theta_{ik}\rho_{kl},$$

recalling that θ_{ik} is the probability of a generic word belonging to topic k in document i and ρ_{kl} is the probability of word l under topic k. These two quantities can be approximated at each iteration of the MCMC algorithm by their current values $\hat{\theta}_{ik}^{(s)}$ and $\hat{\rho}_{kl}^{(s)}$, so that we can approximate the probability of each word by averaging over S samples of the Markov Chain.

$$\hat{p}(w_{il} \mid \Phi) = \frac{1}{S}\sum_{s=1}^{S}\sum_{k=1}^{K} \hat{\theta}_{ik}^{(s)}\hat{\rho}_{kl}^{(s)}.$$

Note that the perplexity is inversely proportional to the likelihood of the data and thus lower values indicate better performance. Chance performance, namely assuming each word to be picked uniformly at random from the dictionary, yields a perplexity equal to the size D of the dictionary.

Different percentages of words were held-out and the model was trained on the remaining data. Testing the model on held-out words is a way to avoid comparing different hyper-parameters, as different treatments of the hyper-parameters could strongly affect the results (Asuncion et al., 2009). For all three models, a dictionary of $D = 1000$ words was used

to generate 30 documents at each of 9 time points. The number of features was fixed to 4 and the algorithms were run 3000 iterations with a burn-in period of 300 iterations. Even though all three algorithms approximately recover the true topic allocations matrices, incorporating time leads to a closer match. This can be measured, for instance, by the Frobenius norm of the difference between each true and inferred Z_t. Table 1 shows that at each time the dynamic model leads to a lower discrepancy with the true topic allocation matrix. Figure 11 shows the posterior trajectories of topic probabilities inferred by the dynamic model and compares them with the posterior feature probabilities inferred by the hierarchical model and the constant values inferred by the static model. It can be observed that the trajectories inferred by the dynamic model are both smoother and closer to the ground truth. Finally, Figure 12 compares the test-set perplexity of the three models (recall that in this case chance performance results in a perplexity of $D = 1000$). As expected, although the hierarchical version performs better than the static counterpart that neglects time-stamp information, it is outperformed by our dynamic model. Indeed, while in the WF-IBP observations that are closer in time exhibit a stronger dependency, the HBP does not explicitly impose an ordering of the time points. The results show that having a suitable model for time dependencies improves on the ability to recover ground truth as well as to generalize to unseen data.

Table 1: Frobenius norm of the difference with the true Z_t. The lower, the better.

	t_1	t_2	t_3	t_4	t_5	t_6	t_7	t_8	t_9
Dynamic	**1.78**	**1.37**	**0.72**	**2.99**	**3.24**	**2.01**	**2.59**	**2.45**	**2.88**
Hierarchical	1.94	1.51	2.80	3.11	3.52	2.91	2.65	2.59	3.24
Static	3.63	4.23	2.84	3.01	3.55	5.27	4.89	3.31	5.90

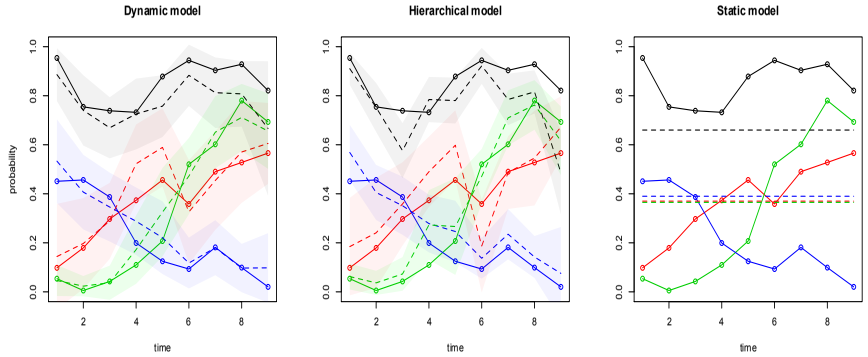

Figure 11: Comparison between true and inferred feature probabilities (respectively continuous and dotted lines) in our fixed-K topic model (left), in the hierarchical version (center) and in the static version (right).

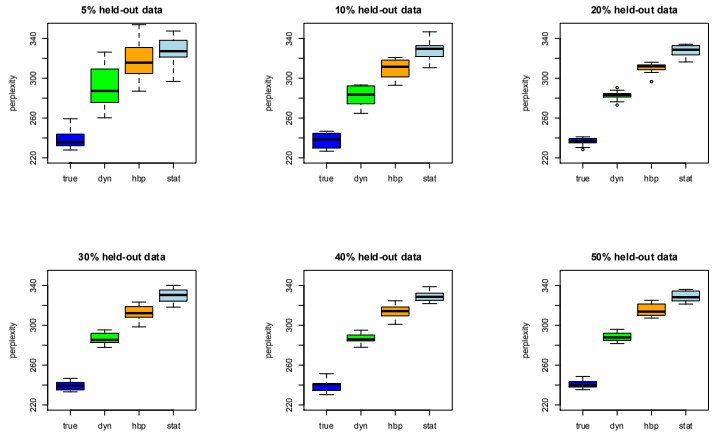

Figure 12: Boxplots of test-set perplexity for different percentages of held-out data for the true model (true), our dynamic model (dyn), the hierarchical version (hbp) and the static version (stat). Each boxplot was obtained by computing the perplexity after holding-out 10 different random subsets of words in the data. Lower values indicate better performance.

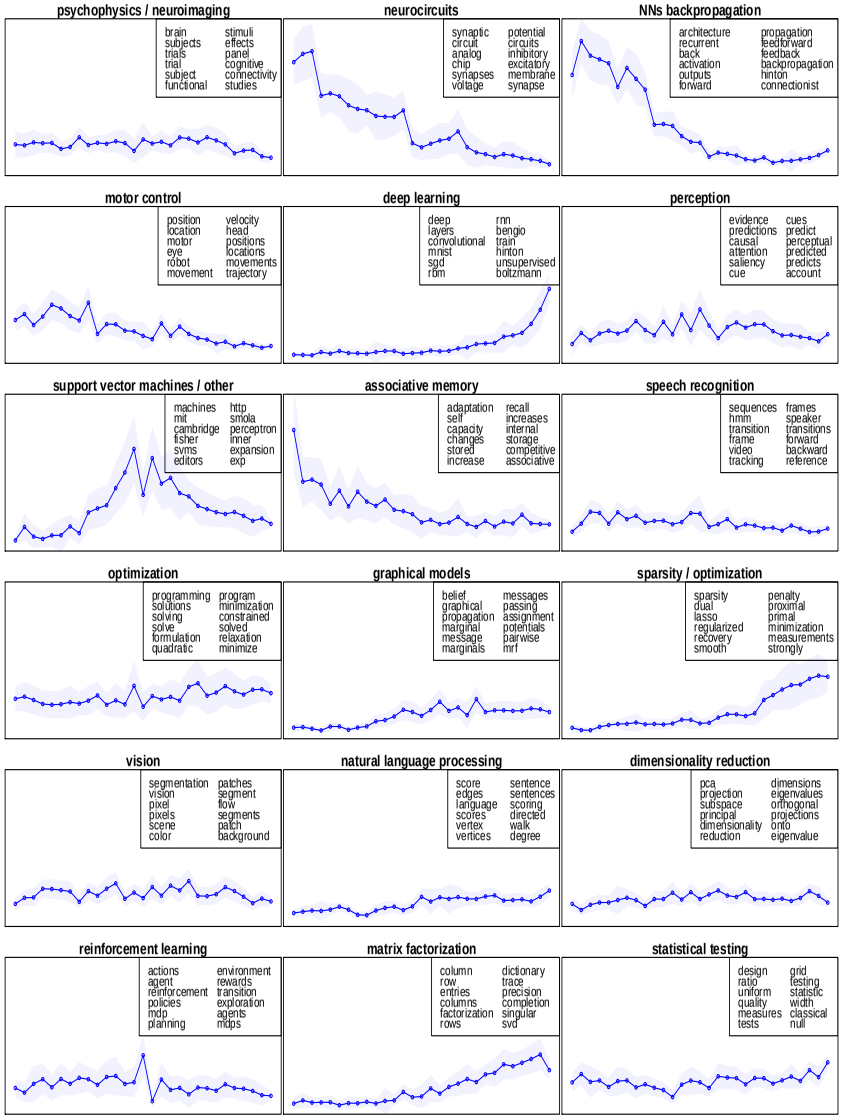
7.3.2 Real-world data experiments

We used the WF-IBP topic model to explore the data set consisting of the full text of 5811 NIPS conference papers published between 1987 to 2015.[1] We pre-processed the data and removed words appearing more than 5000 times or fewer than 250 times. The remaining number of word tokens was 4 728 892 with a vocabulary size of 348 672 unique words. Our goal was to discover what topics appear in the corpus and to track the evolution of their popularity over these 29 years.

We set the hyperparameters α and β equal to 1 and the time step to 0.12 diffusion time-units per year so as to reflect realistic evolutions of topic popularity. The Markov chain was run for 2000 iterations with a burn-in period of 200 iterations, setting $\eta = 0.001$ and placing a Gamma(5,1) hyper-prior on γ.

Qualitative results One of the qualitative advantages of modeling time dependency explicitly is that interesting insights into the evolution of topics underlying large collections of documents can be obtained automatically, and uncertainty in the predictions naturally incorporated. The 12 most likely words of 32 topics found in the corpus together with the evolution of their topic proportions are given in Figure 13, where the shaded areas

1. The data set is available at `https://archive.ics.uci.edu/ml/datasets/NIPS+Conference+Papers+1987-2015`.



represent one standard deviation around the posterior means. As topics are defined by their distribution over words, it is possible to label them by looking at their most likely words. We observe that, with very few exceptions, the topics detected in the corpus are meaningful and easily interpretable. Figure 14 compares how the popularity of three different approaches to machine learning evolved over time. The results indicate that standard neural networks ('NNs backpropagation') were extremely popular until the early 90s. After this, they went through a steady decline, only to increase in popularity later on. This confirms the well known fact that NNs were largely forsaken in the machine learning community in the late 90s (see LeCun et al., 2015). On the other hand, it can be observed that the popularity of deep architectures and convolutional neural networks ('deep learning') steadily increased over these 29 years, to the point that deep learning became the most popular among all topics in NIPS 2015.

Another key benefit of the WF-IBP over alternative nonparametric topic models is that the overall probability of topics and their proportion within documents are modeled separately, which allows rare topics to be the predominant subject within a few documents. This can be observed by comparing the rarest topic probabilities with the corresponding within-document topic proportions. In a number of documents WF-IBP reveals that the predominant topic is among the rarest topics in the corresponding year, such as in "Text Classification using String Kernels" (information retrieval),"Playing is Believing: The Role of Beliefs in Multi-Agent Learning" (game theory), and "Relative Density Nets: A New Way to Combine Backpropagation with HMMs" (speech recognition).

We then compared the document representations learned by WF-IBP with the ones obtained by Dynamic Topic Models (DTM) (Blei and Lafferty, 2006). One of the benefits of WF-IBP is that it provides sparse and less noisy representations. This is due to the fact that, while DTM assigns a positive probability to all topics within each document, the WF-IBP selects only a subset of topics with positive probability via the feature allocation matrices Z. Recall that DTM requires fixing the number of topics K a priori, hence in our experiments we set $K = 50$. For instance, "Recursive Training of 2D-3D Convolutional Networks for Neuronal Boundary Prediction", "Exploring Models and Data for Image Question Answering" and "Are You Talking to a Machine? Dataset and Methods for Multilingual Image Question Answering" are respectively assigned to deep learning, image recognition and NLP by both models; however, they are respectively explained by 9,8 and 10 topics in WF-IBP, as opposed to 50 in DTM. While it is possible to order the topic proportions in DTM and only consider the ones greater than an arbitrary threshold, WF-IBP automatically sets the probability of irrelevant topics to 0 and offers a more interpretable representation.

Quantitative results We then compared the predictive performance of our fixed-K approximation with its static and hierarchical counterparts. Recall that time-stamps are not used in the static model and their ordering is neglected in the hierarchical model. The results in Figure 15 were obtained by holding out different percentages of words (50%, 60%, 70% and 80%) from all the papers published in 1999 and by training the model over the papers published in the time range 1987-1999. The goal was to investigate whether incorporating time dependency improves the predictions on future documents at time $t+1$ when given the documents up to time t. The held-out words were then used to compute the test-set perplexity after 5 repeated runs with random initializations (the error bars represent

one standard deviation). The dynamic model led to consistently better results, especially as the number of held-out words was increased. This follows from the fact that, the less training data is available in the year in which the models are tested, the more important capturing time-dependence to yield sensible predictions.

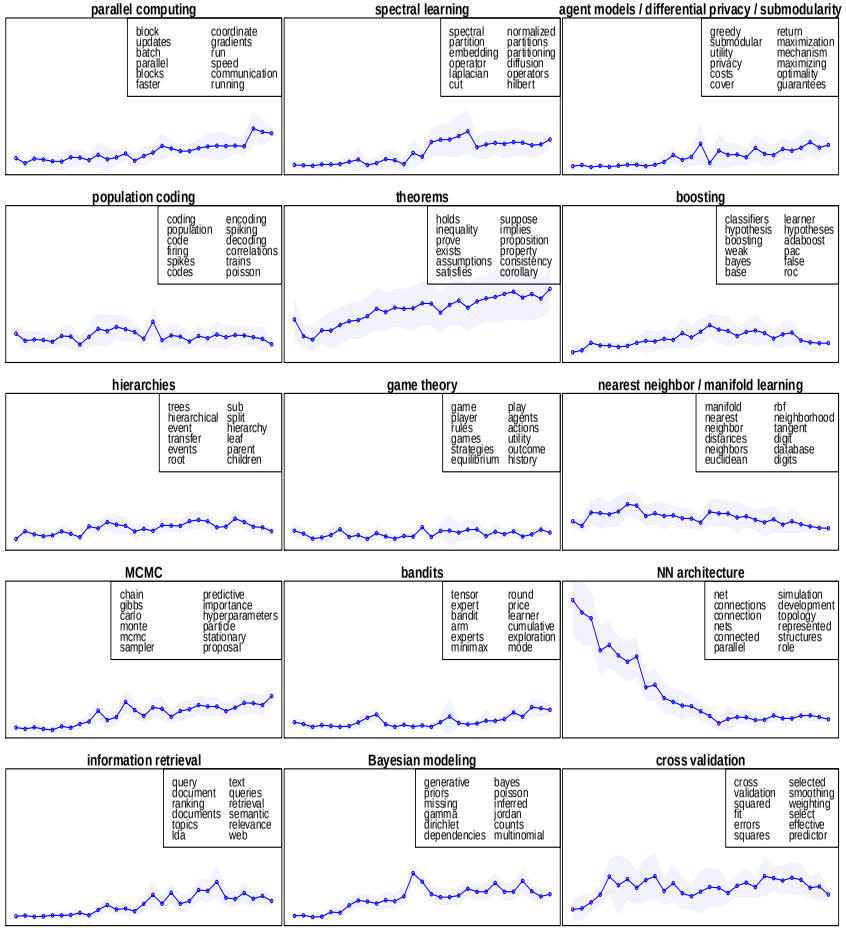


Figure 13: Posterior topic proportions over the years 1987-2015 and 12 most likely words for each topic (NIPS data set).

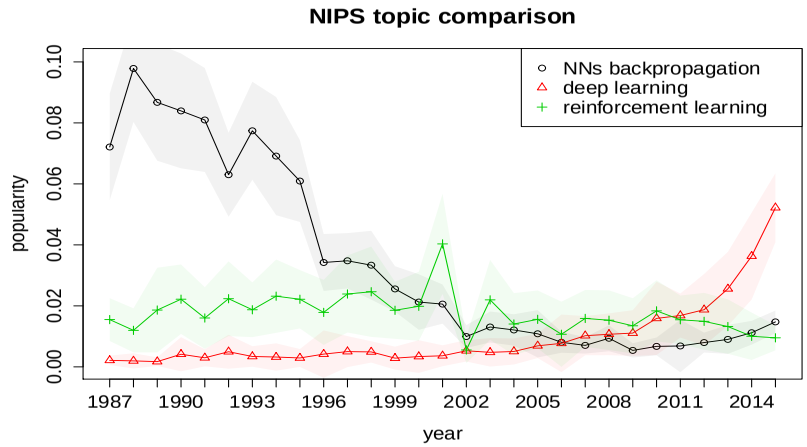

Figure 14: Comparison of a set of posterior topic proportions over the years 1987-2015 (NIPS data set).

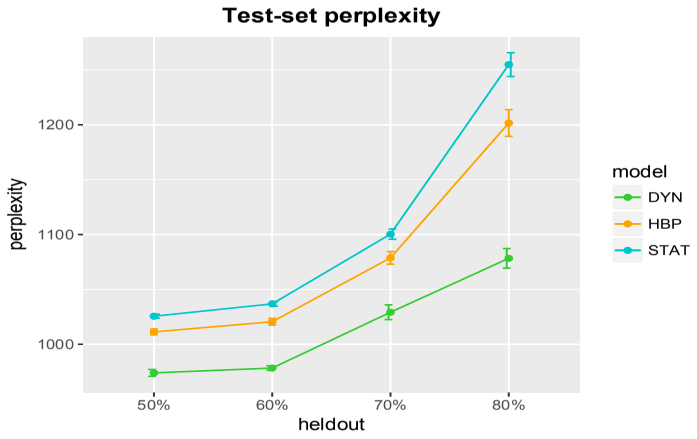

Figure 15: Comparison between the test-set perplexity of our dynamic model (DYN) against its hierarchical (HBP) and static (STAT) counterparts after holding out different percentages of words (NIPS data set). The dynamic model consistently outperforms the other two models, with a substantial difference when the percentage of held-out words is large.

8. Conclusion

We have presented a new framework for generating dependent IBPs by means of a novel time-evolving beta process, whereby feature probabilities evolve over time and are marginally distributed as in the beta process. At each time point items are exchangeable, and the two-parameter IBP is recovered. The key insight has been building on the PRF from population genetics to derive a suitable model for the prevalence and evolution of features over continuous time. We have developed an interesting MCMC framework for exact posterior inference with this model, and presented an alternative finite-dimensional approximation where the number of features is fixed.

As an application of the WF-IBP, we have described a time-dependent focused topic model that builds on Williamson et al. (2010b). The WF-IBP topic model allows for a flexible evolution of the popularity of an unknown number of topics over time, and compares favorably to HDP models by decoupling topic probabilities and within-document topic proportions. We have used our model to explore the data set consisting of the full text of NIPS conference papers from 1987 to 2015 and obtained an interesting visualization of how the popularity of the underlying topics evolved over these 29 years. In addition, test-set perplexity results have shown that incorporating time also improves on the predictive performance of the model.

A number of directions for future work are open. First, as $K \to \infty$ the fixed-K approximation marginally converges to the infinite model, and simulations showed that their dynamics are remarkably similar; further work could formally investigate the exact relationship between the two dynamics. Second, the current MCMC framework could be generalized to include inference on the IBP parameters and the W-F diffusion time step. Third, an extension of this work could modify the PRF by letting features evolve according to a more general W-F diffusion with selection and recombination, which would allow for feature-specific drifts in popularity and the coupled evolution of different features, respectively. Finally, our novel time-dependent beta process is a general construction with applications not limited to topic modeling. Different data and likelihood models could be explored following our work, for applications such as the modeling of time-evolving social networks or gene expression patterns.

Appendix A. Proof of Theorem 1

The mean density of a PRF with immigration parameter α is

$$l(x) = \alpha m(x)dx,$$

where

$$m(x) = \frac{e^{I(x)}}{\sigma^2(x)}, \quad \text{with } I(x) := \int_0^x \frac{2\gamma(y)}{\sigma^2(y)}dy, \tag{12}$$

is the speed density of the process (see Griffiths, 2003). γ and σ are the drift and diffusion terms as defined in (2) and (3). Plugging (2) with $\mu = 0$ and (3) into the integral, we have

$$I(x) = \beta \ln(1-x)$$

so that

$$m(x) = \frac{(1-x)^\beta}{x(1-x)} = x^{-1}(1-x)^{\beta-1}.$$

It follows that

$$l(x) = \alpha m(x)dx = \alpha x^{-1}(1-x)^{\beta-1}dx$$

is the resulting mean density, which completes the proof.

Remark 2 *When $\mu, \beta = 0$ it is necessary to condition each diffusion on hitting the boundary 0 before 1 in reverse time, which leads to an extra term in the analogous result in Sawyer and Hartl (1992).*

Appendix B. Simulating from the model

Consider the problem of simulating from the model, namely generating feature probabilities and the corresponding feature allocation matrices at a discrete set of time points.

Simulating X Set a truncation level $u > 0$ and consider the task of simulating features whose probability is above the threshold u at two times t_0 and t_1. As we know how to simulate marginally from the beta process, we can first generate the feature probabilities above u at time t_0 and let them evolve independently to time t_1. This yields features whose probability is greater than u at time t_0, meaning that we are still missing those features whose probability is below u at time t_0. To simulated these, we proceed as follows: we generate these features by drawing them from the beta process at time t_1 and propagate them backwards to time t_0. Finally, in order not to double-count features, all features that in the reverse simulation have probability greater than u at time t_0 have to be rejected.

Now translate these ideas into the following sampling scheme. At time t_0, sample from a truncated version of the PRF, namely from a Poisson process on $[u, 1)$ with rate measure $\alpha x^{-1}(1-x)^{\beta-1}dx$. This can be done, for instance, via an adaptive thinning scheme as described in Ogata (1981). As the truncation level u eliminates the point zero which has an infinite mass, this sampling procedure yields an almost surely finite number of samples. Denote by $\mathcal{K}$ the resulting set of feature indices and proceed as follows.

1. For all $k \in \mathcal{K}$, simulate $X_k(t) \mid \{X_k(t_0) = x_k(t_0)\} \sim \text{WF}(0, \beta)$ for $t \in [t_0, t_1]$.

2. At time t_1, sample the candidate newborn features $X(t_1)$ from the truncated PRF as above. Let $\mathcal{L}$ denote the resulting set of features.

3. For all $l \in \mathcal{L}$, simulate $X_l(t) \mid \{X_l(t_1) = x_l(t_1)\} \sim \text{WF}(0, \beta)$ backwards for $t \in [t_1, t_0]$ and remove from $\mathcal{L}$ the indices in the set $\{l : x_l(t_0) \geq u\}$.

4. Generate $Z_{ikt} \mid \{X_k(t) = x_k(t)\} \overset{iid}{\sim} \text{Bernoulli}(x_k(t))$, for $t = t_0, t_1$, $\forall k \in \mathcal{K} \cup \mathcal{L}$ and $\forall i = 1, \ldots, N_t$.

As mentioned previously, the idea behind steps 2 and 3 is to compensate for the features with probability smaller than u that were discarded when generating features at time t_0.

This construction generalizes to a set of time points $t = t_0, \ldots, t_T$, observing that at a given time $t_{t^*} \in \{t_1, \ldots, t_T\}$ step 3 needs to be modified by simulating the W-F diffusions backwards to time t_0 and removing from $\mathcal{L}$ the indices such that $\exists t \in \{t_0, \ldots, t_{t^*-1}\}$ such that $x_l(t) \geq u$.

Simulating Z and the underlying X Consider now the more complex task of simulating both the feature allocation matrices Z and the features X appearing in them. First note that, although the PRF describes the evolution of an infinite number of features, we can sample the feature allocation matrices Z_{t_0} and Z_{t_1} at two times t_0 and t_1 exactly, as a property of the IBP is that the number of observed features is almost surely finite (Griffiths and Ghahramani, 2011). It is then possible to sample the features that are active in at least one object at times t_0 and t_1 and the corresponding allocation matrices Z_{t_0} and Z_{t_1} as follows. First, draw Z_{t_0} from the IBP, and use its realisation to draw the posterior probabilities $X(t_0)$ of the features seen in Z_{t_0} as in the posterior beta process. Then, simulate from the W-F diffusion to propagate these features to time t_1 and generate Z_{t_1} using these feature probabilities. We are now only missing the columns of Z_{t_1} corresponding to the features that were seen at time t_1 but not at time t_0. To add those columns, first draw a candidate $Z^C_{t_1}$ from the IBP and the corresponding feature probabilities; then, simulate these candidate features backwards to time t_0 and accept them with probability $(1 - X(t_0))^{N_{t_0}}$ to account for the fact that they were not seen at time t_0. The columns of $Z^C_{t_1}$ corresponding to the rejected features are deleted. Translating these ideas into an algorithm, consider the following steps.

1. Draw $Z_{t_0} \sim \text{IBP}(\alpha, \beta)$ and index the resulting columns as $1, \ldots, K_1$.

2. For $k = 1, \ldots, K_1$ draw the corresponding feature probabilities

$$X_k(t_0) \mid \{Z_{t_0} = z_{t_0}\} \sim \text{Beta}\left(n_{kt_0}, \beta + N_{t_0} - n_{kt_0}\right).$$

3. For $k = 1, \ldots, K_1$ simulate $X_k(t) \mid \{X_k(t_0) = x_k(t_0)\} \sim \text{WF}(0, \beta)$ for $t \in [t_0, t_1]$ and set $X_k(t_1) = x_k(t_1)$.

4. Sample $Z^1_{t_1}$ by drawing each component $Z^1_{ikt_1} \mid \{X(t_1) = x(t_1)\} \overset{iid}{\sim} \text{Bernoulli}(x_k(t_1))$, where $k = 1, \ldots, K_1$ and $i = 1, \ldots, N_{t_1}$.

Then, to sample the features that are active only at time t_1, add the following steps.

5. Draw a candidate $Z^{\mathrm{C}}_{t_1} \sim \mathrm{IBP}(\alpha, \beta)$ and index the resulting columns as $K_1+1, \ldots, K_2$.
6. For $k = K_1+1, \ldots, K_2$ draw the corresponding candidate feature probabilities
$$X^{\mathrm{C}}_k(t_1) \mid \{Z^{\mathrm{C}}_{t_1} = z^{\mathrm{C}}_{t_1}\} \sim \mathrm{Beta}\left(n_{kt_1}, \beta + N_{t_1} - n_{kt_1}\right).$$
7. For $k = K_1+1, \ldots, K_2$, simulate $X_k(t) \mid \{X_k(t_1) = x_k(t_1)\} \sim \mathrm{WF}(0, \beta)$ backwards for $t \in [t_1, t_0]$ and set $X_k(t_0) = x_k(t_0)$.
8. Accept the candidate columns of $Z^C_{t_1}$ with probability $(1 - x^C_k(t_0))^{N_{t_0}}$ and let Z_{t_1} be the matrix obtained by the union of the columns of $Z^1_{t_1}$ with the accepted columns of $Z^C_{t_1}$.

Note that the rejection in the last step is a way to account for the fact that we are considering features that are active for the first time at time t_1. When considering a general set of time points $t_0, \ldots, t_T$, it is necessary to account for the features that are active for the first time at each time $t_1, \ldots, t_T$. In this more general case, features seen for the first time at time t_{t^*} need to be accepted with probability $\prod_{t=t_0}^{t_{t^*-1}} (1 - x^C_k(t))^{N_t}$, as they were not seen in any of the feature allocation matrices at the time points before t^*.

Appendix C. Derivation of full conditionals

As observed in Williamson et al. (2009), in this topic modeling setting there are two equivalent ways of generating documents. Either the total number of words is sampled from a negative binomial $\mathrm{NB}(\sum_k z_{ikt}\phi_{kt}, 1/2)$ and then the topic and word assignments are drawn, or the number of words generated by each topic is drawn from $\mathrm{NB}(z_{ikt}\phi_{kt}, 1/2)$ and then the word assignments are picked. Following Williamson et al. (2009) closely, we make use of the latter construction to derive the full conditional distributions for the Gibbs sampler of the WF-IBP topic model.

Full conditional of a_{il} Recall that $a_{ilt} = k$ indicates that the lth word in document i at time t is assigned to topic k. We have
$$\begin{aligned} p(a_{ilt} = k \mid a_{-il}, Z_t, w_{ilt}, \phi_t) &\propto p(w_{ilt} \mid a_{ilt} = k) p(a_{ilt} = k \mid a_{-il}, z_{ikt}, \phi_{kt}) \\ &\propto p(w_{ilt} \mid a_{ilt} = k)(n^i_{kt} + \phi_{kt} z_{ikt}), \end{aligned}$$
where the last step is given by integrating out θ_{it}, namely the distribution over topics in document i at time t, and using the Dirichlet-Categorical conjugacy. Recall that n^i_{kt} denotes the number of words assigned to topic k in document i at time t and that n_{kt} denotes the total number of words assigned to topic k at time t, both excluding the assignment a_{il}. Similarly, integrating out the parameter ρ_k representing the distribution over words of topic k and using the Dirichlet-Categorical conjugacy, we have that
$$p(w_{ilt} \mid a_{ilt} = k) = \frac{(n^{w_{il}}_k + \eta)}{n_k + \eta D - 1},$$
which, plugged into the previous equation, gives the desired full conditional.

Full conditional of ϕ_k and γ We have that
$$\begin{aligned} p(\phi_{kt}, \gamma \mid n_{kt}, X(t), Z_t) &\propto p(\phi_{kt}, \gamma, n_{kt}, X(t), Z_t) \\ &\propto p(\phi_{kt} \mid \gamma) P(\gamma) P(n_{kt} \mid Z_t, \phi_{kt}), \end{aligned} \tag{13}$$
where
$$p(n_{kt} \mid Z_t, \phi_{kt}) = \prod_{i=1}^{N_t} p(n^i_{kt} \mid Z_{ikt}, \phi_{kt}) = \prod_{i=1}^{N_t} \mathrm{NB}(n^i_{kt}; Z_{ikt}\phi_{kt}, 1/2).$$
Note that $p(\phi_{kt} \mid \gamma)$ is distributed according to its prior $\mathrm{Gamma}(\gamma, 1)$ and γ according to a chosen hyper-prior. The result follows immediately by plugging these three distributions into (13).

Full conditional of Z_{ikt} Recall that n_{ikt} denotes the total number of words assigned to topic k in document i at time t. If $n_{ikt} > 0$, then the corresponding entry Z_{ikt} is active with probability 1. If $n_{ikt} = 0$, we have
$$p(Z_{ikt} = 1 \mid Z_{-(ik)t}, n_{ikt} = 0, X_k(t), \phi_{kt}, S_t) = \frac{p(Z_{ikt} = 1, Z_{-(ik)t}, n_{ikt} = 0, X_k(t), \phi_{kt}, S_t)}{p(Z_{-(ik)t}, n_{ikt} = 0, X_k(t), \phi_{kt}, S_t)}.$$
The numerator is equal to
$$\begin{aligned} p(n_{ikt} = 0 \mid Z_{ikt} = 1, \phi_{kt}) p(S_t \mid Z_{ikt} = 1, Z_{-(ik)t}) p(Z_{ikt} = 1 \mid X_k(t)) p(\phi_{kt}, X_k(t), Z_{-(ik)t}) = \\ \mathrm{NB}(0; \phi_{kt}, 1/2) \frac{1}{x^{min}_1(t)} x_k(t) p(\phi_{kt}, X_k(t), Z_{-(ik)t}) \end{aligned}$$
Denoting by C the product of all terms not depending on z_{ikt}, we have
$$p(Z_{ikt} = 1 \mid Z_{-(ik)t}, n_{ikt} = 0, X_k(t), \phi_{kt}, S_t) = C \frac{1}{2^{\phi_{kt}}} \frac{1}{x^{min}_1(t)} x_k(t). \tag{14}$$
By the same token, we have
$$p(Z_{ikt} = 0 \mid Z_{-(ik)t}, n_{ikt} = 0, X_k(t), \phi_{kt}, S_t) = C \frac{1}{x^{min}_0(t)} (1 - x_k(t)). \tag{15}$$
As the two probabilities must sum to 1, we have that
$$C = \frac{2^{\phi_{kt}} x^{min}_1(t) x^{min}_0(t)}{x^{min}_0(t) x_k(t) + 2^{\phi_{kt}} x^{min}_1(t)(1 - x_k(t))},$$
which, plugged into equations 14 and 15, gives the result.

Abstract

In high dimensional regression settings, sparsity enforcing penalties have proved useful to regularize the data-fitting term. A recently introduced technique called *screening rules* propose to ignore some variables in the optimization leveraging the expected sparsity of the solutions and consequently leading to faster solvers. When the procedure is guaranteed not to discard variables wrongly the rules are said to be *safe*. In this work, we propose a unifying framework for generalized linear models regularized with standard sparsity enforcing penalties such as ℓ_1 or ℓ_1/ℓ_2 norms. Our technique allows to discard safely more variables than previously considered safe rules, particularly for low regularization parameters. Our proposed Gap Safe rules (so called because they rely on duality gap computation) can cope with any iterative solver but are particularly well suited to (block) coordinate descent methods. Applied to many standard learning tasks, Lasso, Sparse-Group Lasso, multi-task Lasso, binary and multinomial logistic regression, etc., we report significant speed-ups compared to previously proposed safe rules on all tested data sets.

Keywords: Convex optimization, screening rules, Lasso, multi-task Lasso, sparse logistic regression, Sparse-Group Lasso

1. Introduction

The computational burden of solving high dimensional regularized regression problem has led to a vast literature on improving algorithmic solvers in the last two decades. With the increasing popularity of ℓ_1-type regularization ranging from the Lasso (Tibshirani, 1996) or group-Lasso (Yuan and Lin, 2006) to regularized logistic regression and multi-task learning, many algorithmic methods have emerged to solve the associated optimization problems (Koh et al., 2007; Bach et al., 2012). Although for the simple ℓ_1 regularized least square a specific algorithm (*e.g.,* the LARS (Efron et al., 2004)) can be considered, for more general formulations, penalties, and possibly larger dimensions, (block) coordinate descent has proved to be an efficient strategy (Friedman et al., 2010).

Our main objective in this work is to propose a technique that can speed-up any iterative solver for such learning problems, and that is particularly well suited for (block) coordinate descent method as this type of method can easily ignore useless coordinates[1].

The *safe rules* introduced by El Ghaoui et al. (2012) for generalized ℓ_1 regularized problems, is a set of rules allowing to eliminate features whose associated coefficients are guaranteed to be zero at the optimum, even before starting any algorithm. Relaxing the safe rule, one can obtain some additional speed-up at the price of possible mistakes. Such heuristic strategies, called *strong rules* by Tibshirani et al. (2012) reduce the computational cost using an active set strategy, but require multiple post-processing to check for features possibly wrongly discarded.

Another road to speed-up screening method has been pursued following the introduction of *sequential safe rules* (El Ghaoui et al., 2012; Wang et al., 2012; Xiang et al., 2014; Wang et al., 2014). The idea is to improve the screening thanks to the computation done for a previous regularization parameter as in homotopy/continuation methods. This scenario is particularly relevant in machine learning, where one computes solutions over a grid of regularization parameters, so as to select the best one, *e.g.,* by cross-validation. Nevertheless, the aforementioned methods suffer from the same problem as strong rules, since relevant features can be wrongly disregarded. Indeed, sequential rules usually rely on the exact knowledge of certain theoretical quantities that are only known approximately. Especially, for such rules to work one needs the exact dual optimal solution from the previous regularization parameter, a quantity (almost) never available to the practitioner.

The recent introduction of *dynamic safe rules* by Bonnefoy et al. (2015, 2014) has opened a new promising venue by performing variable screening, not only before the algorithm starts, but also along the iterations. This screening strategy can be applied for any standard optimization algorithm such as FISTA (Beck and Teboulle, 2009), primal-dual (Chambolle and Pock, 2011), augmented Lagrangian (Boyd et al., 2011). Yet, it is particularly relevant for strategies that can benefit from support reduction or active sets (Kowalski et al., 2011; Johnson and Guestrin, 2015), such as coordinate-descent (Fu, 1998; Friedman et al., 2007, 2010).

This paper contains a synthesis and a unified presentation of the methods introduced first for the Lasso in (Fercoq et al., 2015) and then for ℓ_1/ℓ_2 norms in (Ndiaye et al., 2015) as well as for Sparse-Group Lasso in (Ndiaye et al., 2016b). Our so-called Gap Safe rules (because the screening rules rely on duality gap computations), improved on dynamic safe rules for a broad class of learning problems with the following benefits:

- Gap Safe rules are easy to insert in existing solvers,
- they are proved to be safe and unify sequential and dynamic rules,
- they lead to improved speed-ups in practice *w.r.t.* previously known safe rules,
- they achieve fast variable identifications[2].

1. By construction a method like LARS (Efron et al., 2004), that applies only to the Lasso case, cannot beneficiate from screening rules.
2. more precisely, we identify faster the equicorrelation set, see Theorem 14

Furthermore, it is worth noting that strategies also leveraging dual gap computations have recently been considered to safely discard irrelevant coordinates: Shibagaki et al. (2016) have considered screening rules for learning tasks with both feature sparsity and sample sparsity, such as for ℓ_1-regularized SVM. In this case, some interesting developments have been proposed, namely *safe keeping* strategies, which allow to identify features and samples that are guaranteed to be active. Constrained convex problems such as minimum enclosing ball can also be included as shown in Raj et al. (2016). The Blitz algorithm by Johnson and Guestrin (2015) aims to speed up working set methods using duality gaps computations; significant gains were also obtained in limited-memory and distributed settings.

We introduce the general framework of Gap Safe screening rules in Section 3; in Section 4 we instantiate them on various strategies including static, dynamic and sequential ones, and show how the Gap Safe methodology can encompass all of them. The converging nature of the Gap Safe rules is also discussed. In Section 5, we investigate the specific form of our rules for standard machine learning models: Lasso, Group Lasso, Sparse-Group Lasso, logistic regression with ℓ_1 regularization, etc. Section 6 reports a comprehensive set of experiments on four different learning problems using either dense or sparse data. Results demonstrate the systematic gain in computation time of the Gap Safe rules.

2. Notation and Background on Optimization

For any integer $d \in \mathbb{N}$, we denote by $[d]$ the set $\{1, \dots, d\}$ and by $Q^\top$ the transpose of a matrix Q. Our observation vector is $y \in \mathbb{R}^n$ where n represents the number of samples. The design matrix $X = [x_1, \dots, x_n]^\top \in \mathbb{R}^{n \times p}$ has p explanatory variables (or features) column-wise, and n observations row-wise. For a norm Ω, we write $\mathcal{B}_\Omega$ the associated unit ball, $\|\cdot\|_2$ is the ℓ_2 norm (and $\langle \cdot, \cdot \rangle$ for the associated inner product), $\|\cdot\|_1$ is the ℓ_1 norm, and $\|\cdot\|_\infty$ is the ℓ_∞ norm. The ℓ_2 unit ball is denoted by $\mathcal{B}_2$ (or simply $\mathcal{B}$) and we write $\mathcal{B}(\theta, r)$ the ℓ_2 ball with center θ and radius r. For a vector $\beta \in \mathbb{R}^p$, we denote by $\mathrm{supp}(\beta)$ the support of β (*i.e.,* the set of indices corresponding to non-zero coefficients) and by $\|\mathrm{B}\|_F^2 = \sum_{j=1}^p \sum_{k=1}^q \mathrm{B}_{j,k}^2$ the Frobenius norm of a matrix $\mathrm{B} \in \mathbb{R}^{p \times q}$. We denote $(t)_+ = \max(0, t)$ and $\Pi_{\mathcal{C}}(\cdot)$ the projection operator over a closed convex set $\mathcal{C}$. The soft-thresholding operator ST_τ (at level $\tau \geqslant 0$) is defined for any $x \in \mathbb{R}^d$ by $[\mathrm{ST}_\tau(x)]_j = \mathrm{sign}(x_j)(|x_j| - \tau)_+$.

The parameter to recover is a vector $\beta = (\beta_1, \dots, \beta_p)^\top$ admitting a group structure. A group of features is a subset $g \subset [p]$ and n_g is its cardinality. The set of groups is denoted by $\mathcal{G}$ and we focus only on non-overlapping groups[3] that form a partition of the set $[p]$. We denote by β_g the vector in $\mathbb{R}^{n_g}$ which is the restriction of β to the indices in g. We write $[\beta_g]_j$ the j-th coordinate of β_g. We also use the notation $X_g \in \mathbb{R}^{n \times n_g}$ to refer to the sub-matrix of X assembled from the columns with indices $j \in g$ and X_j when the groups are a single feature, *i.e.,* when $g = \{j\}$.

Some elements of convex analysis used in the following sections are introduced here. For a function $f : \mathbb{R}^d \to [-\infty, +\infty]$, the Fenchel-Legendre transform[4] of f, is the function $f^* : \mathbb{R}^d \to [-\infty, +\infty]$ defined by $f^*(u) = \sup_{z \in \mathbb{R}^d} \langle z, u \rangle - f(z)$. The sub-differential of a function f at a point x is denoted by $\partial f(x)$. For a norm Ω over $\mathbb{R}^d$, its dual norm is written Ω^D and is defined for any $u \in \mathbb{R}^d$ by $\Omega^D(u) = \max_{\Omega(z) \leqslant 1} \langle z, u \rangle$. Note that in the case of a group-decomposable norm, one can check that $\Omega^D(\beta) = \max_{g \in \mathcal{G}} \Omega_g^D(\beta_g)$ and $\partial \Omega(\beta) = \Pi_{g \in \mathcal{G}} \partial \Omega_g(\beta_g)$.

We remind below useful standard results from convex analysis:

Proposition 1 (Fermat's Rule) *(see (Bauschke and Combettes, 2011, Proposition 26.1) for a more general result) For any convex function $f : \mathbb{R}^d \to \mathbb{R}$:*

$$x^\star \in \operatorname*{arg\,min}_{x \in \mathbb{R}^d} f(x) \iff 0 \in \partial f(x^\star). \tag{1}$$

Proposition 2 (Subdifferential of a Norm) *(see (Bach et al., 2012, Proposition 1.2)) The sub-differential of the norm Ω at x, is given by*

$$\partial \Omega(x) = \begin{cases} \{z \in \mathbb{R}^d : \Omega^D(z) \leqslant 1\} = \mathcal{B}_{\Omega^D}, & \text{if } x = 0, \\ \{z \in \mathbb{R}^d : \Omega^D(z) = 1 \text{ and } z^\top x = \Omega(x)\}, & \text{otherwise.} \end{cases} \tag{2}$$

3. Gap Safe Framework

We propose to estimate the vector of parameters β by solving

$$\hat{\beta}^{(\lambda)} \in \operatorname*{arg\,min}_{\beta \in \mathbb{R}^p} P_\lambda(\beta), \text{ for } P_\lambda(\beta) := F(\beta) + \lambda \Omega(\beta) := \sum_{i=1}^n f_i(x_i^\top \beta) + \lambda \Omega(\beta) \ , \tag{3}$$

where all $f_i : \mathbb{R} \mapsto \mathbb{R}$ are convex and differentiable functions with $1/\gamma$-Lipschitz gradient and $\Omega : \mathbb{R}^p \mapsto \mathbb{R}_+$ is a norm that is group-decomposable, *i.e.,* $\Omega(\beta) = \sum_{g \in \mathcal{G}} \Omega_g(\beta_g)$ where each Ω_g is a norm on $\mathbb{R}^{n_g}$. The λ parameter is a non-negative constant controlling the trade-off between the data fitting term and the regularization term. Popular instantiations of problems of the form (3) are detailed in Section 5.

Theorem 3 *A dual formulation of the optimization problem defined in* (3) *is given by*

$$\hat{\theta}^{(\lambda)} = \operatorname*{arg\,max}_{\theta \in \Delta_X} - \sum_{i=1}^n f_i^*(-\lambda \theta_i) =: D_\lambda(\theta), \tag{4}$$

where $\Delta_X = \{\theta \in \mathbb{R}^n : \forall g \in \mathcal{G}, \Omega_g^D(X_g^\top \theta) \leqslant 1\}$. Moreover, the Fermat's rule reads:

$$\forall i \in [n], \ \hat{\theta}_i^{(\lambda)} = -\nabla f_i(x_i^\top \hat{\beta}^{(\lambda)})/\lambda \quad (\textbf{\textit{link equation}}), \tag{5}$$

$$\forall g \in \mathcal{G}, \ X_g^\top \hat{\theta}^{(\lambda)} \in \partial \Omega_g(\hat{\beta}_g^{(\lambda)}) \quad (\textbf{\textit{sub-differential inclusion}}). \tag{6}$$

For any $\theta \in \mathbb{R}^n$ let us introduce $G(\theta) := [\nabla f_1(\theta_1), \dots, \nabla f_n(\theta_n)]^\top \in \mathbb{R}^n$. Then the primal/dual link equation can be written $\hat{\theta}^{(\lambda)} = -G(X\hat{\beta}^{(\lambda)})/\lambda$.

Contrarily to the primal, the dual problem has a unique solution under our assumption on the f_i's. Indeed, the dual function is strongly concave, hence strictly concave.

3. Overlapping groups could be treated as well, some insight is given in Section 5.3

4. Such a transform is often referred to as the (convex) conjugate of a (convex) function

3.1 Safe Screening Rules

Following the seminal work by El Ghaoui et al. (2012) screening techniques have emerged as a way to exploit the known sparsity of the solution by discarding features prior to starting a sparse solver. Such techniques are referred to in the literature as *safe rules* when they screen out coefficients guaranteed to be zero in the targeted optimal solution. Zeroing those coefficients allows to focus exclusively on the non-zero ones (likely to represent signal) and helps reducing the computational burden.

One well known extreme is the following: for $\lambda > 0$ large enough, 0 is the unique solution of (3). Indeed,

$$0 \in \underset{\beta \in \mathbb{R}^p}{\arg\min}\, F(\beta) + \lambda\Omega(\beta) \overset{(1)}{\iff} 0 \in \{\nabla F(0)\} + \lambda \partial\Omega(0) \overset{(2)}{\iff} \Omega^D(\nabla F(0)) \leqslant \lambda.$$

Hence we recall the first "naive" screening rule, stating that for large values of the regularization parameter, all features can be discarded.

Proposition 4 (Critical Parameter: $\lambda_{\max}$) *For any $\lambda > 0$,*

$$0 \in \underset{\beta \in \mathbb{R}^p}{\arg\min}\, P_\lambda(\beta) \iff \lambda \geqslant \lambda_{\max} := \Omega^D(\nabla F(0)) = \Omega^D(X^\top G(0)) \ .$$

So from now on, we will only focus on the case where $\lambda < \lambda_{\max}$. In this case, screening rules rely on a direct consequence of Fermat's rule (6). If $\hat\beta_g^{(\lambda)} \neq 0$, then $\Omega_g^D(X_g^\top \hat\theta^{(\lambda)}) = 1$ thanks to Equation (2). Since $\hat\theta^{(\lambda)} \in \Delta_X$, it implies, by contrapositive, that if $\Omega_g^D(X_g^\top \hat\theta^{(\lambda)}) < 1$ then $\hat\beta_g^{(\lambda)} = 0$. This relation means that the g-th group can be discarded whenever $\Omega_g^D(X_g^\top \hat\theta^{(\lambda)}) < 1$. However, since $\hat\theta^{(\lambda)}$ is **unknown** — unless $\lambda > \lambda_{\max}$, in which case $\hat\theta^{(\lambda)} = G(0)/\lambda$ — this rule is of limited use. Fortunately, it is often possible to construct a set $\mathcal{R} \subset \mathbb{R}^n$, called a *safe region*, that contains $\hat\theta^{(\lambda)}$. This observation leads to the following result.

Proposition 5 (Safe Screening Rule El Ghaoui et al. (2012)) *If $\hat\theta^{(\lambda)} \in \mathcal{R}$, and $g \in \mathcal{G}$:*

$$\max_{\theta \in \mathcal{R}} \Omega_g^D(X_g^\top \theta) < 1 \Longrightarrow \Omega_g^D(X_g^\top \hat\theta^{(\lambda)}) < 1 \Longrightarrow \hat\beta_g^{(\lambda)} = 0 \ . \tag{7}$$

The so-called *safe screening* rule consists in removing the g-th group from the problem whenever the previous test is satisfied, since then $\hat\beta_g^{(\lambda)}$ is guaranteed to be zero. Should $\mathcal{R}$ be small enough to screen many groups, one can observe considerable speed-ups in practice as long as the testing can be performed efficiently. A natural goal is to find safe regions as narrow as possible: smaller safe regions can only increase the number of screened out variables. To have useful screening procedures one needs:

- the safe region $\mathcal{R}$ to be as small as possible (and to contain $\hat\theta^{(\lambda)}$),
- the computation of the quantity $\max_{\theta \in \mathcal{R}} \Omega_g^D(X_g^\top \theta)$ to be cheap.

The later means that safe regions should be simple geometric objects, since otherwise, evaluating the test could lead to a computational burden limiting the benefits of screening.

3.2 Gap Safe Regions

Various shapes have been considered in practice for the safe region $\mathcal{R}$ such as balls (El Ghaoui et al., 2012), domes (Fercoq et al., 2015) or more refined sets (see Xiang et al. (2014) for a survey). Here we consider for simplicity the so-called "sphere regions" (following the terminology introduced by El Ghaoui et al. (2012)) choosing a ball $\mathcal{R} = \mathcal{B}(\theta, r)$ as a safe region. Thanks to the triangle inequality, we have:

$$\max_{\theta \in \mathcal{B}(\theta, r)} \Omega_g^D(X_g^\top \theta) \leqslant \Omega_g^D(X_g^\top \theta) + \max_{\theta \in \mathcal{B}(\theta, r)} \Omega_g^D(X_g^\top(\theta - \theta)),$$

and denoting $\Omega_g^D(X_g) := \sup_{u \neq 0} \frac{\Omega_g^D(X_g^\top u)}{\|u\|_2}$ the operator norm of X_g associated to $\Omega_g^D(\cdot)$, we deduce from Proposition 7 the screening rule for the g-th group:

$$\text{Safe sphere test:} \qquad \text{If} \quad \Omega_g^D(X_g^\top \theta) + r\Omega_g^D(X_g) < 1, \quad \text{then} \quad \hat\beta_g^{(\lambda)} = 0 \ . \tag{8}$$

3.2.1 Finding a Center

To create a useful center for a safe sphere, one needs to be able to create dual feasible points, *i.e.,* points in the dual feasible set Δ_X. One such point is $\theta_{\max} := -G(0)/\lambda_{\max}$ which leads to the original static safe rules proposed by El Ghaoui et al. (2012). Yet, it has a limited interest, being helpful only for a small range of (large) regularization parameters λ, as discussed in Section 4.1. A more generic way of creating a dual point that will be key for creating our safe rules is to rescale any point $z \in \mathbb{R}^n$ such that it is in the dual set Δ_X. The rescaled point is denoted by $\Theta(z)$ and is defined by

$$\Theta(z) := \begin{cases} z, & \text{if } \Omega^D(X^\top z) \leqslant 1, \\ \frac{z}{\Omega^D(X^\top z)}, & \text{otherwise.} \end{cases} \tag{9}$$

This choice guarantees that $\forall z \in \mathbb{R}^n, \Theta(z) \in \Delta_X$. A candidate often considered for computing a dual point is the (generalized) residual term $z = -G(X\beta)/\lambda$. This choice is motivated by the primal-dual link equation 5 *i.e.,* $\hat\theta^{(\lambda)} = -G(X\hat\beta^{(\lambda)})/\lambda$.

3.2.2 Finding a Radius

Now that we have seen how to create a center candidate for the sphere, we need to find a proper radius, that would allow the associated sphere to be safe. The following theorem proposes a way to obtain a radius using the duality gap. The quantity

$$\mathrm{Gap}_\lambda(\beta, \theta) := P_\lambda(\beta) - D_\lambda(\theta) \tag{10}$$

is often referred to as the duality gap in the convex optimization literature, hence the name of our proposed Gap Safe framework. This quantity is also a useful tool when designing a stopping criterion: noting that for any $\beta \in \mathbb{R}^p, \theta \in \Delta_X$, $P_\lambda(\beta) - P_\lambda(\hat\beta^{(\lambda)}) \leqslant \mathrm{Gap}_\lambda(\beta, \theta)$, it suffices to find a primal-dual pair with a duality gap smaller than ϵ to ensure an ϵ-accuracy primal solution for Problem 3.

Theorem 6 (Gap Safe Sphere) *Assuming that F has $1/\gamma$-Lipschitz gradient, we have*

$$\forall \beta \in \mathbb{R}^p, \forall \theta \in \Delta_X, \quad \left\| \hat\theta^{(\lambda)} - \theta \right\|_2 \leqslant \sqrt{\frac{2\mathrm{Gap}_\lambda(\beta, \theta)}{\gamma \lambda^2}} \ . \tag{11}$$

Hence the set $\mathcal{R} = \mathcal{B}(\theta, \sqrt{2\mathrm{Gap}_\lambda(\beta,\theta)/\gamma\lambda^2})$ *is a safe region for any* $\beta \in \mathbb{R}^n$ *and* $\theta \in \Delta_X$.

Proof Remember that $\forall i \in [n], f_i$ is differentiable with a $1/\gamma$-Lipschitz gradient. As a consequence, $\forall i \in [n], f_i^*$ is γ-strongly convex (Hiriart-Urruty and Lemaréchal, 1993, Theorem 4.2.2, p. 83) and so the dual function D_λ is $\gamma\lambda^2$-strongly concave:

$$\forall(\theta_1,\theta_2) \in \mathbb{R}^n \times \mathbb{R}^n, \quad D_\lambda(\theta_2) \leqslant D_\lambda(\theta_1) + \langle \nabla D_\lambda(\theta_1), \theta_2 - \theta_1 \rangle - \frac{\gamma\lambda^2}{2} \|\theta_1 - \theta_2\|_2^2 \ .$$

Specifying the previous inequality for $\theta_1 = \hat{\theta}^{(\lambda)}, \theta_2 = \theta \in \Delta_X$, one has

$$D_\lambda(\theta) \leqslant D_\lambda(\hat{\theta}^{(\lambda)}) + \langle \nabla D_\lambda(\hat{\theta}^{(\lambda)}), \theta - \hat{\theta}^{(\lambda)} \rangle - \frac{\gamma\lambda^2}{2} \left\| \hat{\theta}^{(\lambda)} - \theta \right\|_2^2 \ .$$

By definition, $\hat{\theta}^{(\lambda)}$ maximizes D_λ on Δ_X, so, $\langle \nabla D_\lambda(\hat{\theta}^{(\lambda)}), \theta - \hat{\theta}^{(\lambda)} \rangle \leqslant 0$. This implies

$$D_\lambda(\theta) \leqslant D_\lambda(\hat{\theta}^{(\lambda)}) - \frac{\gamma\lambda^2}{2} \left\| \hat{\theta}^{(\lambda)} - \theta \right\|_2^2 .$$

By weak duality $\forall \beta \in \mathbb{R}^p, D_\lambda(\hat{\theta}^{(\lambda)}) \leqslant P_\lambda(\beta)$, hence $\forall \beta \in \mathbb{R}^p, \forall \theta \in \Delta_X, D_\lambda(\theta) \leqslant P_\lambda(\beta) - \frac{\gamma\lambda^2}{2}\|\hat{\theta}^{(\lambda)} - \theta\|_2^2$ and the conclusion follows. ■

Remark 7 *To build a Gap Safe region as in Equation* (11)*, we only need strong convexity in the dual which is equivalent to smoothness of the loss function whereas the screening property* (7)*, requires group separability of norms. Hence our framework of Gap Safe screening rule automatically applies for a large class of problems.*

Remark 8 *During the review process, we became aware of a possible improvement for the radius Johnson and Guestrin (2016). In the Blitz framework, their approach leads to a potentially smaller radius, using a strongly concave upper bound of the dual function whose maximum is known. In our framework, this can be used to improve the safe radius by a* $\sqrt{2}$ *factor in the static case. This is unclear to us whether this can be done for the sequential and dynamic version. For the SVM problem Zimmert et al. (2015) got the same improvement by writing the duality gap as a function of primal variables only.*

3.2.3 Safe Active Set

Note that any time a safe rule is performed thanks to a safe region $\mathcal{R} = \mathcal{B}(\theta, r)$, one can associate a *safe active set* $\mathcal{A}_{\theta,r}$, consisting of the features that cannot be removed yet by the test in Equation (8). Hence, the safe active set contains the true support of $\hat{\beta}^{(\lambda)}$.

Definition 9 (Safe Active Set) *For a center* $\theta \in \Delta_X$ *and a radius* $r \geqslant 0$*, the safe (sphere) active set consists of the variables not eliminated by the associated (sphere) safe rule,* i.e.,

$$\mathcal{A}(\theta, r) := \{g \in \mathcal{G} : \Omega_g^D(X_g^\top \theta) + r\Omega_g^D(X_g) \geqslant 1\} \ . \tag{12}$$

When choosing $z = -G(X\beta)/\lambda$ as proposed in Section 3.2.1 as the current residual, the computation of $\theta = \Theta(z)$ in Equation (9) involves the computation of $\Omega^D(X^\top z)$. A straightforward implementation would cost $\mathcal{O}(np)$ operations. This can be avoided: when using a safe rule one knows that the index achieving the maximum for this norm is in $\mathcal{A}(\theta, r)$. Indeed, by construction of the safe active set, it is easy to see that $\Omega^D(X^\top z) = \max_{g \in \mathcal{A}(\theta,r)} \Omega_g^D(X_g^\top z)$. In practice the evaluation of the dual gap is therefore $\mathcal{O}(nq)$ where q is the size of $\mathcal{A}(\theta, r)$. In other words, using a safe screening rule also speeds up the evaluation of the stopping criterion.

3.3 Outline of the Algorithm

When designing a supervised learning algorithm with sparsity enforcing penalties, the tuning of the parameter λ in Problem (3) is crucial and is usually done by cross-validation which requires evaluation over a grid of parameter values. A standard grid considered in the literature is $\lambda_t = \lambda_{\max} 10^{-\delta t/(T-1)}$ with a small δ, say $\delta = 10^{-2}$ or 10^{-3}, see for instance (Bühlmann and van de Geer, 2011)[2.12.1] or the *glmnet* package (Friedman et al., 2010). The parameter δ has an important influence on the computational burden: computing time tends to increase for small λ, the primal iterates being less and less sparse, and the problem to solve more and more ill-posed. It is customary to start from the largest regularizer $\lambda_0 = \lambda_{\max}$ and then to perform iteratively the computation of $\hat{\beta}^{(\lambda_t)}$ after the one of $\hat{\beta}^{(\lambda_{t-1})}$. This leads to computing the models in the order of increasing complexity: this allows important speed-up by benefiting of warm start strategies.

Here we propose a simple pathwise algorithm divided in two step:

- **Active warm start**: improve solver initialization by solving the problem restricted to an initial estimation of the support based on sequential informations along the regularization path (see Section 4.4 for details on the various strategies investigated).
- **Dynamic Gap Safe Screening**: use the informations gained during the iterations of the algorithm to obtain a smaller safe region therefore a greater elimination of inactive variables (see Section 4.3).

We summarize our strategy for solving the problem given by Equation (3) in Algorithm 1 and 2. The notation Solver $(\ldots)$ refers to any numerical solver that produces an approximation of the solution of (3) and SolverUpdate $(\ldots)$ is the updating scheme of the current vector along the iterations[5]. We consider solvers that can use a (primal) warm start point.

4. Screening strategies and theoretical analysis

We now describe the simplest safe rule strategy, which we refer to as the static strategy.

4.1 Static Safe Rules

The first static safe rule, introduced by El Ghaoui et al. (2012), discards variables before any computation thanks to Proposition 4. Here, the (safe) sphere is fixed once and for all,

5. For our experiments we have focused on (block) coordinate descent solvers

Algorithm 1 Pathwise algorithm with active warm start

Input : $X,\ y,\ \epsilon,\ K,\ f^{\text{ce}},\ (\lambda_t)_{t\in[T-1]}$
for $t \in [T-1]$ **do**
  $\beta = \check{\beta}^{(\lambda_{t-1})}$ and // Get previous ϵ-solution
  Get an initial (safe or not) support estimator $\mathcal{S} = \mathcal{S}(\check{\beta}^{(\lambda_{t-1})})$
  $\beta_{\mathcal{S}} = \text{Solver}\,(X_{\mathcal{S}},\ y,\ \beta_{\mathcal{S}},\ \epsilon,\ K,\ f^{\text{ce}},\ \lambda_t)$ // Active warm start
  $\check{\beta}^{(\lambda_t)} = \text{Solver}\,(X,\ y,\ \beta,\ \epsilon,\ K,\ f^{\text{ce}},\ \lambda_t)$ // Solve over all variables
Output: $\left(\check{\beta}^{(\lambda_t)}\right)_{t\in[T-1]}$

Algorithm 2 Iterative solver with GAP safe rules: $\text{Solver}\,(X,\ y,\ \beta,\ \epsilon,\ K,\ f^{\text{ce}},\ \lambda)$

Input : $X,\ y,\ \beta,\ \epsilon,\ K,\ f^{\text{ce}},\ \lambda$ // Warm start is authorized here through β
for $k \in [K]$ **do**
  if $k \mod f^{\text{ce}} = 1$ **then**
    Compute a dual variable $\theta = -G(X\beta)/\max(\lambda, \Omega^D(X^\top G(X\beta)))$
    Stop if $\text{Gap}_\lambda(\beta,\theta) \leqslant \epsilon$
    $r = \sqrt{\frac{2\text{Gap}_\lambda(\beta,\theta)}{\gamma\lambda^2}}$ // Get Gap Safe radius as in Equation (11)
    $\mathcal{A} = \left\{g \in \mathcal{G} : \Omega_g^D(X_g^\top\theta) + r\Omega_g^D(X_g) \geqslant 1\right\}$ // Get Safe active set as in Equation (12)
  $\beta_{\mathcal{A}} = \text{SolverUpdate}\,(X_{\mathcal{A}},\ y,\ \beta_{\mathcal{A}},\ \lambda)$ // Solve on current Safe active set
Output: $\check{\beta}^{(\lambda)}$

hence the name static. The static rule reads:

$$\begin{aligned}
\underline{\text{Static sphere rule}}: &\quad \text{If} \quad \Omega_g^D(X_g^\top\theta_{\max}) + r_{\max}\Omega_g^D(X_g) < 1, \quad \text{then} \quad \hat{\beta}_g^{(\lambda)} = 0\ ,\\
\text{Center}: &\quad \theta_{\max} := -G(0)/\lambda_{\max}\ ,\\
\text{Radius}: &\quad r_{\max} := \sqrt{2\text{Gap}_\lambda(0,\theta_{\max})/\gamma\lambda^2}\ .
\end{aligned}$$

There is a threshold λ_{critic} such that for any λ smaller than λ_{critic} the test from the Static sphere rule can never be satisfied. This phenomenon appears clearly in the numerical experiments presented in Section 6. In simple cases a closed form for λ_{critic} can even be provided. For instance, in the case of the Group Lasso, El Ghaoui et al. (2012) proposed to use $r_{\max} = \left|\frac{1}{\lambda} - \frac{1}{\lambda_{\max}}\right| \|y\|_2$, and simple calculation gives:

$$\lambda_{\text{critic}} := \lambda_{\max} \times \min_{g\in\mathcal{G}} \frac{\|y\|_2\, \Omega_g^D(X_g)}{\lambda_{\max} + \|y\|_2\, \Omega_g^D(X_g) - \Omega_g^D(X_g G(0))}\ .$$

4.2 Sequential Safe Rules

Provided that the λ's are close enough along the regularization parameters, knowing an estimate of $\hat{\beta}^{(\lambda_{t-1})}$ gives a clever initialization to compute $\hat{\beta}^{(\lambda_t)}$. To initialize the solver for a new λ_t, a natural choice is to set the primal variable equal to $\check{\beta}^{(\lambda_{t-1})}$, an approximation of $\hat{\beta}^{(\lambda_{t-1})}$ output by the solver (at a prescribed precision). This popular strategy is referred to as "warm start" in the literature (Friedman et al., 2007). On top of this standard strategy,

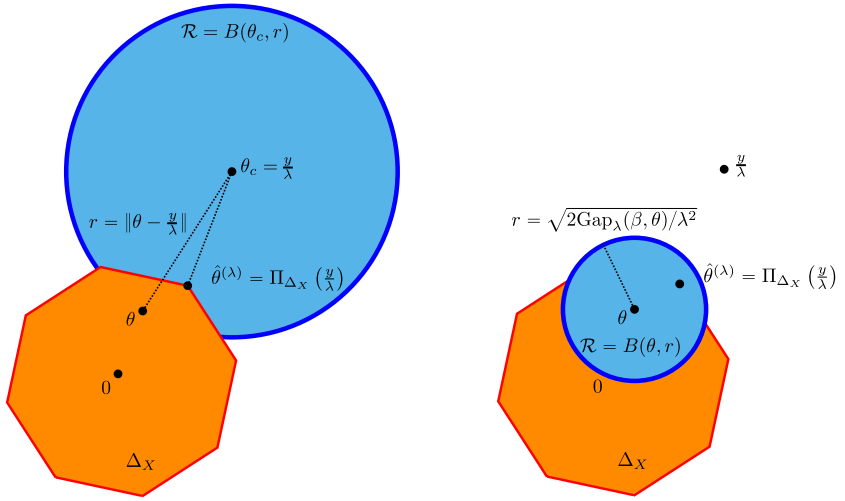
one can reuse prior dual information to improve the screening as well (El Ghaoui et al., 2012). This leads to the sequential strategy to screen for a new λ_t:

$$\begin{aligned}
\underline{\text{Sequential sphere rule}}: &\quad \text{If} \quad \Omega_g^D(X_g^\top\check{\theta}^{(\lambda_{t-1})}) + r_t\Omega_g^D(X_g) < 1, \quad \text{then} \quad \hat{\beta}_g^{(\lambda_t)} = 0\ ,\\
\text{Center}: &\quad \check{\theta}^{(\lambda_{t-1})} := \Theta(-G(X\check{\beta}^{(\lambda_{t-1})})/\lambda_{t-1})\ ,\\
\text{Radius}: &\quad r_t := \sqrt{2\text{Gap}_{\lambda_t}(\check{\beta}^{(\lambda_{t-1})}, \check{\theta}^{(\lambda_{t-1})})/\gamma\lambda_t^2}\ .
\end{aligned}$$

Remark 10 *Previous works in the literature (Wang et al., 2012; Wang and Ye, 2014; Wang et al., 2014; Lee and Xing, 2014) proposed sequential safe rules, though they were generally used in an unsafe way in practice. Indeed, such rules relied on the exact knowledge of $\hat{\theta}^{(\lambda_{t-1})}$ to screen out coordinates of $\hat{\beta}^{(\lambda_t)}$. Unfortunately, it is impossible to obtain such a point*[6] *since it is the solution of an optimization problem typically solved by an iterative solver, hence such it is only known up to a limited precision. By ignoring such inaccuracy in the knowledge of $\hat{\theta}^{(\lambda_{t-1})}$ one can wrongly eliminate variables that do belong to the support of $\hat{\beta}^{(\lambda_t)}$. Without a posteriori checking the screened out features, this could prevent the algorithm from converging, as shown in (Ndiaye et al., 2016b, Appendix B).*

4.3 Dynamic Safe Rules

Another road to speed up solvers using screening rules was proposed by Bonnefoy et al. (2014, 2015) under the name "dynamic safe rules". For a fixed λ, it consists in performing screening along with the iterations of the optimization algorithm used to solve Problem (3). Denoting by k the iteration number, they introduced a rule for the Lasso that consists of a safe sphere with center y/λ and radius $\|y/\lambda - \theta_k\|$, where θ_k is a current dual feasible point.



Let us consider a sequence (β_k) that converges to a primal solution $\hat{\beta}^{(\lambda)}$. For creating a dual feasible point, we apply the rescaling introduced in Equation (9) to $z = -G(X\beta_k)/\lambda$ and the dynamic strategy can be summarized by

$$\begin{aligned}
\underline{\text{Dynamic sphere rule}}: &\quad \text{If} \quad \Omega_g^D(X_g^\top\theta_k) + r_k\Omega_g^D(X_g) < 1, \quad \text{then} \quad \hat{\beta}_g^{(\lambda)} = 0\ ,\\
\text{Center}: &\quad \theta_k := \Theta(-G(X\beta_k)/\lambda) \text{ defined thanks to (9)}\ ,\\
\text{Radius}: &\quad r_k := \sqrt{2\text{Gap}_\lambda(\beta_k,\theta_k)/\gamma\lambda^2}\ .
\end{aligned}$$

In practice the computation of the duality gap can be expensive due to the matrix vector operations needed to compute $X^\top G(X\beta_k)$. For instance in the Lasso case, a dual gap computation requires almost as much computation as a full pass of coordinate descent over the data. Hence, it is recommended to evaluate the dynamic (safe) rule only every few passes over the data set. In all our experiments, we have set this screening frequency parameter to $f^{ce} = 10$.

Note that contrary to the original dynamic screening rules proposed by Bonnefoy et al. (2014, 2015), the Gap Safe rules we introduced are converging in the sense that our safe regions converge to the singleton $\{\hat{\theta}^{(\lambda)}\}$ (see Section 4 for more details). Indeed, their proposed safe sphere was centered on y/λ, and their radius can only be greater than $\|y/\lambda - \hat{\theta}^{(\lambda)}\|$ in the Lasso case they consider. We provide a visual comparison in Figure 1.

6. Except for $\lambda_0 = \lambda_{\max}$, where $\theta_{\max} := -G(0)/\lambda_{\max}$ can be computed exactly

(a) Bonnefoy *et al.* (2014) safe region

(b) Gap Safe region

Figure 1: Illustration of safe region differences between Bonnefoy *et al.* (2014) and Gap Safe strategies for the Lasso case; note that $\gamma = 1$ in this case. Here β is a primal point, θ is a dual feasible point (the feasible region Δ_X is in orange, while the respective safe balls $\mathcal{R}$ are in blue).

4.4 Active Warm Start

An another variant to further reduce running time in the *active warm start*, recently introduced by Ndiaye et al. (2016a) for speeding-up concomitant Lasso computations. Instead of simply leveraging the previous primal solution, the *active warm start* strategy also makes use of the previous safe active set $\mathcal{A}(\theta_{t-1}, r_{t-1})$, with $\theta_{t-1} = \check{\theta}^{(\lambda_{t-1})}$ and $r_{t-1} = r_{\lambda_{t-1}}(\check{\beta}^{(\lambda_{t-1})}, \check{\theta}^{(\lambda_{t-1})})$. The idea is to take as a new primal warm start point, the (approximate) minimizer of P_{λ_t} under the additional constraint that its support is included in the safe active set $\mathcal{A}(\theta_{t-1}, r_{t-1})$ *i.e.,*

$$\widetilde{\beta}^{(\lambda_{t-1}, \lambda_t)} \in \underset{\beta \in \mathbb{R}^p}{\arg\min}\, F(\beta) + \lambda_t \Omega(\beta) \text{ s.t. } \text{supp}(\beta) \subseteq \mathcal{A}(\theta_{t-1}, r_{t-1}) \ . \tag{13}$$

In (13), we still choose $\check{\beta}^{(\lambda_{t-1})}$ as a standard warm start initialization with the same number of inner loops and/or accuracy as in (3) (to avoid the multiplication of parameters to be set by the user). Note that un-safe estimators of the active set can be used as for active warm start. In practice, we can use the (un-safe) strong active set provided by the Strong rules introduced by Tibshirani et al. (2012). This *Strong warm start* strategy is detailed in Section 4.6.

4.5 Theoretical Analysis

Dynamic safe screening rules have practical benefits since they increase the number of screened out variables as the algorithm proceeds. In this section, it is shown that Gap Safe rules allow to have sharper and sharper dual regions along the iterations, accelerating support identification. Before this, the following proposition states that if one relies on a primal converging algorithm, then the dual sequence we propose is also converging. Note that the convergence is maintained to the same primal solution when the primal solution is non-unique.

Proposition 11 (Convergence of the Dual Points) *Let β_k be a current estimate of a primal solution $\hat{\beta}^{(\lambda)}$ and $\theta_k = \Theta(-G(X\beta_k)/\lambda)$ be the current estimate of $\hat{\theta}^{(\lambda)}$. Then, $\lim_{k\to+\infty} \beta_k = \hat{\beta}^{(\lambda)}$ implies $\lim_{k\to+\infty} \theta_k = \hat{\theta}^{(\lambda)}$.*

Proof Let $\alpha_k = \max(\lambda, \Omega^D(X^\top G(X\beta_k)))$, we have:

$$\left\|\theta_k - \hat{\theta}^{(\lambda)}\right\|_2 = \left\|\frac{G(X\hat{\beta}^{(\lambda)})}{\lambda} - \frac{G(X\beta_k)}{\alpha_k}\right\|_2 \leqslant \left|\frac{1}{\lambda} - \frac{1}{\alpha_k}\right| \|G(X\beta_k)\|_2 + \frac{\left\|G(X\hat{\beta}^{(\lambda)}) - G(X\beta_k)\right\|_2}{\lambda}.$$

If $\beta_k \to \hat{\beta}^{(\lambda)}$, then $\alpha_k \to \max(\lambda, \Omega^D(X^\top G(X\hat{\beta}^{(\lambda)}))) = \max(\lambda, \lambda\Omega^D(X^\top\hat{\theta}^{(\lambda)})) = \lambda$ since $G(X\hat{\beta}^{(\lambda)}) = -\lambda\hat{\theta}^{(\lambda)}$ thanks to the link-equation (5) and since $\hat{\theta}^{(\lambda)}$ is feasible, $\Omega^D(X^\top\hat{\theta}^{(\lambda)}) \leqslant 1$. Hence, both terms in the previous inequality converge to zero. ■

Let us now describe the notion of converging safe regions and converging safe rules introduced in (Fercoq et al., 2015, Definition 1).

Definition 12 *Let $(\mathcal{R}_k)_{k\in\mathbb{N}}$ be a sequence of closed convex sets in $\mathbb{R}^n$ containing $\hat{\theta}^{(\lambda)}$. It is a converging sequence of safe regions if the diameters of the sets converge to zero. The associated safe screening rules are referred to as converging.*

When $\theta_k = \Theta(-G(X\beta_k)/\lambda)$, Proposition 11 guarantees that Gap Safe spheres are converging. Indeed, the sequence of radius $r_k = (2\text{Gap}_\lambda(\beta_k, \theta_k)/(\gamma\lambda^2))^{1/2}$ converges to 0 with k by strong duality, hence the sequence $\mathcal{B}(\theta_k, r_k)$ converges to $\{\hat{\theta}^{(\lambda)}\}$ which means that the proposed Gap Safe sphere is asymptotically optimal.

We now prove that one recovers a specific set, called the *equicorrelation set* in finite time with any converging strategy.

Definition 13 *The equicorrelation set is defined as* $\mathcal{E}_\lambda := \left\{g \in \mathcal{G} : \Omega_g^D(X_g^\top\hat{\theta}^{(\lambda)}) = 1\right\}$.

Indeed, the following proposition asserts that after a finite number of steps, the equicorrelation set $\mathcal{E}_\lambda$ is exactly identified. Such a property is sometimes referred to as finite identification of the support (Liang et al., 2014) and is summarized in the following proposition. Yet, note that the (primal) optimal support can be strictly smaller than the equicorrelation set, see Tibshirani (2013). For clarity, links between optimal support, sure active sets, equicorrelation set are illustrated in Figure 2.

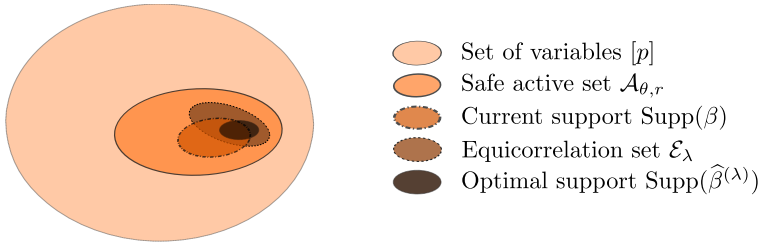


Figure 2: Illustration of the inclusions between several remarkable sets: supp$(\beta) \subseteq \mathcal{A}(\theta, r) \subseteq [p]$ and supp$(\hat{\beta}^{(\lambda)}) \subseteq \mathcal{E}_\lambda \subseteq \mathcal{A}(\theta, r) \subseteq [p]$, where β, θ is a primal/dual pair.

Proposition 14 (Identification of the Equicorrelation Set)
For any sequence of converging safe active set $(\mathcal{A}(\theta_k, r_k))_{k\in\mathbb{N}}$, we have $\lim_{k\to\infty} \mathcal{A}(\theta_k, r_k) = \mathcal{E}_\lambda$. More precisely, there exists an integer $k_0 \in \mathbb{N}$ such that $\mathcal{A}(\theta_k, r_k) = \mathcal{E}_\lambda$ for all $k \geqslant k_0$.

Proof We proceed by double inclusion. First remark that $\mathcal{E}_\lambda = \mathcal{A}(\hat{\theta}^{(\lambda)}, \hat{r}_\lambda)$ where $\hat{r}_\lambda := 2(P_\lambda(\hat{\beta}^{(\lambda)}) - D_\lambda(\hat{\theta}^{(\lambda)}))/\gamma\lambda^2 = 0$ (thanks to strong duality), so for all $k \in \mathbb{N}$, we have $\mathcal{E}_\lambda \subseteq \mathcal{A}(\theta_k, r_k)$.

Reciprocally, suppose that there exists a non active group $g \in \mathcal{G}$ *i.e.,* $\Omega_g^D(X_g^\top \hat{\theta}^{(\lambda)}) < 1$ that remains in the active set $\mathcal{A}(\theta_k, r_k)$ for all iterations *i.e.,* $\forall k \in \mathbb{N}$, $\Omega_g^D(X_g^\top \theta_k) + r_k \Omega_g^D(X_g) \geqslant 1$. Since $\lim_{k\to\infty} \theta_k = \hat{\theta}^{(\lambda)}$ and $\lim_{k\to\infty} r_k = 0$, we obtain $\Omega_g^D(X_g^\top \hat{\theta}^{(\lambda)}) \geqslant 1$ by passing to the limit. Hence, by contradiction, there exits an integer $k_0 \in \mathbb{N}$ such that $\mathcal{E}_\lambda^c \subseteq \mathcal{A}(\theta_{k_0}, r_{k_0})^c$. ■

4.6 Alternative Strategies: a Brief Survey

4.6.1 The Seminal Safe Regions

The first Safe Screening rules introduced by El Ghaoui et al. (2012) can be generalized to Problem (3) as follows. Take $\hat{\theta}^{(\lambda_0)}$ the optimal solution of the dual problem (4) with a regularization parameter λ_0. Since $\hat{\theta}^{(\lambda)}$ is optimal for problem (4) one obtains $\hat{\theta}^{(\lambda)} \in \{\theta : D_\lambda(\theta) \geqslant D_\lambda(\hat{\theta}^{(\lambda_0)})\}$. This set was proposed as a safe region by El Ghaoui et al. (2012).

In the regression case (where $f_i(z) = (y_i - z)^2/2$), it is straightforward to see that it corresponds to the safe sphere $\mathcal{B}(y/\lambda, \|y/\lambda - \hat{\theta}^{(\lambda_0)}\|_2)$.

4.6.2 ST3 and Dynamic ST3

Following (7), the safe sphere test given by Equation (8) is more efficient when θ is near $\hat{\theta}^{(\lambda)}$ and r close to zero. This motivated the following improvements.

A refined sphere rule can be obtained in the regression case by exploiting geometric informations in the dual space. This method was originally proposed in Xiang et al. (2011) and extended in Bonnefoy et al. (2014) with a dynamic refinement of the safe region.

Let $g_\star \in \arg\max_{g\in\mathcal{G}} \Omega_g^D(X^\top y)$ (note that $\Omega_{g_\star}^D(X^\top y) = \lambda_{\max}$), and let us define

$$\mathcal{V}_\star := \{\theta \in \mathbb{R}^n : \Omega_{g_\star}^D(X_{g_\star}^\top \theta) \leqslant 1\} \text{ and } \mathcal{H}_\star := \{\theta \in \mathbb{R}^n : \Omega_{g_\star}^D(X_{g_\star}^\top \theta) = 1\}.$$

We assume that the dual norm is differentiable at $X_{g_\star}^\top y/\lambda_{\max}$ (which is true in all the cases presented in Section 5). Let $\eta := X_{g_\star} \nabla \Omega_{g_\star}^D(X_{g_\star}^\top y/\lambda_{\max})$ be the vector normal to $\mathcal{V}_\star$ at $y/\lambda_{\max}$ and define

$$\theta := \Pi_{\mathcal{H}_\star}\left(\frac{y}{\lambda}\right) = \frac{y}{\lambda} - \frac{\langle \frac{y}{\lambda}, \eta\rangle - 1}{\|\eta\|_2^2}\eta \text{ and } r_\theta := \sqrt{\left\|\frac{y}{\lambda} - \theta\right\|_2^2 - \left\|\frac{y}{\lambda} - \theta\right\|_2^2},$$

where $\theta \in \Delta_X$ is any dual feasible vector. Following the proof in (Ndiaye et al., 2016b, Appendix D), one can show that $\hat{\theta}^{(\lambda)} \in \mathcal{B}(\theta, r_\theta)$. The special case where $\theta = y/\lambda_{\max}$ corresponds to the original ST3 introduced in Xiang et al. (2011) for the Lasso. A further improvement can be obtained by choosing dynamically $\theta = \theta_k$ along the iterations of an algorithm, this strategy corresponding to DST3 introduced in Bonnefoy et al. (2014, 2015) for the Lasso and Group Lasso, and in Ndiaye et al. (2016b) for the Sparse-Group Lasso.

4.6.3 Dual Polytope Projection

In the regression case, Wang et al. (2012) explore other geometric properties of the dual solution. Their method is based on the non-expansiveness of projection operators[7]. Indeed, for $\hat{\theta}^{(\lambda)}$ (resp. $\hat{\theta}^{(\lambda_0)}$)) being optimal dual solution of (4) with parameter λ (resp. λ_0), one has: $\|\hat{\theta}^{(\lambda)} - \hat{\theta}^{(\lambda_0)}\|_2 = \|\Pi_{\Delta_X}(y/\lambda) - \Pi_{\Delta_X}(y/\lambda_0)\|_2 \leqslant \|y/\lambda - y/\lambda_0\|_2$ and hence $\hat{\theta}^{(\lambda)} \in \mathcal{B}(\hat{\theta}^{(\lambda_0)}, \|y/\lambda - y/\lambda_0\|_2)$. Unfortunately, those regions are intractable since they required the *exact* knowledge of the optimal solution $\hat{\theta}^{(\lambda_0)}$ which is not available in practice (except for $\lambda_0 = \lambda_{\max}$). It may lead to un-safe screening rules as discussed in Remark 10.

Remark 15 *The preceding spheres are mainly based on the fact that $\hat{\theta}^{(\lambda)} = \Pi_{\Delta_X}(y/\lambda)$ which is limited to the regression case. Thus, those methods are not appropriate for more general data fitting term which greatly reduces the scope of such rules.*

Remark 16 *The radius of the regions above do not converge to zero even in the dynamic case (DST3), and the (fixed) center of the preceding sphere can be far from $\hat{\theta}^{(\lambda)}$ when λ gets small. Thus, those regions are not converging and are irrelevant for dynamic screening.*

4.6.4 Strong rules

The Strong rules were introduced in Tibshirani et al. (2012) as a *heuristic* extension of the safe rules. It consists in relaxing the *safe* properties to discard features more aggressively, and can be formalized as follows. Assume that the gradient of the data fitting term ∇F is group-wise non-expansive w.r.t. the dual norm $\Omega_g^D(\cdot)$ along the regularization path *i.e.,* that

7. The authors also proved an enhanced version of this safe region by using the firm non-expansiveness of the projection operator.

for any $g \in \mathcal{G}$, any $\lambda > 0, \lambda' > 0$, $\Omega_g^D\big(\nabla_g F(\hat{\beta}^{(\lambda)}) - \nabla_g F(\hat{\beta}^{(\lambda')})\big) \leqslant |\lambda - \lambda'|$. When choosing two regularization parameters such that $\lambda < \lambda'$ one has:

$$\begin{aligned}\lambda\Omega_g^D\left(X_g^\top\hat{\theta}^{(\lambda)}\right) = \Omega_g^D\left(\nabla_g F(\hat{\beta}^{(\lambda)})\right) &\leqslant \Omega_g^D\left(\nabla_g F(\hat{\beta}^{(\lambda')})\right) + \Omega_g^D\left(\nabla_g F(\hat{\beta}^{(\lambda)}) - \nabla_g F(\hat{\beta}^{(\lambda')})\right)\\ &\leqslant \Omega_g^D\left(\nabla_g F(\hat{\beta}^{(\lambda')})\right) + |\lambda - \lambda'|\\ &= \lambda'\Omega_g^D\left(X_g^\top\hat{\theta}^{(\lambda')}\right) + \lambda' - \lambda.\end{aligned}$$

Combining this with the screening rule (7), one obtains:

$$\Omega_g^D\left(X_g^\top\hat{\theta}^{(\lambda')}\right) < \frac{2\lambda - \lambda'}{\lambda'} \Longrightarrow \Omega_g^D\left(X_g^\top\hat{\theta}^{(\lambda)}\right) < 1 \Longrightarrow \hat{\beta}_g^{(\lambda)} = 0. \tag{14}$$

The set of variables not eliminated is called the *strong active set* and is defined as:

$$\mathcal{STG}(\hat{\theta}^{(\lambda')}, \lambda, \lambda') := \left\{g \in \mathcal{G} : \Omega_g^D\left(X_g^\top\hat{\theta}^{(\lambda')}\right) \geqslant \frac{2\lambda - \lambda'}{\lambda'}\right\}. \tag{15}$$

Note that Strong rules are un-safe because the non-expansiveness condition on the (gradient of the) data fitting term is usually not satisfied without stronger assumptions on the design matrix X; see discussion in (Tibshirani et al., 2012, Section 3). It requires the exact knowledge of $\hat{\theta}^{(\lambda')}$ which is not available in practice. Using such rules, the authors advised to check the KKT condition[8] a posteriori, to avoid removing wrongly some features.

To overcome this limitation, we propose to use the strong active set $\mathcal{STG}(\hat{\theta}^{(\lambda_{t-1})}, \lambda_t, \lambda_{t-1})$ defined by Equation (15) for an active warm start strategy (cf. Section 4.4). We compare below this strategy with the one using $\mathcal{A}(\theta_{t-1}, r_{t-1})$ in Equation (13) as initial active set. A similar strategy is also used in the "big lasso" package by Zeng and Breheny (2017) as a hybrid screening strategy that *"alleviates the computational burden of KKT post-convergence checking for the strong rules by not checking features that can be safely eliminated"*. However, our warm start strategy (active or strong) does not require post-processing steps.

4.6.5 Correlation Based Rule

Previous works in statistics have proposed various model-based screening methods to select important variables. Those methods discard variables with small correlation between the features and response variables. For instance Sure Independence Screening (SIS) by Fan and Lv (2008) reads: for a chosen critical threshold γ (such that the number of selected variables is smaller than a prescribed proportion of the features),

$$\text{If } \Omega_g^D(X_g^\top y) < \gamma \text{ then remove } X_g \text{ from the problem.}$$

8. The post-processing for the Lasso (with the notation from Section 5.1) adds back variables violating the approximated KKT conditions

$$KKT_\epsilon : \begin{cases} |X_j^\top\theta| \leqslant 1 + \epsilon, & \text{if } \beta_j = 0,\\ |X_j^\top\theta - \operatorname{sign}(\beta_j)| \leqslant \epsilon, & \text{if } \beta_j \neq 0.\end{cases} \tag{16}$$

One can show that $\operatorname{Gap}_\lambda(\beta, \theta) \leqslant (1 - \lambda/\alpha)^2 \|y - X\beta\|^2/2 + \lambda\epsilon\|\beta\|_1$ where $\alpha = \max(\lambda, \|X^\top(y - X\beta)\|_\infty)$. Hence choosing $\epsilon = \epsilon'/P_\lambda(\beta) - (1 - \lambda/\alpha)^2$ imply an ϵ'-duality gap.

	Lasso	Multi-task regr.	Logistic regr.	Multinomial regr.
$f_i(z)$	$\frac{(y_i - z)^2}{2}$	$\frac{\|Y_i - z\|^2}{2}$	$\log(1 + \mathrm{e}^z) - y_i z$	$\log\left(\sum_{k=1}^q \mathrm{e}^{z_k}\right) - \sum_{k=1}^q Y_{i,k} z_k$
$f_i^*(u)$	$\frac{(u+y_i)^2 - y_i^2}{2}$	$\frac{\|u+y_i\|^2 - \|Y_i\|_2^2}{2}$	$\mathrm{Nh}(u + y_i)$	$\mathrm{NH}(u + Y_i)$
$G(\theta)$	$\theta - y$	$\theta - Y$	$\frac{\mathrm{e}^\theta}{1+\mathrm{e}^\theta} - y$	$\mathrm{RowNorm}(\mathrm{e}^\theta) - Y$
γ	1	1	4	1

	ℓ_1	ℓ_1/ℓ_2	$\ell_1 + \ell_1/\ell_2$
$\Omega(\beta)$	$\|\beta\|_1$	$\sum_{g\in\mathcal{G}} \|\beta_g\|_2$	$\tau\|\beta\|_1 + (1-\tau)\sum_{g\in\mathcal{G}} w_g\|\beta_g\|_2$
$\Omega^D(\xi)$	$\max_{j\in[p]} \lvert\xi_j\rvert$	$\max_{g\in\mathcal{G}} \|\xi_g\|_2$	$\max_{g\in\mathcal{G}} \frac{\|\xi_g\|_{\epsilon_g}}{\tau + (1-\tau)w_g}$, $\epsilon_g := \frac{(1-\tau)w_g}{\tau + (1-\tau)w_g}$

Table 1: Useful ingredients for computing Gap Safe rules. We have used lower case to indicate when the parameters are vectors or not (following the notation used in Section 5.5 and 5.6). The function RowNorm consists in normalizing a (non-negative) matrix row-wise, such that each row sums to one. The details for computing the ϵ-norm $\|\cdot\|_{\epsilon_g}$ is given in Proposition 17.

It is a marginal oriented variable selection method and it is worth noting that SIS can be recast as a static sphere test in linear regression scenarios:

$$\text{If } \Omega_g^D(X_g^\top y) < \gamma = \lambda\left(1 - r\Omega_g^D(X_g)\right) \text{ then } \hat{\beta}_g^{(\lambda)} = 0 \,(\text{remove } X_g).$$

Other refinements can also be found in the literature such as iterative screening (ISIS) (Fan and Lv, 2008), that bears some similarities with dynamic sphere safe tests.

5. Gap Safe Rule for Popular Estimators

We now detail how our results apply to relevant supervised learning problems. A summary synthesizing the different learning task we are addressing is given in Table 1.

5.1 Lasso

For the Lasso estimator (Tibshirani, 1996), the data-fitting term is the standard least square, *i.e.*, $F(\beta) = \|y - X\beta\|_2^2/2 = \sum_{i=1}^n (y_i - x_i^\top\beta)^2/2$ (meaning that $f_i(z) = (y_i - z)^2/2$). The regularization term enforces sparsity at the feature level and is defined by

$$\Omega(\beta) = \|\beta\|_1 \quad \text{and} \quad \Omega^D(\xi) = \|\xi\|_\infty = \max_{j\in[p]} |\xi_j|.$$

5.2 Group Lasso

For the Group Lasso estimator (Yuan and Lin, 2006), the data-fitting term is the same $F(\beta) = \|y - X\beta\|_2^2/2$ but the penalty considered enforces group sparsity. Hence, we consider

the norm $\Omega(\beta) = \Omega_w(\beta)$, often referred to as an ℓ_1/ℓ_2 norm, defined by:

$$\Omega_w(\beta) := \sum_{g\in\mathcal{G}} w_g \left\|\beta_g\right\|_2 \quad \text{and} \quad \Omega_w^D(\xi) := \max_{g\in\mathcal{G}} \frac{\|\xi_g\|_2}{w_g} \ ,$$

where $w = (w_g)_{g\in\mathcal{G}}$ are some weights satisfying $w_g > 0$ for all $g \in \mathcal{G}$.

5.3 Sparse-Group Lasso

In the Sparse-Group Lasso case, we also have $\beta \in \mathbb{R}^p$ and $F(\beta) = \|y - X\beta\|_2^2/2$ but the regularization $\Omega(\beta) = \Omega_{\tau,w}(\beta)$ is defined by

$$\Omega_{\tau,w}(\beta) := \tau\|\beta\|_1 + (1-\tau)\sum_{g\in\mathcal{G}} w_g \left\|\beta_g\right\|_2 ,$$

for $\tau \in [0,1], w = (w_g)_{g\in\mathcal{G}}$ with $w_g \geqslant 0$ for all $g \in \mathcal{G}$. Note that we recover the Lasso if $\tau = 1$, and the Group Lasso if $\tau = 0$; the case where $w_g = 0$ for some $g \in \mathcal{G}$ together with $\tau = 0$ is excluded ($\Omega_{\tau,w}$ is not a norm in such a case). This estimator was introduced by Simon et al. (2013) to enforce sparsity both at the feature and at the group level, and was used in different applications such as brain imaging in Gramfort et al. (2013) or in genomics in Peng et al. (2010). Other hierarchical norms have also been proposed in Sprechmann et al. (2010) or Jenatton et al. (2011) and could be handled in our framework modulo additional technical details.

For the Sparse-Group Lasso, the geometry of the dual feasible set Δ_X is more complex (*cf.* Figure 3 for a comparison w.r.t. Lasso and Group Lasso). As a consequence, additional geometrical insights are needed to derive efficient safe rules, especially to compute the dual norm required by Equation (9) and the computation of the safe screening rules given in (7).

We now introduce the ϵ-norm (denoted $\|\cdot\|_\epsilon$) as it has a connection with the Sparse-Group Lasso norm $\Omega_{\tau,w}$. The ϵ-norm was first proposed in Burdakov (1988) for other purposes (see also Burdakov and Merkulov (2001)). For any $\epsilon \in [0,1]$ and any $x \in \mathbb{R}^d$, $\|x\|_\epsilon$ is defined as the unique nonnegative solution ν of the following equation (for $\epsilon = 0$, we define $\|x\|_{\epsilon=0} := \|x\|_\infty$):

$$\sum_{i=1}^{d} (|x_i| - (1-\epsilon)\nu)_+^2 = (\epsilon\nu)^2. \tag{17}$$

Using soft-thresholding, this is equivalent to solve in ν the equation $\|\mathrm{ST}_{(1-\epsilon)\nu}(x)\|_2 = \epsilon\nu$. Moreover, its dual norm is given by; see (Burdakov and Merkulov, 2001, Equation (42)):

$$\|\xi\|_\epsilon^D = \epsilon\|\xi\|_2^D + (1-\epsilon)\|\xi\|_\infty^D = \epsilon\|\xi\|_2 + (1-\epsilon)\|\xi\|_1 \ . \tag{18}$$

This allows to express the Sparse-Group Lasso norm $\Omega_{\tau,w}$ using the dual ϵ-norm. We now derive an explicit formulation for the dual norm of the Sparse-Group Lasso, originally proposed in (Ndiaye et al., 2016b, Prop. 4):

Proposition 17 *For all groups g in $\mathcal{G}$, let us introduce $\epsilon_g := \dfrac{(1-\tau)w_g}{\tau + (1-\tau)w_g}$. Then, the Sparse-Group Lasso norm satisfies the following properties: for any β and ξ in $\mathbb{R}^p$,*

$$\Omega_{\tau,w}(\beta) = \sum_{g\in\mathcal{G}} (\tau + (1-\tau)w_g)\|\beta_g\|_{\epsilon_g}^D \quad \textit{and} \quad \Omega_{\tau,w}^D(\xi) = \max_{g\in\mathcal{G}} \frac{\|\xi_g\|_{\epsilon_g}}{\tau + (1-\tau)w_g}.$$

$$\mathcal{B}_{\Omega_{t,w}^D} = \left\{\xi \in \mathbb{R}^p : \forall g \in \mathcal{G}, \|\mathrm{ST}_\tau(\xi_g)\|_2 \leqslant (1-\tau)w_g\right\}.$$

$$\partial\Omega_{\tau,w}(\beta) = \left\{z \in \mathbb{R}^p : \forall g \in \mathcal{G}, z_g \in \tau\partial\|\cdot\|_1(\beta_g) + (1-\tau)w_g\partial\|\cdot\|_2(\beta_g)\right\}.$$

Hence the dual feasible set is given by

$$\begin{aligned}\Delta_X &= \left\{\theta \in \mathbb{R}^n : \forall g \in \mathcal{G}, \|\mathrm{ST}_\tau\left(X_g^\top\theta\right)\|_2 \leqslant (1-\tau)w_g\right\} \\ &= \left\{\theta \in \mathbb{R}^n : \forall g \in \mathcal{G}, \|X_g^\top\theta\|_{\epsilon_g} \leqslant \tau + (1-\tau)w_g\right\}.\end{aligned}$$

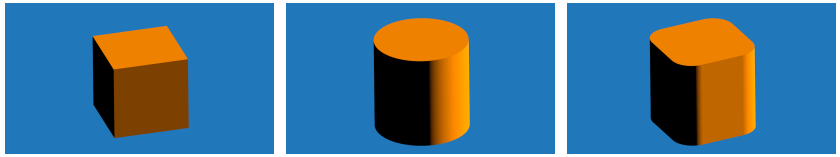
Remark 18 *Computing the dual norm of the Sparse-Group Lasso involves solving for each group $g \in \mathcal{G}$, a problem similar to the one given in (17) which has a quadratic complexity. To overcome this difficulty, an efficient algorithm relying on sorting techniques was proposed in (Ndiaye et al., 2016b, Prop. 5) to perform exact dual norm evaluation.*

The Sparse-Group Lasso benefits from two levels of screening: the safe rules can detect both group-wise zeros and coordinate-wise zeros in the remaining groups: for any group g in $\mathcal{G}$ and any safe sphere $\mathcal{B}(\theta, r)$, Equation (7) and the sub-differential of the Sparse-Group Lasso norm in Proposition 17 give (a detailed proof is given in (Ndiaye et al., 2016b, Appendix C))

$$\textbf{\textit{Group level safe screening rule:}} \qquad \max_{\theta\in\mathcal{B}(\theta,r)} \frac{\|X_g^\top\theta\|_{\epsilon_g}}{\tau + (1-\tau)w_g} < 1 \Rightarrow \hat{\beta}_g^{(\lambda)} = 0.$$

$$\textbf{\textit{Feature level safe screening rule:}} \qquad \forall j \in g, \max_{\theta\in\mathcal{B}(\theta,r)} |X_j^\top\theta| < \tau \Rightarrow \hat{\beta}_j^{(\lambda)} = 0.$$

Noting that $\|\mathrm{ST}_\tau(x)\|_2 = (1-\tau)w_g \iff \|x\|_{\epsilon_g} = \tau + (1-\tau)w_g$, the above screening test on the group level can be rewritten as



$$\max_{\theta\in\mathcal{B}(\theta,r)} \left\|\mathrm{ST}_\tau(X_g^\top\theta)\right\|_2 < (1-\tau)w_g \Rightarrow \hat{\beta}_g^{(\lambda)} = 0.$$

The advantage of this formulation is that one can easily derive a "tight" upper-bound of the non-convex optimization problem in the left hand side of the preceding test. Indeed, we have $\mathrm{ST}_\tau(x) = x - \Pi_{\tau\mathcal{B}_\infty}(x)$ which brings us finally into a geometric problem easier to solve. We recall from (Ndiaye et al., 2016b, Prop. 1) that for any center $\theta \in \Delta_X$, any group $g \in \mathcal{G}$ and any $j \in g$, we have the following upper-bound

$$\max_{\theta\in\mathcal{B}(\theta,r)} |X_j^\top\theta| \leqslant |X_j^\top\theta| + r\left\|X_j\right\|_2 ,$$

$$\max_{\theta\in\mathcal{B}(\theta,r)} \left\|\mathrm{ST}_\tau(X_g^\top\theta)\right\|_2 \leqslant T_g := \begin{cases} \left\|\mathrm{ST}_\tau(X_g^\top\theta)\right\|_2 + r\left\|X_g\right\|_2 , & \text{if } \left\|X_g^\top\theta\right\|_\infty > \tau, \\ (\left\|X_g^\top\theta\right\|_\infty + r\left\|X_g\right\|_2 - \tau)_+, & \text{otherwise.} \end{cases}$$

Hence we derive the two level of safe screening rule:

(a) Lasso dual ball $\mathcal{B}_{\Omega^D}$ for $\Omega^D(\theta) = \|\theta\|_\infty$.

(b) Group Lasso dual ball $\mathcal{B}_{\Omega^D}$ for $\Omega^D(\theta) = \max(\sqrt{\theta_1^2 + \theta_2^2}, |\theta_3|)$.

(c) Sparse-Group Lasso dual ball $\mathcal{B}_{\Omega^D} = \{\theta : \forall g \in \mathcal{G}, \|\mathrm{ST}_\tau(\theta_g)\|_2 \leqslant (1-\tau)w_g\}$.

Figure 3: Lasso, Group Lasso and Sparse-Group Lasso dual unit balls: $\mathcal{B}_{\Omega^D} = \{\theta : \Omega^D(\theta) \leqslant 1\}$. For the illustration, the group structure is chosen such that $\mathcal{G} = \{\{1,2\},\{3\}\}$, *i.e.,* $g_1 = \{1,2\}, g_2 = \{3\}$, $n = p = 3$, $w_{g_1} = w_{g_2} = 1$ and $\tau = 1/2$.

Proposition 19 (Safe screening rule for the Sparse-Group Lasso)

Group level screening: $\forall g \in \mathcal{G}, \quad$ *if* $T_g < (1-\tau)w_g, \quad$ *then* $\hat{\beta}_g^{(\lambda)} = 0.$

Feature level screening: $\forall g \in \mathcal{G}, \forall j \in g,$ *if* $|X_j^\top \theta| + r\|X_j\|_2 < \tau, \quad$ *then* $\hat{\beta}_j^{(\lambda)} = 0.$

In the same spirit than Proposition 14, for any safe region $\mathcal{R}$, *i.e.,* a set containing $\hat{\theta}^{(\lambda)}$, we define two levels of active sets, one for the group level and one for the feature level:

$$\mathcal{A}_{\mathrm{gp}}(\mathcal{R}) := \{g \in \mathcal{G}, \max_{\theta \in \mathcal{R}} \left\|\mathrm{ST}_\tau(X_g^\top \theta)\right\|_2 \geqslant (1-\tau)w_g\},$$
$$\mathcal{A}_{\mathrm{ft}}(\mathcal{R}) := \bigcup_{g \in \mathcal{A}_{\mathrm{gp}}(\mathcal{R})} \{j \in g : \max_{\theta \in \mathcal{R}} |X_j^\top \theta| \geqslant \tau\}.$$

If one considers sequence of converging regions, then the next proposition (see (Ndiaye et al., 2016b, Prop. 3)) states that we can identify in finite time the optimal active sets defined as follows:

$$\mathcal{E}_{\mathrm{gp}} := \left\{g \in \mathcal{G} : \left\|\mathrm{ST}_\tau(X_g^\top \hat{\theta}^{(\lambda)})\right\|_2 = (1-\tau)w_g\right\}, \ \mathcal{E}_{\mathrm{ft}} := \bigcup_{g \in \mathcal{E}_{\mathrm{gp}}} \left\{j \in g : |X_j^\top \hat{\theta}^{(\lambda)}| \geqslant \tau\right\}.$$

Proposition 20 *Let $(\mathcal{R}_k)_{k\in\mathbb{N}}$ be a sequence of safe regions whose diameters converge to 0. Then, $\lim_{k\to\infty} \mathcal{A}_{gp}(\mathcal{R}_k) = \mathcal{E}_{gp}$ and $\lim_{k\to\infty} \mathcal{A}_{ft}(\mathcal{R}_k) = \mathcal{E}_{ft}$.*

5.4 ℓ_1 Regularized Logistic Regression

Here, we consider the formulation given in (Bühlmann and van de Geer, 2011, Chapter 3) for the two-class logistic regression. In such a context, one observes for each $i \in [n]$ a class label $l_i \in \{1,2\}$. This information can be recast as $y_i = \mathbb{1}_{\{l_i=1\}}$ (where $\mathbb{1}$ is the indicator function), and it is then customary to minimize (3) where

$$F(\beta) = \sum_{i=1}^n \left(-y_i x_i^\top \beta + \log\left(1 + \exp\left(x_i^\top \beta\right)\right)\right), \tag{19}$$

with $f_i(z) = -y_i z + \log(1 + \exp(z))$, and the penalty is simply the ℓ_1 norm: $\Omega(\beta) = \|\beta\|_1$. Let us introduce Nh, the (binary) negative entropy function defined by:

$$\mathrm{Nh}(x) = \begin{cases} x\log(x) + (1-x)\log(1-x), & \text{if } x \in [0,1] \ , \\ +\infty, & \text{otherwise} \ . \end{cases} \tag{20}$$

We use the convention $0\log(0) = 0$, and one can check that $f_i^*(z_i) = \mathrm{Nh}(z_i + y_i)$ and $\gamma = 4$.

Remark 21 *We have privileged the formulation with the label $y \in \{0,1\}^n$ instead of $y \in \{+1,-1\}^n$ in order to be consistent with the multinomial cases below. One can simply switch from one formulation to the other thanks to the mapping $\tilde{y} = 2y - 1$.*

5.5 ℓ_1/ℓ_2 Multi-task Regression

The multi-task Lasso is a regression problem where the parameters form a matrix $\mathrm{B} \in \mathbb{R}^{p\times q}$. Denoting n the number of observations for each task $k \in [q]$, it is defined as

$$\min_{\mathrm{B}\in\mathbb{R}^{p\times q}} \frac{1}{2}\|Y - X\mathrm{B}\|_F^2 + \lambda \sum_{j=1}^p \|\mathrm{B}_{j,:}\|_2, \tag{21}$$

where $X \in \mathbb{R}^{n\times p}$ and $Y \in \mathbb{R}^{n\times q}$. Here we assume that the explanatory variables X are shared among the tasks however the Gap Safe rules would readily apply to the non-shared design formulation as in Lee et al. (2010) or in Liu et al. (2009) since the loss is still smooth (*cf.* Remark 7).

Introducing the vec operator that vectorizes a matrix by stacking its columns to form a column vector, and the Kronecker product $\otimes$ of two matrices, the multi-task Lasso can be rewritten as a special case of Group Lasso. In fact, we have n class of observations $c_i = (i + (k-1)n)_{k\in[q]}$ of size q for each $i \in [n]$ (the overall number of observations is $n' = nq$) and p groups $g_j = (j + (k-1)p)_{k\in[q]}$ such that $|g_j| = q$ for $j \in [p]$. The design matrix $\tilde{X} = I_q \otimes X \in \mathbb{R}^{n'\times p'} = \mathbb{R}^{nq\times pq}$ is a q-block diagonal matrix defined as $\tilde{X} = \mathrm{diag}(X,\ldots,X)$, $y = \mathrm{vec}(Y)$ and $\beta = \mathrm{vec}(\mathrm{B})$, we have:

$$\min_{\beta\in\mathbb{R}^{p'}} \frac{1}{2}\sum_{i=1}^n \left\|y_{c_i} - \tilde{x}_i^\top \beta\right\|_2^2 + \lambda \sum_{j=1}^p \left\|\beta_{g_j}\right\|_2, \tag{22}$$

i.e., $f_i(z) = \|y_{c_i} - z\|_2^2/2$. The advantage of this formulation is that it can be concisely written using the matrix forms of y and β, without the need to actually construct the large matrix X'. This is particularly appealing for the implementation.

In signal processing, this model is also referred to as the Multiple Measurement Vector (MMV) problem. It allows to jointly select the same features for multiple regression tasks, see (Argyriou et al., 2006, 2008; Obozinski et al., 2010). This estimator has been used in various applications such as prediction of the location of a protein within a cell (Xu et al., 2011) or in neuroscience (Gramfort et al., 2012), for instance to diagnose Alzheimer's disease (Zhang et al., 2012).

5.6 ℓ_1/ℓ_2 Multinomial Logistic Regression

We adapt the formulation given in (Bühlmann and van de Geer, 2011, Chapter 3) for the multinomial regression. In such a context, one observes for each $i \in [n]$ a class label $l_i \in [q]$. This information can be recast into a matrix $Y \in \mathbb{R}^{n\times q}$ filled by 0's and 1's: $Y_{i,k} = \mathbb{1}_{\{l_i=k\}}$ (where $\mathbb{1}$ is the indicator function). In the same spirit as for the multi-task Lasso, a matrix $\mathrm{B} \in \mathbb{R}^{p\times q}$ is formed by q vectors encoding the hyperplanes for the linear classification. Thus the multinomial ℓ_1/ℓ_2 regularized regression reads:

$$\min_{\mathrm{B}\in\mathbb{R}^{p\times q}} \sum_{i=1}^{n} \left(\sum_{k=1}^{q} -Y_{i,k} x_i^\top \mathrm{B}_{:,k} + \log\left(\sum_{k=1}^{q} \exp\left(x_i^\top \mathrm{B}_{:,k}\right)\right)\right) + \lambda \sum_{j=1}^{p} \|\mathrm{B}_{j,:}\|_2 \,. \tag{23}$$

Using a similar reformulation as in Section 5.5 *i.e.,* defining $c_i = (i + (k-1)n)_{k\in[q]}$ for each $i \in [n]$ and $g_j = (j + (k-1)p)_{k\in[q]}$ for each $j \in [p]$, the ℓ_1/ℓ_2 multinomial logistic regression can be cast into our framework as:

$$\min_{\beta\in\mathbb{R}^{p'}} \sum_{i=1}^{n} f_i\left(\tilde{x}_i^\top \beta\right) + \lambda \sum_{j=1}^{p} \left\|\beta_{g_j}\right\|_2 , \tag{24}$$

with $f_i : \mathbb{R}^q \to \mathbb{R}$ such that $f_i(z) = -y_{c_i}^\top z + \log\left(\sum_{k=1}^{q} \exp\left(z_k\right)\right)$. Note that generalizing (3) to functions $f_i : \mathbb{R}^q \to \mathbb{R}$ does not bear difficulties, see Ndiaye et al. (2015).

Let us introduce NH, the negative entropy function defined by

$$\mathrm{NH}(x) = \begin{cases} \sum_{i=1}^{q} x_i \log(x_i), & \text{if } x \in \Sigma_q = \{x \in \mathbb{R}_+^q : \sum_{i=1}^{q} x_i = 1\}, \\ +\infty, & \text{otherwise.} \end{cases} \tag{25}$$

We use the convention $0\log(0) = 0$, and one can check that $f_i^*(z) = \mathrm{NH}(z + Y_i)$ and $\gamma = 1$.

For multinomial logistic regression, D_λ implicitly encodes the additional constraint $\theta \in \operatorname{dom} D_\lambda = \{\theta' \in \mathbb{R}^n \ : \ \forall i \in [n], -\lambda\theta'_{c_i} + y_{c_i} \in \Sigma_q\}$ where Σ_q is the q dimensional simplex, see Equation (25). By the dual scaling Equation (9), we have:

$$\theta = \Theta\left(\frac{-G(\tilde{X}\beta)}{\lambda}\right) = \frac{R}{\max(\lambda, \Omega^D(X^\top R))}, \text{ with } R = y - \mathrm{RowNorm}(\exp(\tilde{X}\beta))$$

where the function RowNorm consists in normalizing a (non-negative) matrix row-wise, such that each row sums to one. Thus for any $i \in [n]$ and $\alpha := \lambda/\max(\lambda, \Omega^D(X^\top R)) \in [0, 1]$,

$$-\lambda\theta_{c_i} + y_{c_i} = (1-\alpha)y_{c_i} + \alpha\,\mathrm{RowNorm}(\exp(\tilde{x}_i^\top\beta))$$

which is a convex combination of elements in Σ_q. Hence the dual scaling (9) preserves this additional constraint.

Remark 22 *The intercept has been neglected in our models for simplicity. The Gap Safe framework can also handle such a feature to the cost of more technical details (by adapting the results from Koh et al. (2007) for instance). However, in practice, the intercept can be handled in the present formulation by adding a constant column to the design matrix X. The intercept is then regularized. However, if the constant is set high enough, regularization is small and experiments show that it has little to no impact for high-dimensional problems. This is the strategy used in the* Liblinear *package by Fan et al. (2008). Another alternative could be to handle the constant term as is performed by El Ghaoui et al. (2012).*

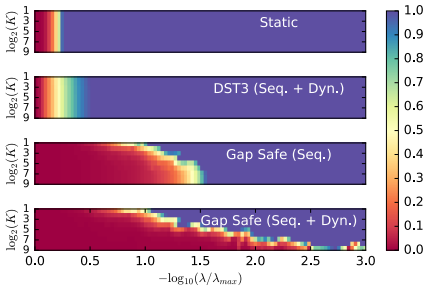
6. Experiments

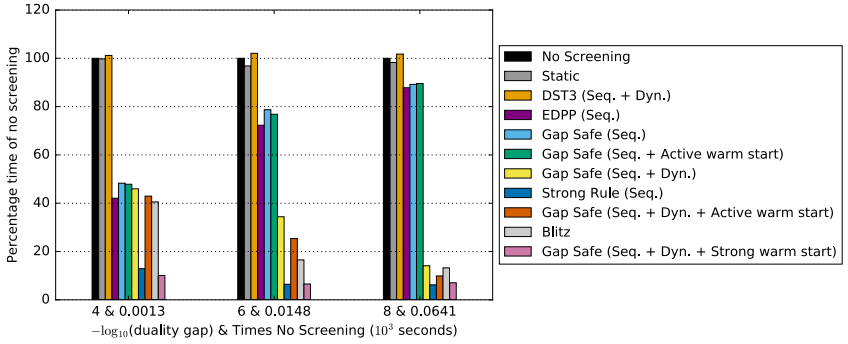
In this section we present results obtained with the Gap Safe rules on various data sets. Implementation[9] has been done in Python and Cython (Behnel et al., 2011) for low level critical parts. A coordinate descent algorithm is used with a scaled dual gap stopping criterion *i.e.,* we normalize the targeted accuracy ϵ (in the stopping criterion) in order to have a running time that is independent from the data scaling, *i.e.,* $\epsilon \leftarrow \epsilon\|y\|_2^2$ for the regression cases and $\epsilon \leftarrow \epsilon\min(n_1, n_2)/n$ where n_i is the number of observations in the class i, for the logistic cases.

Note that in the Lasso case, to compare our method with the un-safe *strong rules* by Tibshirani et al. (2012) and with the sequential screening rule such as the *eddp+* by Wang et al. (2012), we have added an approximated KKT post-processing step. We do this following Footnote 8, since they require the previous (exact) dual optimal solution which is not available in practice (Ndiaye et al., 2016b, Appendix B). The same limit holds true for the *TLFre* approach of Wang and Ye (2014) addressing the Sparse-Group Lasso formulation, as well as for the method explored by Lee and Xing (2014) to handle overlapping groups and *slores* by Wang et al. (2014) for the binary logistic regression.

We have compared our method to various known safe screening rules (El Ghaoui et al., 2012; Xiang et al., 2011; Bonnefoy et al., 2014). For the Sparse-Group Lasso, such rules did not exist, so we have proposed natural extensions (Ndiaye et al., 2016b) thanks to exact computation of the dual norm in Proposition 17. For the Lasso estimator, we have also compared our implementation with the *Blitz* algorithm (Johnson and Guestrin, 2015) which combines Gap Safe screening rules, *Prox-Newton* coordinate descent and an active set strategy.

6.1 ℓ_1 Lasso Regression





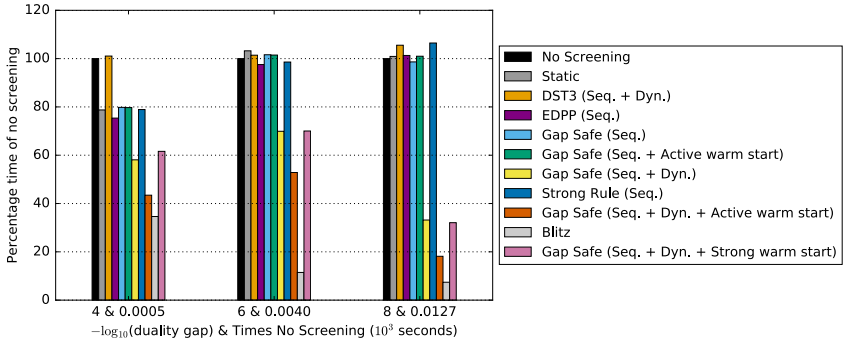


Figure 4: Lasso on the Leukemia (dense data with $n = 72$ observations and $p = 7129$ features). fraction of the variables that are active. Each line corresponds to a fixed number of iterations for which the algorithm is run.

9. The source code can be found in `https://github.com/EugeneNdiaye`.

(a) Dense grid with 100 values of λ.

(b) Coarse grid with 10 values of λ.

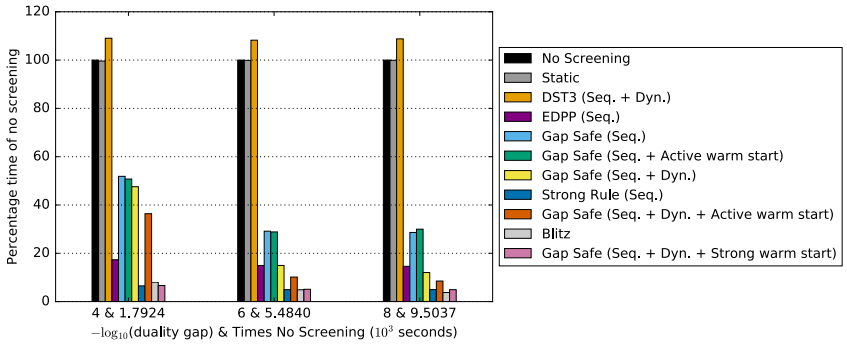

Figure 5: Lasso on the Leukemia (dense data with $n = 72$ observations and $p = 7129$ features). Computation times needed to solve the Lasso regression path to desired accuracy for a grid of λ from $\lambda_{\max}$ to $\lambda_{\max}/10^3$.

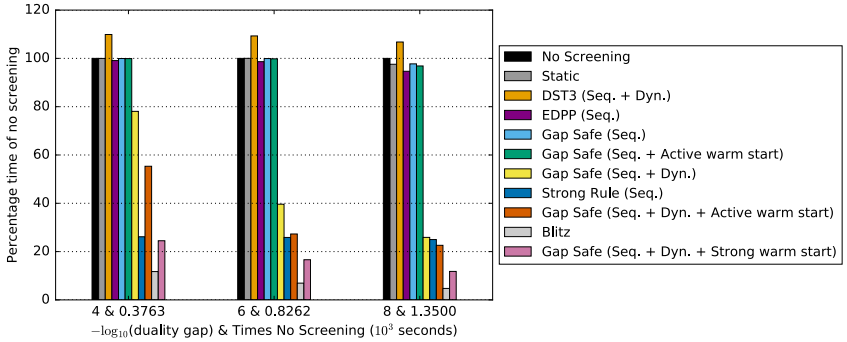
We have evaluated the computing time for the Gap Safe rules with and without active warm start, and compared with the static rule El Ghaoui et al. (2012) and the refined dynamic rule DST3 by Xiang et al. (2011), as well as Bonnefoy et al. (2015). We used the classic dense data set Leukemia, and the large sparse financial data set E2006-log1p available from LIBSVM[10]. We have normalized the column of X and standardized y to have zero mean and unit variance.



The experiments on Figure 4 focuses on the Leukemia data set. The screening performance for a fixed number of iterations, from 2 to 2^9, is investigated for each λ. It

10. `http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/`

demonstrates that increasing the number of iterations benefits to the dynamic screening rule. Also, the closer the estimate is from the global minimum, the better the screening. This is inline with the results in running time in the benchmark on Figure 5(a). Note that the dynamic Gap Safe rule is the only rule that significantly improves the running time of the Lasso.

(a) Dense grid with 100 values of λ.

(b) Sparse grid with 10 values of λ.

Figure 6: Lasso on financial data E2006-log1p (sparse data with $n = 16087$ observations and $p = 1668737$ features). Computation times needed to solve the Lasso regression path to desired accuracy for a grid of λ from $\lambda_{\max}$ to $\lambda_{\max}/20$.

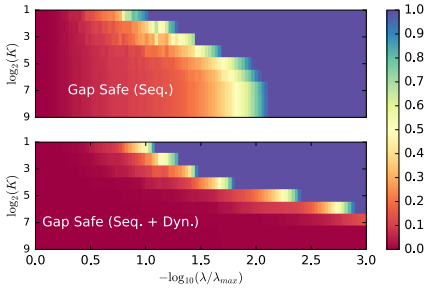
Results presented in the financial data set in Figure 6 are inline with the results on Leukemia. We observe that the *Blitz* algorithm (Johnson and Guestrin, 2015), also achieves a significant speed-up with gains in the same order of magnitude than our dynamic Gap Safe

implementation combined with active or strong warm start. One advantage of our approach though, is the simplicity to insert it in any iterative algorithm as shown in Algorithm 1 and 2.

To demonstrate the limitations of the strong rules, we report in Figure 5(b) results with a coarse grid with only 10 values of λ from $\lambda_{\max}$ to $\lambda_{\max}/10^3$ such that $2\lambda_t < \lambda_{t-1}$. The strong rules become then useless since the screening test (14) selects all variables, *i.e.*, $\mathcal{STG}(\hat{\theta}^{(\lambda_{t-1})}, \lambda_t, \lambda_{t-1}) = \mathcal{G}$. Overall, the greater the gap between grid points, the lower the benefits of (active) warm start.

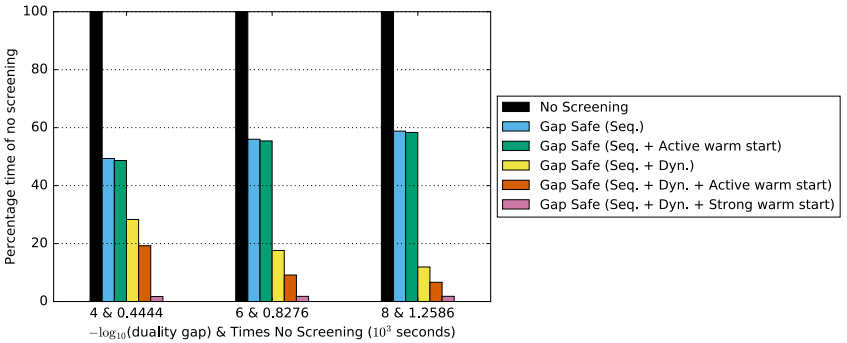
In the experiment in Figure 6(b), we have stopped the grid at $\lambda_{\max}/20$ leading to a sparse solution with 1562 active variables. We obtain an important speed-up for both coarse and dense grids demonstrating the consistent efficiency of the active warm start strategy specially in a sparse regime.

Finally, with an extremely coarse grid, we therefore recommend the active warm start with the previous safe active set (which performance is only affected through the initialization point) rather than the strong active set (*cf.* Figure 5(b)).



6.2 ℓ_1 Binary Logistic Regression

Results on the Leukemia data set for standard logistic regression are reported in Figure 7. We compare the dynamic strategy of Gap Safe to the sequential strategy. Results demonstrate the clear benefit of the dynamic rule in terms of high number of screened out variables. This is reflected in the graph of running times, which shows that dynamic Gap Safe rule with strong warm start can yield up to a 30× speed-up compared to sequential rule and even more compared to an absence of screening (up to 50× speed-up).

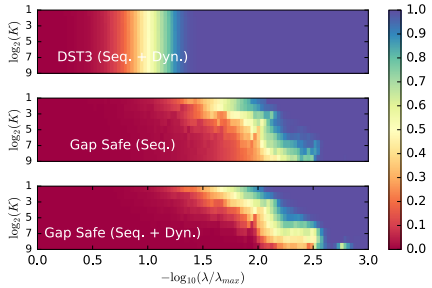


6.3 ℓ_1/ℓ_2 Multi-task Regression

To demonstrate the benefit of the Gap Safe screening rules for a multi-task Lasso problem we have considered neuroimaging data. Electroencephalography (EEG) and magnetoencephalography (MEG) are brain imaging modalities that allow to identify active brain regions. The problem to solve is a multi-task regression problem with squared loss where every task corresponds to a time instant. Using a multi-task Lasso one can constrain the recovered sources to be identical during a short time interval (Gramfort et al., 2012). This corresponds to a temporal stationary assumption. In this experiment we used a joint MEG/EEG data with 301 MEG and 59 EEG sensors leading to $n = 360$. The number of possible sources is $p = 22,494$ and the number of time instants is $q = 20$. With a 1 kHz sampling rate it is equivalent to say that the sources stay the same for 20 ms.

Results are presented in Figure 8. The Gap Safe rule is compared with the dynamic safe rule from Bonnefoy et al. (2015). Figure 8(a) shows the fraction of active variables. It demonstrates that the Gap Safe rule screens out much more variables than the compared methods. Thanks to the converging nature of our rule, the more iterations are performed the more variables are screened out. On Figure 8(b), the computation time confirms the effective speed-up. Our rule significantly improves the computation time for all duality gap tolerance from 10^{-2} to 10^{-8}, especially when accurate estimates are required, *e.g.*, for feature selection.

(a) Fraction of the variables that are active. Each line corresponds to a fixed number of iterations for which the algorithm is run.



(b) Computation times needed to solve the logistic regression path to desired accuracy with 100 values of λ from $\lambda_{\max}$ to $\lambda_{\max}/10^3$.

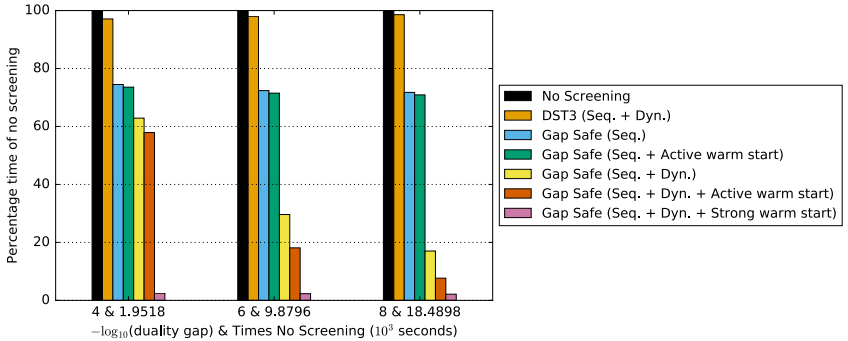


Figure 7: ℓ_1 regularized binary logistic regression on the Leukemia (dense data with $n = 72$ observations and $p = 7129$ features). Sequential and full dynamic screening Gap Safe rules are compared.

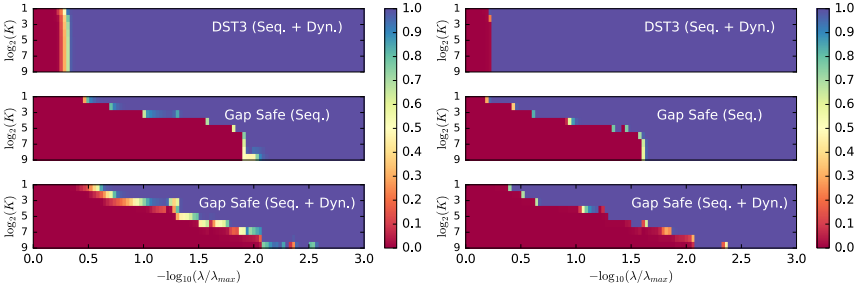
6.4 Sparse-Group Lasso Regression

We consider the data set NCEP/NCAR Reanalysis 1 Kalnay et al. (1996) which contains monthly means of climate data measurements spread across the globe in a grid of $2.5^\circ \times 2.5^\circ$ resolutions (longitude and latitude 144×73) from 1948/1/1 to 2015/10/31. Each grid point constitutes a group of 7 predictive variables (*Air Temperature, Precipitable water, Relative humidity, Pressure, Sea Level Pressure, Horizontal Wind Speed* and *Vertical Wind Speed*) whose concatenation across time constitutes our design matrix $X \in \mathbb{R}^{814 \times 73577}$. Such data have therefore a natural group structure, with seven features per group. As target variable $y \in \mathbb{R}^{814}$, we use the values of *Air Temperature* in a neighborhood of Dakar.



(a) Fraction of active variables as a function of λ and the number of iterations K. The Gap Safe strategy has a much longer range of λ with (red) small active sets.

(b) Computation time to reach convergence using different screening strategies. We have run the algorithm with 100 values of λ from $\lambda_{\max}$ to $\lambda_{\max}/10^3$.

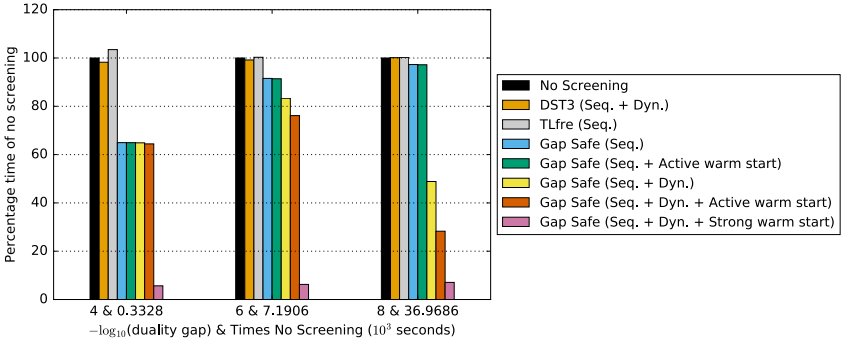


Figure 8: Experiments on MEG/EEG brain imaging data set (dense data with $n = 360$ observations, $p = 22494$ features and $q = 20$ time instants).

For preprocessing, we remove the seasonality (we center the data month by month) and the trend (we remove the linear trend obtained by least squares) present in the data set. We then standardize the data so that each feature has a variance of one. This preprocessing is usually done in climate analysis to prevent some bias in the regression estimates. Similar data have been used in the past by Chatterjee et al. (2012), demonstrating that the Sparse-Group Lasso estimator is well suited for prediction in such climatology applications. Indeed, thanks to the sparsity structure, the estimates delineate via their support some predictive regions at the group level, as well as predictive feature via coordinate-wise screening.

(a) Proportion of active coordinate-wise variables as a function of parameters (λ_t) and the number of iterations K.

(b) Proportion of active group variables as a function of parameters (λ_t) and the number of iterations K.

(c) Time to reach convergence as a function of increasing prescribed accuracy, using various screening strategies and a logarithmic grid from $\lambda_{\max}$ to $\lambda_{\max}/10^{2.5}$.

Figure 9: Sparse-Group Lasso experiments on climate data NCEP/NCAR Reanalysis 1 (dense data with $n = 814$ observations and $p = 73577$ features) with $\tau = 0.4$ chosen by cross-validation.

We choose the parameter τ in the set $\{0, 0.1, \ldots, 0.9, 1\}$ by splitting in half the observations, and run a training-test validation procedure. For each value of τ, we require a duality gap of 10^{-8} on the training set and pick the best one in term of prediction accuracy on the test set. Since the prediction error degrades increasingly for $\lambda \leqslant \lambda_{\max}/10^{-2.5}$, we fix $\delta = 2.5$. We have fixed the weight $w_g = 1$ since all groups have the same size. The computational time benchmark is presented in Figure 9(c). Here also, we observe a significant gain by using a dynamic Gap Safe screening rule, which is further improved by the active warm start.

7. Conclusion

We have proposed a unified presentation of the Gap Safe screening rules for accelerating algorithms solving supervised learning problems under sparsity constraints. The proposed approach applies to many popular estimators that boil down to convex optimization problems where the data fitting term has a Lipschitz gradient and the regularization term is a separable sparsity enforcing function. We have shown that our methodology is more flexible than previously known safe rules as it conveniently unifies both regression and classification settings. The efficiency of the Gap Safe rules along with the new *active /strong warm start* strategies was demonstrated on multiple experiments using real high dimensional data set, suggesting that Gap Safe screening rules are always helpful to speed-up solvers targeting sparse regularization.

Minimax Filter: Learning to Preserve Privacy from Inference Attacks

Editor: Amos Storkey

Abstract

Preserving privacy of continuous and/or high-dimensional data such as images, videos and audios, can be challenging with syntactic anonymization methods which are designed for discrete attributes. Differentially privacy, which uses a more rigorous definition of privacy loss, has shown more success in sanitizing continuous data. However, both syntactic and differential privacy are susceptible to inference attacks, i.e., an adversary can accurately infer sensitive attributes from sanitized data. The paper proposes a novel filter-based mechanism which preserves privacy of continuous and high-dimensional attributes against inference attacks. Finding the optimal utility-privacy tradeoff is formulated as a min-diff-max optimization problem. The paper provides an ERM-like analysis of the generalization error and also a practical algorithm to perform minimax optimization. In addition, the paper proposes a noisy minimax filter which combines minimax filter and differentially-private mechanism. Advantages of the method over purely noisy mechanisms is explained and demonstrated with examples. Experiments with several real-world tasks including facial expression classification, speech emotion classification, and activity classification from motion, show that the minimax filter can simultaneously achieve similar or higher target task accuracy and lower inference accuracy, often significantly lower than previous methods.

Keywords: inference attack, empirical risk minimization, minimax optimization, differential privacy, k-anonymity

1. Introduction

Privacy is an important issue when data collected from or related to individuals are analyzed and released to a third party. In response to growing privacy concerns, various methods for privacy-preserving data publishing have been proposed (see Fung et al. 2010 for a review.) *Syntactic anonymization* methods, such as k-anonymity (Sweeney, 2002) and l-diversity (Machanavajjhala et al., 2007) focus on anonymization of quasi-identifiers and protection of sensitive attributes in static databases. However, it is known that syntactic anonymization is susceptible to several types of attacks such as the DeFinetti attack (Kifer, 2009). An adversary may be able to accurately *infer* sensitive attributes of individuals from insensitive, sanitized attributes. High-dimensional data also poses a challenge for syntactic anonymization methods. For example, k-anonymity is known to be ineffective for high-dimensional sparse databases (Narayanan and Shmatikov, 2008). In addition, syntactic anonymization methods are designed with discrete attributes in mind. However, continuous attributes such as videos, images, or audios cannot be discretized by binning or clustering without loss of information. Besides, conventional categorization of attributes as identifiers, quasi-identifiers, or sensitive information becomes ambiguous with multimedia-type data. For example, an image can be an identifier if it contains the face of the data owner. However, even if the face is blurred, other attributes considered sensitive by the owner such as gender or race can still be recognizable. Furthermore, identifying or sensitive information can be revealed through correlation with other information such as the background or other people in the scene.

Differential privacy (Dwork and Nissim, 2004; Dwork et al., 2006; Dwork, 2006) was proposed to address many weaknesses of syntactic methods (see the discussion by Clifton and Tassa 2013.) Differential privacy has a more formal privacy guarantee than that of syntactic methods, and is applicable to many problems beyond database release (Dwork et al., 2014). In particular, differential privacy can be defined for continuous and/or high-dimensional attributes as well as for functions (Hall et al., 2013). However, similarly to syntactic anonymization, differential privacy is not immune to inference attacks (Cormode, 2011), as differentially privacy only prevents an adversary from gaining *additional* knowledge by inclusion/exclusion of a subject (Dwork et al., 2014), and not from gaining knowledge from released data itself. Therefore, an adversary may still guess sensitive attributes of subjects from differentially-private attributes with confidence.

To preserve privacy of continuous high dimensional data from inference attacks, this paper proposes an approach which differs significantly from previous syntactic or differentially-private approaches. Consider a scenario where a social media user wants to obfuscate all faces in her picture with minimal distortion before posting the picture online. The obfuscation mechanism proposed in the paper is a type of *filtering* of the original features by a non-invertible transformation. How to choose an optimal filter is explained in the following general description. Once the filtered data (e.g., obfuscated pictures) are released, an adversary will try to infer sensitive or identifying attributes from the data in particular using machine learning predictors. Therefore the data owner needs a filter that can minimize the maximum accuracy that any adversary may achieve in predicting the sensitive or identifying attributes. This is an instance of *minimax games* between the data owner and the adversary. The privacy of filtered data is measured by the *expected risk* of adversarial algorithms on specific inference tasks such as identification. However, if privacy is the only goal, near-perfect privacy is achievable with a simple mechanism that sends no or garbage data, which has no utility for any party. To avoid those trivial solutions, (dis)utility of filtered data needs to be considered as the second goal. Disutility can be measured by the amount of distortion of the original data after filtering. Alternatively, if there are particular tasks of interest to be performed on the data by non-adversarial analysts, then again the expected risk of the target tasks can be used as disutility. The two goals—achieving privacy and utility—are often mutually conflicting, and finding an optimal tradeoff between the two is a central question in privacy research (see Related work.) This paper proposes to minimize the difference of two risks by the minimax optimization of (7). The solution to the optimization problem will be referred to as **minimax filter**. In the literature, several methods have been used to solve continuous minimax optimization problems, including the method by Kiwiel (1987) used in Hamm (2015). The paper uses a simpler optimization method based on the classic theorem of Danskin (1967).

A notable assumption this paper makes is that the training data for computing an optimal filter are independent of the test data. For example, there are publicly available data sets that can be used to compute minimax filters such as those from the UCI data repository.[1] As the training data set is already public information, the paper considers only the privacy of the subjects who use the filter at test time. A similar assumption was made in Hamm et al. (2016) for knowledge transfer purposes. After the filter is learned from training data, a new test subject can use the filter to obfuscate her data by herself without requiring a third party to collect and process her raw data. Note that this setting is analogous to the setting of local differential privacy (Duchi et al., 2013) where the entity that collects data is not trusted. Since the training procedure can only access empirical risks, the performance of the filter on test data is given in the form of expectation/probability. The paper presents an analysis of generalization error for empirical minimax optimizers in analogy with the analysis of empirical risk minimizers (ERM).

The goal of minimax filter is to prevent inference attacks, and its privacy guarantee is quite different from those of other privacy mechanisms. It is task-dependent and is given in probability or expectation rather than given absolutely, which may be considered weaker than other privacy criteria such as differential privacy. Furthermore, the sanitized data whose sensitive information is filtered out may become unsafe in the future if people's perception of which attribute is sensitive changes over time. Since the goal of minimax filter and the goal of differential privacy are very different, it is natural to ask if the two methods can be combined to take advantages of both methods. Consequently, this paper presents an extension of minimax filter called **noisy minimax filter**, which combines the filter with additive noise mechanism to satisfy the differential privacy criterion. Two methods of combination—preprocessing and postprocessing—are proposed (see Fig. 2.) In the preprocessing approach, minimax filter is applied before perturbation to reduce the sensitivity of transformed data, so that the same level of differential privacy is achieved with less noise. Similar ideas have been utilized before, where data are transformed by Discrete Fourier Transform (Rastogi and Nath, 2010) and by Wavelet Transform (Xiao et al., 2011) before noise is added. In the postprocessing approach, minimax filter is applied after perturbation, and its performance is compared with the preprocessing approach.

Minimax filter and its extensions are evaluated with several real-world tasks including facial expression classification, speech emotion classification, and activity classification from motion. Experiments show that publicly available continuous and high-dimensional data sets are surprisingly susceptible to subject identification attacks, and that minimax filters can reduce the privacy risks to near chance levels without sacrificing utility much. Experiments with noisy minimax filter also yield intuitive results. Differential privacy and resilience to inference attack are indeed different goals, such that using differentially private mechanism alone to achieve the latter requires a large amount of noise that destroys utility of data. In contrast, minimax filters can suppress inference attack with little loss of utility with or without perturbation. Therefore, adding a small amount of noise to the minimax filter can provide a formal differential privacy to a degree and also high on-average task-dependent utility and privacy against inference attacks.

To summarize, the paper has the following contributions.

1. `http://archive.ics.uci.edu/ml/`

- The paper proposes a novel filtering approach which preserves privacy of continuous and high-dimensional attributes against inference attacks. This mechanism is different from previous mechanisms in many ways; in particular, it is a learning-based approach and is task-dependent.
- The paper measures utility and privacy by expected risks, and formulates the utility-privacy tradeoff as a min-diff-max optimization problem. The paper provides an ERM-like analysis of the generalization performance of empirical optimizers.
- The paper presents a practical algorithm which can find minimax filters for a broad family of filters and losses/classifiers. The proposed optimization algorithm and supporting classes can be found on the open-source repository.[2]
- The paper proposes preprocessing and postprocessing approaches to combine minimax filter with noisy mechanisms. The resulting combination can achieve resilience to inference attacks and differential privacy at the same time.
- The paper evaluates proposed algorithms on real-world tasks and compares them with representative algorithms from the literature.

The rest of the paper is organized as follows. Sec. 2 presents related work in the literature. Sec. 3 presents minimax filters and analyzes its generalization performance on test data. Sec. 4 explains the difficulty of solving general minimax problems, and present a simple alternating optimization algorithm. Sec. 5 presents noisy minimax filters and two types of perturbation by additive noise. Sec. 6 evaluates minimax filters with three data sets compared to non-minimax approaches and also evaluates noisy minimax filters under various conditions. Sec. 7 concludes the paper with discussions.

2. Related work

Optimal utility-privacy tradeoff is one of the main goals in privacy research. Utility-privacy tradeoff has particularly been well-studied under differential privacy assumptions (Dwork and Nissim, 2004; Dwork et al., 2006; Dwork, 2006), in the context of the statistical estimation (Smith, 2011; Alvim et al., 2012; Duchi et al., 2013) and learnability (Kasiviswanathan et al., 2011). Other measures of privacy and utility were also proposed. Information-theoretic quantities were proposed by Sankar et al. (2010); Rebollo-Monedero et al. (2010); du Pin Calmon and Fawaz (2012) who analyzed privacy in terms of the rate-distortion theory in communication. One problem with using mutual information or related quantity is that it is difficult to estimate mutual information of high-dimensional and continuous variables in practice without assuming a simple distribution. In contrast, this paper proposes to use classification or regression risks to measure privacy and utility, which is directly computable from data without making assumptions on the distribution. Regarding the use of risks in this paper, classification error-based quantities have been suggested in the literature (Iyengar, 2002; Brickell and Shmatikov, 2008; Li and Li, 2009). However, privacy in those works is measured either by syntactic anonymity or probabilistic divergence which are mainly suitable for discrete attributes. In this paper, privacy and utility are both defined using risks and are therefore directly comparable when defining the tradeoff of the two. Furthermore, the proposed method explicitly preserves privacy against inference attacks, which

2. `https://github.com/jihunhamm/MinimaxFilter`

both syntactic and differentially-private methods are known to be susceptible to (Cormode, 2011).

Most of the aforementioned works focused on the analyses of utility-privacy tradeoff using different measures and assumptions. Few studied efficient algorithms to actively find optimal tradeoff which this paper aims to do. For discrete variables, Krause and Horvitz (2008) showed the NP-hardness of optimal utility-privacy tradeoff in discrete attribute selection, and demonstrated near-optimality of greedy selection. In particular, they used a weighted difference of utility and privacy cost as the joint cost similar to this work. Ghosh et al. (2009) proposed geometric mechanism and linear programming to achieve near-optimal utility for unknown users. Note that the optimization problems with discrete distributions are quite different from the problems involving high-dimensional and/or continuous distributions.

Algorithms for preserving privacy of high-dimensional face images has been proposed previously. Newton et al. (2005) applied k-anonymity to images; Enev et al. (2012) proposed to learn a linear filter using Partial Least Squares to reduce the covariance between filtered data and private labels; Whitehill and Movellan (2012) also proposed a linear filter using the log-ratio of the Fisher's Linear Discriminant Analysis metrics. Xu et al. (2017) presented a related method of preserving privacy of linear predictors using the Augmented Fractional Knapsack algorithm. This paper differs from these in several aspects: it is not limited to linear filters and is applicable to arbitrary differentiable nonlinear filters such as multilayer neural networks; it directly optimizes the utility-privacy risk instead of optimizing heuristic criteria such as covariance differences or LDA log-ratios.

The noisy minimax filter proposed in Sec. 5 bears a resemblance to the work of Rastogi and Nath (2010) and Xiao et al. (2011). Rastogi and Nath (2010) presented a differentially private method of answering queries on time-series data. They used Discrete Fourier Transform to reduce the data dimension and homomorphic encryption to perform distributed noise addition which outperformed the naive noise addition method. Xiao et al. (2011) presented a differentially private range-counting method where they used wavelets to transform the data before adding noise. Effectiveness of the method was analyzed and also demonstrated empirically. The noisy minimax filter presented in this paper, especially the preprocessing approach, is similar in concept to those works in that the combination of data transformation and perturbation is used to enhance utility. However, the transform in this paper (i.e., the minimax filter) is learned from data for specific tasks unlike the Fourier or the Wavelet transform which are data and task independent.

Lastly, the alternating optimization algorithm (Alg. 1) presented in this paper is related to the algorithm proposed by Goodfellow et al. (2014). The algorithm proposed in this paper solves a min-diff-max problem to find an optimal utility-privacy tradeoff, while Goodfellow et al. (2014) solve a minimax problem to learn generative models.

Parts of this paper have appeared in conference proceedings (Hamm, 2015, 2017). New materials in this paper include reformulations of concepts and terms, ERM-like analysis of generalization error, new closed-form examples for minimax optimization, and an alternating optimization algorithm to solve minimax problems.

3. Minimax Filter

In this section, minimax filter is introduced and discussed in detail, and its generalization error is analyzed.

3.1 Formulation

Minimax filter is a non-invertible transformation of raw features/attributes such that the transformed data have optimal utility-privacy tradeoff. Non-invertibility is assumed so that original features are not always recoverable from the filtered data. Let's assume the filter is deterministic; randomize filters will be discussed in Sec. 5. Let $\mathcal{X} \subset \mathbb{R}^D$ be the space of features/attributes as real-valued vectors. Note that discrete attributes can also be represented by real vectors, e.g., by one-hot vector. Let the filter be a map

$$g(x;u) \in G : \mathcal{X} \times \mathcal{U} \to \mathbb{R}^d \tag{1}$$

which is continuous in x and is continuously differentiable w.r.t. the parameter $u \in \mathcal{U}$. Given a filtered output $g(x)$, an adversary can make a prediction $h_p(g(x);v)$ of a private variable y which can be an identifying or sensitive attribute. The prediction function $h_p(g(x);v)$ parameterized by $v \in \mathcal{V}$ is also assumed to be continuous in v and continuously differentiable w.r.t. to the input $g(x)$. The paper proposes to use expected risk to measure the privacy of filtered output against adversarial inference:

$$f_{\text{priv}}(u,v) \triangleq E[l_p(h_p(g(x;u);v),y)], \tag{2}$$

where $l_p(\cdot)$ is a continuously differentiable loss function. From the assumptions above, f_{priv} is continuously differentiable w.r.t. the filter parameter u.

Trivial solutions to maximize privacy already exist, which are the filters that output random or constant numbers independent of actual data. However, such filters have no utility whatsoever for any party. To avoid such trivial solutions, it is necessary to consider the secondary goal of maximizing utility.

Suppose the disutility of filtered data is measured by the distortion of the original data. If $g(x;u)$ is the filter/encoder $\mathcal{X} \to \mathbb{R}^d$, then one can construct the decoder $h(\cdot\,;w) : \mathbb{R}^d \to \mathcal{X}$, such that following reconstruction error

$$f_{\text{util}}(u,w) \triangleq E[\|h_u(g(x;u);w) - x\|^2], \tag{3}$$

is minimized (i.e., $\min_w f_{\text{util}}(u,w)$.)

For another example of utility, let z be a target variable that is of interest to the subjects and analysts such as medical diagnosis of users' data. An analyst can make a prediction $h_u(g(x);w)$ parameterized by $w \in \mathcal{W}$, which is assumed to be continuous in w and continuously differentiable w.r.t. the input $g(x)$. The (dis)utility of the filtered output for a non-adversarial analyst can also be measured by the expected risk

$$f_{\text{util}}(u,w) \triangleq E[l_u(h_u(g(x;u);w),z)], \tag{4}$$

where $l_u(\cdot)$ is a continuously differentiable loss function, such that f_{util} is continuously differentiable w.r.t. the filter parameter u. To facilitate the analysis, the paper assumes

that the constraint sets $\mathcal{W}$, $\mathcal{V}$, and $\mathcal{U}$ are compact and convex subsets of Euclidean spaces such as a ball with a large but finite radius. Along with the assumption that the filter g and the risks f_{priv} and f_{util} are all continuous, min and max values are bounded and attainable. In addition, the solutions to min or max problems are assumed to be in the interior of $\mathcal{W}$, $\mathcal{V}$, and $\mathcal{U}$, enforced by adding appropriate regularization (e.g, $\lambda\|w\|^2$) to the optimization problems if necessary. For this reason, min or max problems that appear in the paper will be treated as unconstrained and the notations $u \in \mathcal{U}$, $v \in \mathcal{V}$, and $w \in \mathcal{W}$ will be omitted.

Having defined the privacy measure and the utility measure, the goal of a filter designer is to find a filter that achieves the following two objectives. The first objective is to *maximize privacy*

$$\max_u \min_v f_{\text{priv}}(u,v) \quad (\text{or equivalently}, \quad \min_u \max_v -f_{\text{priv}}(u,v)) \tag{5}$$

where $\min_v f_{\text{priv}}(u,v)$ represents the risk of the worst (i.e., most capable) adversary: the smaller the risk, the more accurately can she infer the sensitive variable y. As mentioned before, this problem alone has a trivial solution such as a constant filter that outputs zeros. The second objective is to *minimize disutility*

$$\min_u \min_w f_{\text{util}}(u,w) \quad (\text{or equivalently}, \quad \min_u -\max_w -f_{\text{util}}(u,w)) \tag{6}$$

where $\min_w f_{\text{util}}(u,w)$ represents the risk of the best analyst: the smaller the risk, the more accurately can the analyst reconstruct original data x or predict the variable of interest z. To achieve the two opposing goals, we can solve the joint problem of minimizing the weighted sum

$$\min_u \left[\max_v -f_{\text{priv}}(u,v) + \rho \min_w f_{\text{util}}(u,w)\right], \tag{7}$$

or equivalently the weighted difference of max values

$$\min_u \left[\max_v -f_{\text{priv}}(u,v) - \rho \max_w -f_{\text{util}}(u,w)\right]. \tag{8}$$

The constant $\rho > 0$ determines the relative importance of utility versus privacy. For a small $\rho \ll 1$, the problem is close to a trivial privacy-only task, and for a large $\rho \gg 1$, the problem is close to a utility-only task. The solution to (7) or (8) will be referred to as **minimax filter**[3] and is by definition an optimal filter for utility-privacy tradeoff in terms of expected risks given the family of filters $\{g(\cdot\,;u)|u \in \mathcal{U}\}$, the family of private losses/classifiers $\{l_p(h_p(\cdot\,;v))|v \in \mathcal{V}\}$ and the family of utility losses/classifiers $\{l_u(h_u(\cdot\,;w))|w \in \mathcal{W}\}$. Note that the choice of filter and loss/classifier families is very flexible, with the assumption of differentiability only. In practice, almost-everywhere differentiability suffices to use the algorithm in the paper. Fig. 1 shows an example filter/classifier from the class of multilayer neural networks. As an aside, the joint problem may be formulated as minimization of disutility with a hard constraint on privacy risk. When using interior-point methods, the procedure is similar to solving (8) iteratively with an increasing ρ, which is more demanding than minimizing the weighted sum only once as the paper proposes.

3. To be precise, the joint task (7) is a min-diff-max problem and the privacy-only task (5) is a minimax problem. However, both will be referred to as minimax as (7) can be rewritten as a standard minimax problem.

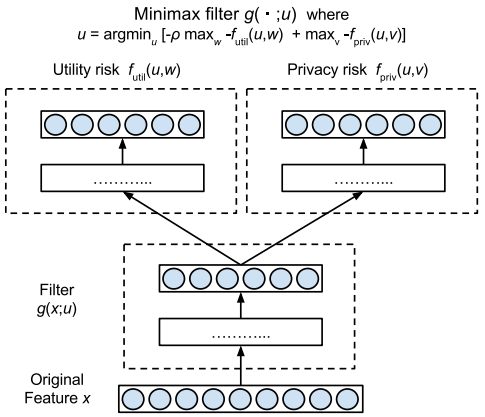

Figure 1: Minimax filter with a filter/classifiers from the class of multilayer neural networks.

3.2 Notes on private and utility tasks

The private variable y can be any attribute which is considered sensitive or identifying. For example, let y be any number or string unique to a person in the data set. Such identifiers are bijective with $\{1,...,S\}$, where S is the total number of subjects, so assume $y \in \{1,...,S\}$. The private task for an adversary is then to predict the subject number y from the filtered data $g(x)$, whose inaccuracy is measured by the expected risk of the identification task. That is, the less accurate the private classifier is, the more anonymous the filtered output is. The identity variable can also be group identifiers, e.g., y is a demographic grouping based on age, sex, ethnicity, etc. Another example of private tasks is to single-out a particular subject among the rest, in which case y is binary: $y = -1$ means 'not the target subject' and $y = 1$ means 'target subject'. To summarize, anonymity of filtered data in this paper means resilience to inference attacks on any variable y that we choose. This unifying approach is convenient since we need not determine whether an attribute is an identifier, a quasi-identifier or a sensitive attribute as in syntactic anonymization. Any information hidden in the continuous high-dimensional features which are relevant to the private variable y—whatever it may be—will be maximally filtered out by construction. Similarly, the target variable z of interest can be any variable that is not the same as the private variable y. In the pathological case where they are the same ($z = y$), the objective (8) becomes

$$\min_u \left[(1-\rho)\max_v -f(u,v)\right] \tag{9}$$

which is either a trivial privacy-only problem when $0 \le \rho < 1$, or a utility-only problem when $\rho > 1$. In general, z and y will be correlated to a certain degree, and the minimax filter will find the best compromise of utility and privacy risks.

Also, private and target tasks need not be classification tasks only. Regression tasks can also be used as a target task, as well as unsupervised tasks that do not require label z. Unsupervised tasks are useful when the target task is unknown or non-specific. For example, (3) measures the expected least-squares error between the original and the reconstructed features.

3.3 Multiple tasks

Extension of the idea in the previous section to multiple private and target tasks is straightforward. Suppose there are N_p private tasks $f^1_{\text{priv}}(u, v_1), ..., f^{N_p}_{\text{priv}}(u, v_{Np})$ associated with private random variables $y^1, ..., y^{Np}$. Note that $f^i_{\text{priv}}(u, v_i) = E[l^i_p(h^i(g(x; u); v_i), y^i)]$. Similarly, suppose there are N_u target tasks $f^1_{\text{util}}(u, w_1), ..., f^{N_u}_{\text{util}}(u, w_{Nu})$ associated with target random variables $z_1, ..., z_{Nu}$. If $\kappa_1, ..., \kappa_{Np}$ are the coefficients representing relative importance of private tasks, and $\rho_1, ..., \rho_{Nu}$ are the coefficients for utility tasks, then the final objective is to solve the following problem

$$\min_u \left[\sum_{i=1}^{N_p} \kappa_i \max_{v_i} -f^i_{\text{priv}}(u, v_i) \; + \; \sum_{i=1}^{N_u} \rho_i \min_{w_i} f^i_{\text{util}}(u, w_i) \right]. \tag{10}$$

Since this can be rewritten as

$$\min_u \left[\max_{v_1,...,v_{Np}} -\sum_{i=1}^{N_p} \kappa_i f^i_{\text{priv}}(u, v_i) \; + \; \min_{w_1,...,w_{Nu}} \sum_{i=1}^{N_u} \rho_i f^i_{\text{util}}(u, w_i) \right], \tag{11}$$

this multiple task problem is nearly identical to the original single task problem (7), with the new utility and privacy tasks defined as

$$\hat{f}_{\text{priv}}(u, v{=}(v_1, ..., v_{Np})) \;\triangleq\; \sum_i \kappa_i f^i_{\text{priv}}(u, v_i), \quad \text{and} \tag{12}$$

$$\hat{f}_{\text{util}}(u, w{=}(w_1, ..., w_{Nu})) \;\triangleq\; \sum_i \rho_i f^i_{\text{util}}(u, w_i), \tag{13}$$

with $\rho = 1$. Using this, it is straightforward to extend the analysis and algorithms developed for single tasks to those for multiple tasks.

3.4 Generalization performance of minimax filter

The proposed privacy mechanism is a learning-based approach. An optimal filter is one that solves the expected risk optimization (7). However, in reality, an optimal filter has to be estimated from finite training samples, and we need a guarantee on the performance of the learned filter on unseen test samples. This section derives generalization bounds for empirical minimax filter similar to the derivation of bounds for empirical risk minimizers (ERM).

The joint problem for expected risks was

$$\min_u \left[\max_v -f_{\text{priv}}(u, v) + \rho \min_w f_{\text{util}}(u, w) \right] = \min_u \left[\max_v -E[l_p(u, v)] + \rho \min_w E[l_u(u, w)] \right]. \tag{14}$$

A joint loss l_J is introduced for convenience:

$$l_J(u, v, w) \triangleq -l_p(u, v) + \rho \, l_u(u, w). \tag{15}$$

Let (u^*, v^*, w^*) be a solution to the expected risk optimization problem:

$$E_D[l_J(u^*, v^*, w^*)] = \min_u \left[\max_v E_D[-l_p(u, v)] + \rho \min_w E_D[l_u(u, w)] \right], \tag{16}$$

where $E_D[\cdot]$ is the expected value w.r.t. the unknown data distribution $P(x, y)$. Similarly, let $(\hat{u}, \hat{v}, \hat{w})$ be a solution to the empirical risk minimax problem:

$$E_S[l_J(\hat{u}, \hat{v}, \hat{w})] = \min_u \left[\max_v E_S[-l_p(u, v)] + \rho \min_w E_S[l_u(u, w)] \right], \tag{17}$$

where the empirical mean $E_S[\cdot]$ for $S = \{(x_1, y_1), \cdots, (x_N, y_N)\}$ is

$$E_S[l(x, y)] \triangleq \frac{1}{N} \sum_{(x,y)\in S} l(x, y). \tag{18}$$

The goal in this analysis is to show that the expected and the empirical optimizers perform equally well in expectation/probability given enough training samples:

$$E_D[l_J(\hat{u}, \hat{v}, \hat{w})] \simeq E_D[l_J(u^*, v^*, w^*)], \;\text{ as }\; N \to \infty. \tag{19}$$

The main result is the Theorem 4 which is proved in the remainder of this section. Let's define optimal parameters $v(u)$ and $w(u)$ given u as

$$v^*(u) \;\triangleq\; \arg\max_v E_D[-l_p(u, v)], \qquad \hat{v}(u) \;\triangleq\; \arg\max_v E_S[-l_p(u, v)], \tag{20}$$

$$w^*(u) \;\triangleq\; \arg\min_w E_D[l_u(u, w)], \qquad \hat{w}(u) \;\triangleq\; \arg\min_w E_S[l_u(u, w)]. \tag{21}$$

One can then write

$$\begin{aligned} E_D[l_J(u^*, v^*, w^*)] &= \min_u \left[E_D[-l_p(u, v^*(u))] + \rho E_D[l_u(u, w^*(u))] \right] && (22) \\ &= \min_u E_D[l_J(u, v^*(u), w^*(u))], && (23) \end{aligned}$$

and similarly

$$E_S[l_J(\hat{u}, \hat{v}, \hat{w})] = \min_u \left[E_S[-l_p(u, \hat{v}(u))] + \rho E_S[l_u(u, \hat{w}(u))] \right] = \min_u E_S[l_J(u, \hat{v}(u), \hat{w}(u))]. \tag{24}$$

From these definitions we have for all u,

$$\begin{aligned} E_D[l_J(u^*, v^*, w^*)] &\le E_D[l_J(u, v^*(u), w^*(u))], && (25) \\ E_S[l_J(\hat{u}, \hat{v}, \hat{w})] &\le E_S[l_J(u, \hat{v}(u), \hat{w}(u))]. && (26) \end{aligned}$$

Also from definition, for all (u, v, w),

$$\begin{aligned} E_D[l_J(u, v, w^*(u))] \;\le\; E_D[l_J(u, v, w)] \;\le\; E_D[l_J(u, v^*(u), w)], && (27) \\ E_S[l_J(u, v, \hat{w}(u))] \;\le\; E_S[l_J(u, v, w)] \;\le\; E_S[l_J(u, \hat{v}(u), w)]. && (28) \end{aligned}$$

These observations imply the following theorem.

Theorem 1 *The risk difference of expected and empirical optimizers is at most twice the largest difference of expected and empirical risks of any set of parameters:*

$$|E_D[l_J(\hat{u},\hat{v},\hat{w})] - E_D[l_J(u^*,v^*,w^*)]| \leq 2 \sup_{u,v,w} |E_D[l_J(u,v,w)] - E_S[l_J(u,v,w)]|\,. \quad (29)$$

Proof The expected risk of empirical risk optimizers $(\hat{u},\hat{v},\hat{w})$ is upper-bounded by the risk of expected risk optimizers (u^*,v^*,w^*) as follows:

$$\begin{aligned}
& E_D[l_J(\hat{u},\hat{v},\hat{w})] - E_D[l_J(u^*,v^*,w^*)] \\
= \;& E_D[l_J(\hat{u},\hat{v},\hat{w})] - E_S[l_J(\hat{u},\hat{v},\hat{w})] - (E_D[l_J(u^*,v^*,w^*)] - E_S[l_J(\hat{u},\hat{v},\hat{w})]) \\
\leq \;& E_D[l_J(\hat{u},\hat{v},\hat{w})] - E_S[l_J(\hat{u},\hat{v},\hat{w})] - (E_D[l_J(u^*,v^*,w^*)] - E_S[l_J(u^*,\hat{v}(u^*),\hat{w}(u^*))]) \quad \text{(from (26))} \\
\leq \;& E_D[l_J(\hat{u},\hat{v},\hat{w})] - E_S[l_J(\hat{u},\hat{v},\hat{w})] - (E_D[l_J(u^*,\hat{v}(u^*),w^*)] - E_S[l_J(u^*,\hat{v}(u^*),\hat{w}(u^*))]) \quad \text{(from (27))} \\
\leq \;& E_D[l_J(\hat{u},\hat{v},\hat{w})] - E_S[l_J(\hat{u},\hat{v},\hat{w})] - (E_D[l_J(u^*,\hat{v}(u^*),w^*)] - E_S[l_J(u^*,\hat{v}(u^*),w^*)]) \quad \text{(from (28))} \\
\leq \;& 2 \sup_{u,v,w} |E_D[l_J(u,v,w)] - E_S[l_J(u,v,w)]|\,.
\end{aligned}$$

The difference can also be lower-bounded as follows:

$$\begin{aligned}
& E_D[l_J(u^*,v^*,w^*)] - E_D[l_J(\hat{u},\hat{v},\hat{w})] \\
= \;& E_D[l_J(u^*,v^*,w^*)] - E_S[l_J(\hat{u},\hat{v},\hat{w})] - (E_D[l_J(\hat{u},\hat{v},\hat{w})] - E_S[l_J(\hat{u},\hat{v},\hat{w})]) \\
\leq \;& E_D[l_J(\hat{u},v^*(\hat{u}),w^*(\hat{u}))] - E_S[l_J(\hat{u},\hat{v},\hat{w})] - (E_D[l_J(\hat{u},\hat{v},\hat{w})] - E_S[l_J(\hat{u},\hat{v},\hat{w})]) \quad \text{(from (25))} \\
\leq \;& E_D[l_J(\hat{u},v^*(\hat{u}),w^*(\hat{u}))] - E_S[l_J(\hat{u},v^*(\hat{u}),\hat{w})] - (E_D[l_J(\hat{u},\hat{v},\hat{w})] - E_S[l_J(\hat{u},\hat{v},\hat{w})]) \quad \text{(from (28))} \\
\leq \;& E_D[l_J(\hat{u},v^*(\hat{u}),\hat{w})] - E_S[l_J(\hat{u},v^*(\hat{u}),\hat{w})] - (E_D[l_J(\hat{u},\hat{v},\hat{w})] - E_S[l_J(\hat{u},\hat{v},\hat{w})]) \quad \text{(from (27))} \\
\leq \;& 2 \sup_{u,v,w} |E_D[l_J(u,v,w)] - E_S[l_J(u,v,w)]|\,.
\end{aligned}$$

■

To bound the RHS of (29), one can use the Rademacher complexity theory (e.g., Lemma 26.2 of Shalev-Shwartz and Ben-David (2014).)

Lemma 2 *Let F be a class of real-valued functions, and let S be a set of N samples $S = \{(x_1,y_1),...,(x_N,y_N)\}$. Then,*

$$E_{S\sim D^N}\left[\sup_{f\in F} |E_D[f] - E_S[f]|\right] \leq 2E_{S\sim D^N}[\mathfrak{R}(F\circ S)], \quad (30)$$

where $\mathfrak{R}(F\circ S)$ is the empirical Rademacher complexity

$$\mathfrak{R}(f\circ S) \triangleq \frac{1}{N} E_{\sigma\sim\{-1,+1\}^N}\left[\sup_{f\in F}\sum_{i=1}^N \sigma_i f(x_i,y_i)\right] \quad (31)$$

for the class of real-valued functions $\{(x,y)\mapsto f(x,y) \;:\; \forall f\in F\}$.

Consider the class of real-valued functions defined from the joint loss (15):

$$\begin{aligned}
l_J\circ H_J\circ S &\triangleq \{(x,y,z)\mapsto l_J(x,y,z;u,v,w) \;:\; u\in\mathcal{U}, v\in\mathcal{V}, w\in\mathcal{W}\} \quad (32)\\
&= \{(x,y,z)\mapsto -l_p(h_v(g_u(x)),y) + \rho\, l_u(h_w(g_u(x)),z) \;:\; u\in\mathcal{U}, v\in\mathcal{V}, w\in\mathcal{W}\}.
\end{aligned}$$

Let $\mathfrak{R}(l_J\circ H_J\circ S)$ denote the empirical Rademacher complexity of the joint loss class. Furthermore, the Rademacher complexity of sum of functions can be upper-bounded by the sum of complexities:

Lemma 3 *The empirical Rademacher complexity of the joint privacy-utility loss is upper-bounded as*

$$\mathfrak{R}(l_J\circ H_J\circ S) \leq \mathfrak{R}(l_p\circ H_p\circ G\circ S) + \rho\,\mathfrak{R}(l_u\circ H_u\circ G\circ S), \quad (\rho>0) \quad (33)$$

where

$$\begin{aligned}
l_p\circ H_p\circ G\circ S &\triangleq \{(x,y,z)\mapsto l_p(h_p(g_u(x)),y) \;:\; u\in\mathcal{U}, v\in\mathcal{V}\}, \quad (34)\\
l_u\circ H_u\circ G\circ S &\triangleq \{(x,y,z)\mapsto l_u(h_u(g_u(x)),z) \;:\; u\in\mathcal{U}, w\in\mathcal{W}\}. \quad (35)
\end{aligned}$$

Proof

$$\begin{aligned}
\mathfrak{R}(l_J\circ H_J\circ S) &= \frac{1}{N}E_\sigma\left[\sup_{u,v,w}\left|\sum_{i=1}^N \sigma_i l_J(x_i,y_i,z_i;u,v,w)\right|\right] \quad (36)\\
&= \frac{1}{N}E_\sigma\left[\sup_{u,v,w}\left|\sum_{i=1}^N \sigma_i(-l_p(x_i,y_i;u,v) + \rho\, l_u(x_i,z_i;u,w))\right|\right] \quad (37)\\
&\leq \frac{1}{N}E_\sigma\left[\sup_{u,v}\left|\sum_{i=1}^N \sigma_i l_p(x_i,y_i;u,v)\right| + \rho\sup_{u,w}\left|\sum_{i=1}^N \sigma_i l_u(x_i,z_i;u,w)\right|\right] \quad (38)\\
&= \mathfrak{R}(l_p\circ H_p\circ G\circ S) + \rho\,\mathfrak{R}(l_u\circ H_u\circ G\circ S). \quad (39)
\end{aligned}$$

■

From Theorem 1 and Lemmas 2 and 3, we get the following generalization bounds in terms of the Rademacher complexity.

Theorem 4

$$\begin{aligned}
& E_{S\sim D^m}\left[|E_D[l_J(u^*,v^*,w^*)] - E_D[l_J(\hat{u},\hat{v},\hat{w})]|\right] \\
\leq \;& 4E_{S\sim D^m}\left[\mathfrak{R}(l_p\circ H_p\circ G\circ S) + \rho\,\mathfrak{R}(l_u\circ H_u\circ G\circ S)\right]. \quad (40)
\end{aligned}$$

A probabilistic bound instead of expected value can also be obtained by applying McDiarmid's inequality, which is omitted.

The Rademacher complexity of privacy and utility losses depends on our choice of loss functions, hypothesis classes, and filter classes. For the simple case of linear filters and linear classifiers, one can compute the complexity using the following lemmas (26.9 and 26.10 from Shalev-Shwartz and Ben-David (2014)):

Lemma 5 *Suppose $\phi:\mathbb{R}\to\mathbb{R}$ is α-Lipschitz, i.e., $|\phi(a)-\phi(b)|\leq\alpha|a-b|$, $\forall a,b\in\mathbb{R}$. Then,*

$$\mathfrak{R}(\phi\circ F) = \alpha\mathfrak{R}(F). \quad (41)$$

Lemma 6 *For the class of linear classifiers* $H = \{x \mapsto w^T x \ : \ \|w\|_2 \leq 1\}$,

$$\mathfrak{R}(H \circ S) \leq \frac{1}{\sqrt{N}} \sup_{x \in S} \|x\|_2. \tag{42}$$

.

From these lemmas and Theorem 4, we have a corollary for a simple case of linear filters and classifiers.

Corollary 7 *Let the loss functions* l_u *and* l_p *be* α*-Lipschitz (e.g.,* $\alpha = 1$ *for logistic regression.) Suppose* U *is a* $d \times D$ *real matrix with a bounded norm* $\|U\|_2 \leq 1$*, and* w *and* v *are vectors with bounded norms (*$\|w\|_2 \leq 1$ *and* $\|v\|_2 \leq 1$*). If the feature domain* $\mathcal{X}$ *is also bounded with a radius* $r = \max_{x \in \mathcal{X}} \|x\|_2$*, then we have*

$$|E_D[l_J(u^*, v^*, w^*)] - E_D[l_J(\hat{u}, \hat{v}, \hat{w})]| \leq \frac{4(1+\rho)\ \alpha\ r}{\sqrt{N}}. \tag{43}$$

Alternatively, one can use the VC dimension to specify the bound.

In any case, the generalization bounds in this section justify the claim that minimax filter can preserve utility-privacy of unseen test data in expectation or probability.

4. Minimax Optimization

This section presents theoretical and numerical solutions of the joint problem (8), which is a variant of unconstrained continuous minimax problems. (See Rustem and Howe (2009) for a review.) The problem (8) can be written in an equivalent form

$$\begin{aligned} \min_u \Phi(u) &= \min_u [\Phi_{\text{priv}}(u) - \rho\ \Phi_{\text{util}}(u)] && (44) \\ &= \min_u [\max_v -f_{\text{priv}}(u, v) - \rho\ \max_w -f_{\text{util}}(u, w)] && (45) \end{aligned}$$

The optimization above is a min-diff-max problem and can be considered as simultaneously solving two subproblems $\min_u[\max_v -f_{\text{priv}}(u,v)]$ and $\min_u[-\max_w -f_{\text{util}}(u,w)]$, but is evidently not the same as summing individual solutions

$$\min_u \Phi(u) \neq \min_u [\max_v -f_{\text{priv}}(u, v)] \ + \ \min_u [-\rho \max_w -f_{\text{util}}(u, w)]. \tag{46}$$

Since the second subproblem $\min_u[-\max_w -f_{\text{util}}(u,w)] = \min_{u,w} f_{\text{util}}(u,w)$ is a standard minimization problem, let's focus only on the first subproblem $\min_u[\max_v -f_{\text{priv}}(u,v)]$ which is a continuous minimax problem. Continuous minimax problems are in general more challenging to solve than standard minimization problems, as the inner optimization $\Phi_{\text{priv}}(u) = \max_v -f_{\text{priv}}$ does not usually have a closed-form solution; when it does, the whole problem can be treated as a standard minimization problem. Furthermore, there can be more than one solution to $\Phi_{\text{priv}}(u) = \max_v -f_{\text{priv}}$. To better understand minimax problems, we look at several examples starting from a simple case where Φ_{priv} and Φ_{util} have closed-form solutions.

4.1 Simple case: eigenvalue problem

Consider finding a minimax filter for the following problem. The filter class is a linear dimensionality reduction ($g(x;u) = U^T x$) parameterized by the matrix $U \in \mathbb{R}^{D \times d}$, and the private and target tasks are least-squares regressions parameterized by the matrices V and W:

$$\begin{aligned} f_{\text{priv}}(U, V) &= \frac{1}{N} \sum_i \|V^T U^T x_i - y_i\|^2, \ \text{and} && (47) \\ f_{\text{util}}(U, W) &= \frac{1}{N} \sum_i \|W^T U^T x_i - z_i\|^2. && (48) \end{aligned}$$

In this case, $\Phi_{\text{priv}}(U) = \max_V -f_p(U,V)$ and $\Phi_{\text{util}}(U) = \max_W -f_u(U,W)$ are both concave problems with closed-form solutions

$$\begin{aligned} \hat{V} &= \arg\min_V f_{\text{priv}} = (U^T C_{xx} U)^{-1} U^T C_{xy} \ \text{and} && (49) \\ \hat{W} &= \arg\min_W f_{\text{util}} = (U^T C_{xx} U)^{-1} U^T C_{xz}, && (50) \end{aligned}$$

where

$$C_{xy} = \frac{1}{N} \sum_i x_i y_i^T, \ \ C_{xz} = \frac{1}{N} \sum_i x_i z_i^T, \ \ \text{and} \ \ C_{xx} = \frac{1}{N} \sum_i x_i x_i^T. \tag{51}$$

The corresponding min values are

$$\begin{aligned} \Phi_{\text{priv}}(U) &= -f_{\text{priv}}(U, \hat{V}) = \text{Tr}\left[(U^T C_{xx} U)^{-1} U^T C_{xy} C_{xy}^T U\right] + \text{const, and} && (52) \\ \Phi_{\text{util}}(U) &= -f_{\text{util}}(U, \hat{W}) = \text{Tr}\left[(U^T C_{xx} U)^{-1} U^T C_{xz} C_{xz}^T U\right] + \text{const.} && (53) \end{aligned}$$

The outer minimization over u is then

$$\begin{aligned} \min_U \Phi(U) &= \min_U \left[\Phi_{\text{priv}}(U) - \rho \Phi_{\text{util}}(U)\right] && (54) \\ &= \min_U \left[-f_{\text{priv}}(U, \hat{V}) + \rho f_{\text{util}}(U, \hat{W})\right] = \min_U \text{Tr}\left[(U^T C_{xx} U)^{-1}\ U^T C_{xyz} U\right] && (55) \end{aligned}$$

where

$$C_{xyz} = C_{xy} C_{xy}^T - \rho C_{xz} C_{xz}^T. \tag{56}$$

The problem (55) can be reformulated as a generalized eigenvalue problem. Let $Q = C_{xx}^{1/2} U$ be a $D \times d$ full-rank matrix. The problem can be rewritten as

$$\min_U \text{Tr}\left[(U^T C_{xx} U)^{-1}\ U^T C_{xyz} U\right] = \min_Q \text{Tr}\left[(Q^T Q)^{-1} Q^T C_{xx}^{-1/2} C_{xyz} C_{xx}^{-1/2} Q\right]. \tag{57}$$

Furthermore, note that min value (55) is invariant to the right multiplication of U by any $d \times d$ nonsingular matrix R. So chose R so that $Q^T Q = R^T U^T C_{xx} U R = I_d$ without loss of generality. Let $A = (C_{xx}^{-1/2})^T C_{xyz} C_{xx}^{-1/2}$, and the minimax problem becomes the following eigenvalue problem:

$$\min_U \Phi(U) = \min_{\{Q \ | \ Q^T Q = I_d\}} \text{Tr}\ Q^T A Q, \tag{58}$$

which is the sum of the d smallest eigenvalues of A which may not be positive semidefinite. Note that this special case problem is quite similar to the objective of Enev et al. (2012):

$$\max_u \ [-\lambda u^T C_{xy}^T C_{xy} u + u^T C_{xz}^T C_{xz} u], \ \text{ s. t. } \ u^T u = 1.$$

The paper also proposes a variant of the eigenvalue problem (58), called **Privacy LDS** which is an analogue of linear discriminant analysis (LDS) for privacy-utility optimization problem. Define the symmetric positive semidefinite matrix C_u as

$$C_u = \sum_{k=1}^{K} N_k (\mu_k - \mu)(\mu_k - \mu)^T, \tag{59}$$

where

$$z \in \{1, ..., K\}, \ \ N_k = \sum_{i=1}^{N} I[z_i = k], \ \ \mu_k = \frac{1}{N_k} \sum_{i=1}^{N} x_i I[z_i = k], \ \text{ and } \ \mu = \frac{1}{N} \sum_{i=1}^{N} x_i, \tag{60}$$

Define C_p similarly with

$$y \in \{1, ..., K'\}, \ \ N'_k = \sum_{i=1}^{N'} I[y_i = k], \ \text{ and } \ \mu'_k = \frac{1}{N'_k} \sum_{i=1}^{N'} x_i I[y_i = k]. \tag{61}$$

The proposed Privacy LDS is a linear filter $g(x; U) = U^T x$, where $U = [u_1, ..., u_d]$ is a matrix of top eigenvectors u_i's from the following generalized eigenvalue problem:

$$\max_{\|u\|=1} \ \frac{u^T (C_u + \lambda I) u}{u^T (C_p + \lambda I) u}. \tag{62}$$

This paper uses Privacy LDS as a heuristic to find the initial linear filter before fine-tuning the parameter u using a general optimization method presented in the following sections. Note that this initialization is applicable only to linear filters.

4.2 Saddle-point problem

Continuous minimax problems cannot in general be solved in closed form and require numerical solvers. There is a subclass of continuous minimax problems which are easier to solve than others. Saddle-point problems are minimax problems for which $f(u, v)$ is convex in u and concave in v, such as the following "saddle" problem

$$\min_u \max_v f(u, v) = \min_u \max_v \ [u^2 - v^2]. \tag{63}$$

Analogous to convex problems, $f(u, v)$ has a global optimum (u^*, v^*) which satisfies

$$f(u^*, v) \le f(u^*, v^*) \le f(u, v^*). \tag{64}$$

The convergence rate of a simple subgradient-descent method for saddle-point problems was previously analyzed by Nedić and Ozdaglar (2009). Unfortunately, the minimax problem

$\min_u \max_v -f_{\text{priv}}$ considered in this paper is not a saddle-point problem even for a relatively simple case. Suppose one chooses linear filters, convex differentiable losses (e.g., least-squares, logistic, or exponential losses) and linear classifiers for the problem. Then

$$-f_{\text{priv}}(u, v) = -E[l(g(u); v)] = -E[l(yv^T U^T x)] \tag{65}$$

is the negative expected value of the composition of a convex $l(\cdot)$ and a linear $U^T x$, which is concave in U and is also concave in v, which cannot be a saddle-point problem.

4.3 General problem

A general numerical solution to the optimization (44) is described in this section. Let $f(u, v)$ be a real-valued function $f : \mathcal{U} \times \mathcal{V} \to \mathbb{R}$, where $\mathcal{U}$ and $\mathcal{V}$ are compact subsets of the Euclidean space. Suppose f is jointly continuous and has a continuous partial derivative $\nabla_u f$ w.r.t. the first variable u. The maximum over v

$$\Phi(u) = \max_{v \in \mathcal{V}} f(u, v) \tag{66}$$

has a property that $\Phi(u)$ is in general not differentiable in u even if $f(u, v)$ is (Danskin, 1967). Suppose $V(u)$ is the set of maximizers of f given u:

$$V(u) = \{\hat{v} \in \mathcal{V} \mid f(u, \hat{v}) = \max_{v \in \mathcal{V}} f(u, v)\}. \tag{67}$$

Danskin proved that the directional derivative $D_y \Phi(u)$ in any direction $y \in \mathbb{R}^d$ can be written as the maximum directional derivatives of $f(u, v)$ over all $\hat{v} \in V(u)$:

$$D_y \Phi(u) = \max_{\hat{v} \in V(u)} D_y f(u, \hat{v}), \tag{68}$$

where $D_y f(u, v)$ is the directional derivative of f w.r.t. u. Furthermore, in the case where $V(u)$ is a singleton $\{\hat{v}(u)\}$ for each u, we have

$$D_y \Phi(u) = D_y f(u, \hat{v}(u)). \tag{69}$$

There are several classic minimax optimization algorithms using this property. Suppose $f(u, v)$ is also continuously differentiable w.r.t. v, and $\nabla_u f$ is continuously differentiable w.r.t. v. A first-order method for minimax problems was proposed by Panin (1981) and was later refined by Kiwiel (1987). The latter uses a linear approximation of f at a fixed $\bar{u}$ along the direction q

$$f^l(q, v) = f(\bar{u}, v) + \langle \nabla_u f(\bar{u}, v), \ q \rangle, \tag{70}$$

and uses it to compute the approximate max value

$$\Phi^l(q) = \max_v f^l(q, v). \tag{71}$$

Using this approximation, a line search can be performed along the descent direction q that minimizes the max function $\Phi(\bar{u} + \alpha q)$. In particular, with additional assumptions of Lipschitz continuity of $\nabla_u f$ and compactness of $\mathcal{U}$ and $\mathcal{V}$, Kiwiel's algorithm monotonically decreases f for each iteration and converges to a stationary point u^*, i.e., a point u for

which $\max_v \langle \nabla_u f(u^*, v),\ q \rangle \geq 0$ for all directions q. Previously, Hamm (2015) used Kiwiel's algorithm to solve the optimization problems (44). However, one disadvantage of the method was its slow speed in practice, due to the auxiliary routine of finding the descent direction q at each iteration, described in the supplementary material of Hamm (2015).

Instead, this paper proposes a simple alternating algorithm (Alg. 1) for solving min-diff-max problem based directly on Danskin's theorem. The algorithm only assumes $f_{\text{priv}}(u, v)$ and $f_{\text{util}}(u, w)$ to be jointly continuous and have continuous partial derivatives $\nabla_u f_{\text{priv}}$ and $\nabla_u f_{\text{util}}$. Additionally, if $f_{\text{priv}}(u, v)$ and $f_{\text{util}}(u, w)$ are convex in v and w respectively, then the global minima

$$v_t = \arg\min_v f_{\text{priv}}(u_t, v) \ \text{ and } \ w_t = \arg\min_w f_{\text{util}}(u_t, w) \tag{72}$$

can be found easily, either approximately or accurately. Furthermore, if f_{util} and f_{priv} are strongly convex (e.g., due to regularization), the solutions are unique. Consequently, the descent direction q_t in Alg. 1 is truly the (negative) gradient of $\Phi(u)$ (44) as desired:

$$q_t = \nabla_u f_{\text{priv}}(u, v_t) - \rho \nabla_u f_{\text{util}}(u, w_t) = -\nabla_u \Phi_{\text{priv}}(u) + \rho\ \nabla_u \Phi_{\text{util}}(u) = -\nabla_u \Phi(u). \tag{73}$$

Note that it is still a heuristic for non-convex f_{util} and f_{priv} such as when using neural networks for the filter and/or the classifiers. A related heuristic for minimax problems was proposed by Goodfellow et al. (2014) for learning generative models.

Algorithm 1 Alternating algorithm for min-diff-max

Input: data $\{(x_i, y_i, z_i)\}$, filter g, loss l, classifier h, tradeoff coefficient ρ, max iteration T, learning rates (α_t)
Output: optimal filter parameter u
Begin:
Initialize u_1
for $t = 1, ..., T$ **do**
Solve (approximately)

$$v_t = \arg\min_v f_{\text{priv}}(u_t, v) \ \text{ and } \ w_t = \arg\min_w f_{\text{util}}(u_t, w), \quad \text{where} \tag{74}$$

$$f_{\text{priv}}(u, v) = \frac{1}{N}\sum_{i=1}^{N} l_p(h_p(g(x_i; u); v), y_i) \ \text{ and } \ f_{\text{util}}(u, w) = \frac{1}{N}\sum_{i=1}^{N} l_u(h_u(g(x_i; u); w), z_i). \tag{75}$$

Compute the descent direction by

$$q_t = \nabla_u f_{\text{priv}}(u, v_t) - \rho \nabla_u f_{\text{util}}(u, w_t) \tag{76}$$

Perform line search along q_t and update $u_{t+1} = u_t + \alpha_t \cdot q_t$
Exit if solution converged
end for

The proposed optimization algorithm and supporting classes are implemented in Python and are available on the open-source repository[4].

5. Noisy Minimax Filter

The privacy guarantee that minimax filter provides is very different from that of differentially-private mechanisms. As the filter is learned from training data, its privacy guarantee for test data is given only in expectation/probability. Besides, it is a deterministic mechanism which cannot provide differential privacy. This section presents the *noisy minimax filter* that combines minimax filter with additive noise mechanism to satisfy the differential privacy criterion. Two methods of combination—preprocessing and postprocessing—are proposed and compared. For completeness, the definition of differential privacy is given briefly.

5.1 Differential privacy

A randomized algorithm that takes data $\mathcal{D}$ as input and outputs $\tilde{f}(\mathcal{D})$ is called ϵ-differentially private if

$$Pr(\tilde{f}(\mathcal{D}) \in \mathcal{S}) \leq e^{\epsilon} Pr(\tilde{f}(\mathcal{D}') \in \mathcal{S}) \tag{77}$$

for all measurable $\mathcal{S} \subset \mathcal{T}$ of the output range and for all data sets $\mathcal{D}$ and $\mathcal{D}'$ differing in a single item, denoted by $\mathcal{D} \sim \mathcal{D}'$. That is, even if an adversary knows the whole data set $\mathcal{D}$ except for a single item, she cannot infer much more about the unknown item from the output of the algorithm. A well-known mechanism for turning a non-private function f into a private function $\tilde{f}$ is the perturbation by additive noise. When an algorithm outputs a real-valued vector $f(\mathcal{D}) \in \mathbb{R}^D$, its global sensitivity (Dwork et al., 2006) is defined as

$$S(f) = \max_{\mathcal{D} \sim \mathcal{D}'} \|f(\mathcal{D}) - f(\mathcal{D}')\| \tag{78}$$

where $\|\cdot\|$ is a norm such as the Euclidean norm. An important result from Dwork et al. (2006) is that the perturbation by additive noise

$$\tilde{f}(\mathcal{D}) = f(\mathcal{D}) + \xi, \tag{79}$$

where ξ has the Laplace-like probability density whose scale parameter is proportional to $S(f)$

$$P(\xi) \propto e^{-\frac{\epsilon}{S(f)}\|\xi\|}, \tag{80}$$

is ϵ-differentially private.

This paper considers local differential privacy (Duchi et al., 2013) of the filter output $g(x)$, that is, perturbation is applied by each subject before $g(x)$ is released to a third party. Let $X = \{x_1, ..., x_S\}$ be a collection of data from S subjects. Then, $X = \{x_1, ..., x_S\}$ and $X' = \{x'_1, ..., x'_S\}$ are defined as neighbors if $x_i = x'_i$ for all $i = 1, ..., S$ except for some $j \in 1, ..., S$. For this subject, x_j and x'_j can be any two samples from the common feature space $\mathcal{X}$ of all subjects. Consequently, a randomized filter $\tilde{g}(\cdot)$ is ϵ-differentially private if for all $x, x' \in \mathcal{X}$ and all measurable $\mathcal{S} \subset \mathcal{T}$ of the output range,

$$Pr(\tilde{g}(x) \in S) \leq e^{\epsilon} Pr(\tilde{g}(x') \in S). \tag{81}$$

4. `https://github.com/jihunhamm/MinimaxFilter`

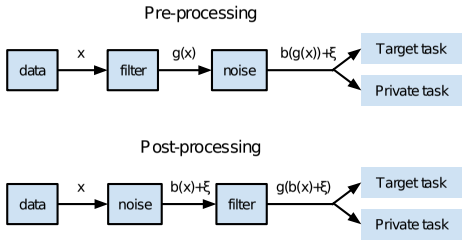

Figure 2: Preprocessing and postprocessing approaches to differentially private minimax filtering.

To use additive noise mechanism (79), the sensitivity (78) of the output $g(\cdot)$ needs to be determined:

$$S(g) = \sup_{x,x' \in \mathcal{X}} \|g(x) - g(x')\|, \tag{82}$$

which is finite if $\mathcal{X}$ is compact and $g(\cdot)$ is continuous. If $\mathcal{X}$ is unbounded, one can directly bound the diameter of $g(\mathcal{X})$ by *bounding functions*. Examples of the bounding function $b : \mathbb{R}^D \to \mathbb{R}^D$ are

1. Hard-bounding by clipping: $b(h) = \min\{1/a,\ 1/\|h\|\} \cdot h$ for some $a > 0$,
2. Soft-bounding by squashing: $b(h) = \tanh(a\|h\|)$ for some $a > 0$, and
3. Normalization after clipping: $b(h) = h/\|h\|$,

where $h = g(x)$ is the filter output of a sample $x \in \mathcal{X}$. Note that these functions enforce the sensitivity $S(b(g))$ to be at most 2, regardless of $\mathcal{X}$ or $g(\cdot)$. The threshold a can be determined from the training data.

5.2 Preprocessing vs postprocessing

Minimax filters can be made locally differentially private using the additive noise mechanism (79) in the signal chain of filtering. The paper proposes two approaches. In the *preprocessing* approach, filtering is performed first and is followed by perturbation. In the *postprocessing* approach, perturbation is applied first and is followed by filtering. Note that preprocessing and postprocessing approaches are similar to output perturbation and input perturbation in Sarwate and Chaudhuri (2013). Fig. 2 shows the signal chains of the two approaches. In preprocessing, the original feature x is first filtered by $g(x)$, and then made differential private by a bounding function and perturbation $b(g(x))+\xi$. In postprocessing, the original feature x is first made differentially private by a bounding function and perturbation $b(x)+\xi$ followed by filtering $g(b(x)+\xi)$. By adding an appropriate amount of noise, both approaches can be made ϵ-differentially private regardless of data distribution. However, when the noisy mechanism is used in conjunction with a minimax filter which is dependent on data

distribution $P(x, y, z)$, preprocessing and postprocessing approaches have different effects that depend on the distribution.

A scenario when preprocessing is preferable to postprocessing is as follows. For the convenience of explanation, let's assume that subject identification is the private task. Let $y(x)$ be the subject identity label of sample x and let $z(x)$ be the target label of sample x for any target task. Define *between-subject diameter* as the max distance of two samples x, x' from different subjects that have the same target label:

$$S_b \triangleq \max_{x,x' \in \mathcal{X}} \|x - x'\| \quad \text{s.t.} \quad y(x) \neq y(x'),\ z(x) = z(x'). \tag{83}$$

Similarly, define *within-subject diameter* as the max distance of two samples x, x' from the same subject that have different target labels:

$$S_w \triangleq \max_{x,x' \in \mathcal{X}} \|x - x'\| \quad \text{s.t.} \quad y(x) = y(x'),\ z(x) \neq z(x'). \tag{84}$$

Also for the purpose of explanation, assume that the filter g is an orthogonal projection onto a lower-dimensional Euclidean space. For a given data set $\mathcal{X}$, if the between-subject diameter is larger than the within-subject diameter ($S_b > S_w$) in the original feature space (Fig. 3a), then minimax filtering can potentially reduce the diameter $S(g) = \max_{x,x'} \|g(x) - g(x')\|$ significantly. This translates to less amount of noise required to achieve the same ϵ-privacy than the amount of noise required before filtering, as the data diameter has shrunk. This will result in better utility of the preprocessing approach over the postprocessing approach where noise is added before filtering. From the same reasoning, if the opposite is true ($S_w > S_b$) (Fig. 3b), then the diameter $S(g)$ after minimax filtering does not change much, and the preprocessing approach may not offer much benefit over the postprocessing approach. However, there are still other differences between the two approaches. This paper assumes that the training data are public information and their privacy is not the primary concern unlike the privacy of test data. However, if we begin to consider the privacy of training data as well, then one should be aware that the learned filters can leak private information, analogous to how the PCA components can leak information about training data (Chaudhuri et al., 2012), and that the filters also need to be sanitized before release. The postprocessing approach makes the whole process simpler. In this case, after each data owner perturbs the data by herself, any subsequent postprocessing, whether it is the process of applying pretrained filters or the process of training minimax filters, does not worsen differential privacy guarantees (Dwork et al., 2014), and therefore the postprocessing approach is a safer choice when the data owners cannot trust the entity that collects training data.

6. Experiments

In this section, the algorithms proposed in the paper are evaluated using three real-world data sets: face data for gender/expression classification, speech data for emotion classification, and motion data for activity classification. Firstly, minimax filters are compared with non-minimax methods in terms of privacy breach vs utility as measured by accuracy of private and target tasks classifiers on test data. Secondly, noisy minimax filters are tested under various conditions using the same data sets.

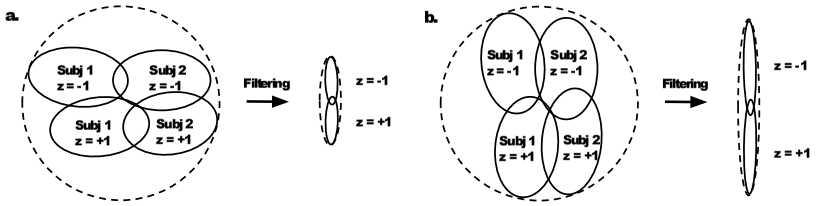

Figure 3: Two example data distributions which have the same data diameter before filtering but have different diameters after filtering. a. an example where between-subject diameter (83) is large. b. an example where within-subject diameter (84) is large.

6.1 Methods

Filters. The following minimax and non-minimax filters are compared.

- Rand: random subspace projection with $g(x;U) = U^T x$, where U is a random full rank $D \times d$ matrix.
- PCA: principal component analysis with $g(x;U) = U^T x$, where U is the eigenvectors corresponding to d largest eigenvalues of $\mathrm{Cov}(x)$.
- PPLS: private partial least squares, using Algorithm 1 from Enev et al. (2012).
- DDD: discriminately decreasing discriminability (DDD) from Whitehill and Movellan (2012) with a mask-type filter from the code[5].
- Minimax 1: linear filter $g(x;U) = U^T x$ where U is computed from Alg. (1).
- Minimax 2: nonlinear filter $g(x)$ from a two-layer sigmoid neural network with of hidden nodes of 20 and 10, computed from Alg. 1.

Remarks. DDD requires analytical solutions to eigenvalue problems which are unavailable for multiclass problems, and is used only in the binary problem with the face database. Also, DDD uses a mask-type filter in the codes, and the dimension d is same as the image size. The dimension d is also irrelevant to nonlinear Minimax filter 2 since it does not use linear dimensionality reduction. The nonlinear filter is pretrained as a stacked denoising autoencoders (Vincent et al., 2008) followed by supervised backpropagation with the target task. **Classifier/loss**. For all experiments, binary or multinomial logistic regression is used a classifier for both utility and privacy risks, where the loss $l(h(g(x;u);v),y)$ is the negative log-likelihood with regularization:

$$l = -v(y)^T g(x;u) + \log(\sum_{k=1}^{K} e^{v(k)^T g(x;u)}) + \frac{\lambda}{2}\sum_{k=1}^{K} \|v(k)\|^2 \tag{85}$$

5. `http://mplab.ucsd.edu/~jake`

where K is the number of classes. The regularization coefficient was $\lambda = 10^{-6}$ and the utility-privacy tradeoff coefficient was $\rho = 10$. The main iteration in Alg. 1 was stopped when the progress was slow, which was between $T = 20 - 200$.

6.2 Data sets

Gender/expression classification from face: The GENKI database (Whitehill and Movellan, 2012) consists of face images with varying poses and facial expressions. The original data set is used unchanged, which has $N = 1740$ training images (50% male and 50% female; 50% smile and 50% non-smile). The test set has 100 images (50 males and 50 females; 50 smiling and 50 non-smiling) not overlapping with the training set. The dimensionality of the original data is $D = 256$, and the filters are tested with $d = 10, 20, 50, 100$. The data set has gender and expression labels but no subject label. Consequently, gender classification is used as the private task and expression classification is used as the target task.

Emotion classification from speech: The ENTERFACE database (Martin et al., 2006) is an audiovisual emotion database of 43 speakers from 14 nations reading predefined English sentences in six induced emotions. From the raw speech signals sampled in 48 KHz, MFCC coefficients are computed using 20 ms windows with 50% overlap and 13 Mel-frequency bands. The mean, max, min, and standard deviation of the MFCC coefficients over the duration of each sentence are computed, resulting in $N = 427$ samples of $D = 52$ dimensional feature vectors from $S = 43$ subjects. Each subject's samples are randomly split to generate training (80%) and test (20%) sets. Average test accuracy over 10 such trials is reported. Filters are tested with $d = 10, 20, 30, 40$. The target task is the binary classification of 'happy' and 'non-happy' emotions from speech, and the privacy task is the multiclass ($S = 43$) subject classification.

Activity classification from motion: The UCI Human Activity Recognition (HAR) data set (Anguita et al., 2012) is a collection of motion sensor data on a smartphone by 30 subjects performing six activities (*walking*, *walking upstairs*, *walking downstairs*, *sitting*, *standing*, *laying*). Various time and frequency domain variables are extracted from the signal, resulting in $N = 10299$ samples of $D = 561$ dimensional features from 30 subjects which are used unchanged. Out of 30 subjects, 15 subjects are chosen randomly. For each domain, each subject's samples are randomly split to generate training (50%) and test (50%) sets. At each trial, the subjects and the training/test sets are randomized, and the average test accuracy over 10 such trials is reported. Filters with dimensions $d = 10, 20, 50, 100$ are used. The target task is the multiclass ($C = 6$) classification of activity, and the privacy task is the multiclass ($S = 15$) subject classification.

6.3 Result 1: Minimax filters

Before any filter is applied, the accuracy of the target tasks with raw data is 0.90 (GENKI), 0.84 (ENTERFACE), and 0.97 (HAR). On the other hand, the accuracy of the private tasks with raw data is 0.90 (GENKI), 0.62 (ENTERFACE), and 0.70 (HAR). The high accuracy of the private tasks (considering the chance level accuracy of 0.5 (GENKI), 0.02 (ENTERFACE), and 0.067 (HAR)) demonstrates that an adversary can accurately infer private variables such as gender and identity from raw data if no filter is used. A simple defense

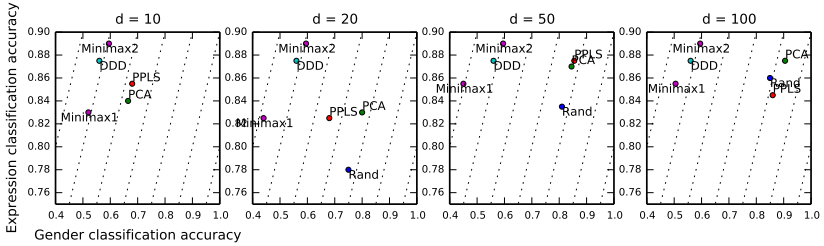

Figure 4: GENKI: Expression classification vs and gender classification from faces.

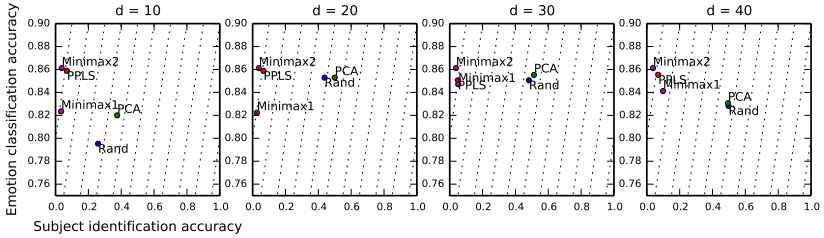

Figure 5: ENTERFACE: Emotion classification vs and subject identification from speech.

against inference attack is to perform dimensionality reduction on the original data, such as Rand and PCA projections. As the dimensionality d decreases from the original value D towards zero, one can expect both the private and the target accuracy to decrease toward the chance level. This trend is indeed the case with both the non-private (Rand,PCA) and the private (PPLS,DDD,Minimax) filters used in the paper. Therefore these filters are evaluated at several different values of the dimensionality d to make fine-grained comparisons of utility-privacy.

Fig. 4 shows the test accuracy with GENKI. The dotted lines are level sets of utility-privacy tradeoff (i.e., target task accuracy - private task accuracy) shown for reference. Minimax 2 achieves the best utility (i.e., most accurate expression classification) and Minimax 1 (linear) achieves the best privacy (i.e., least accurate gender classification). For all dimensions d, Minimax 1 achieves the best utility-privacy compromise (i.e., closest to the top-left corner of the plot), with Minimax 2 and DDD performing similarly. In terms of private task accuracy, Minimax 1 achieves almost the chance level accuracy (0.5), which implies a strong privacy preservation. DDD comes close to Minimax 1, while another private method PPLS is not very successful in preventing the inference of the private variable. As

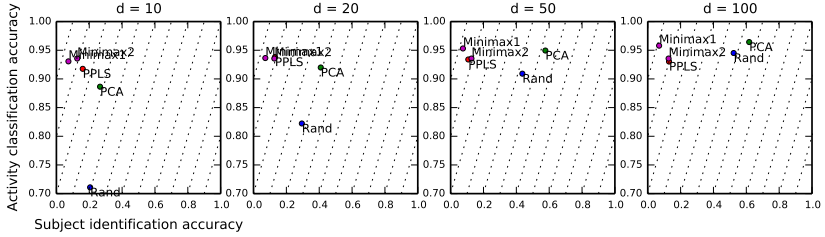

Figure 6: HAR: Activity classification vs subject identification from motion.

expected, non-private methods Rand and PCA also do not reduce the privacy task accuracy. As dimension d increases from 10 to 100, the accuracy of both the target and the private tasks increase (toward the top-right corner of the plot) for PPLS, PCA and Rand, but the value of utility-privacy tradeoff (i.e., target task accuracy - private task accuracy) remains relatively similar even though d changes. Note that d is irrelevant to Minimax 2 and DDD.

Fig. 5 shows the test accuracy of ENTERFACE. Minimax 2 achieves the best utility (i.e., most accurate emotion classification) and the best privacy (i.e., least accurate subject classification) at the same time. PPLS performs well in this task; its private and target task accuracy is close to those of Minimax 2. The private task accuracy of Minimax 2 is near the chance level ($1/S = 0.02$) compared to $0.4 - 0.5$ of non-private methods, suggesting that seemingly harmless statistics (mean, max, min, s.d. of MFCC) are quite susceptible to identification attacks if no privacy mechanism is used. Similar to GENKI, the accuracy of both the target and the private tasks increases with the dimension d for PCA and Rand, and the value of utility-privacy tradeoff remains similar regardless of d.

Fig. 6 shows the test accuracy of HAR. Minimax 1 achieves the best utility (i.e., most accurate activity recognition) and the best privacy (i.e., least accurate subject classification), while Minimax 2 and PPLS performs similarly well. The private task accuracy of Minimax 1 is lower than others close to the chance level ($1/S = 0.067$). The figure also shows that motion data are susceptible ($0.2 - 0.7$) to identification attacks when no privacy mechanism is used. For all dimensions d, Minimax 1 achieves the best compromise of all methods similar to previous experiments. Also the accuracy of both the target and the private tasks roughly increases with d for PCA and Rand, but the value of utility-privacy tradeoff remains similar.

6.4 Result 2: Noisy minimax filters

The same data sets from the previous section are used to demonstrate the effect of noisy mechanism on minimax filters. Four types of noisy filters are compared: PCA-pre, PCA-post, Minimax-pre, and Minimax-post. PCA is chosen as a non-minimax reference filter which preserves the original signal the best in the least mean-squared-error sense. PCA-pre/post means that PCA is applied before/after the perturbation similarly to Minimax-

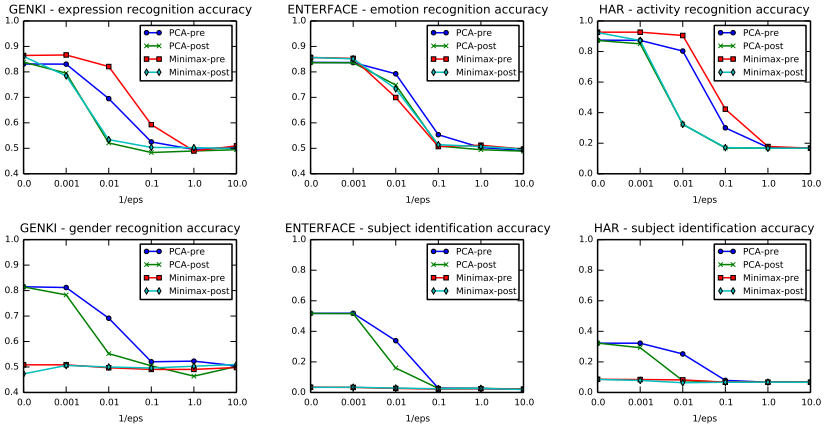

Figure 7: Impact of four noisy filters (PCA-pre/post and Minimax-pre/post) on the accuracy of target and private tasks for three data sets (GENKI, ENTERFACE, HAR), over the range of $\epsilon^{-1} = \{0, 10^{-3}, 10^{-2}, 10^{-1}, 10^{0}, 10^{1}\}$. Top row is the target task accuracy (higher the better) and bottom row is the private task accuracy (lower the better.) Minimax-pre/post can limit the accuracy of inference attack (bottom row) to almost chance levels regardless of the value of ϵ, while PCA-pre/post requires a significantly high ϵ to prevent inference attacks which also destroy the utility.

pre/post from Fig. 2. For Minimax-pre/post, a linear filter of the same dimension d as PCA-pre/post is used. Tests are performed for the same ranges of dimension d as in Sec 6.3. The results for $d = 20$ with all three data sets are summarized in Fig. 7. Results for different dimensions show similar trends and are summarized in Fig. 8. Optimization of (7) is done similarly to the previous section. All tests are repeated 10 times for different noise samples of (80), for each of 10 random training/test splits.

Fig. 7 shows the following results. Firstly, within each plot, increasing the privacy level from left (ϵ^{-1}=0) to right (ϵ^{-1}=10) lowers the accuracy of both target and private tasks for all filter types and data sets, which is intuitively correct. Secondly, target task accuracy (top row) shows that the four filters are equally accurate with no noise (ϵ^{-1}=0), with Minimax-pre/post slightly more accurate than PCA-pre/post. This observation is consistent with the results in Sec. 6.3. In GENKI and HAR, preprocessing is better than postprocessing for both PCA and Minimax, and Minimax-pre performs the best. In ENTERFACE, preprocessing and postprocessing approaches perform similarly, and all four filters is perform similarly on the target task. This result may be ascribed to the discussion of different data distribution in Sec. 5.2. Thirdly, and most importantly, private task accuracy (bottom row) is quite

different between Minimax-pre/post and non-minimax PCA-pre/post. For both Minimax-pre and Minimax-post, the private task accuracy is almost as low as the chance accuracy of each data set (0.5, 0.03, 0.07) regardless of the noise level ϵ. This demonstrates that minimax filter can prevent inference attacks with little help of noise. In contrast, the non-minimax filters (PCA-pre/post) allow an adversary to infer private variables quite accurately (0.8, 0.5, 0.3) when no noise is used. Preventing such attacks for non-minimax filters requires a significant amount of additive noise (e.g., $\epsilon^{-1} \geq 0.1$) which destroys the utility of data. These results show that differentially privacy is indeed different from privacy against inference attacks and the combination of two methods is beneficial.

7. Conclusion

This work presents a new learning-based mechanism for preventing inference attacks on continuous and high-dimensional data. In this mechanism, a filter transforms continuous and high-dimensional raw features to dimensionality-reduced representations of data. After filtering, information on target tasks remains but information on identifying or sensitive attributes is removed which makes it difficult for an adversary to accurately infer such attributes from the released filtered output. Minimax filters are designed to achieve the optimal utility-privacy tradeoff in terms of expected risks. The paper proves that a filter learned from empirical risks is not far from an ideal filter that is learned from expected risks as the number of samples increases. This property and its dependency on the task make this mechanism quite different from previous mechanisms, including syntactic anonymization and differential privacy. Algorithms for finding minimax filters are presented and evaluated on real-world data sets to show its practical usages. Experiments show that publicly available multisubject data sets are surprisingly susceptible to subject identification attacks, and that even simple linear minimax filters can reduce the privacy risks close to chance level without sacrificing target task accuracy by much.

This work also presents preprocessing and postprocessing approaches to combine minimax privacy and differential privacy. While differential privacy has become a popular criterion of privacy loss, it is not without limitations, in particular against inference attacks as empirically demonstrated in the paper. This leaves room for development of new mechanisms such as the noisy minimax filter presented in the paper, which aims to achieve high on-average utility and protection against inference attacks, and a formal privacy guarantee to a degree. The results from experiments encourage further research on potential benefits of combining different notions and mechanisms of privacy, which is left as future work.

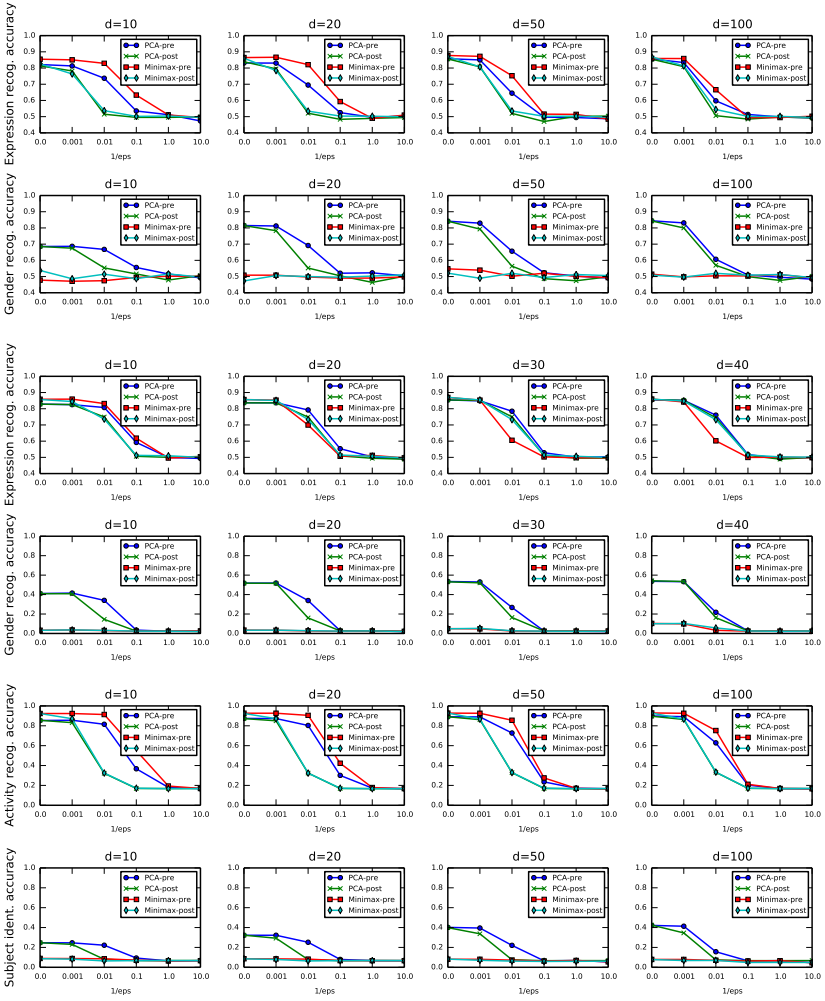

Figure 8: The full result of the performance noisy filters (PCA-pre/post and Minimax-pre/post) on the accuracy of target and private tasks on three data sets: GENKI (1st & 2nd row), ENTERFACE (3rd & 4th row), HAR (5th & 6th row).

Abstract

In statistical relational learning, knowledge graph completion deals with automatically understanding the structure of large knowledge graphs—labeled directed graphs—and predicting missing relationships—labeled edges. State-of-the-art embedding models propose different trade-offs between modeling expressiveness, and time and space complexity. We reconcile both expressiveness and complexity through the use of complex-valued embeddings and explore the link between such complex-valued embeddings and unitary diagonalization. We corroborate our approach theoretically and show that *all* real square matrices—thus all possible relation/adjacency matrices—are the real part of some unitarily diagonalizable matrix. This results opens the door to a lot of other applications of square matrices factorization. Our approach based on complex embeddings is arguably simple, as it only involves a Hermitian dot product, the complex counterpart of the standard dot product between real vectors, whereas other methods resort to more and more complicated composition functions to increase their expressiveness. The proposed complex embeddings are scalable to large data sets as it remains linear in both space and time, while consistently outperforming alternative approaches on standard link prediction benchmarks.[1]

Keywords: complex embeddings, tensor factorization, knowledge graph, matrix completion, statistical relational learning

1. Introduction

Web-scale knowledge graph provide a structured representation of world knowledge, with projects such as the Google Knowledge Vault (Dong et al., 2014). They enable a wide range of applications including recommender systems, question answering and automated personal agents. The incompleteness of these knowledge graphs—also called knowledge bases—has stimulated research into predicting missing entries, a task known as *link prediction* or *knowledge graph completion*. The need for high quality predictions required by link prediction applications made it progressively become the main problem in statistical relational learning (Getoor and Taskar, 2007), a research field interested in relational data representation and modeling.

Knowledge graphs were born with the advent of the Semantic Web, pushed by the World Wide Web Consortium (W3C) recommendations. Namely, the Resource Description Framework (RDF) standard, that underlies knowledge graphs' data representation, provides for the first time a common framework across all connected information systems to share their data under the same paradigm. Being more expressive than classical relational databases, all existing relational data can be translated into RDF knowledge graphs (Sahoo et al., 2009).

Knowledge graphs express data as a directed graph with labeled edges (relations) between nodes (entities). Natural redundancies between the recorded relations often make it possible to fill in the missing entries of a knowledge graph. As an example, the relation `CountryOfBirth` could not be recorded for all entities, but it can be inferred if the relation `CityOfBirth` is known. The goal of link prediction is the automatic discovery of such regularities. However, many relations are non-deterministic: the combination of the two facts `IsBornIn(John,Athens)` and `IsLocatedIn(Athens,Greece)` does not always imply the fact `HasNationality(John,Greece)`. Hence, it is natural to handle inference probabilistically, and jointly with other facts involving these relations and entities. To this end, an increasingly popular method is to state the knowledge graph completion task as a 3D binary tensor completion problem, where each tensor slice is the adjacency matrix of one relation in the knowledge graph, and compute a decomposition of this partially-observed tensor from which its missing entries can be completed.

Factorization models with low-rank embeddings were popularized by the Netflix challenge (Koren et al., 2009). A partially-observed matrix or tensor is decomposed into a product of embedding matrices with much smaller dimensions, resulting in fixed-dimensional vector representations for each entity and relation in the graph, that allow completion of the missing entries. For a given fact *r(s,o)* in which the subject entity s is linked to the object entity o through the relation r, a score for the fact can be recovered as a multilinear product between the embedding vectors of s, r and o, or through more sophisticated composition functions (Nickel et al., 2016a).

Binary relations in knowledge graphs exhibit various types of patterns: hierarchies and compositions like `FatherOf`, `OlderThan` or `IsPartOf`, with strict/non-strict orders or preorders, and equivalence relations like `IsSimilarTo`. These characteristics maps to different combinations of the following properties: reflexivity/irreflexivity, symmetry/antisymmetry and transitivity. As described in Bordes et al. (2013a), a relational model should (i) be able to learn all combinations of such properties, and (ii) be linear in both time and memory in order to scale to the size of present-day knowledge graphs, and keep up with their growth.

A natural way to handle any possible set of relations is to use the classic canonical polyadic (CP) decomposition (Hitchcock, 1927), which yields two different embeddings for each entity and thus low prediction performances as shown in Section 5. With unique entity embeddings, multilinear products scale well and can naturally handle both symmetry

and (ir)-reflexivity of relations, and when combined with an appropriate loss function, dot products can even handle transitivity (Bouchard et al., 2015). However, dealing with antisymmetric—and more generally asymmetric—relations has so far almost always implied superlinear time and space complexity (Nickel et al., 2011; Socher et al., 2013) (see Section 2), making models prone to overfitting and not scalable. Finding the best trade-off between expressiveness, generalization and complexity is the keystone of embedding models.

In this work, we argue that the standard dot product between embeddings can be a very effective composition function, provided that one uses the right *representation*: instead of using embeddings containing real numbers, we discuss and demonstrate the capabilities of complex embeddings. When using complex vectors, that is vectors with entries in $\mathbb{C}$, the dot product is often called the *Hermitian* (or sesquilinear) dot product, as it involves the conjugate-transpose of one of the two vectors. As a consequence, the dot product is not symmetric any more, and facts about one relation can receive different scores depending on the ordering of the entities involved in the fact. In summary, complex embeddings naturally represent arbitrary relations while retaining the efficiency of a dot product, that is linearity in both space and time complexity.

This paper extends a previously published article (Trouillon et al., 2016). This extended version adds proofs of existence of the proposed model in both single and multi-relational settings, as well as proofs of the non-uniqueness of the complex embeddings for a given relation. Bounds on the rank of the proposed decomposition are also demonstrated and discussed. The learning algorithm is provided in more details, and more experiments are provided, especially regarding the training time of the models.

The remainder of the paper is organized as follows. We first provide justification and intuition for using complex embeddings in the square matrix case (Section 2), where there is only a single type of relation between entities, and show the existence of the proposed decomposition for all possible relations. The formulation is then extended to a stacked set of square matrices in a third-order tensor to represent multiple relations (Section 3). The stochastic gradient descent algorithm used to learn the model is detailed in Section 4, where we present an equivalent reformulation of the proposed model that involves only real embeddings. This should help practitioners when implementing our method, without requiring the use of complex numbers in their software implementation. We then describe experiments on large-scale public benchmark knowledge graphs in which we empirically show that this representation leads not only to simpler and faster algorithms, but also gives a systematic accuracy improvement over current state-of-the-art alternatives (Section 5). Related work is discussed in Section 6.

2. Relations as the Real Parts of Low-Rank Normal Matrices

We consider in this section a simplified link prediction task with a single relation, and introduce complex embeddings for low-rank matrix factorization.

We will first discuss the desired properties of embedding models, show how this problem relates to the spectral theorems, and discuss the classes of matrices these theorems encompass in the real and in the complex case. We then propose a new matrix decomposition—to the best of our knowledge—and a proof of its existence for all real square matrices. Finally we discuss the rank of the proposed decomposition.

2.1 Modeling Relations

Let $\mathcal{E}$ be a set of entities, with $|\mathcal{E}| = n$. The truth of the single relation holding between two entities is represented by a sign value $y_{so} \in \{-1, 1\}$, where 1 represents true facts and -1 false facts, $s \in \mathcal{E}$ is the subject entity and $o \in \mathcal{E}$ is the object entity. The probability for the relation holding true is given by

$$P(y_{so} = 1) = \sigma(x_{so}) \tag{1}$$

where $X \in \mathbb{R}^{n \times n}$ is a latent matrix of scores indexed by the subject (rows) and object entities (columns), Y is a partially-observed sign matrix indexed in identical fashion, and σ is a suitable sigmoid function. Throughout this paper we used the logistic inverse link function $\sigma(x) = \frac{1}{1+e^{-x}}$.

2.1.1 Handling Both Asymmetry and Unique Entity Embeddings

In this work we pursue three objectives: finding a generic structure for X that leads to (i) a computationally efficient model, (ii) an expressive enough approximation of common relations in real world knowledge graphs, and (iii) good generalization performances in practice. Standard matrix factorization approximates X by a matrix product $UV^\top$, where U and V are two functionally-independent $n \times K$ matrices, K being the rank of the matrix. Within this formulation it is assumed that entities appearing as subjects are different from entities appearing as objects. In the Netflix challenge (Koren et al., 2009) for example, each row u_i corresponds to the user i and each column v_j corresponds to the movie j. This extensively studied type of model is closely related to the singular value decomposition (SVD) and fits well with the case where the matrix X is rectangular.

However, in many knowledge graph completion problems, the same entity i can appear as both subject *or* object and will have two different embedding vectors, u_i and v_i, depending on whether it appears as subject or object of a relation. It seems natural to learn unique embeddings of entities, as initially proposed by Nickel et al. (2011) and Bordes et al. (2011) and since then used systematically in other prominent approaches (Bordes et al., 2013b; Yang et al., 2015; Socher et al., 2013). In the factorization setting, using the same embeddings for left- and right-side factors boils down to a specific case of eigenvalue decomposition: *orthogonal diagonalization*.

Definition 1 *A real square matrix $X \in \mathbb{R}^{n \times n}$ is orthogonally diagonalizable if it can be written as $X = EWE^\top$, where $E, W \in \mathbb{R}^{n \times n}$, W is diagonal, and E orthogonal so that $EE^\top = E^\top E = I$ where I is the identity matrix.*

The spectral theorem for symmetric matrices tells us that a matrix is orthogonally diagonalizable if and only if it is symmetric (Cauchy, 1829). It is therefore often used to approximate covariance matrices, kernel functions and distance or similarity matrices.

However as previously stated, this paper is explicitly interested in problems where matrices—and thus the relation patterns they represent—can also be antisymmetric, or even not have any particular symmetry pattern at all (asymmetry). In order to both use a unique embedding for entities and extend the expressiveness to asymmetric relations, researchers have generalised the notion of dot products to *scoring functions*, also known as

Model	Scoring Function ϕ	Relation Parameters	$\mathcal{O}_{time}$	$\mathcal{O}_{space}$
CP (Hitchcock, 1927)	$\langle w_r, u_s, v_o \rangle$	$w_r \in \mathbb{R}^K$	$\mathcal{O}(K)$	$\mathcal{O}(K)$
RESCAL (Nickel et al., 2011)	$e_s^T W_r e_o$	$W_r \in \mathbb{R}^{K^2}$	$\mathcal{O}(K^2)$	$\mathcal{O}(K^2)$
TransE (Bordes et al., 2013b)	$-\|\|(e_s + w_r) - e_o\|\|_p$	$w_r \in \mathbb{R}^K$	$\mathcal{O}(K)$	$\mathcal{O}(K)$
NTN (Socher et al., 2013)	$u_r^\top f(e_s W_r^{[1..D]} e_o + V_r \begin{bmatrix} e_s \\ e_o \end{bmatrix} + b_r)$	$W_r \in \mathbb{R}^{K^2 D}, b_r \in \mathbb{R}^K$ $V_r \in \mathbb{R}^{2KD}, u_r \in \mathbb{R}^K$	$\mathcal{O}(K^2 D)$	$\mathcal{O}(K^2 D)$
DistMult (Yang et al., 2015)	$\langle w_r, e_s, e_o \rangle$	$w_r \in \mathbb{R}^K$	$\mathcal{O}(K)$	$\mathcal{O}(K)$
HolE (Nickel et al., 2016b)	$w_r^T(\mathcal{F}^{-1}[\overline{\mathcal{F}[e_s]} \odot \mathcal{F}[e_o]]))$	$w_r \in \mathbb{R}^K$	$\mathcal{O}(K \log K)$	$\mathcal{O}(K)$
ComplEx (this paper)	$\text{Re}(\langle w_r, e_s, \bar{e}_o \rangle)$	$w_r \in \mathbb{C}^K$	$\mathcal{O}(K)$	$\mathcal{O}(K)$

Table 1: Scoring functions of state-of-the-art latent factor models for a given fact $r(s, o)$, along with the representation of their relation parameters, and time and space (memory) complexity. K is the dimensionality of the embeddings. The entity embeddings e_s and e_o of subject s and object o are in $\mathbb{R}^K$ for each model, except for ComplEx, where $e_s, e_o \in \mathbb{C}^K$. $\bar{x}$ is the complex conjugate, and D is an additional latent dimension of the NTN model. $\mathcal{F}$ and $\mathcal{F}^{-1}$ denote respectively the Fourier transform and its inverse, $\odot$ is the element-wise product between two vectors, Re(.) denotes the real part of a complex vector, and $\langle \cdot, \cdot, \cdot \rangle$ denotes the trilinear product.

composition functions, that allow more general combinations of embeddings. We briefly recall several examples of scoring functions in Table 1, as well as the extension proposed in this paper.

These models propose different trade-offs between the three essential points:

- Expressiveness, which is the ability to represent symmetric, antisymmetric and more generally asymmetric relations.
- Scalability, which means keeping linear time and space complexity scoring function.
- Generalization, for which having unique entity embeddings is critical.

RESCAL (Nickel et al., 2011) and NTN (Socher et al., 2013) are very expressive, but their scoring functions have quadratic complexity in the rank of the factorization. More recently the HolE model (Nickel et al., 2016b) proposes a solution that has quasi-linear complexity in time and linear space complexity. DistMult (Yang et al., 2015) can be seen as a joint orthogonal diagonalization with real embeddings, hence handling only symmetric relations. Conversely, TransE (Bordes et al., 2013b) handles symmetric relations to the price of strong constraints on its embeddings. The canonical-polyadic decomposition (CP) (Hitchcock, 1927) generalizes poorly with its different embeddings for entities as subject and as object.

We reconcile expressiveness, scalability and generalization by going back to the realm of well-studied matrix factorizations, and making use of complex linear algebra, a scarcely used tool in the machine learning community.

2.1.2 Decomposition in the Complex Domain

We introduce a new decomposition of real square matrices using unitary diagonalization, the generalization of orthogonal diagonalization to complex matrices. This allows decomposition of *arbitrary* real square matrices with unique representations of rows and columns.

Let us first recall some notions of complex linear algebra as well as specific cases of diagonalization of real square matrices, before building our proposition upon these results.

A complex-valued vector $x \in \mathbb{C}^K$, with $x = \text{Re}(x) + i\text{Im}(x)$ is composed of a real part $\text{Re}(x) \in \mathbb{R}^K$ and an imaginary part $\text{Im}(x) \in \mathbb{R}^K$, where i denotes the square root of -1. The conjugate $\overline{x}$ of a complex vector inverts the sign of its imaginary part: $\overline{x} = \text{Re}(x) - i\text{Im}(x)$.

Conjugation appears in the usual dot product for complex numbers, called the *Hermitian* product, or *sesquilinear* form, which is defined as:

$$\begin{aligned} \langle u, v \rangle &:= \bar{u}^\top v \\ &= \text{Re}(u)^\top \text{Re}(v) + \text{Im}(u)^\top \text{Im}(v) \\ &\quad + i(\text{Re}(u)^\top \text{Im}(v) - \text{Im}(u)^\top \text{Re}(v)) \,. \end{aligned}$$

A simple way to justify the Hermitian product for composing complex vectors is that it provides a valid topological norm in the induced vector space. For example, $\bar{x}^\top x = 0$ implies $x = 0$ while this is not the case for the bilinear form $x^\top x$ as there are many complex vectors x for which $x^\top x = 0$.

This yields an interesting property of the Hermitian product concerning the order of the involved vectors: $\langle u, v \rangle = \overline{\langle v, u \rangle}$, meaning that the real part of the product is symmetric, while the imaginary part is antisymmetric.

For matrices, we shall write $X^* \in \mathbb{C}^{n \times m}$ for the conjugate-transpose $X^* = (\overline{X})^\top = \overline{X^\top}$. The conjugate transpose is also often written $X^\dagger$ or X^{H}.

Definition 2 *A complex square matrix $X \in \mathbb{C}^{n \times n}$ is unitarily diagonalizable if it can be written as $X = EWE^*$, where $E, W \in \mathbb{C}^{n \times n}$, W is diagonal, and E is unitary such that $EE^* = E^*E = I$.*

Definition 3 *A complex square matrix X is normal if it commutes with its conjugate-transpose so that $XX^* = X^*X$.*

We can now state the spectral theorem for normal matrices.

Theorem 1 (Spectral theorem for normal matrices, von Neumann (1929)) *Let X be a complex square matrix. Then X is unitarily diagonalizable if and only if X is normal.*

It is easy to check that all real symmetric matrices are normal, and have pure real eigenvectors and eigenvalues. But the set of purely real normal matrices also includes all real antisymmetric matrices (useful to model hierarchical relations such as `IsOlder`), as well as all real orthogonal matrices (including permutation matrices), and many other matrices that are useful to represent binary relations, such as assignment matrices which represent bipartite graphs. However, far from all matrices expressed as $X = EWE^*$ are purely real, and Equation (1) requires the scores X to be purely real.

As we only focus on *real* square matrices in this work, let us summarize all the cases where X is real square and $X = EWE^*$ if X is unitarily diagonalizable, where $E, W \in \mathbb{C}^{n\times n}$, W is diagonal and E is unitary:

- X is symmetric if and only if X is orthogonally diagonalizable and E and W are purely real.
- X is normal and non-symmetric if and only if X is unitarily diagonalizable and E and W are *not* both purely real.
- X is not normal if and only if X is not unitarily diagonalizable.

We generalize all three cases by showing that, for any $X \in \mathbb{R}^{n\times n}$, there exists a unitary diagonalization in the complex domain, of which the real part equals X:

$$X = \mathrm{Re}(EWE^*)\,. \tag{2}$$

In other words, the unitary diagonalization is projected onto the real subspace.

Theorem 2 *Suppose $X \in \mathbb{R}^{n\times n}$ is a real square matrix. Then there exists a normal matrix $Z \in \mathbb{C}^{n\times n}$ such that $\mathrm{Re}(Z) = X$.*

Proof Let $Z := X + iX^\top$. Then

$$Z^* = X^\top - iX = -i(iX^\top + X) = -iZ\,,$$

so that

$$ZZ^* = Z(-iZ) = (-iZ)Z = Z^*Z\,.$$

Therefore Z is normal. ■

Note that there also exists a normal matrix $Z = X^\top + iX$ such that $\mathrm{Im}(Z) = X$.

Following Theorem 1 and Theorem 2, any real square matrix can be written as the real part of a complex diagonal matrix through a unitary change of basis.

Corollary 1 *Suppose $X \in \mathbb{R}^{n\times n}$ is a real square matrix. Then there exist $E, W \in \mathbb{C}^{n\times n}$, where E is unitary, and W is diagonal, such that $X = \mathrm{Re}(EWE^*)$.*

Proof From Theorem 2, we can write $X = \mathrm{Re}(Z)$, where Z is a normal matrix, and from Theorem 1, Z is unitarily diagonalizable. ■

Applied to the knowledge graph completion setting, the rows of E here are vectorial representations of the entities corresponding to rows and columns of the relation score matrix X. The score for the relation holding true between entities s and o is hence

$$x_{so} = \mathrm{Re}(e_s^\top W \bar{e}_o) \tag{3}$$

where $e_s, e_o \in \mathbb{C}^n$ and $W \in \mathbb{C}^{n\times n}$ is diagonal. For a given entity, its subject embedding vector is the complex conjugate of its object embedding vector.

To illustrate this difference of expressiveness with respect to real-valued embeddings, let us consider two complex embeddings $e_s, e_o \in \mathbb{C}$ of dimension 1, with arbitrary values: $e_s = 1 - 2i$, and $e_o = -3 + i$; as well as their real-valued, twice-bigger counterparts: $e'_s = \binom{1}{-2} \in \mathbb{R}^2$ and $e'_o = \binom{-3}{1} \in \mathbb{R}^2$. In the real-valued case, that corresponds to the DistMult model (Yang et al., 2015), the score is $x_{so} = e'^\top_s W' e'_o$. Figure 1 represents the heatmaps of the scores x_{so} and x_{os}, as a function of $W \in \mathbb{C}$ in the complex-valued case, and as a function of $W' \in \mathbb{R}^2$ diagonal in the real-valued case. In the real-valued case, that is symmetric in the subject and object entities, the scores x_{so} and x_{os} are equal for any value of $W' \in \mathbb{R}^2$ diagonal. Whereas in the complex-valued case, the variation of $W \in \mathbb{C}$ allows to score x_{so} and x_{os} with any desired pair of values.

This decomposition however is non-unique, a simple example of this non-uniqueness is obtained by adding a purely imaginary constant to the eigenvalues. Let $X \in \mathbb{R}^{n\times n}$, and $X = \mathrm{Re}(EWE^*)$ where E is unitary, W is diagonal. Then for any real constant $c \in \mathbb{R}$ we have:

$$\begin{aligned} X &= \mathrm{Re}(E(W + icI)E^*) \\ &= \mathrm{Re}(EWE^* + icEIE^*) \\ &= \mathrm{Re}(EWE^* + icI) \\ &= \mathrm{Re}(EWE^*)\,. \end{aligned}$$

In general, there are many other possible couples of matrices E and W that preserve the real part of the decomposition. In practice however this is no synonym of low generalization abilities, as many effective matrix and tensor decomposition methods used in machine learning lead to non-unique solutions (Paatero and Tapper, 1994; Nickel et al., 2011). In this case also, the learned representations prove useful as shown in the experimental section.

2.2 Low-Rank Decomposition

Addressing knowledge graph completion with data-driven approaches assumes that there is a sufficient regularity in the observed data to generalize to unobserved facts. When formulated as a matrix completion problem, as it is the case in this section, one way of implementing this hypothesis is to make the assumption that the matrix has a low rank or approximately low rank. We first discuss the rank of the proposed decomposition, and then introduce the sign-rank and extend the bound developed on the rank to the sign-rank.

2.2.1 Rank Upper Bound

First, we recall one definition of the rank of a matrix (Horn and Johnson, 2012).

Definition 4 *The rank of an m-by-n complex matrix $\mathrm{rank}(X) = \mathrm{rank}(X^\top) = k$, if X has exactly k linearly independent columns.*

Also note that if X is diagonalizable so that $X = EWE^{-1}$ with $\mathrm{rank}(X) = k$, then W has k non-zero diagonal entries for some diagonal W and some invertible matrix E. From this it is easy to derive a known additive property of the rank:

$$\mathrm{rank}(B + C) \leq \mathrm{rank}(B) + \mathrm{rank}(C) \tag{4}$$

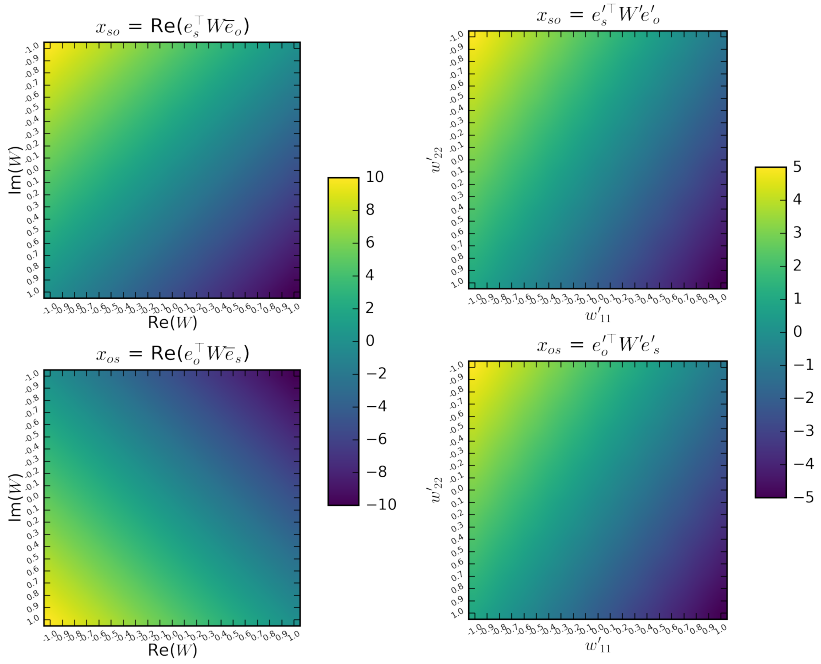

Figure 1: Left: Scores $x_{so} = \mathrm{Re}(e_s^\top W \overline{e}_o)$ (top) and $x_{os} = \mathrm{Re}(e_o^\top W \overline{e}_s)$ (bottom) for the proposed complex-valued decomposition, plotted as a function of $W \in \mathbb{C}$, for fixed entity embeddings $e_s = 1-2i$, and $e_o = -3+i$. Right: Scores $x_{so} = e_s'^\top W' e_o'$ (top) and $x_{os} = e_o'^\top W' e_s'$ (bottom) for the corresponding real-valued decomposition with the same number of free real-valued parameters (*i.e.* in twice the dimension), plotted as a function of $W' \in \mathbb{R}^2$ diagonal, for fixed entity embeddings $e_s' = \binom{1}{-2}$ and $e_o' = \binom{-3}{1}$. By varying $W \in \mathbb{C}$, the proposed complex-valued decomposition can attribute any pair of scores to x_{so} and x_{os}, whereas $x_{so} = x_{os}$ for all $W' \in \mathbb{R}^2$ with the real-valued decomposition.

where $B, C \in \mathbb{C}^{m \times n}$.

We now show that any rank k real square matrix can be reconstructed from a $2k$-dimensional unitary diagonalization.

Corollary 2 *Suppose $X \in \mathbb{R}^{n \times n}$ and rank$(X) = k$. Then there exist $E \in \mathbb{C}^{n \times 2k}$ such that the columns of E form an orthonormal basis of $\mathbb{C}^{2k}$, $W \in \mathbb{C}^{2k \times 2k}$ is diagonal, and $X = \mathrm{Re}(EWE^*)$.*

Proof Consider the complex square matrix $Z := X + iX^\top$. We have $\mathrm{rank}(iX^\top) = \mathrm{rank}(X^\top) = \mathrm{rank}(X) = k$.

From Equation (4), $\mathrm{rank}(Z) \leq \mathrm{rank}(X) + \mathrm{rank}(iX^\top) = 2k$.

The proof of Theorem 2 shows that Z is normal. Thus $Z = EWE^*$ with $E \in \mathbb{C}^{n \times 2k}$, $W \in \mathbb{C}^{2k \times 2k}$ where the columns of E form an orthonormal basis of $\mathbb{C}^{2k}$, and W is diagonal. ■

Since E is not necessarily square, we replace the unitary requirement of Corollary 1 by the requirement that its columns form an orthonormal basis of its smallest dimension, $2k$.

Also, given that such decomposition always exists in dimension n (Theorem 2), this upper bound is not relevant when $\mathrm{rank}(X) \geq \frac{n}{2}$.

2.2.2 Sign-Rank Upper Bound

Since we encode the truth values of each fact with ± 1, we deal with square *sign matrices*: $Y \in \{-1, 1\}^{n \times n}$. Sign matrices have an alternative rank definition, the *sign-rank*.

Definition 5 *The sign-rank* $\mathrm{rank}_\pm(Y)$ *of an m-by-n sign matrix Y, is the rank of the m-by-n real matrix of least rank that has the same sign-pattern as Y, so that*

$$\mathrm{rank}_\pm(Y) := \min_{X \in \mathbb{R}^{m \times n}} \{\mathrm{rank}(X) \,|\, \mathrm{sign}(X) = Y\},$$

where $\mathrm{sign}(X)_{ij} = \mathrm{sign}(x_{ij})$.

We define the *sign function* of $c \in \mathbb{R}$ as

$$\mathrm{sign}(c) = \begin{cases} 1 & \text{if } c \geq 0 \\ -1 & \text{otherwise} \end{cases}$$

where the value $c = 0$ is here arbitrarily assigned to 1 to allow zero entries in X, conversely to the stricter usual definition of the sign-rank.

To make generalization possible, we hypothesize that the true matrix Y has a low sign-rank, and thus can be reconstructed by the sign of a low-rank score matrix X. The low sign-rank assumption is theoretically justified by the fact that the sign-rank is a natural complexity measure of sign matrices (Linial et al., 2007) and is linked to learnability (Alon et al., 2016) and empirically confirmed by the wide success of factorization models (Nickel et al., 2016a).

Using Corollary 2, we can now show that any square sign matrix of sign-rank k can be reconstructed from a rank $2k$ unitary diagonalization.

Corollary 3 *Suppose $Y \in \{-1, 1\}^{n \times n}$, $\mathrm{rank}_\pm(Y) = k$. Then there exists $E \in \mathbb{C}^{n \times 2k}$, $W \in \mathbb{C}^{2k \times 2k}$ where the columns of E form an orthonormal basis of $\mathbb{C}^{2k}$, and W is diagonal, such that $Y = \mathrm{sign}(\mathrm{Re}(EWE^*))$.*

Proof By definition, if $\mathrm{rank}_\pm(Y) = k$, there exists a real square matrix X such that $\mathrm{rank}(X) = k$ and $\mathrm{sign}(X) = Y$. From Corollary 2, $X = \mathrm{Re}(EWE^*)$ where $E \in \mathbb{C}^{n \times 2k}$, $W \in \mathbb{C}^{2k \times 2k}$ where the columns of E form an orthonormal basis of $\mathbb{C}^{2k}$, and W is diagonal. ■

Previous attempts to approximate the sign-rank in relational learning did not use complex numbers. They showed the existence of compact factorizations under conditions on the sign matrix (Nickel et al., 2014), or only in specific cases (Bouchard et al., 2015). In contrast, our results show that if a square sign matrix has sign-rank k, then it can be exactly decomposed through a $2k$-dimensional unitary diagonalization.

Although we can only show the existence of a complex decomposition of rank $2k$ for a matrix with sign-rank k, the sign rank of Y is often *much* lower than the rank of Y, as we do not know any matrix $Y \in \{-1,1\}^{n\times n}$ for which $\text{rank}_{\pm}(Y) > \sqrt{n}$ (Alon et al., 2016). For example, the $n \times n$ identity matrix has rank n, but its sign-rank is only 3! By swapping the columns $2j$ and $2j-1$ for j in $1,\ldots,\frac{n}{2}$, the identity matrix corresponds to the relation `marriedTo`, a relation known to be hard to factorize over the reals (Nickel et al., 2014), since the rank is invariant by row/column permutations. Yet our model can express it at most in rank 6, for any n.

Hence, by enforcing a low-rank $K \ll n$ on EWE^*, individual relation scores $x_{so} = \text{Re}(e_s^\top W \bar{e}_o)$ between entities s and o can be efficiently predicted, as $e_s, e_o \in \mathbb{C}^K$ and $W \in \mathbb{C}^{K\times K}$ is diagonal.

Finding the K that matches the sign-rank of Y corresponds to finding the smallest K that brings the 0–1 loss on X to 0, as link prediction can be seen as binary classification of the facts. In practice, and as classically done in machine learning to avoid this NP-hard problem, we use a continuous surrogate of the 0–1 loss, in this case the logistic loss as described in Section 4, and validate models on different values of K, as described in Section 5.

2.2.3 Rank Bound Discussion

Corollaries 2 and 3 use the aforementioned subadditive property of the rank to derive the $2k$ upper bound. Let us give an example for which this bound is strictly greater than k.

Consider the following 2-by-2 sign matrix:

$$Y = \begin{bmatrix} -1 & -1 \\ 1 & 1 \end{bmatrix}.$$

Not only is this matrix not normal, but one can also easily check that there is no *real* normal 2-by-2 matrix that has the same sign-pattern as Y. Clearly, Y is a rank 1 matrix since its columns are linearly dependent, hence its sign-rank is also 1. From Corollary 3, we know that there is a normal matrix whose real part has the same sign-pattern as Y, and whose rank is at most 2.

However, there is no rank 1 unitary diagonalization of which the real part equals Y. Otherwise we could find a 2-by-2 complex matrix Z such that $\text{Re}(z_{11}) < 0$ and $\text{Re}(z_{22}) > 0$, where $z_{11} = e_1 w \bar{e}_1 = w|e_1|^2$, $z_{22} = e_2 w \bar{e}_2 = w|e_2|^2$, $e \in \mathbb{C}^2, w \in \mathbb{C}$. This is obviously unsatisfiable. This example generalizes to any n-by-n square sign matrix that only has -1 on its first row and is hence rank 1, the same argument holds considering $\text{Re}(z_{11}) < 0$ and $\text{Re}(z_{nn}) > 0$.

This example shows that the upper bound on the rank of the unitary diagonalization showed in Corollaries 2 and 3 can be strictly greater than k, the rank or sign-rank, of the decomposed matrix. However, there might be other examples for which the addition of

an imaginary part could—additionally to making the matrix normal—create some linear dependence between the rows/columns and thus decrease the rank of the matrix, up to a factor of 2.

We summarize this section in three points:

1. The proposed factorization encompasses all possible score matrices X for a single binary relation.
2. By construction, the factorization is well suited to represent both symmetric and antisymmetric relations.
3. Relation patterns can be efficiently approximated with a low-rank factorization using complex-valued embeddings.

3. Extension to Multi-Relational Data

Let us now extend the previous discussion to models with multiple relations. Let $\mathcal{R}$ be the set of relations, with $|\mathcal{R}| = m$. We shall now write $\mathbf{X} \in \mathbb{R}^{m\times n\times n}$ for the score tensor, $X_r \in \mathbb{R}^{n\times n}$ for the score matrix of the relation $r \in \mathcal{R}$, and $\mathbf{Y} \in \{-1,1\}^{m\times n\times n}$ for the partially-observed sign tensor.

Given one relation $r \in \mathcal{R}$ and two entities $s, o \in \mathcal{E}$, the probability that the fact *r(s,o)* is true given by:

$$P(y_{rso} = 1) = \sigma(x_{rso}) = \sigma(\phi(r, s, o; \Theta)) \tag{5}$$

where ϕ is the scoring function of the model considered and Θ denotes the model parameters. We denote the set of all possible facts (or triples) for a knowledge graph by $\mathcal{T} = \mathcal{R} \times \mathcal{E} \times \mathcal{E}$. While the tensor $\mathbf{X}$ as a whole is unknown, we assume that we observe a set of true and false triples $\Omega = \{((r,s,o), y_{rso}) \,|\, (r,s,o) \in \mathcal{T}_\Omega\}$ where $y_{rso} \in \{-1,1\}$ and $\mathcal{T}_\Omega \subseteq \mathcal{T}$ is the set of observed triples. The goal is to find the probabilities of entries $y_{r's'o'}$ for a set of targeted unobserved triples $\{(r',s',o') \in \mathcal{T} \setminus \mathcal{T}_\Omega\}$.

Depending on the scoring function $\phi(r,s,o;\Theta)$ used to model the score tensor $\mathbf{X}$, we obtain different models. Examples of scoring functions are given in Table 1.

3.1 Complex Factorization Extension to Tensors

The single-relation model is extended by jointly factorizing all the square matrices of scores into a 3rd-order tensor $\mathbf{X} \in \mathbb{R}^{m\times n\times n}$, with a different diagonal matrix $W_r \in \mathbb{C}^{K\times K}$ for each relation r, and by sharing the entity embeddings $E \in \mathbb{C}^{n\times K}$ across all relations:

$$\begin{aligned} \phi(r,s,o;\Theta) &= \text{Re}(e_s^\top W_r \bar{e}_o) \\ &= \text{Re}\Big(\sum_{k=1}^{K} w_{rk} e_{sk} \bar{e}_{ok}\Big) \\ &= \text{Re}(\langle w_r, e_s, \bar{e}_o \rangle) \end{aligned} \tag{6}$$

where K is the rank hyperparameter, $e_s, e_o \in \mathbb{C}^K$ are the rows in E corresponding to the entities s and o, $w_r = \text{diag}(W_r) \in \mathbb{C}^K$ is a complex vector, and $\langle a,b,c \rangle := \sum_k a_k b_k c_k$ is the

component-wise multilinear dot product[2]. For this scoring function, the set of parameters Θ is $\{e_i, w_r \in \mathbb{C}^K, i \in \mathcal{E}, r \in \mathcal{R}\}$. This resembles the real part of a complex matrix decomposition as in the single-relation case discussed above. However, we now have a different vector of eigenvalues for every relation. Expanding the real part of this product gives:

$$\begin{aligned}\mathrm{Re}(\langle w_r, e_s, \bar{e}_o\rangle) \;=\; & \langle \mathrm{Re}(w_r), \mathrm{Re}(e_s), \mathrm{Re}(e_o)\rangle \\ & + \langle \mathrm{Re}(w_r), \mathrm{Im}(e_s), \mathrm{Im}(e_o)\rangle \\ & + \langle \mathrm{Im}(w_r), \mathrm{Re}(e_s), \mathrm{Im}(e_o)\rangle \\ & - \langle \mathrm{Im}(w_r), \mathrm{Im}(e_s), \mathrm{Re}(e_o)\rangle \;. \end{aligned} \tag{7}$$

These equations provide two interesting views of the model:

- *Changing the representation*: Equation (6) would correspond to DistMult with real embeddings (see Table 1), but handles asymmetry thanks to the complex conjugate of the object-entity embedding.
- *Changing the scoring function*: Equation (7) only involves real vectors corresponding to the real and imaginary parts of the embeddings and relations.

By separating the real and imaginary parts of the relation embedding w_r as shown in Equation (7), it is apparent that these parts naturally act as weights on each latent dimension: $\mathrm{Re}(w_r)$ over the real part of $\langle e_o, e_s\rangle$ which is symmetric, and $\mathrm{Im}(w)$ over the imaginary part of $\langle e_o, e_s\rangle$ which is antisymmetric.

Indeed, the decomposition of each score matrix X_r for each $r \in \mathcal{R}$ can be written as the sum of a symmetric matrix and an antisymmetric matrix. To see this, let us rewrite the decomposition of each score matrix X_r in matrix notation. We write the real part of matrices with primes $E' = \mathrm{Re}(E)$ and imaginary parts with double primes $E'' = \mathrm{Im}(E)$:

$$\begin{aligned} X_r &= \mathrm{Re}(E W_r E^*) \\ &= \mathrm{Re}((E' + iE'')(W'_r + iW''_r)(E' - iE'')^\top) \\ &= (E'W'_rE'^\top + E''W'_rE''^\top) + (E'W''_rE''^\top - E''W''_rE'^\top)\,. \end{aligned} \tag{8}$$

It is trivial to check that the matrix $E'W'_rE'^\top + E''W'_rE''^\top$ is symmetric and that the matrix $E'W''_rE''^\top - E''W''_rE'^\top$ is antisymmetric. Hence this model is well suited to model jointly symmetric and antisymmetric relations between pairs of entities, while still using the same entity representations for subjects and objects. When learning, it simply needs to collapse $W''_r = \mathrm{Im}(W_r)$ to zero for symmetric relations $r \in \mathcal{R}$, and $W'_r = \mathrm{Re}(W_r)$ to zero for antisymmetric relations $r \in \mathcal{R}$, as X_r is indeed symmetric when W_r is purely real, and antisymmetric when W_r is purely imaginary.

From a geometrical point of view, each relation embedding w_r is an anisotropic scaling of the basis defined by the entity embeddings E, followed by a projection onto the real subspace.

2. This is not the Hermitian extension of the multilinear dot product as there appears to be no standard definition of the Hermitian multilinear product in the linear algebra literature.

3.2 Existence of the Tensor Factorization

Let us first discuss the existence of the multi-relational model where the rank of the decomposition $K \leq n$, which relates to simultaneous unitary decomposition.

Definition 6 *A family of matrices $X_1, \ldots, X_m \in \mathbb{C}^{n\times n}$ is simultaneously unitarily diagonalizable, if there is a single unitary matrix $E \in \mathbb{C}^{n\times n}$, such that $X_i = EW_iE^*$ for all i in $1, \ldots, m$, where $W_i \in \mathbb{C}^{n\times n}$ are diagonal.*

Definition 7 *A family of normal matrices $X_1, \ldots, X_m \in \mathbb{C}^{n\times n}$ is a commuting family of normal matrices, if $X_iX_j^* = X_i^*X_j$, for all i, j in $1, \ldots, m$.*

Theorem 3 (see Horn and Johnson (2012)) *Suppose $\mathcal{F}$ is the family of matrices X_1, $\ldots$, $X_m \in \mathbb{C}^{n\times n}$. Then $\mathcal{F}$ is a commuting family of normal matrices if and only if $\mathcal{F}$ is simultaneously unitarily diagonalizable.*

To apply Theorem 3 to the proposed factorization, we would have to make the hypothesis that the relation score matrices X_r are a commuting family, which is too strong a hypothesis. Actually, the model is slightly different since we take only the real part of the tensor factorization. In the single-relation case, taking only the real part of the decomposition rids us of the normality requirement of Theorem 1 for the decomposition to exist, as shown in Theorem 2.

In the multiple-relation case, it is an open question whether taking the real part of the simultaneous unitary diagonalization will enable us to decompose families of arbitrary real square matrices—that is with a single unitary matrix E that has *at most* n columns. Though it seems unlikely, we could not find a counter-example yet.

However, by letting the rank of the tensor factorization K to be greater than n, we can show that the proposed tensor decomposition exists for families of arbitrary real square matrices, by simply concatenating the decomposition of Theorem 2 of each real square matrix X_i.

Theorem 4 *Suppose $X_1, \ldots, X_m \in \mathbb{R}^{n\times n}$. Then there exists $E \in \mathbb{C}^{n\times nm}$ and $W_i \in \mathbb{C}^{nm\times nm}$ are diagonal, such that $X_i = \mathrm{Re}(EW_iE^*)$ for all i in $1, \ldots, m$.*

Proof From Theorem 2 we have $X_i = \mathrm{Re}(E_iW_iE_i^*)$, where $W_i \in \mathbb{C}^{n\times n}$ is diagonal, and each $E_i \in \mathbb{C}^{n\times n}$ is unitary for all i in $1, \ldots, m$.

Let $E = [E_1 \ldots E_m]$, and

$$\Lambda_i = \begin{bmatrix} \mathbf{0}^{((i-1)n)\times((i-1)n)} & & \\ & W_i & \\ & & \mathbf{0}^{((m-i)n)\times((m-i)n)} \end{bmatrix}$$

where $\mathbf{0}^{l\times l}$ the zero $l \times l$ matrix. Therefore $X_i = \mathrm{Re}(E\Lambda_iE^*)$ for all i in $1, \ldots, m$. ■

By construction, the rank of the decomposition is at most nm. When $m \leq n$, this bound actually matches the general upper bound on the rank of the canonical polyadic (CP) decomposition (Hitchcock, 1927; Kruskal, 1989). Since m corresponds to the number

of relations and n to the number of entities, m is always smaller than n in real world knowledge graphs, hence the bound holds in practice.

Though when it comes to relational learning, we might expect the actual rank to be much lower than nm for two reasons. The first one, as discussed above, is that we are dealing with sign tensors, hence the rank of the matrices X_r need only match the sign-rank of the partially-observed matrices Y_r. The second one is that the matrices are related to each other, as they all represent the same entities in different relations, and thus benefit from sharing latent dimensions. As opposed to the construction exposed in the proof of Theorem 4, where other relations dimensions are canceled out. In practice, the rank needed to generalize well is indeed much lower than nm as we show experimentally in Figure 5.

Also, note that with the construction of the proof of Theorem 4, the matrix $E = [E_1 \dots E_m]$ is not unitary any more. However the unitary constraints in the matrix case serve only the proof of existence, which is just one solution among the infinite ones of same rank. In practice, imposing orthonormality is essentially a numerical commodity for the decomposition of dense matrices, through iterative methods for example (Saad, 1992). When it comes to matrix and tensor completion, and thus generalisation, imposing such constraints is more of a numerical hassle than anything else, especially for gradient methods. As there is no apparent link between orthonormality and generalisation properties, we did not impose these constraints when learning this model in the following experiments.

4. Algorithm

Algorithm 1 describes stochastic gradient descent (SGD) to learn the proposed multi-relational model with the AdaGrad learning-rate updates (Duchi et al., 2011). We refer to the proposed model as ComplEx, for Complex Embeddings. We expose a version of the algorithm that uses only real-valued vectors, in order to facilitate its implementation. To do so, we use separate real-valued representations of the real and imaginary parts of the embeddings.

These real and imaginary part vectors are initialized with vectors having a zero-mean normal distribution with unit variance. If the training set Ω contains only positive triples, negatives are generated for each batch using the *local closed-world assumption* as in Bordes et al. (2013b). That is, for each triple, we randomly change either the subject or the object, to form a negative example. In this case the parameter $\eta > 0$ sets the number of negative triples to generate for each positive triple. Collision with positive triples in Ω is not checked, as it occurs rarely in real world knowledge graphs as they are largely sparse, and may also be computationally expensive.

Squared gradients are accumulated to compute AdaGrad learning rates, then gradients are updated. Every s iterations, the parameters Θ are evaluated over the evaluation set Ω_v (*evaluate_AP_or_MRR*$(\Omega_v; \Theta)$ function in Algorithm 1). If the data set contains both positive and negative examples, average precision (AP) is used to evaluate the model. If the data set contains only positives, then mean reciprocal rank (MRR) is used as average precision cannot be computed without true negatives. The optimization process is stopped when the measure considered decreases compared to the last evaluation (early stopping).

Bern(p) is the Bernoulli distribution, the *one_random_sample*$(\mathcal{E})$ function sample uniformly one entity in the set of all entities $\mathcal{E}$, and the *sample_batch_of_size_b*(Ω, b) function sample b true and false triples uniformly at random from the training set Ω.

For a given embedding size K, let us rewrite Equation (7), by denoting the real part of embeddings with primes and the imaginary part with double primes: $e'_i = \mathrm{Re}(e_i)$, $e''_i = \mathrm{Im}(e_i)$, $w'_r = \mathrm{Re}(w_r)$, $w''_r = \mathrm{Im}(w_r)$. The set of parameters is $\Theta = \{e'_i, e''_i, w'_r, w''_r \in \mathbb{R}^K, i \in \mathcal{E}, r \in \mathcal{R}\}$, and the scoring function involves only real vectors:

$$\begin{aligned}\phi(r, s, o; \Theta) = \quad & \langle w'_r, e'_s, e'_o \rangle + \langle w'_r, e''_s, e''_o \rangle \\ & + \langle w''_r, e'_s, e''_o \rangle - \langle w''_r, e''_s, e'_o \rangle \end{aligned} \tag{9}$$

where each entity and each relation has two real embeddings.

Gradients are now easy to write:

$$\begin{aligned}
\nabla_{e'_s} \phi(r, s, o; \Theta) &= (w'_r \odot e'_o) + (w''_r \odot e''_o), \\
\nabla_{e''_s} \phi(r, s, o; \Theta) &= (w'_r \odot e''_o) - (w''_r \odot e'_o), \\
\nabla_{e'_o} \phi(r, s, o; \Theta) &= (w'_r \odot e'_s) - (w''_r \odot e''_s), \\
\nabla_{e''_o} \phi(r, s, o; \Theta) &= (w'_r \odot e''_s) + (w''_r \odot e'_s), \\
\nabla_{w'_r} \phi(r, s, o; \Theta) &= (e'_s \odot e'_o) + (e''_s \odot e''_o), \\
\nabla_{w''_r} \phi(r, s, o; \Theta) &= (e'_s \odot e''_o) - (e''_s \odot e'_o),
\end{aligned}$$

where $\odot$ is the element-wise (Hadamard) product.

We optimized the negative log-likelihood of the logistic model described in Equation (5) with L^2 regularization on the parameters Θ:

$$\gamma(\Omega; \Theta) = \sum_{((r,s,o),y) \in \Omega} \log(1 + \exp(-y\phi(r, s, o; \Theta))) + \lambda ||\Theta||_2^2 \tag{10}$$

where $\lambda \in \mathbb{R}_+$ is the regularization parameter.

To handle regularization, note that using separate representations for the real and imaginary parts does not change anything as the squared L^2-norm of a complex vector $v = v' + iv''$ is the sum of the squared modulus of each entry:

$$\begin{aligned}
||v||_2^2 &= \sum_j \sqrt{v'^2_j + v''^2_j}^2 \\
&= \sum_j v'^2_j + \sum_j v''^2_j \\
&= ||v'||_2^2 + ||v''||_2^2 ,
\end{aligned}$$

which is actually the sum of the L^2-norms of the vectors of the real and imaginary parts.

We can finally write the gradient of γ with respect to a *real* embedding v for one triple (r, s, o) and its truth value y:

$$\nabla_v \gamma(\{((r, s, o), y)\}; \Theta) = -y\sigma(-y\phi(r, s, o; \Theta)) \nabla_v \phi(r, s, o; \Theta) + 2\lambda v \,. \tag{11}$$

5. Experiments

We evaluated the method proposed in this paper on both synthetic and real data sets. The synthetic data set contains both symmetric and antisymmetric relations, whereas the real data sets are standard link prediction benchmarks based on real knowledge graphs.

We compared ComplEx to state-of-the-art models, namely TransE (Bordes et al., 2013b), DistMult (Yang et al., 2015), RESCAL (Nickel et al., 2011) and also to the canonical polyadic decomposition (CP) (Hitchcock, 1927), to emphasize empirically the importance of learning unique embeddings for entities. For experimental fairness, we reimplemented these models within the same framework as the ComplEx model, using a Theano-based SGD implementation[3] (Bergstra et al., 2010).

For the TransE model, results were obtained with its original max-margin loss, as it turned out to yield better results for this model only. To use this max-margin loss on data sets with observed negatives (Sections 5.1 and 5.2), positive triples were replicated when necessary to match the number of negative triples, as described in Garcia-Duran et al. (2016). All other models are trained with the negative log-likelihood of the logistic model (Equation (10)). In all the following experiments we used a maximum number of iterations $m = 1000$, a batch size $b = \frac{|\Omega|}{100}$, and validated the models for early stopping every $s = 50$ iterations.

5.1 Synthetic Task

To assess our claim that ComplEx can accurately model jointly symmetry and antisymmetry, we randomly generated a knowledge graph of two relations and 30 entities. One relation is entirely symmetric, while the other is completely antisymmetric. This data set corresponds to a $2 \times 30 \times 30$ tensor. Figure 2 shows a part of this randomly generated tensor, with a symmetric slice and an antisymmetric slice, decomposed into training, validation and test sets. To ensure that all test values are predictable, the upper triangular parts of the matrices are always kept in the training set, and the diagonals are unobserved. We conducted a 5-fold cross-validation on the lower-triangular matrices, using the upper-triangular parts plus 3 folds for training, one fold for validation and one fold for testing. Each training set contains 1392 observed triples, whereas validation and test sets contain 174 triples each.

Figure 3 shows the best cross-validated average precision (area under the precision-recall curve) for different factorization models of ranks ranging up to 50. The regularization parameter λ is validated in {0.1, 0.03, 0.01, 0.003,0.001, 0.0003, 0.00001, 0.0} and the learning rate α was initialized to 0.5.

As expected, DistMult (Yang et al., 2015) is not able to model antisymmetry and only predicts the symmetric relations correctly. Although TransE (Bordes et al., 2013b) is not a symmetric model, it performs poorly in practice, particularly on the antisymmetric relation. RESCAL (Nickel et al., 2011), with its large number of parameters, quickly overfits as the rank grows. Canonical Polyadic (CP) decomposition (Hitchcock, 1927) fails on both relations as it has to push symmetric and antisymmetric patterns through the entity embeddings. Surprisingly, only ComplEx succeeds even on such simple data.

Red pixels are positive triples, blue are negatives, and green missing ones. Top: Plots of the symmetric slice (relation) for the 10 first entities. Bottom: Plots of the antisymmetric slice for the 10 first entities.

5.2 Real Fully-Observed Data Sets: Kinships and UMLS

We then compare all models on two fully observed data sets, that contain both positive and negative triples, also called the *closed-world assumption*. The Kinships data set (Denham, 1973) describes the 26 different kinship relations of the Alyawarra tribe in Australia, among 104 individuals. The unified medical language system (UMLS) data set (McCray, 2003) represents 135 medical concepts and diseases, linked by 49 relations describing their interactions. Metadata for the two data sets is summarized in Table 2.

Data set	$\lvert\mathcal{E}\rvert$	$\lvert\mathcal{R}\rvert$	Total number of triples
Kinships	104	26	281,216
UMLS	135	49	893,025

Table 2: Number of entities $|\mathcal{E}|$, relations $|\mathcal{R}|$, and observed triples (all are observed) for the Kinships and UMLS data sets.

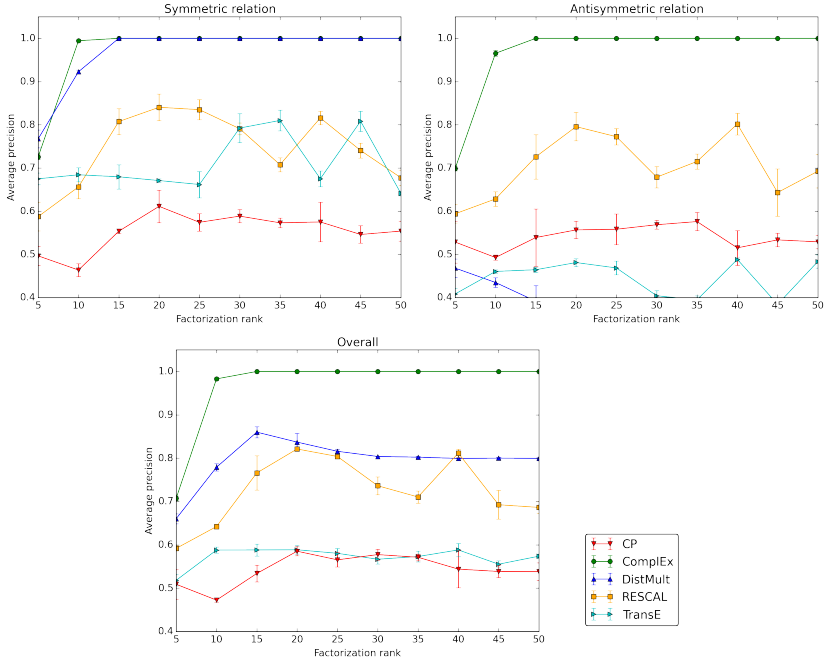

Figure 3: Average precision (AP) for each factorization rank ranging from 5 to 50 for different state-of-the-art models on the synthetic task. Learning is performed jointly on the symmetric relation and on the antisymmetric relation. Top-left: AP over the symmetric relation only. Top-right: AP over the antisymmetric relation only. Bottom: Overall AP.

We performed a 10-fold cross-validation, keeping 8 for training, one for validation and one for testing. Figure 4 shows the best cross-validated average precision for ranks ranging up to 50, and error bars show the standard deviation over the 10 runs. The regularization parameter λ is validated in $\{0.1, 0.03, 0.01, 0.003, 0.001, 0.0003, 0.00001, 0.0\}$ and the learning rate α was initialized to 0.5.

On both data sets ComplEx, RESCAL and CP are very close, with a slight advantage for ComplEx on Kinships, and for RESCAL on UMLS. DistMult performs poorly here as many relations are antisymmetric both in UMLS (causal links, anatomical hierarchies) and Kinships (being father, uncle or grand-father).

The fact that CP, RESCAL and ComplEx work so well on these data sets illustrates the importance of having an expressive enough model, as DistMult fails because

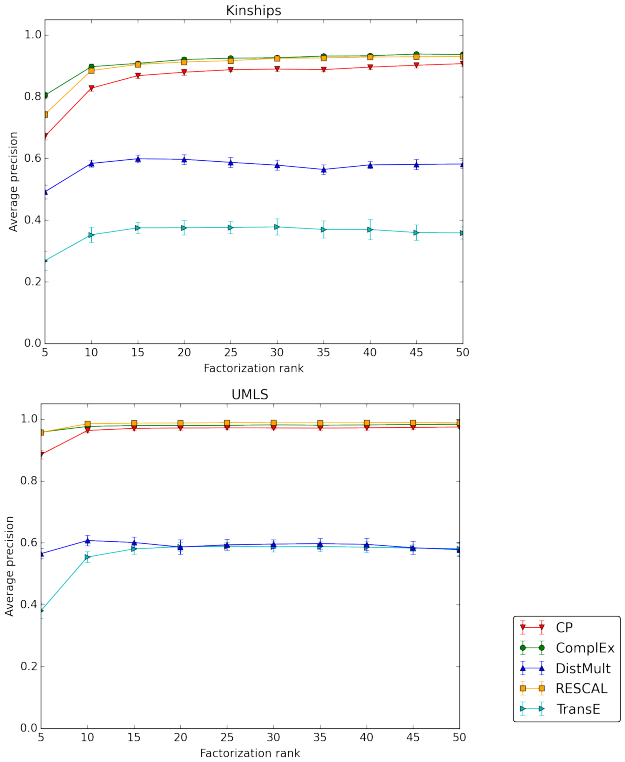

Figure 4: Average precision (AP) for each factorization rank ranging from 5 to 50 for different state-of-the-art models on the Kinships data set (top) and on the UMLS data set (bottom).

of antisymmetry; the power of the multilinear product—that is the tensor factorization approach—as TransE can be seen as a sum of bilinear products (Garcia-Duran et al., 2016); but not yet the importance of having unique entity embeddings, as CP works well. We believe having separate subject and object-entity embeddings works well under the closed-world assumption, because of the amount of training data compared to the number of embeddings to learn. Though when only a fractions of the positive training examples are observed (as it is most often the case), we will see in the next experiments that enforcing unique entity embeddings is key to good generalization.

			Number of triples in sets:		
Data set	$\lvert\mathcal{E}\rvert$	$\lvert\mathcal{R}\rvert$	Training	Validation	Test
WN18	40,943	18	141,442	5,000	5,000
FB15K	14,951	1,345	483,142	50,000	59,071

Table 3: Number of entities $|\mathcal{E}|$, relations $|\mathcal{R}|$, and observed triples in each split for the FB15K and WN18 data sets.

5.3 Real Sparse Data Sets: FB15K and WN18

Finally, we evaluated ComplEx on the FB15K and WN18 data sets, as they are well established benchmarks for the link prediction task. FB15K is a subset of Freebase (Bollacker et al., 2008), a curated knowledge graph of general facts, whereas WN18 is a subset of WordNet (Fellbaum, 1998), a database featuring lexical relations between words. We used the same training, validation and test set splits as in Bordes et al. (2013b). Table 3 summarizes the metadata of the two data sets.

5.3.1 Experimental Setup

As both data sets contain only positive triples, we generated negative samples using the local closed-world assumption, as described in Section 4. For evaluation, we measure the quality of the ranking of each test triple among all possible subject and object substitutions : $r(s', o)$ and $r(s, o')$, for each s', o' in $\mathcal{E}$, as used in previous studies (Bordes et al., 2013b; Nickel et al., 2016b). Mean Reciprocal Rank (MRR) and Hits at N are standard evaluation measures for these data sets and come in two flavours: raw and filtered. The filtered metrics are computed *after* removing all the other positive observed triples that appear in either training, validation or test set from the ranking, whereas the raw metrics do not remove these.

Since ranking measures are used, previous studies generally preferred a max-margin ranking loss for the task (Bordes et al., 2013b; Nickel et al., 2016b). We chose to use the negative log-likelihood of the logistic model—as described in the previous section—as it is a continuous surrogate of the sign-rank, and has been shown to learn compact representations for several important relations, especially for transitive relations (Bouchard et al., 2015). As previously stated, we tried both losses in preliminary work, and indeed training the models with the log-likelihood yielded better results than with the max-margin ranking loss, especially on FB15K—except with TransE.

We report both filtered and raw MRR, and filtered Hits at 1, 3 and 10 in Table 4 for the evaluated models. The HolE model has recently been shown to be equivalent to ComplEx (Hayashi and Shimbo, 2017), we record the original results for HolE as reported in Nickel et al. (2016b) and briefly discuss the discrepancy of results obtained with ComplEx.

Reported results are given for the best set of hyper-parameters evaluated on the validation set for each model, after a distributed grid-search on the following values: $K \in \{10, 20, 50, 100, 150, 200\}$, $\lambda \in \{0.1, 0.03, 0.01, 0.003, 0.001, 0.0003, 0.0\}$, $\alpha \in \{1.0, 0.5, 0.2, 0.1, 0.05, 0.02, 0.01\}$, $\eta \in \{1, 2, 5, 10\}$ with λ the L^2 regularization parameter, α the initial learning rate, and η the number of negatives generated per positive training triple. We also

Table 4: Filtered and raw mean reciprocal rank (MRR) for the models tested on the FB15K and WN18 data sets. Hits@N metrics are filtered. *Results reported from Nickel et al. (2016b) for the HolE model, that has been shown to be equivalent to ComplEx (Hayashi and Shimbo, 2017), score divergence on FB15K is only due to the loss function used (Trouillon and Nickel, 2017).

tried varying the batch size but this had no impact and we settled with 100 batches per epoch. With the best hyper-parameters, training the ComplEx model on a single GPU (NVIDIA Tesla P40) takes 45 minutes on WN18 ($K = 150, \eta = 1$), and three hours on FB15K ($K = 200, \eta = 10$).

5.3.2 Results

WN18 describes lexical and semantic hierarchies between concepts and contains many antisymmetric relations such as hypernymy, hyponymy, and being part of. Indeed, the DistMult and TransE models are outperformed here by ComplEx and HolE, which are on a par with respective filtered MRR scores of 0.941 and 0.938, which is expected as both models are equivalent.

Table 5 shows the filtered MRR for the reimplemented models and each relation of WN18, confirming the advantage of ComplEx on antisymmetric relations while losing nothing on the others. 2D projections of the relation embeddings (Figures 8 & 9) visually corroborate the results.

On FB15K, the gap is much more pronounced and the ComplEx model largely outperforms HolE, with a filtered MRR of 0.692 and 59.9% of Hits at 1, compared to 0.524 and 40.2% for HolE. This difference of scores between the two models, though they have been proved to be equivalent (Hayashi and Shimbo, 2017), is due to the use of the aforementioned max-margin loss in the original HolE publication (Nickel et al., 2016b) that performs worse than the log-likelihood on this dataset, and to the generation of more than one negative sample per positive in these experiments. This has been confirmed and discussed in details by Trouillon and Nickel (2017). The fact that DistMult yields fairly high scores (0.654 filtered MRR) is also due to the task itself and the evaluation measures used. As the dataset only involves true facts, the test set never includes the opposite facts $r(o, s)$ of each test fact $r(s, o)$ for *antisymmetric* relations—as the opposite fact is always false. Thus highly scoring the opposite fact barely impacts the rankings for antisymmetric relations. This is not the case in the fully observed experiments (Section 5.2), as the opposite fact is known

Table 5: Filtered Mean Reciprocal Rank (MRR) for the models tested on each relation of the WordNet data set (WN18).

to be false—for antisymmetric relations—and largely impacts the average precision of the DistMult model (Figure 4).

RESCAL, that represents each relation with a $K \times K$ matrix, performs well on WN18 as there are few relations and hence not so many parameters. On FB15K though, it probably overfits due to the large number of relations and thus the large number of parameters to learn, and performs worse than a less expressive model like DistMult. On both data sets, TransE and CP are largely left behind. This illustrates again the power of the multilinear product in the first case, and the importance of learning unique entity embeddings in the second. CP performs especially poorly on WN18 due to the small number of relations, which magnifies this subject/object difference.

Figure 5 shows that the filtered MRR of the ComplEx model quickly converges on both data sets, showing that the low-rank hypothesis is reasonable in practice. The little gain of performances for ranks comprised between 50 and 200 also shows that ComplEx does not perform better because it has twice as many parameters for the same rank—the real and imaginary parts—compared to other linear space complexity models but indeed thanks to its better expressiveness.

Best ranks were generally 150 or 200, in both cases scores were always very close for all models, suggesting there was no need to grid-search on higher ranks. The number of negative samples per positive sample also had a large influence on the filtered MRR on FB15K (up to +0.08 improvement from 1 to 10 negatives), but not much on WN18. On both data sets regularization was important (up to +0.05 on filtered MRR between $\lambda = 0$ and optimal one). We found the initial learning rate to be very important on FB15K, while not so

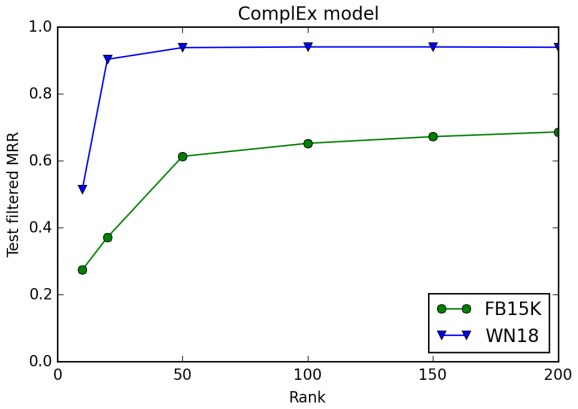

Figure 5: Best filtered MRR for ComplEx on the FB15K and WN18 data sets for different ranks. Increasing the rank gives little performance gain for ranks of $50 - 200$.

much on WN18. We think this may also explain the large gap of improvement ComplEx provides on this data set compared to previously published results—as DistMult results are also better than those previously reported (Yang et al., 2015)—along with the use of the log-likelihood objective. It seems that in general AdaGrad is relatively insensitive to the initial learning rate, perhaps causing some overconfidence in its ability to tune the step size online and consequently leading to less efforts when selecting the initial step size.

5.4 Training time

As defended in Section 2, having a linear time and space complexity becomes critical when the dataset grows. To illustrate this, we report in Figure 6 the evolution of the filtered MRR on the validation set as a function of time, for the best set of validated hyper-parameters for each model. The convergence criterion used is the decrease of the validation filtered MRR—computed every 50 iterations—with a maximum number of iterations of 1000 (see Algorithm 1). All models have a linear complexity except for RESCAL that has a quadratic one in the rank of the decomposition, as it learns one matrix embedding for each relation $r \in \mathcal{R}$. Timings are measured on a single NVIDIA Tesla P40 GPU.

On WN18, all models reach convergence in a reasonable time, between 15 minutes and 1 hour and 20 minutes. The difference between RESCAL and the other models is not sharp there, first because its optimal embedding size ($K = 50$) is lower compared to the other models. Secondly, there are only $|\mathcal{R}| = 18$ relations in WN18, hence the memory footprint of RESCAL is pretty similar to the other models—because it represents only relations with matrices and not entities. On FB15K, the difference is much more pronounced, as RESCAL optimal rank is similar to the other models; and with $|\mathcal{R}| = 1345$ relations, RESCAL has

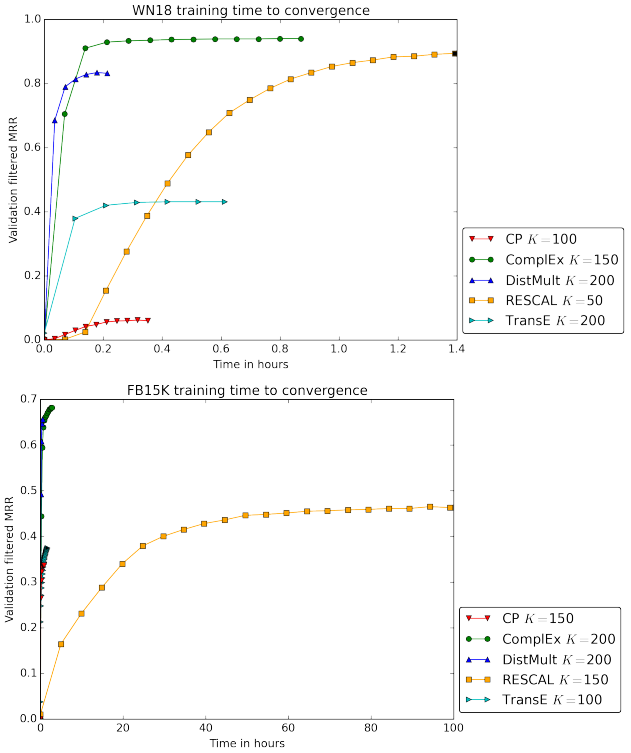

Figure 6: Evolution of the filtered MRR on the validation set as a function of time, on WN18 (top) and FB15K (bottom) for each model for its best set of hyper-parameters. The best rank K is reported in legend. Final black marker indicates that the maximum number of iterations (1000) has been reached (RESCAL on WN18, TransE on FB15K).

a much higher memory footprint, which implies more processor cache misses due to the uniformly-random nature of the SGD sampling.

RESCAL took more than four days to train on FB15K, whereas other models took between 40 minutes and 3 hours. While a few days might seem manageable, this could not be the case on larger data sets, as FB15K is but a small subset of Freebase that contains $|\mathcal{R}| = 35000$ relations (Bollacker et al., 2008). This experimentally supports our claim that linear complexity is required for scalability.

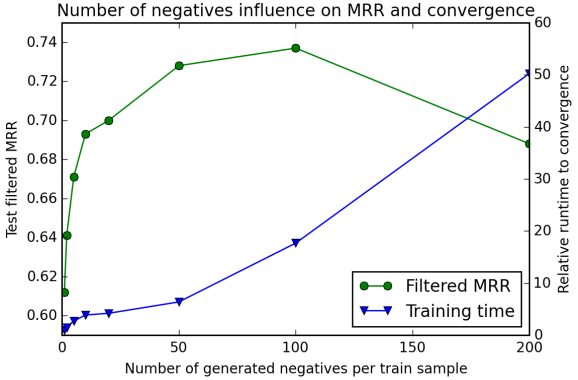

Figure 7: Influence of the number of negative triples generated per positive training example on the filtered test MRR and on training time to convergence on FB15K for the ComplEx model with $K = 200$, $\lambda = 0.01$ and $\alpha = 0.5$. Times are given relative to the training time with one negative triple generated per positive training sample ($= 1$ on time scale).

5.4.1 Influence of Negative Samples

We further investigated the influence of the number of negatives generated per positive training sample. In the previous experiment, due to computational limitations, the number of negatives per training sample, η, was validated over the set $\{1, 2, 5, 10\}$. On WN18 it proved to be of no help to have more than one generated negative per positive. Here we explore in which proportions increasing the number of generated negatives leads to better results on FB15K. To do so, we fixed the best validated λ, K, α obtained from the previous experiment. We then let η vary in $\{1, 2, 5, 10, 20, 50, 100, 200\}$.

Figure 7 shows the influence of the number of generated negatives per positive training triple on the performance of ComplEx on FB15K. Generating more negatives clearly improves the results up to 100 negative triples, with a filtered MRR of 0.737 and 64.8% of Hits@1, before decreasing again with 200 negatives, probably due to the too large class imbalance. The model also converges with fewer epochs, which compensates partially for the additional training time per epoch, up to 50 negatives. It then grows linearly as the number of negatives increases.

5.4.2 WN18 Embeddings Visualization

We used principal component analysis (PCA) to visualize embeddings of the relations of the WordNet data set (WN18). We plotted the four first components of the best DistMult and ComplEx model's embeddings in Figures 8 & 9. For the ComplEx model, we simply concatenated the real and imaginary parts of each embedding.

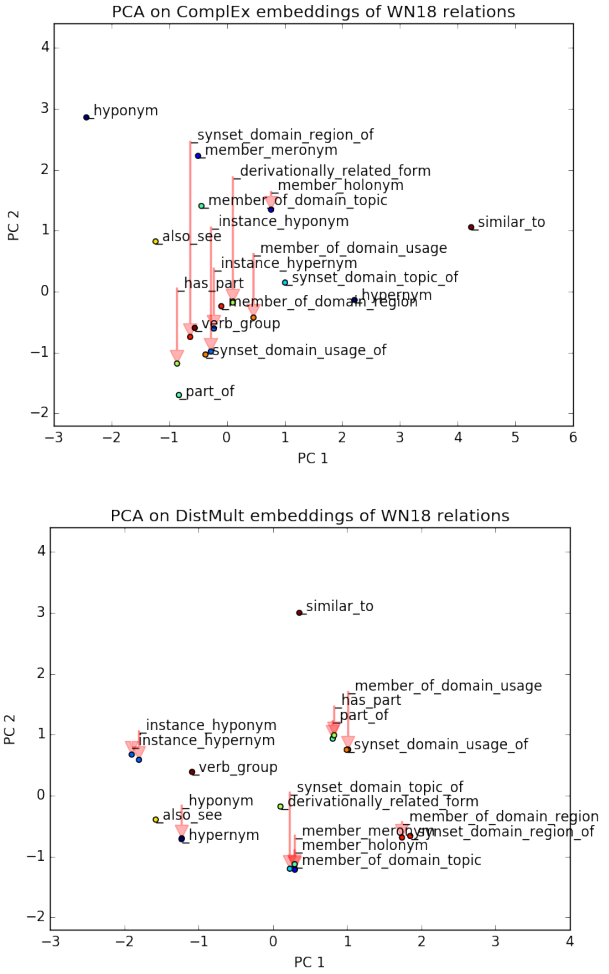

Figure 8: Plots of the first and second components of the WN18 relations embeddings using principal component analysis. Red arrows link the labels to their point. Top: ComplEx embeddings. Bottom: DistMult embeddings. Opposite relations are clustered together by DistMult while correctly separated by ComplEx.

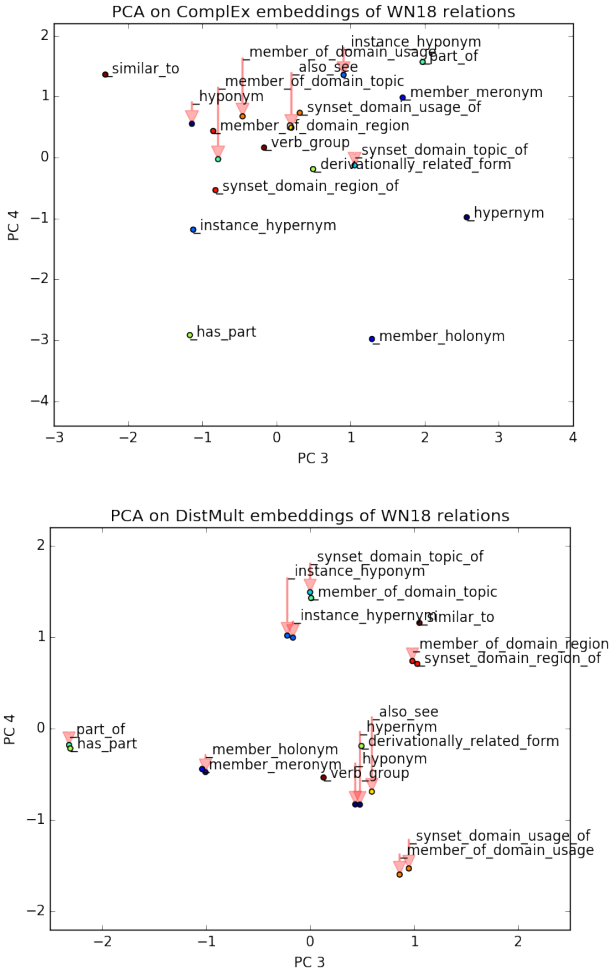

Figure 9: Plots of the third and fourth components of the WN18 relations embeddings using principal component analysis. Red arrows link the labels to their point. Top: ComplEx embeddings. Bottom: DistMult embeddings. Opposite relations are clustered together by DistMult while correctly separated by ComplEx.

Most of WN18 relations describe hierarchies, and are thus antisymmetric. Each of these hierarchic relations has its inverse relation in the data set. For example: `hypernym` / `hyponym`, `part_of` / `has_part`, `synset_domain_topic_of` / `member_of_domain_topic`. Since DistMult is unable to model antisymmetry, it will correctly represent the nature of each pair of opposite relations, but not the direction of the relations. Loosely speaking, in the `hypernym` / `hyponym` pair the nature is sharing semantics, and the direction is that one entity generalizes the semantics of the other. This makes DistMult representing the opposite relations with very close embeddings. It is especially striking for the third and fourth principal component (Figure 9). Conversely, ComplEx manages to oppose spatially the opposite relations.

6. Related Work

We first discuss related work about complex-valued matrix and tensor decompositions, and then review other approaches for knowledge graph completion.

6.1 Complex Numbers

When factorization methods are applied, the representation of the decomposition is generally chosen in accordance with the data, despite the fact that most real square matrices only have eigenvalues in the complex domain. Indeed in the machine learning community, the data is usually real-valued, and thus eigendecomposition is used for symmetric matrices, or other decompositions such as (real-valued) singular value decomposition (Beltrami, 1873), non-negative matrix factorization (Paatero and Tapper, 1994), or canonical polyadic decomposition when it comes to tensors (Hitchcock, 1927).

Conversely, in signal processing, data is often complex-valued (Stoica and Moses, 2005) and the complex-valued counterparts of these decompositions are then used. Joint diagonalization is also a much more common tool than in machine learning for decomposing sets of (complex) dense square matrices (Belouchrani et al., 1997; De Lathauwer et al., 2001).

Some works on recommender systems use complex numbers as an encoding facility, to merge two real-valued relations, similarity and liking, into one single complex-valued matrix which is then decomposed with complex embeddings (Kunegis et al., 2012; Xie et al., 2015). Still, unlike our work, it is not real data that is decomposed in the complex domain.

In deep learning, Danihelka et al. (2016) proposed an LSTM extended with an associative memory based on complex-valued vectors for memorization tasks, and Hu et al. (2016) a complex-valued neural network for speech synthesis. In both cases again, the data is first encoded in complex vectors that are then fed into the network.

Conversely to these contributions, this work suggests that processing real-valued data with complex-valued representation, through a projection onto the real-valued subspace, can be a very simple way of increasing the expressiveness of the model considered.

6.2 Knowledge Graph Completion

Many knowledge graphs have recently arisen, pushed by the W3C recommendation to use the resource description framework (RDF) (Cyganiak et al., 2014) for data representation. Examples of such knowledge graphs include DBPedia (Auer et al., 2007), Freebase (Bollacker

et al., 2008) and the Google Knowledge Vault (Dong et al., 2014). Motivating applications of knowledge graph completion include question answering (Bordes et al., 2014b) and more generally probabilistic querying of knowledge bases (Huang and Liu, 2009; Krompaß et al., 2014).

First approaches to relational learning relied upon probabilistic graphical models (Getoor and Taskar, 2007), such as bayesian networks (Friedman et al., 1999) and markov logic networks (Richardson and Domingos, 2006; Raedt et al., 2016).

With the first embedding models, asymmetry of relations was quickly seen as a problem and asymmetric extensions of tensors were studied, mostly by either considering independent embeddings (Franz et al., 2009) or considering relations as matrices instead of vectors in the RESCAL model (Nickel et al., 2011), or both (Sutskever, 2009). Direct extensions were based on uni-,bi- and trigram latent factors for triple data (Garcia-Duran et al., 2016), as well as a low-rank relation matrix (Jenatton et al., 2012). Bordes et al. (2014a) propose a two-layer model where subject and object embeddings are first separately combined with the relation embedding, then each intermediate representation is combined into the final score.

Pairwise interaction models were also considered to improve prediction performances. For example, the Universal Schema approach (Riedel et al., 2013) factorizes a 2D unfolding of the tensor (a matrix of entity pairs vs. relations) while Welbl et al. (2016) extend this also to other pairs. Riedel et al. (2013) also consider augmenting the knowledge graph facts by exctracting them from textual data, as does Toutanova et al. (2015). Injecting prior knowledge in the form of Horn clauses in the objective loss of the Universal Schema model has also been considered (Rocktaschel et al., 2015). Chang et al. (2014) enhance the RESCAL model to take into account information about the entity types. For recommender systems (thus with different subject/object sets of entities), Baruch (2014) proposed a non-commutative extension of the CP decomposition model. More recently, Gaifman models that learn neighborhood embeddings of local structures in the knowledge graph showed competitive performances (Niepert, 2016).

In the Neural Tensor Network (NTN) model, Socher et al. (2013) combine linear transformations and multiple bilinear forms of subject and object embeddings to jointly feed them into a nonlinear neural layer. Its non-linearity and multiple ways of including interactions between embeddings gives it an advantage in expressiveness over models with simpler scoring function like DistMult or RESCAL. As a downside, its very large number of parameters can make the NTN model harder to train and overfit more easily.

The original multilinear DistMult model is symmetric in subject and object for every relation (Yang et al., 2015) and achieves good performance on FB15K and WN18 data sets. However it is likely due to the absence of true negatives in these data sets, as discussed in Section 5.3.2.

The TransE model from Bordes et al. (2013b) also embeds entities and relations in the same space and imposes a geometrical structural bias into the model: the subject entity vector should be close to the object entity vector once translated by the relation vector.

A recent novel way to handle antisymmetry is via the Holographic Embeddings (HolE) model by Nickel et al. (2016b). In HolE the circular correlation is used for combining entity embeddings, measuring the covariance between embeddings at different dimension

shifts. This model has been shown to be equivalent to the ComplEx model (Hayashi and Shimbo, 2017; Trouillon and Nickel, 2017).

7. Discussion and Future Work

Though the decomposition proposed in this paper is clearly not unique, it is able to learn meaningful representations. Still, characterizing all possible unitary diagonalizations that preserve the real part is an interesting open question. Especially in an approximation setting with a constrained rank, in order to characterize the decompositions that minimize a given reconstruction error. That might allow the creation of an iterative algorithm similar to eigendecomposition iterative methods (Saad, 1992) for computing such a decomposition for any given real square matrix.

The proposed decomposition could also find applications in many other asymmetric square matrices decompositions applications, such as spectral graph theory for directed graphs (Cvetković et al., 1997), but also factorization of asymmetric measures matrices such as asymmetric distance matrices (Mao and Saul, 2004) and asymmetric similarity matrices (Pirasteh et al., 2015).

From an optimization point of view, the objective function (Equation (10)) is clearly non-convex, and we could indeed not be reaching a globally optimal decomposition using stochastic gradient descent. Recent results show that there are no spurious local minima in the completion problem of positive semi-definite matrix (Ge et al., 2016; Bhojanapalli et al., 2016). Studying the extensibility of these results to our decomposition is another possible line of future work. The first step would be generalizing these results to symmetric real-valued matrix completion, then generalization to normal matrices should be straightforward. The two last steps would be extending to matrices that are expressed as real part of normal matrices, and finally to the joint decomposition of such matrices as a tensor. We indeed noticed a remarkable stability of the scores across different random initialization of ComplEx for the same hyper-parameters, which suggests the possibility of such theoretical property.

Practically, an obvious extension is to merge our approach with known extensions to tensor factorization models in order to further improve predictive performance. For example, the use of pairwise embeddings (Riedel et al., 2013; Welbl et al., 2016) together with complex numbers might lead to improved results in many situations that involve non-compositionality. Adding bigram embeddings to the objective could also improve the results as shown on other models (Garcia-Duran et al., 2016). Another direction would be to develop a more intelligent negative sampling procedure, to generate more informative negatives with respect to the positive sample from which they have been sampled. This would reduce the number of negatives required to reach good performance, thus accelerating training time. Extension to relations between more than two entities, n-tuples, is not straightforward, as ComplEx's expressiveness comes from the complex conjugation of the object-entity, that breaks the symmetry between the subject and object embeddings in the scoring function. This stems from the Hermitian product, which seems to have no standard multilinear extension in the linear algebra literature, this question hence remains largely open.

8. Conclusion

We described a new matrix and tensor decomposition with complex-valued latent factors called ComplEx. The decomposition exists for all real square matrices, expressed as the real part of normal matrices. The result extends to sets of real square matrices—tensors—and answers to the requirements of the knowledge graph completion task : handling a large variety of different relations including antisymmetric and asymmetric ones, while being scalable. Experiments confirm its theoretical versatility, as it substantially improves over the state-of-the-art on real knowledge graphs. It shows that real world relations can be efficiently approximated as the real part of low-rank normal matrices. The generality of the theoretical results and the effectiveness of the experimental ones motivate for the application to other real square matrices factorization problems. More generally, we hope that this paper will stimulate the use of complex linear algebra in the machine learning community, even and especially for processing real-valued data.

Abstract

Stochastic gradient descent (SGD) is commonly used for optimization in large-scale machine learning problems. Langford et al. (2009) introduce a sparse online learning method to induce sparsity via truncated gradient. With high-dimensional sparse data, however, this method suffers from slow convergence and high variance due to heterogeneity in feature sparsity. To mitigate this issue, we introduce a stabilized truncated stochastic gradient descent algorithm. We employ a soft-thresholding scheme on the weight vector where the imposed shrinkage is adaptive to the amount of information available in each feature. The variability in the resulted sparse weight vector is further controlled by stability selection integrated with the informative truncation. To facilitate better convergence, we adopt an annealing strategy on the truncation rate, which leads to a balanced trade-off between exploration and exploitation in learning a sparse weight vector. Numerical experiments show that our algorithm compares favorably with the original truncated gradient SGD in terms of prediction accuracy, achieving both better sparsity and stability.

Keywords: sparse online learning, sparse features, truncated gradient, stability selection, adaptive shrinkage

1. Introduction

Modern data sets pose many challenges for existing learning algorithms due to their unprecedented large scales in both sample sizes and input dimensions. It demands both efficient processing of massive data and effective extraction of crucial information from an enormous pool of heterogeneous features. In response to these challenges, a promising approach is to exploit online learning methodologies that performs incremental learning over the training samples in a sequential manner. In an online learning algorithm, one sample instance is processed at a time to obtain a simple update, and the process is repeated via multiple passes over the entire training set. In comparison with batch learning algorithms in which all sample points are scrutinized at every single step, online learning algorithms have been shown to be more efficient and scalable for data of large size that cannot fit into the limited memory of a single computer. As a result, online learning algorithms have been widely adopted for solving large-scale machine learning tasks (e.g., Bottou, 1998).

In this paper, we focus on first-order subgradient-based online learning algorithms, which have been studied extensively in the literature for dense data.[1] Among these algorithms, popular methods include the Stochastic Gradient Descent (SGD) algorithm in (Zhang, 2004) and (Bottou, 2010), the mirror descent algorithm introduced by Beck and Teboulle (2003) and the dual averaging algorithm by Nesterov (2009). Since these methods only require the computation of a (sub)gradient for each incoming sample, they can be scaled efficiently to high-dimensional inputs by taking advantage of the finiteness of the training sample. In particular, the stochastic gradient descent algorithm is the most commonly used algorithm in the literature of subgradient-based online learning. It enjoys an exceptionally low computational complexity while attaining steady convergence under mild conditions as discussed in (Bottou, 1998), even for cases where the loss function is not everywhere differentiable.

Despite of their computational efficiency, online learning algorithms without further constraint on the parameter space suffers the "curse of dimensionality" to the same extent as their non-online counterparts. Embedded in a dense high-dimensional parameter space, not only does the resulted model lack interpretability, its variance is also inflated. As a solution, *sparse online learning* was introduced to induce sparsity in the parameter space under the online learning framework (e.g., Langford et al., 2009). It aims at learning a linear classifier with a sparse weight vector, which has been an active topic in this area. For most efforts in the literature, sparsity is introduced by applying L_1 regularization on a loss function, such as in (Shalev-Shwartz and Tewari, 2011), in the same fashion as in the classific LASSO method by Tibshirani (1996). For example, Duchi and Singer (2009) extend the framework of Forward-Backward splitting method introduced by Lions and Mercier (1979) which alternates between an unconstrained truncation step on the sample gradient and an optimization step on the loss function with a penalty on the distance from the truncated weight vector.Langford et al. (2009) and Carpenter (2008) both explore the idea of imposing a *soft-threshold* on the weight vector $\mathbf{w} \in \mathbb{R}^p$ updated by the stochastic gradient descent algorithm:

$$w_j = \text{sign}(w_j)\max(|w_j| - \lambda, 0), \quad j = 1, \ldots, p.$$

This class of methods is known as the *truncated gradient algorithm*. For every K standard SGD updates, the weight vector is shrunk by a fixed amount to induce sparsity. In (Duchi et al., 2010), the same strategy has also been combined with a variant of the mirror descent algorithm in (Beck and Teboulle, 2003). Wang et al. (2015) further extends the truncated gradient framework to adjust for cost-effectiveness. This simple yet efficient method of truncated gradients particularly motivates the algorithm proposed in this paper. Strategies different from the truncation-based algorithm have also been proposed. For example, Xiao (2009) proposed the Regularized Dual-Averaging (RDA) algorithm which builds upon the primal-dual subgradient method by Nesterov (2009). The RDA algorithm learns a sparse weight vector by solving an optimization problem using the running average over all preceding gradients, instead of a single gradient at each iteration.

Closely related to sparse online learning is another area of active research, *online feature selection*. Instead of enforcing just a shrinkage on the weight vectors via L_1 regularization, online feature selection algorithms explicitly invoke feature selection by imposing a hard L_0 constraint on the weight vector, (e.g., Wang et al., 2014; Wu et al., 2014). In other words, online feature selection algorithms focus on generating a resulted weight vector that has a high sparsity level by directly

1. *Dense data* is defined as a data set in which the number of nonzero entries in all columns of its design matrix are in the order of $O(n)$ while the ones of *sparse data* are in the order of $O(\log(n))$ or less.

shrinking a large proportion of the weights directly to zero (also referred to as a *hard thresholding*). In practice, L_0 regularization is computationally expensive to solve due to its non-differentiability. The set of selected features also suffers from high variability as the decisions of hard-thresholding are based on single random samples in an online learning setting. Therefore, important features can be discarded simply owing to random perturbations.

Most recent subgradient-based online learning algorithms do not consider potential structures or heterogeneity in the input features. As pointed out by Duchi et al. (2011), current methods largely follow a predetermined procedural scheme that is oblivious to the characteristics of data being used at each iteration. In large-scale applications, a common and important structure is heterogeneity in sparsity levels of the input features, i.e., the variability in the number of nonzero entries among features. For instance, consider the bag-of-word features in text mining applications.[2] For a learning task, the importance of a feature is not necessarily associated with the frequencies of its values. In genetics, for example in (Morris and Zeggini, 2010), rare variants ($\leq 1\%$ in the population) have been found to be associated with disease risks. Both dense and sparse features may contain important information for the learning task. However, in the presence of heterogeneity in sparsity levels, using a simple L_1 regularization in an online setting will predispose rare features to be truncated more than necessary. The resulted sparse weight vectors usually exhibit high variance in terms of both weight values and the membership in the set of features with nonzero weights. As a result, the convergence of the standard truncation-based framework may also be hampered by this high variability. When the amount of information is scarce due to sparsity at each iteration, the convergence of the weight vector would understandably take a large number of iterations to approach the optimum. In two recent papers, Oiwa et al. (2011) and Oiwa et al. (2012) tackle this problem via L_1 penalty weighted by the accumulated norm of subgradients for extending several basic frameworks in sparse online learning. Their results suggest that, by acknowledging the sparsity structure in the features, both prediction accuracy and sparsity are improved over the original algorithms while maintaining the same convergence rate. However, their resulted weight vectors are unstable as the imposed subgradient-based regularization are excessively noisy due to the randomness of incoming samples in online learning. The membership in the set of selected features with nonzero weights is also very sensitive to the orderings of the training samples.

In this paper, we propose a *stabilized truncated stochastic gradient descent* algorithm for high-dimensional sparse data. The learning framework is motivated by that of the Truncated Gradient algorithm proposed by Langford et al. (2009). To deal with the aforementioned issues with sparse online learning methods applied to high-dimensional sparse data, we introduce three innovative components to reduce variability in the learned weight vector and stabilize the selected features. First, when applying the soft-thresholding, instead of a uniform truncation on all features, we perform only *informative truncations*, based on actual information from individual features during the preceding computation window of K updates. By doing so, we reduce the heterogeneous truncation bias associated with feature sparsity. The key idea here is to ensure that each truncation for each feature is based on sufficient information, and the amount of shrinkage is adjusted for the information available on each feature. Second, beyond the soft-thresholding corresponding to the ordinary L_1 regularization, the resulted weight vector is *stabilized* by staged purges of irrelevant features permanently from the active set of features. Here, *irrelevant features* are defined as features whose weights have been repeatedly truncated. Motivated by *stability selection* introduced

2. Here, by *sparse features*, we refer to features for which most samples assume a constant value (e.g., 0) and a few samples take on other values. Without loss of generality, we assume the majority constant is 0 throughout this paper.

by Meinshausen and Bühlmann (2010), these permanent purges prevent irrelevant features from oscillating between the active and non-active set of features, The "*purging*" process also resembles hard-thresholding in online feature selection and results in a stabler sparse solution than other sparse online learning algorithms. Results on the theoretical regret bound (See Section 4) show that this stabilization step helps improve over the original truncated gradient algorithm, especially when the target weight vector is notably sparse. To attune the proposed learning algorithm to the sparsity of the remaining active features, the third component of our algorithm is adjusting the amount of shrinkage progressively instead of fixing it at a predetermined value across all stages of the learning process. A novel hyperparameter, *rejection rate*, is introduced to balance between *exploration* of different sparse combinations of features at the beginning and the *exploitation* of the selected features to construct accurate estimate at a later stage. Our method gradually anneal the rejection rate to acquire the necessary amount of shrinkage on the fly for achieving the desired balance.

The rest of paper is organized as follows. Section 2 reviews the Truncated Gradient algorithm based on Stochastic Gradient Descent (SGD) framework for sparse learning proposed by Langford et al. (2009). In Section 3, we introduce, in details, the three novel components of our proposed algorithm. Theoretical analysis of the expected online regret bound is given in Section 4, along with the computational complexity. Section 5 gives practical remarks for efficient implementation. In Section 6, we evaluate the performance of the proposed algorithm on several real-world high-dimensional data sets with varying sparsity levels. We illustrate that the proposed method leads to improved stability and prediction performance for both sparse and dense data, with the most improvement observed in data with the highest average sparsity level. Section 7 concludes with further discussion on the proposed algorithm.

2. Truncated Stochastic Gradient Descent for Sparse Learning

Assume that we have a set of training data $\mathcal{D} = \{z_i = (\mathbf{x}_i, y_i), i = 1, \ldots, n\}$, where the feature vector $\mathbf{x}_i \in \mathbb{R}^p$ and the scalar output $y_i \in \mathbb{R}$. In the following, we use $\mathbf{x}_i$ to represent the vector of the i^{th} sample of length p and $\mathbf{x}_{\cdot j}$ for the j^{th} feature vector of all samples of length n. In this paper, we are interested in the case that both p and n are large and the feature vectors $\mathbf{x}_{\cdot j}$'s, $j = 1, \ldots, p$, are sparse. We consider a loss function $l(\hat{y}, y)$ that measures the cost of predicting $\hat{y}$ when the truth is y. The prediction $\hat{y}$ is given by function $f_{\mathbf{w}}(\mathbf{x})$ from a family $\mathcal{F}$ parametrized by a weight vector $\mathbf{w}$. Denote $L(\mathbf{w}, \mathbf{z}) \stackrel{\text{def}}{=\!=} l(f_{\mathbf{w}}(\mathbf{x}), y)$. The learning goal is to obtain an optimal weight vector $\hat{\mathbf{w}}$ that minimize the loss function $\sum_{i=1}^{n} L(\mathbf{w}, z_i)$ over the training data, with sparsity in the weight vector induced by a regularization term $\Psi(\mathbf{w})$. We can then formulate the learning task as a regularized minimization problem:

$$\hat{\mathbf{w}} = \arg\min_{\mathbf{w} \in \mathbb{R}^p} \sum_{i=1}^{n} L(\mathbf{w}, z_i) + \Psi(\mathbf{w}). \tag{1}$$

The above optimization problem is often solved using some version of *gradient descent*. When both p and n are large, the computation becomes very demanding. To address this computational complexity, the Stochastic Gradient Descent (SGD) algorithm was proposed as a stochastic approximation of the full gradient algorithm. Instead of computing the gradient over the entire training set as under the batch setting, the stochastic gradient descent algorithm uses approximate gradients

based on subsets of the training data. This is particularly attractive to large scale problems as it leads to a substantial reduction in computing complexity and potentially distributed implementation.

For applications with large data sets or streaming data feeds, SGD has also been used as a subgradient-based *online learning* method. Cesa-Bianchi et al. (2004) argue that online learning and stochastic optimization are closely related and interchangeable most of the time. For simplicity, in the following, we focus our discussion and algorithmic description under the online learning framework with regret bound models. Nonetheless, our results can be readily generalized to stochastic optimization as well.

In online learning, the algorithm receives a training sample $z_t = (\mathbf{x}_t, y_t)$ at a time from a continuous feed. Without sparsity regularization, at time t, the weight vector is updated in an online fashion with a single training sample $z_t \in \mathcal{D}$ drawn randomly

$$\mathbf{w}_t = \mathbf{w}_{t-1} - \eta L'(\mathbf{w}_{t-1}, z_t), \tag{2}$$

where $\eta > 0$ is the learning rate and $L'(\mathbf{w}_t, z_t) \in \partial_{\mathbf{w}_t} L(\mathbf{w}_t, z_t)$ is a subgradient of the loss function $L(\mathbf{w}_t, z_t)$ with respect to $\mathbf{w}_t$. The set of subgradients of f at the point x is called the subdifferential of f at x, and is denoted $\partial f(x)$. A function f is called subdifferentiable if it is subdifferentiable at all $x \in \mathbf{dom}\ f$. When $L(\mathbf{w}, \cdot)$ is differentiable at $\mathbf{w}$, $\partial_{\mathbf{w}} L(\mathbf{w}, \cdot) = \{\nabla_{\mathbf{w}} L(\mathbf{w}, \cdot)\}$. At the same time, a sequence of decisions $\mathbf{w}_t$ is generated at $t = 1, 2, \ldots,$ that encounters a loss $L(\mathbf{w}_t, z_t)$ respectively.

The goal of online learning algorithm with sparsity regularization is to achieve *low* regret with respect to a fixed optimal weight vector $\mathbf{w}^* \in \mathcal{W} \subset \mathbb{R}^p$. Here, $\mathcal{W}$ is the parameter space for sparse weights vectors (see Assumption 3 on page 15 for more details.) The regret is defined as:

$$R_T(\mathbf{w}^*) \triangleq \sum_{t=1}^{T} \left(L(\mathbf{w}_t, z_t) + \Psi(\mathbf{w}_t)\right) - \sum_{t=1}^{T} \left(L(\mathbf{w}^*, z_t) + \Psi(\mathbf{w}^*)\right). \tag{3}$$

In this paper, we focus on the L_1 regularization where $\Psi(\mathbf{w}) = g||\mathbf{w}||_1$ and g is the regularizing parameter. When adopted in an online learning framework, standard SGD algorithm does not work well in addressing (1) with L_1 penalty. Firstly, a simple online update requires the projection of the weight vector $\mathbf{w}$ onto a L_1-ball at each step, which is computationally expensive with a large number of features. Secondly, with noisy approximate subgradient computed using a single sample, the weights can easily deviate from zero due to the random fluctuations in z_t's. Such a scheme is therefore inefficient to maintain a sufficiently sparse weight vector.

To address this issue, Langford et al. (2009) induced sparsity in $\mathbf{w}$ by subjecting the stochastic gradient descent algorithm to soft-thresholding. For every $K \in \mathbb{N}^+$ iterations at step t, each of which is as defined in (2), the weight vector is shrunk by a soft-threshold operator T with a *gravity parameter* $\mathbf{g} \in \mathcal{G} \subset \mathbb{R}^p$ with $g_j \geq 0$ for $j = 1, \ldots, p$. For a vector $\mathbf{w} = [w_1, \ldots, w_p] \in \mathbb{R}^p$,

$$\hat{\mathbf{w}}_t = T(\mathbf{w}_t, \mathbf{g}), \tag{4}$$

where $T(\mathbf{w}, \mathbf{g}) = [T(w_1, g_1), \ldots, T(w_p, g_p)]$ with the operator T defined by

$$T(w_j, g_j) \triangleq \begin{cases} \max(w_j - g_j, 0), & \text{if } w_j > 0; \\ \min(w_j + g_j, 0), & \text{if } w_j \leq 0. \end{cases} \tag{5}$$

Algorithm 1 $B_0(\mathbf{w}_0, g_0)$: A burst of K updates with truncation using a universal gravity as in truncated SGD by Langford et al. (2009).

Input: $\mathbf{w}_0$ at initialization and the base gravity g_0.
Parameters: K, η.
for $t = 1$ **to** K **do**
  Draw $z_t \in \mathcal{D}$ uniformly at random.
  $\mathbf{w}_t = \mathbf{w}_{t-1} - \eta L'(\mathbf{w}_{t-1}, z_t)$, where $L'(\mathbf{w}_{t-1}, z_t) \in \partial_{\mathbf{w}_{t-1}} L(\mathbf{w}_{t-1}, z_t)$.
end for
$\hat{\mathbf{w}} = T(\mathbf{w}_K, g_0 K \mathbf{1}_p)$.
Return: $\hat{\mathbf{w}}$.

As one can see, the sequence of K SGD updates can be treated as a unit computational block, which will be referred to as a *burst* hereafter. Here the word *burst* indicates that it is a sequence of repetitive actions, e.g., the standard SGD updates as defined in (2), without interruption. Each burst is followed by a *soft-thresholding truncation* defined in (4), which puts a shrinkage on the learned weight vector.

A burst can be viewed as a base feature selection realized on a set of random samples with L_1 regularization as in the classical LASSO by Tibshirani (1996). Within a burst, let $\mathcal{X}_K$ be the set of K random samples on which the weight vector $\hat{\mathbf{w}}$ is stochastically learned. We define the set of features with nonzero weights in $\hat{\mathbf{w}}$ as its *active (feature) set*:

$$\hat{\mathcal{S}}^g(\hat{\mathbf{w}}; \mathcal{X}_K) = \{j : |\hat{w}_j| > 0\}, \tag{6}$$

with a corresponding gravity $\mathbf{g}$. The steps within a truncated burst are summarized in Algorithm 1.

In the truncated gradient algorithm, the gravity parameter is a constant across all dimensions as $\mathbf{g} = g_0 K \mathbf{1}_p$, where $g_0 \in \mathbb{R} \geq 0$ is a *base gravity* for each update in a burst and $\mathbf{1}_p \triangleq (1, \ldots, 1) \in \mathbb{R}^p$. In general, with greater parameter g_0 and smaller burst size K, more sparsity is attained. When $g_0 = 0$, the update in (4) becomes identical to the standard stochastic gradient descent update in (2). Langford et al. (2009) showed that this updating process can be regarded as an online counterpart of L_1 regularization in the sense that it approximately solves (1) in the limit as $K \to \infty$ and $\eta \to 0$.

3. Stabilized Truncated SGD for Sparse Learning

Truncated SGD works well for dense data. When it comes to high-dimensional *sparse* inputs, however, it suffers from a number of issues. Shalev-Shwartz and Tewari (2011) observe that the truncated gradient algorithm is incapable of maintaining sparsity of the weight vector as it iterates. Recall that, under the online learning setting, the weight vector $\mathbf{w}$ is updated with a noisy approximation of the true expected gradient using one sample at a time, from a random ordering of the data. With sparse inputs, it is highly probable that an important feature does not have a nonzero entry for many consequent samples, and is meaningfully updated for only a few times out of the K updates in a burst. As a result, it would be truncated after a few iterations and brought back to nonzero after another few updates. At the same time, sparsity in inputs will also give rise to sporadic large nonzero updates for irrelevant features, which cannot be fully resolved by the soft-threshold operator. The derived weight vector $\mathbf{w}$'s are of high variance, inadequate sparsity and poor generalizability. As an example, the number of nonzero variables in the weight vector during the last

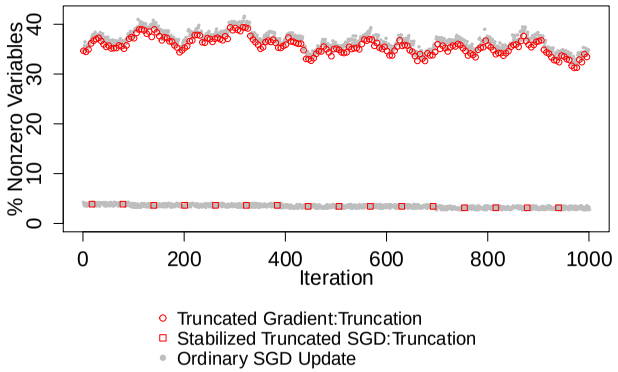

Figure 1: An example of the truncated SGD algorithm by Langford et al. (2009) and the proposed stabilized truncated SGD algorithm applied to a high-dimensional sparse data set. Here we compare the percentage of nonzero variables in the resulted weight vector at each iteration during the last 1000 iterations of both algorithms. The underlying data set is the text mining data set, *Dexter*, with $10,000$ features and 0.48% of sparsity, which is described in details in Section 6.

1000 stochastic updates from the truncated gradient algorithm implemented on a high-dimensional sparse data set are shown in Figure 1[3]. It can be seen that the numbers of nonzero features in the weight vectors learned by the truncated SGD algorithm ($K = 5$) remain large and highly unstable throughout these 1000 iterations, oscillating within 10% of the total number of features. As a comparison, also in Figure 1, we plot the results from our proposed stabilized truncated SGD applied to the same data. During these last 1000 updates, the proposed algorithm is using a less frequent truncation schedule due to our *annealed reject rate*. It attains both high sparsity in the weight vector and high stability with high-dimensional sparse data.

In this section, we introduce the *stabilized truncated Stochastic Gradient Descent (SGD)* algorithm. It attains a truly sparse weight vector that is stable and gives generalizable performance. Our proposed method attunes to the sparsity of each feature and adopts *informative truncation*. The algorithm keeps track of whether individual features have had enough information to be confidently subject to soft-thresholding. Based on the truncation results, we systematically reduce the active feature set by permanently discarding features that are truncated to zero with high probability via *stability selection*. We further improve the efficiency of our algorithm by adapting gravity to the sparsity of the current active feature set as the algorithm proceeds.

3. The results are based on the Dexter text mining data set. Please see Section 6 for details.

3.1 Informative Truncation

In the truncated SGD algorithm, Langford et al. (2009) suggest a general guideline for determining gravity in the batch mode by scaling a base gravity g_0 by K, the number of updates, for a single truncation after a burst. A direct online adaptation of a L_1 regularization would shrinks the weight vector at every iteration. The above batch mode operation is to delay the shrinkage for K iterations so that the truncation is executed based on information collected from K random samples instead of from a single instance. This guideline implicitly assumes that the K SGD updates in a burst are equally informative, which is in general true for dense features. For sparse features, however, under the online learning setting, not every update is informative about every feature due to the scarcity of nonzero entries. The original uniform formula, $\mathbf{g} = Kg_0\mathbf{1}_p$, for gravity would then create an undesirable differential treatment for features with different levels of sparsity. With a relatively small K, it is very likely that a substantial proportion of features would have no non-zero values on a size-K subsample used in a particular burst. The weights for these features remain unchanged after K updates. Consequently, the set of sparse features run the risk of being truncated to zero based on very few informative updates. The truncation decision is therefore mostly determined by a feature's sparsity level, rather than its relevance to the class boundary.

To make the learning be informed of the heterogeneity in sparsity level among features, we introduce the *informative truncation* step, extended from the idea of base gradient used in Algorithm 1. Instead of applying a universal gravity proportional to K to all features, the amount of shrinkage is set proportional to the number of times that a feature is actually updated with nonzero values in the size-K subsample, i.e., the number of *informative updates*. Specifically, within each burst, the algorithm keeps a vector of *counters*, $\tilde{\mathbf{k}} \in \mathbb{R}^p$, of the numbers of informative updates for the features $\mathbf{x}_{\cdot,j}$, $j = 1, \ldots, p$. Let $g_0 \in \mathbb{R} \geq 0$ be the base gravity parameter that serves as the unit amount of shrinkage for each informative update on each feature. At the end of each burst, we shrink feature $\mathbf{x}_{\cdot,j}$ by $g_0\tilde{k}_j$. In other words, here we set $\mathbf{g} = g_0\tilde{\mathbf{k}}$. The computational steps for a burst with informative truncation in summarized in Algorithm 2.

Algorithm 2 $B_1(w_0, g_0)$: A burst of K updates with informative truncation.

Input: $\mathbf{w}_0$ at initialization and the base gravity g_0.
Initialization: $\tilde{\mathbf{k}} = \mathbf{0}_p \in \mathbb{R}^p$.
Parameters: K, η.
for $t = 1$ **to** K **do**
  Draw $z_t = (\mathbf{x}_t, y_t) \in \mathcal{D}$ uniformly at random.
  $\mathbf{w}_t = \mathbf{w}_{t-1} - \eta L'(\mathbf{w}_{t-1}, z_t)$, where $L'(\mathbf{w}_{t-1}, z_t) \in \partial_{\mathbf{w}_{t-1}} L(\mathbf{w}_{t-1}, z_t)$.
  $\tilde{\mathbf{k}} \leftarrow \tilde{\mathbf{k}} + I(|\mathbf{x}_t| > 0)$.
end for
$\hat{\mathbf{w}} = T(\mathbf{w}_K, g_0\tilde{\mathbf{k}})$.
Return: $\hat{\mathbf{w}}$, $\tilde{\mathbf{k}}$.

The proposed informative truncation scheme ensures that the decision of truncation is made based on sufficient and equivalent amount of evidence for evaluating each feature. A theoretical justification of how informative truncation helps improving truncation bias can be found in Lemma 3 (Section 4). This feature-specific gravity attunes to the sparsity structure incurred at each burst without *ad-hoc* adjustment. It also avoids data pre-processing for locating sparse entries, which can be computationally expensive and compromises the advantage of online computation. In comparison

to the truncated gradient algorithm that quickly shrinks many features to zero indiscriminately, informative truncation keeps sparse features until enough evaluation is conducted. In doing so, sparse yet important features will be retained. The proposed approach also reduce the variability in the resulted sparse weight vector during the training process. Duchi et al. (2011) use a similar strategy that allows the learning algorithm to adaptively adjust its learning rates for different features based on cumulative update history. They use the L_2 norm of accumulated gradients to regulate the learning rate. By adapting the gravity with the counter $\tilde{\mathbf{k}}$ within each burst, our proposed strategy here can be viewed as applying the L_0 norm to the accumulated gradients that is refreshed every K steps.

3.2 Stability Selection

Despite of its scalability, subgradient-based online learning algorithms commonly suffer from instability. It has been shown both theoretically and empirically that stochastic gradient descent algorithms are sensitive to random perturbations in training data as well as specifications of learning rate (e.g., Toulis et al., 2015; Hardt et al., 2015). This instability is particularly pronounced in sparse online learning with sparse data, as discussed in Section 1. Under an online learning setting, using random ordering of the training sample as inputs, the algorithm would produce distinct weight vectors and unstable memberships of the final active feature set. Moreover, there has been a lot of discussion on the link between the instability of an learning algorithm and its deteriorated generalizability in the literature (e.g., Bousquet and Elisseeff, 2002; Kutin and Niyogi, 2002; Rakhlin et al., 2005; Shalev-Shwartz et al., 2010).

To tackle this instability issue, in the proposed algorithm, we exploit the method of *stability selection* to improve its robustness to random perturbation in the training data. Stability selection by Meinshausen and Bühlmann (2010) does not launch a new feature selection method. Rather, its aim is to enhance and improve a sparse learning method via subsampling. The key idea of stability selection is similar to the generic bootstrap. It feeds the base feature selection procedure with multiple random subsamples to derive an empirical selection probability. Based on aggregated results from subsamples, a subset of features is selected with low variability across different subsamples. With proven consistency in variable selection, stability selection helps remove noisy irrelevant features and thus reduce the variability in learning a sparse weight vector.

Incorporating stability selection into our proposed framework, each truncated burst with gravity parameter $\mathbf{g}$ is treated as an individual sparse learning engine. It takes K random samples and carries out a feature selection to obtain a sparse weight vector. In the following, we define first the notion of *selection probability* for the stability selection step in our proposed algorithm.

Definition 1 (selection probability) *Let $\mathcal{X}_K$ be a random subsample of $\{1,\ldots,n\}$ of size K, drawn without placement. Parametrized by the gravity parameter $\mathbf{g}$, the probability of the feature $\mathbf{x}_{\cdot,j}$ being in the active set of a truncated burst that returns $\hat{\mathbf{w}}$ is*

$$\Pi_j^{\mathbf{g}} = P^*\left(j \in \hat{S}^{\mathbf{g}}(\hat{\mathbf{w}}; \mathcal{X}_K)\right) = \mathbb{E}_{\mathcal{D}}\left[I(|\hat{w}_j| > 0)\right],$$

where the probability P^* is with respect to the random subsampling of $\mathcal{X}_K$. Let $\Pi^{\mathbf{g}} = [\Pi_1^{\mathbf{g}}, \ldots, \Pi_p^{\mathbf{g}}]$.

For simplicity, we drop the superscript $\mathbf{g}$ of $\Pi^{\mathbf{g}}$ in later discussions. For the rest of the paper, the selection probability Π always refers to $\Pi^{\mathbf{g}}$ that corresponds to weight vector $\hat{\mathbf{w}}$ with gravity parameter $\mathbf{g}$.

Under unknown data distribution, the selection probabilities cannot be computed explicitly. Instead, they are estimated empirically. Since each truncation burst performs a screening on all features, the frequency of each feature being selected by a sequence of bursts can be used to derive an estimator of the selection probability. We denote a sequence of $n_K > 0$ truncated bursts as a *stage*. A preliminary empirical estimate of the selection probability is given by

$$\hat{\Pi}_j = \begin{cases} \frac{\sum_{\tau:\tilde{k}_{j,\tau}>0} I(|\hat{\mathbf{w}}_{j,\tau}|>0)}{\sum_{\tau=1}^{n_K} I(\tilde{k}_{j,\tau}>0)}, & \text{for } j \text{ s.t. } \sum_{\tau=1}^{n_K} \tilde{k}_{j,\tau} > 0; \\ 1, & \text{otherwise,} \end{cases} \tag{7}$$

where $\tilde{\mathbf{k}}_\tau$ are the counters of informative updates for burst τ, $\tau = 1,\ldots,n_K$.

Different from the conventional stability selection setting, $\hat{\mathbf{w}}_\tau$'s are obtained sequentially and thus are dependent with each other. When n_K is small, different subsamples produce selection probability estimates using (7) exhibit high variability, even when initialized with the same weight vector at $\tau = 1$. On the other hand, a large value of n_K requires a prohibitively large number of iterations for convergence. To resolve the issues of estimating selection probability using a single sequence of SGD updates, we introduce a multi-thread framework of updating paths. Multiple threads of sequential SGD updates are executed in a distributed fashion, which readily utilizes modern multi-core computer architecture. With M processors, we initialize the algorithm on each path of SGD updates with a random permutation of the training data, $\mathcal{D}$, denoted as $\mathcal{D}^{(1)},\ldots,\mathcal{D}^{(m)}$. Then independently, M stages of bursts run in parallel along M paths, which return with $\hat{\mathbf{w}}_\tau^{(m)}$, $\tau = 1,\ldots,n_K$, $m = 1,\ldots,M$. The joint estimate of selection probability with gravity $\mathbf{g}$ is obtained as

$$\hat{\Pi}_j = \begin{cases} \frac{\sum_{m=1}^{M}\sum_{\tau:\tilde{k}_{j,\tau}^{(m)}>0} I(|\hat{\mathbf{w}}_{j,\tau}^{(m)}|>0)}{\sum_{m=1}^{M}\sum_{\tau=1}^{n_K} I(\tilde{k}_{j,\tau}^{(m)}>0)}, & \text{for } j \text{ s.t. } \sum_{m=1}^{M}\sum_{\tau=1}^{n_K} \tilde{k}_{j,\tau}^{(m)} > 0; \\ 1, & \text{otherwise.} \end{cases} \tag{8}$$

When more processors are available, a smaller n_K is required for the algorithm to obtain a stable estimate of selection probability. The dependence among $\hat{\mathbf{w}}_\tau$'s is also attenuated when M random subsets of samples are used for the estimation. This strategy falls under parallelized stochastic gradient descent methods, which is discussed in detail by Zinkevich et al. (2010).

Under the framework of stability selection, each stage on every path uses a random subsample. The estimated selection probability quantifies the chance that a feature is found to have high relevance to class differences given a random subsample. At the end of each stage, *stable features* are identified as those that belong to a large fraction of active sets incurred during this stage of bursts.

Definition 2 (Stable Features) *For a purging threshold $\pi_0 \in [0,1]$, the set of stable features with gravity parameter $\mathbf{g}$ is defined as*

$$\hat{\Omega}^{\mathbf{g}} = \{j : \Pi_j^{\mathbf{g}} \geq \pi_0\}. \tag{9}$$

For simplicity, we write the stable set $\hat{\Omega}^{\mathbf{g}}$ as $\hat{\Omega}$ when there is no ambiguity.

Stability selection retains features that have high selection probabilities and discard those with low selection probabilities. At the end of a stage of M paths, we *purge* the features that are not in

Algorithm 3 $B_2(\mathbf{w}_0, g_0, \hat{\Omega}, \mathcal{D}^{(m)})$: Informative truncated burst with stability selection in thread m.

Input: $\mathbf{w}_0$, g_0, the input data $\mathcal{D}^{(m)}$ and the current set of stable features $\hat{\Omega}$, which is the output of equation (9) using (8) with predetermined threshold π_0.
Parameters: K, η.
Initialize $\mathbf{v}_0 = (w_{0,j})_{j\in\hat{\Omega}}$, $\tilde{\mathbf{k}} = \mathbf{0}_{|\hat{\Omega}|}$.
for $t = 1$ **to** K **do**
  Draw $z_t = (\mathbf{x}_t, y_t)$ sequentially from $\mathcal{D}^{(m)}$.
  $\tilde{z}_t = (z_{t,j})_{j\in\hat{\Omega}}$.
  $\mathbf{v}_t = \mathbf{v}_{t-1} - \eta L'(\mathbf{v}_{t-1}, \tilde{z}_t)$, , where $L'(\mathbf{v}_{t-1}, z_t) \in \partial_{\mathbf{v}_{t-1}} L(\mathbf{v}_{t-1}, z_t)$.
  $\tilde{\mathbf{k}} \leftarrow \tilde{\mathbf{k}} + I(|\mathbf{x}_t| > 0)$.
end for
$\hat{\mathbf{u}} = T(\mathbf{v}_K, g_0\tilde{\mathbf{k}})$.
$\hat{w}_j = \begin{cases} \hat{u}_{j'}, & \text{if } j \in \hat{\Omega} \text{ and } \hat{\Omega}_{j'} = j; \\ 0, & \text{if } j \notin \hat{\Omega}. \end{cases}$
Return: $\hat{\mathbf{w}}$, $\tilde{\mathbf{k}}$.

the set of stable features by permanently setting their corresponding weights to zero, and remove them from subsequent updates. We define the *stabilized* weight vector as

$$\tilde{\mathbf{w}} = \hat{\mathbf{w}} \cdot I_{\hat{\Omega}}. \tag{10}$$

As discussed above, due to the nature of online learning with sparse data, there are two undesirable learning setbacks in a single truncated burst. The first occurs when an important feature has its weight stuck at zero due to inadequate information in the subsample used, while the second case is when a noise feature's weight gets sporadic large updates by chance. Using informative bursts, we can avert the first type of setbacks and using selection probability based on multiple bursts, we can spot noisy features more easily. In the presence of a large number of noisy features, the learned weights for important features suffer from high variance. Via stability selection, we systematically remove noisy features permanently from the feature pool. Furthermore, the choice of a proper regularization parameter is crucial yet known to be difficult for sparse learning, especially due to the unknown noise level. Applying stability selection renders the algorithm less sensitive to choice of the base gravity parameter g_0 in learning a sparse weight vector via truncated gradient. As we will show using results from our numerical experiments, this purging by stability selection leads to a notable reduction in the estimation variance of the weight vector. Here, π_0 is a tuning parameter in practice. We have found that the learning results in the numerical experiments are not sensitive to different values of π_0 within a reasonable range. Under mild assumptions discussed in Section 4, we derive a lower bound of the expected improvement in convergence by employing stability selection in the learning process in Lemma 2.

3.3 Adaptive Gravity with Annealed Rejection Rate

The truncated SGD algorithm adopts a universal and fixed base gravity parameter at all truncations. As pointed out by Langford et al. (2009) , a large value of the base gravity g_0 achieves more sparsity but the accuracy is compromised, while a small value of g_0 leads to less sparse weight vector yet attaining better performance. In other words, different extents of shrinkage serve different

purposes of a learning algorithm. The needs for shrinkage also changes as the weight vector and the stable set evolves. Intuitively, the truncation is expected to be greedy at the beginning so that the number of nonzero feature can be quickly reduced for better computational efficiency and learning performance. As the algorithm proceeds, fewer features remain in the stable set. We should then be careful not to shrink important features with a truncation that is too harsh.

A large base gravity g_0 is effective in inducing sparsity at the beginning of the algorithm when the weight vector $\hat{\mathbf{w}}$ is dense. As the algorithm proceeds, the same value of gravity is likely to impose too much shrinkage when the learned weight vector $\hat{\mathbf{w}}$ becomes very sparse, exposing some truly important features at the risk of being purged. On the other hand, a small fixed gravity is over-conservative so that the algorithm will not shrink irrelevant features effectively, leading to slow convergence and a dense weight vector overridden by noise. Tuning a reasonable fixed base gravity parameter for a particular data set does not only creates additional computational burden, but also inadequate in addressing different learning needs during different stages of the algorithm.

As the role of *gravity* in a learning algorithm is to induce sparse estimates, in this paper, we propose an *adaptive gravity* scheme that delivers the right amount of shrinkage at each stage of the algorithm towards a desirable level of sparsity for the learned weight vector. We propose to control sparsity by a target *rejection rate* β, that is, the proportion of updates that are expected to be truncated. Guided by this target rejection rate, we derive the necessary shrinkage amount and the corresponding gravity. As we discussed in Section 3.1, a base gravity g_0 is used in our learning algorithms to create gravity values for individual features that are attuned to their data sparsity levels. Therefore our adaptive gravity scheme is carried out by adjusting g_0. At the beginning of a particular stage, we examine the truncations carried out during the previous stage. The base gravity g_0 is then adjusted to project the target rejection rate during the current stage. Specifically, at stage s, we look at the pooled set of non-truncated weight vectors and informative truncation counters $\left\{\mathbf{w}_\tau^{(m)}, \tilde{\mathbf{k}}_\tau^{(m)}, \tau = 1, \ldots, n_K, m = 1, \ldots, M\right\}$ from all the bursts conducted in the previous stages on multiple threads. The adaptive base gravity g_0 for a target rejection rate $\beta_s \in [0, 1]$ is then obtained as

$$g_{0,s}(\beta_s) \triangleq \sup\{g_0 \geq 0 : \hat{p}_s(g_0) \leq \beta_s\}. \tag{11}$$

Here $\hat{p}_s(g_0)$ is the empirical probability, i.e.,

$$\hat{p}_s(g_0) \triangleq \frac{\sum_{m=1}^{M}\sum_{\tau=1}^{n_k}\sum_{\{j:j\in\hat{\Omega}_s,\tilde{k}_{j,\tau}^{(m)}>0\}} I\left(\left|\frac{\Delta w_{j,\tau}^{(m)}}{\tilde{k}_{j,\tau}^{(m)}}\right| > g_0\right)}{\sum_{m=1}^{M}\sum_{\tau=1}^{n_k}\sum_{j\in\hat{\Omega}_s} I\left(\tilde{k}_{j,\tau}^{(m)} > 0\right)},$$

where $\Delta w_{j,\tau}^{(m)} \triangleq w_{j,\tau}^{(m)} - w_{j,\tau-1}^{(m)}$ is the amount of updates on feature $\mathbf{x}_{\cdot,j}$ during the τ^{th} burst.

We initialize the algorithm with a high rejection rate so that a large proportion of the weight vector can be reduced to zero at the end of each burst during the early stage of the algorithm. It allows the algorithm to explore as many sparse combination of features as possible at the early stage of the learning process. Along with the stability selection, the set of stable features can be quickly reduced to a manageable size by removing the majority of noises. When the weight vector becomes sparse, we decrease the rejection rate proportionally. With a lower rejection rate, and consequently a lower gravity, the algorithm can better exploit the subsequent standard SGD updates for a more accurate estimate of the true weight vector. As the rejection rate decreases to 0, the algorithm converges to the standard stochastic gradient descent algorithm on a small subset of stable features.

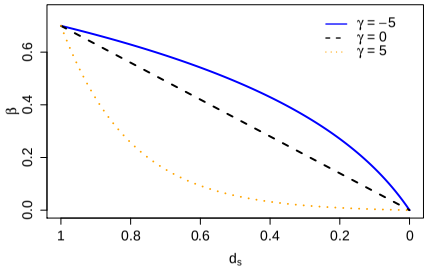

Figure 2: Examples of the rejection rate annealing function with different values of γ as defined in (12). Here $\gamma = -5, 0$, and 5 respectively. A positive annealing rate would reduce the rejection rate quickly as the proportion of non-zeros weight values, d_s, decreases, whereas a negative annealing rate would maintain it at a relatively high level.

To achieve the balance between exploration and exploitation, we construct an annealing function for the rejection rate that decreases monotonically as the level of sparsity decreases. Let $\beta_0 \in [0, 1]$ be the *maximum rejection rate* at initialization and let γ be the *annealing rate*. The annealing function ϕ for the rejection rate at stage $s + 1$ is given by

$$\begin{aligned} \beta_{s+1} &= \phi(d_s; \beta_0, \gamma) \\ &= \begin{cases} \beta_0 \left[\exp\left(-\gamma d_s\right) - d_s e^{-\gamma}\right] & \gamma \geq 0; \\ \beta_0 \frac{\log(1-\gamma(1-d_s))}{\log(1-\gamma)}, & \gamma < 0, \end{cases} \end{aligned} \tag{12}$$

where $d_s = \frac{|\hat{\Omega}_s|}{p}$ is the level of weight vector sparsity at the end of stage s. The greater the value γ is, the faster the rejection rate is annealed to zero as the number of stable features decreases.

A positive, zero and negative value of γ corresponds to exponential decay, linear decay and logarithmic decay of the rejection rate, respectively. Figure 2 presents examples of the rejection rate anneal function with $\gamma = -5, 0$, and 5 respectively.

By using adaptive gravity (11) with annealed rejection rate (12), the amount of shrinkage is adjusted to the current level of sparsity of the weight vector quantified by the size of the stable set $|\hat{\Omega}_s|$ or the L_0 norm of the purged $\tilde{\mathbf{w}}$. Instead of tuning a fixed gravity parameter as in (Langford et al., 2009), for our proposed algorithm, we tune the annealing rate γ and the maximum rejection rate β_0. Here γ balances the trade-off between exploration and exploitation and β_0 determines the initial intensity of truncation. It enables the tuning process to be tailored to the data at hand as well as being comparable across different data sets. In Section 6, the tuning results instantiate that a negative annealing rate is preferred for highly sparse data, such as the RCV1 data set, since the a high rejection rate needs to be maintained longer allowing sufficient information of sparse features to be evaluated by the learning process. On the other hand, a positive annealing rate is chosen for relatively dense data, such as the Arcene data set, where the high frequency of nonzero values

Algorithm 4 $\Psi(\mathcal{D})$: Stabilized truncated stochastic gradient descent for sparse learning.

Input: the training data $\mathcal{D}$.
Parameters: β_0, γ, π_0, K, n_K, M, η.
Initialization: For each $m \in \{1, \ldots, M\}$, initialize $\tilde{\mathbf{w}}_0^{(m)} = \mathbf{0}_p$, $\tilde{\mathbf{k}} = \mathbf{0}_p$ and $\mathcal{D}^{(m)}$ is a random permutation of $\mathcal{D}$; $\hat{\Omega}_0 = \{1, \ldots, p\}$.
For $s = 1, 2, \ldots,$
Set $\hat{\mathbf{w}}_0^{(m)} = \tilde{\mathbf{w}}_{s-1}^{(m)}$
repeat
  Obtain $g_{0,s}(\beta_s)$ as in (11).
  for all $m \in \{1, \ldots, M\}$ **parallel do**
    for $\tau = 1$ **to** n_K **do**
      $\hat{\mathbf{w}}_\tau^{(m)} = B_2\left(\hat{\mathbf{w}}_{\tau-1}^{(m)}, g_{0,s}(\beta_s), \hat{\Omega}_{s-1}, \mathcal{D}^{(m)}\right)$.
    end for
  end for
  Compute $\hat{\Pi}_s$ as in (8) and update the set of stable features $\hat{\Omega}_s = \left\{j : \hat{\Pi}_{s,j} \geq \pi_0\right\}$.
  $\tilde{\mathbf{w}}_s^{(m)} = \hat{\mathbf{w}}_{n_K}^{(m)} I_{\hat{\Omega}_s}$, $m = 1, \ldots, M$.
  $\beta_{s+1} = \phi(d_s; \beta_0, \gamma)$ where $d_s = \frac{|\hat{\Omega}_s|}{p}$.
  Aggregation: $\underline{\mathbf{w}} = \frac{1}{M} \sum_{m=1}^{M} \tilde{\mathbf{w}}_s^{(m)}$.
until $\underline{\mathbf{w}}$ converges.
Return: $\underline{\mathbf{w}}$.

permit fast reduction of the active set. The complete algorithm of the stabilized truncated stochastic gradient descent algorithm is summarized in Algorithm 4. .

4. Properties of the Stabilized Truncated Stochastic Gradient Descent Algorithm

The learning goal of sparse online learning is to achieve a low regret as defined in (3). In this section, we analyze the online regret bound of the proposed stabilized truncated SGD algorithm in Algorithm 4 with convex loss. For simplicity, the effect of adaptive gravity with annealed rejection rate is not considered here. To achieve viable result, we make the following assumptions.

Assumption 1 *The absolute values of the weight vector* $\mathbf{w}$ *are bounded above, that is,* $|w_j| \leq C$ *for some* $C \in [0, \infty)$, $j = 1, \ldots, p$.

Assumption 2 *The loss function* $L(\mathbf{w}, z)$ *is convex in* $\mathbf{w}$*, and there exist non-negative constants* A *and* B *such that, for all* $\mathbf{w} \in \mathbb{R}^p$ *and* $z \in \mathbb{R}^{p+1}$, $||\nabla_{\mathbf{w}} L(\mathbf{w}, z)||^2 \leq AL(\mathbf{w}, z) + B$.

For linear prediction problems, the class of loss function that satisfies Assumption 2 includes common loss functions used in machine learning problems, such as the L_2 loss, the hinge loss and the logistic loss, with the condition that $\sup_{\mathbf{x}} ||x|| \leq C_x$ for some constant $C_x > 0$.

Assumption 3 *Assume that the set* $\mathcal{W}$ *for identifying* $\mathbf{w}^*$ *has the following properties:*

1. *$\mathcal{W}$ is the parameter space for weight vectors $\mathbf{w}$ that is subject to a sparsity constraint*

$$||\mathbf{w}||_0 = d^*.$$

For the optimal weight vector $\mathbf{w}^*$, we denote $\Omega^* = \{j : |w_j^*| > 0\}$ and $d^* = |\Omega^*|$. We further assume that d^* is sufficiently small and the gravity parameter g associated with $\mathbf{w}^*$ is reasonably large so that, for $\tau = 1, 2, \ldots$, the average number of active selected features from each truncated bursts, $q^{\mathbf{g}}$, given a gravity $\mathbf{g}$, is greater than or equal to d^*.

2. *Assume features $\mathbf{x}_1, \ldots, \mathbf{x}_p$ has various sparsity distribution that $\Pr(|x_{i,j}| > 0) = \lambda_j$, where $\lambda_j \in [0, 1]$, for $i = 1, \ldots, n$, and $\mathbf{w}_j^* = 0$ if $\lambda_j = 0$, for $j = 1, \ldots, p$.*

Assumption 3 posits that $\mathbf{w}$'s parameter space of interest is substantially sparse, which is the main focus of sparse learning and of this paper. The theoretical analysis in the following concerns for an fixed optimal weight vector $\mathbf{w}^*$, if exists, under such a constraint. Nevertheless, this condition does not confine the applicable scenarios of the proposed method to a fixed subclass of problems. It suggests a balance between the model sparsity and the value of the gravity parameter that is implicitly embedded within the parameter tuning process.

Assumption 4 *Let $\Omega = \{1, \ldots, p\}$ and $N = \Omega \setminus \Omega^*$. Let $\hat{\Omega}^{\mathcal{G}} = \bigcup_{\mathbf{g} \in \mathcal{G}} \hat{\Omega}^{\mathbf{g} \in \mathcal{G}}$. Assume that the classifier $f_{\mathbf{w}}$ is not worse than random guessing. That is,*

$$\frac{\mathbb{E}(|\Omega^* \bigcap \hat{\Omega}^{\mathcal{G}}|)}{\mathbb{E}(|N \bigcap \hat{\Omega}^{\mathcal{G}}|)} \geq \frac{|\Omega^*|}{|N|}.$$

Lemma 1 (Error Control in Stability Selection (Meinshausen and Bühlmann, 2010)) *Let V be the set of falsely selected variables. Given that the distribution of $\left\{ I\left(j \in \hat{S}^g(\hat{\mathbf{w}}; \mathcal{X}_K \right),\ j \in 1, \ldots, p \right\}$ is exchangeable for all $g \in \mathcal{G}$ and if Assumption 4 holds, the expected cardinality of $|V|$ is then bounded for $\pi_0 \in \left(\frac{1}{2}, 1\right)$ by*

$$\mathbb{E}(|V|) \leq \frac{1}{2\pi_0 - 1} \frac{(q^{\mathbf{g}})^2}{p}. \tag{13}$$

Lemma 2 *Assume all assumptions above holds. Let $\hat{\mathbf{w}}$ be a non-stabilized dense weight vector, i.e., an output weight vector from Algorithm 3. Let $\tilde{\mathbf{w}}$ be the stabilized weight vector derived from $\hat{\mathbf{w}}$, which is purged by the stability selection* (10) *with a set of stable features $\hat{\Omega}$. Let $q^{\mathbf{g}}$ be the average number of nonzero entries in $\hat{\mathbf{w}}$'s of the previous truncated bursts, i.e.,the number of selected features from n_k truncated bursts, with gravity $\mathbf{g}$. Then, there exists an $\varepsilon \in \left(0, \frac{\pi_0 C(p - |\hat{\Omega}|)}{|\hat{\Omega}|}\right)$ with $\hat{S}_\varepsilon = \{j : \mathbb{E}(|\hat{w}_j|) > \varepsilon\}$ such that the bound on the expected difference between the distance from the non-stabilized weight vector to $\mathbf{w}^*$ and the distance from the stabilized weight vector to $\mathbf{w}^*$ is given by*

$$\mathbb{E}\left(||\hat{\mathbf{w}} - \mathbf{w}^*||^2 - ||\tilde{\mathbf{w}} - \mathbf{w}^*||^2\right) \geq \varepsilon^2(|\hat{S}_\varepsilon| - |\hat{\Omega}|) + 2\pi_0 C^2 \left[\left(1 - \frac{q^{\mathbf{g}}}{2\pi_0 p - p}\right) q^{\mathbf{g}} - d^* \right]. \tag{14}$$

When the purging threshold is sufficiently high such that $\pi_0 \in \left(\frac{1}{2} + \frac{(q^{\mathbf{g}})^2}{2p(q^{\mathbf{g}} - d^*)}, 1\right)$,

$$\mathbb{E}\left(||\hat{\mathbf{w}} - \mathbf{w}^*||^2 - ||\tilde{\mathbf{w}} - \mathbf{w}^*||^2\right) \geq 0.$$

Proof : See Appendix A. ■

Lemma 2 quantifies the gain of using stabilization when $\mathbf{w}^*$ is highly sparse, where stability selection efficiently shrinks high variable estimates to zero. When the purging threshold π_0 is sufficiently high such that $\pi_0 \in \left(\frac{1}{2} + \frac{(q^{\mathbf{g}})^2}{2p(q^{\mathbf{g}} - d^*)}, 1\right)$, the lower bound achieved by (14) is guaranteed to be positive. Furthermore, this result also indicates that the expected difference between distances from the non-stabilized and stabilized weight vector to the sparse $\mathbf{w}^*$ depends on the differences between the sizes of the temporary nonzero set of features before purging, $|\hat{S}_\varepsilon|$, and the size of the stable features after purging. In expectation, the stabilized weight vector is closer to the target sparse weight vector as the operation of purging efficiently reduces the size of stable features. This suggests a much faster convergence with stabilization. Lemma 2 also provides an insight on the benefit from using adaptive gravity with annealed rejection rate. At the beginning of the algorithm, the gap between the size of $|\hat{S}_\varepsilon|$ and the size of the set of stable features $|\hat{\Omega}|$ is large when aiming for extensive exploration of different sparse combination of features. Hence, the improvement brought by stabilization is more substantial during the early state of learning period. As the algorithm proceeds and the set of stable features becomes smaller and stabler, it dwindles the leeway that allows the aforementioned two sets to be different. Consequently, the proposed algorithm is gradually tuned toward the standard stochastic gradient descent algorithm to facilitate better convergence at the later period of the learning process.

Lemma 3 *Let $\mathbf{w}_0$ be the weight vector at initialization. After the first burst, let $\bar{\mathbf{w}}_1$ be the truncated weight vector using universal gravity $g_0 K$ as in Algorithm 1 and let $\hat{\mathbf{w}}_1$ be the truncated weight vector with informative truncation as in Algorithm 2. Then, under Assumption 3,*

$$\mathbb{E}\left(||\bar{\mathbf{w}}_1 - \mathbf{w}^*||^2 - ||\hat{\mathbf{w}}_1 - \mathbf{w}^*||^2\right) \geq 2g_0 \sum_{t=1}^{K} \|\zeta_t \mathbf{w}^*\|_1 \geq 0, \tag{15}$$

where $\zeta_{t,j} = I(|x_{t,j}| = 0)$ for $j = 1, \ldots, p$ and $\zeta_t = (\zeta_{t,1}, \ldots, \zeta_{t,p})^T$.

Proof : See Appendix B. ■

In Lemma 3, we compare the distances towards $\mathbf{w}^*$ from *1)* the weight vector with uniform gravity and *2)* the weight vector with informative truncation that depends on the number of zero entries occurred in a burst. Such a gap suggests the effectiveness of informative truncation on sparse data in which feature sparsity is highly heterogeneous. In the scenarios where very few nonzero entries appear in a burst, the informative truncation imposes gravity that is proportional to the information presented in a burst. It is a fairer treatment than uniform truncation and leads to a large improvement in expectation. When features are all considerably dense in a burst, the informative truncation is equivalent to the uniform truncation.

In short, Lemma 2 demonstrates the improvement in expected squared error due to stabilization on the weight vector. Lemma 3, on the other hand, quantifies the improvements in reduce truncation bias when implementing informative truncation on sparse features with heterogeneous sparsity levels.

Given Lemma 2 and Lemma 3, we have the expected regret bound of the proposed Algorithm 4 in Theorem 1.

Theorem 1 *Assume all assumptions above holds. Consider the updating rules for the weight vector in Algorithm 3. On an arbitrary path, with* $\underline{\mathbf{w}}_0 = 0$ *and* $\eta > 0$*, let* $\{\underline{\mathbf{w}}_t\}_{t=1}^T$ *be the resulted weight vector and* $\left\{\underline{g}_t\right\}_{t=1}^T$ *be the gravity values applied to the weight vectors generated by Algorithm 4, along with the base gravity parameters* $\left\{\underline{g}_{0,t}\right\}_{t=1}^T$*. Set the purging threshold* π_0 *to be sufficiently large such that* $\pi_0 \in \left(\frac{1}{2} + \frac{(q^{\mathbf{g}})^2}{2p(q^{\mathbf{g}}-d^*)}, 1\right)$*. There exists a sequence of* $\varepsilon_t \in \left(0, \frac{\pi_0 C(p-|\hat{\Omega}_t|)}{|\hat{\Omega}_t|}\right)$ *at each stability selection with the set of stable features* $\hat{\Omega}_t$ *such that the expectation of the regret defined in* (3) *is bounded above by*

$$\begin{aligned}
&\mathbb{E}\left(\sum_{t=1}^T \left[L(\underline{\mathbf{w}}_t, z_t) + K\underline{g}_t||\underline{\mathbf{w}}_t||_1\right] - \sum_{t=1}^T \left[L(\mathbf{w}^*, z_t) + K\underline{g}_t||\mathbf{w}^*||_1\right]\right) \\
\leq &\frac{\eta A}{2-\eta A}\left(\mathbb{E}\left[\sum_{t=1}^T L(\mathbf{w}^*, z_t) + K\underline{g}_{0,t}(||\mathbf{w}^*||_1 - ||\underline{\mathbf{w}}_t||_1)\right]\right) + \frac{1}{2-\eta A}\left(\eta TB + \frac{1}{\eta}||\mathbf{w}^*||^2\right) \\
&- \frac{1}{2\eta - \eta^2 A}\sum_{t=1}^T \varepsilon_t^2 I\left(\frac{t}{Kn_K} \in \mathbb{Z}\right)(|\hat{S}_{\varepsilon_t,t}| - |\hat{\Omega}_t|), \qquad (16)
\end{aligned}$$

where $\hat{S}_{\varepsilon,t} = \{j : \mathbb{E}(|\hat{w}_{t,j}|) > \varepsilon_t\}$ *and* $\hat{\mathbf{w}}_t$ *is the weight vector at time* t *before stabilization.*

Proof : See Appendix C. ■

In the result of Theorem 1, the first two parts of the right-hand-side of the expected regret bound (16) is similar to the bound obtained in (Langford et al., 2009). It implies the trade-off between attained sparsity in the resulted weight vector and the regret performance. When the applied gravity is small under the joint effect of the base gravity g_0 and the size of each burst K, the sparsity is less but the expected regret bound is lower. On the other hand, when the applied gravity is large, the resulted weight vector is more sparse but at the risk of higher regret. Based on Lemma 2, the proposed algorithm is guaranteed to achieve lower regret bound in expectation when the target sparse weight vector is highly sparse. As quantified in the third term of the right-hand-side of (16), the improvement comes from the reduction of the active set at each purging. By its virtue, noisy features are removed from the set of stable features and thus are absent in later SGD updates and truncations.

Theorem 1 is stated with a constant learning rate η. It is possible to obtain a lower regret bound in expectation with adaptive learning rate η_t decaying with t, such as $\eta_t = \frac{1}{\sqrt{t}}$, which is commonly used in the literature of online learning and stochastic optimization. However, the discussion of using an varying learning rate is not a main focus of this paper and adds extra complexity of the analysis. Without knowing T in advance, this may lead to a no-regret bound as suggested in (Langford et al., 2009). Instead, in Corollary 1, we show that the convergence rate of the proposed algorithm is $O(\sqrt{T})$ with $\eta = \frac{1}{\sqrt{T}}$.

Corollary 1 *Assume that all conditions of Theorem 1 are satisfied. Let the learning rate* η *be* $\frac{1}{\sqrt{T}}$*. The upper bound of the expected regret is*

$$\mathbb{E}\left(\sum_{t=1}^T \left[L(\underline{\mathbf{w}}_t, z_t) + \underline{g}_t||\underline{\mathbf{w}}_t||_1\right] - \sum_{t=1}^T \left[L(\mathbf{w}^*, z_t) + \underline{g}_t||\mathbf{w}^*||_1\right]\right) \leq O(\sqrt{T}),$$

where $\underline{g}_t = K\underline{g}_{0,t}$*.*

Proof By plugging in $\eta = \frac{1}{\sqrt{T}}$ to the result from Theorem 1, we get

$$\begin{aligned}
&\mathbb{E}\left(\sum_{t=1}^T \left[L(\underline{\mathbf{w}}_t, z_t) + \underline{g}_t||\underline{\mathbf{w}}_t||_1\right] - \sum_{t=1}^T \left[L(\mathbf{w}^*, z_t) + \underline{g}_t||\mathbf{w}^*||_1\right]\right) \\
\leq &\frac{A}{2\sqrt{T} - A}\left(\mathbb{E}\left[\sum_{t=1}^T L(\mathbf{w}^*, z_t) + \underline{g}_t(||\mathbf{w}^*||_1 - ||\underline{\mathbf{w}}_t||_1\right]\right) \\
&+ \frac{T}{2\sqrt{T} - A}\left(\eta TB + \frac{1}{\eta}||\mathbf{w}^*||^2\right) - \frac{T}{2\sqrt{T} - A}\sum_{t=1}^T \varepsilon_t^2 I(\frac{t}{Kn_K} \in \mathbb{Z})(|\hat{S}_{\varepsilon,t}| - |\hat{\Omega}_t|).
\end{aligned}$$

The result is then straightforward. ■

Assume that the input features have d nonzero entries on average. With linear prediction model $f_{\mathbf{w}}(x) = \mathbf{w}^T x$, the computational complexity at each iteration is $O(d)$. Leveraging the sparse structure, the informative truncation only requires an additional $O(Kd)$ space for recording the counters. The purging process of stability selection consumes $O(\delta)$, $\delta = Kn_K Md$, space for storing the generated intermediate weight vectors and $O(\delta \log(\delta))$ computational complexity. Both storage and computational cost decrease when the set of stable features diminishes as the algorithm proceeds. Since the parameters K, n_K, and M is normally set to be small values, the complexity mostly depends on $O(d \log(d))$. In summary, the proposed algorithm scales with the number of nonzero entries instead of the total dimensions, making it appealing to high-dimensional applications.

5. Practical Remarks

When implementing Algorithm 4 in practice, the performance can be further improved in terms of both accuracy and computational efficiency by employing a couple of practical techniques. It includes applying *informative purging* and attenuating the truncation frequency to achieve more accurate sparse learning and steadier convergence.

The first improvement can be implemented by better addressing the issue of scarcity of incoming samples. For computing selection probabilities, instead of using only information from the current stage, we can inherit information from previous stages for features that are too scarce to accumulate enough updates during one stage. Specifically, we introduce an *accumulated counter* κ_s at stage s as the total number of times that a feature is updated within a burst during this stage:

$$\kappa_{j,s} = \sum_{m=1}^M \sum_{\tau=1}^{n_K} \tilde{k}_{j,\tau}^{(m)}, \quad j = 1, \ldots, p,$$

which is essentially the denominator of the selection probability in (8). Similarly, we define an *accumulated truncation indicator* $\mathbf{b}_s$ at stage s as the total number of times that a feature is truncated to zero given valid update(s):

$$\mathbf{b}_{j,s} = \sum_{m=1}^{M} \sum_{\tau:\tilde{k}_{j,\tau}^{(m)}>0} I(|\hat{\mathbf{w}}_{j,\tau}^{(m)}| > 0), \quad j = 1, \ldots, p.$$

A feature is then evaluated in the stability selection *only* if there are enough updates from the present stage and from any unused information carried over from previous stages. Given a threshold $\delta_K \geq 0$, let $\tilde{\kappa}_{j,s} \triangleq \tilde{\kappa}_{j,s-1} I(\tilde{\kappa}_{j,s-1} < \delta_K) + \kappa_{j,s}$ and $\tilde{\mathbf{b}}_{j,s} \triangleq \tilde{\mathbf{b}}_{j,s-1} I(\tilde{\kappa}_{j,s-1} < \delta_K) + \mathbf{b}_{j,s}$. The selection probability is modified as

$$\hat{\Pi}_{j,s} = \begin{cases} \frac{\tilde{\mathbf{b}}_{j,s}}{\tilde{\kappa}_s}, & \text{for } j \text{ s.t.} \tilde{\kappa}_s > \delta_K; \\ 1, & \text{otherwise,} \end{cases} \qquad \text{for } j = 1, \ldots, p. \tag{17}$$

This strategy extends the key idea in Section 3.1 that, with sparse data, each decision need to be based on sufficient evidence. Using the "carried-over" information allows the algorithm to utilize information available in a sequence of SGD updates while attuned to the needs of features with different levels of sparsity. In practice, this modification facilitates faster convergence especially for ultra-sparse data.

The second practical strategy is that the size of each burst, K, can be adaptively adjusted in a similar fashion as the rejection rate β in (12). At the end of each stage, the burst size K_s is updated as

$$K_s = \left\lceil K_0 \log\left(\frac{1}{\alpha d_{s-1}}\right)\right\rceil,$$

where $K_0 > 0$ is the initial burst size and, as in (12), $d_s = \frac{|\hat{\Omega}_s|}{p}$. The tuning parameter $\alpha > 0$ adjusts the annealing rate of the truncation frequency. Although the result in Theorem 1 is based on a fixed K, it can be easily shown that the same upper bound can also be attained with an increasing K_s. By increasing K in the later stage of the algorithm, when the majority of irrelevant features have been removed from the stable set, the chance of erroneous truncation is reduced. Such scheme further steers the algorithm from the mode of exploring potential sparse combination of features in the early stage toward the fine tuning of the weight vector by exploiting information from more samples in a sequence. It also facilitates faster convergence as the size of the stable set approaches to a sufficiently small number, as the algorithm converges to the standard stochastic gradient descent approximately.

6. Results

In this section, we present experimental results evaluating the performance of the proposed stabilized truncated SGD algorithm in high-dimensional classification problems with sparsity regularization. In this paper, we focus on linear prediction model for binary classification where $f_{\mathbf{w}}(x) = \mathbf{w}^T x$ and $\hat{y} = \text{sign}(f_w(x))$ with the observed class label $y \in \{-1, 1\}$. We consider two commonly used convex loss functions in machine learning tasks that both satisfy Assumption 1:

- Hinge loss: $l(f, y) = \max(1 - fy, 0)$;

- Logistic loss: $l(f, y) = \log(1 + \exp(-fy))$.

Using five data sets from different domains, the performance of our algorithm and other algorithms for comparison are evaluated on classification performance and feature selection stability and sparsity. We first define measure of feature stability in Section 6.1.

6.1 Feature Selection Stability

The goal of sparse learning is to select a subset of truly informative features with stabilized estimation variance as well as increased classification accuracy and model interpretability. Subgradient-based online learning methods depend heavily by the random ordering of samples on which they are fed to the algorithm. Such dependence leads to much deteriorated performance when it comes to high-dimensional sparse inputs. For a particular feature, the positions of its nonzero occurrences in a random ordering of samples greatly affect its learning outcome, in terms of learnt weight and membership in the set of selected features. Therefore, in addition to attaining a low generalization error, a desirable sparse online learning method should also produce an informative feature subset that is stable and robust to random permutations of input data. To evaluate feature selection stability of subgradient-based sparse learning methods, we define in the following a numerical measure of similarity between selected feature subsets resulted from different random permutations of data. Given an output weight vector $\underline{\mathbf{w}}$ from a subgradient-based algorithm with input data $\mathcal{D}$, similarly as in (6), we denote the selected feature subset as

$$\mathcal{S}(\underline{\mathbf{w}}; \mathcal{D}) = \{j : |\underline{w}_j| > 0, \underline{\mathbf{w}} = \Psi(\mathcal{D}\}.$$

Given two random permutations of the training data $\mathcal{D}$, $\mathcal{D}^{(1)}$ and $\mathcal{D}^{(2)}$, the similarity between the two sets of selected feature subsets $\mathcal{S}_1 = \mathcal{S}(\underline{\mathbf{w}}_1; \mathcal{D}^{(1)})$ and $\mathcal{S}_2 = \mathcal{S}(\underline{\mathbf{w}}_2; \mathcal{D}^{(2)})$ is measured by the Cohen's kappa coefficient introduced by Cohen (1960),

$$\kappa(\mathcal{S}_1, \mathcal{S}_2) = \frac{q_o - q_e}{1 - q_e},$$

where q_o is the *relative observed agreement* between $\mathcal{S}_1$ and $\mathcal{S}_2$:

$$q_o = \frac{p_{11} + p_{22}}{p},$$

and q_e is the *hypothetical probability of change agreement*: $\mathcal{S}_1$ and $\mathcal{S}_2$

$$q_e = \frac{(p_{11} + p_{12})(p_{11} + p_{21})}{p^2} + \frac{(p_{12} + p_{22})(p_{21} + p_{22})}{p^2},$$

with $p_{11} = |\mathcal{S}_1 \cap \mathcal{S}_2|$, $p_{12} = |\mathcal{S}_1 \cap \mathcal{S}_2^C|$, $p_{21} = |\mathcal{S}_1^C \cap \mathcal{S}_2|$, $p_{22} = |\mathcal{S}_1^C \cap \mathcal{S}_2^C|$, and $p = p_{11} + p_{12} + p_{21} + p_{22}$ is the size of variable pool.

Note that $\kappa(\mathcal{S}_1, \mathcal{S}_2) \in [-1, 1]$, where $\kappa(\mathcal{S}_1, \mathcal{S}_2) = 1$ if $\mathcal{S}_1$ and $\mathcal{S}_2$ completely overlap with each other and $\kappa(\mathcal{S}_1, \mathcal{S}_2) = -1$ when $\mathcal{S}_1$ and $\mathcal{S}_2$ are in complete disagreement with $\mathcal{S}_1 \cap \mathcal{S}_2 = \emptyset$ and $\mathcal{S}_1^C \cap \mathcal{S}_2^C = \emptyset$.

Based on Cohen's kappa coefficient, we define the measure of feature selection stability of $\mathcal{S}(\underline{\mathbf{w}}; \cdot)$ returned by a procedure Ψ using randomly ordered data $\mathcal{D}^{(1)}$ and $\mathcal{D}^{(2)}$ as

$$s(\Psi) = \mathbb{E}_{\mathcal{D}^{(1)}, \mathcal{D}^{(2)}} \left[\kappa(\mathcal{S}(\underline{\mathbf{w}}_1; \mathcal{D}^{(1)}), \mathcal{S}(\underline{\mathbf{w}}_2; \mathcal{D}^{(2)})\right],$$

which is motivated by (Sun et al., 2013).

In practice, we use the empirical average $\hat{s}(\Psi)$ over B random permutations of the training data to measure the stability of the a subgradient-based online learning algorithm $\Psi(\cdot)$:

$$\hat{s}(\Psi) = \frac{1}{B(B-1)} \sum_{i=1}^{D} \sum_{j \neq i} \left[\kappa(\mathcal{S}_{\underline{\mathbf{w}}_i}; \mathcal{D}^{(i)}), \mathcal{S}(\underline{\mathbf{w}}_j; \mathcal{D}^{(j)}) \right]. \tag{18}$$

6.2 Experiment Setup

We evaluate the performance of our algorithm on several real-world classification data sets with up to $100,000$ features. These data sets have different levels of sparsity with various sample sizes. The information of experiment data sets are summarized in Table 1. The first four data sets were constructed for NIPS 2003 Feature Selection Challenge[4] (see Guyon et al., 2004, for details), which were preprocessed with added "probes" as random features distributed similarly to the real features. Thus, a good performance does not only lie in low generalization error rates, but also in sparse weight vectors that identify the truly important features. Reuters CV1 (RCV1) is a popular text classification data set with a bag-of-words representation. We use the binary version from the LIBSVM data set collection[5] introduced by Cai and He (2012). We create the training and validation set using a 70-30 random splits. All datasets are normalized such that each feature has variance 1.

Data Set	Domain	Dimensions	Data Density (Sparsity)	Training Size	Validation Size
RCV1	Text Mining	47,236	0.16%	14,169	6,073
Dexter	Text Mining	20,000	0.48%	300	300
Dorothea	Drug Discovery	100,000	0.91%	800	350
Gisette	Digits Recognition	5,000	13.00%	6,000	1,000
Arcene	Mass-Spectrometry	10,000	50.00%	100	100

Table 1: Datasets used in the numerical experiments. Sparsity is defined as the average feature sparsity levels, which is the column-wise average percentage of nonzero entries, in the training data.

We compare the proposed algorithm with the standard stochastic gradient descent algorithm in (Bottou, 1998) and another three other sparsity-inducing stochastic methods, including the truncated gradient algorithm in (Langford et al., 2009), the Regularized Dual Averaging (RDA) algorithm in (Xiao, 2009), and the forward backward splitting (FOBOS) algorithm in (Duchi and Singer, 2009). The RDA algorithm updates the weight vector at each step based on a running average $\bar{\mathbf{g}}_t$ of all subgradients $\{\mathbf{g}_\tau = L'(\mathbf{w}_\tau, z_\tau) \in \partial_{\mathbf{w}_\tau} L(\mathbf{w}_\tau, z_\tau), \tau = 1, \ldots, t\}$ in previous iterations as

$$\bar{\mathbf{g}}_t = \frac{t-1}{t} \mathbf{g}_{t-1} + \frac{1}{t} \mathbf{g}_t.$$

4. The data source can be found on `https://archive.ics.uci.edu/ml/index.html`.
5. The data source can be found on `https://www.csie.ntu.edu.tw/~cjlin/libsvmtools/datasets/`.

Given the average subgradient , the next weight vector is computed by solving the minimization problem

$$\mathbf{w}_{t+1} = \arg\min_{\mathbf{w}} \left\{ \frac{1}{t} \sum_{\tau}^{t} \langle L'(\mathbf{w}_t, z_t), \mathbf{w} \rangle + \Psi(\mathbf{w}) + \frac{\beta_t}{t} h(\mathbf{w}) \right\}, \tag{19}$$

where $\Psi(\mathbf{w})$ is the regularizer, $h(w)$ is an auxiliary strongly convex function, and $\{\beta_t\}_{t \geq 1}$ is a nonnegative and nondecreasing input sequence, which determines the convergence properties of the algorithm.

In the context of L_1 regularization, the RDA algorithm is derived by setting $\Psi(\mathbf{w}) = \lambda ||\mathbf{w}||_1$, $\beta_t = \gamma \sqrt{t}$, and replacing $h(w)$ with a parametrized version:

$$h_\rho = \frac{1}{2} ||\mathbf{w}||_2^2 + \rho ||\mathbf{w}||_1,$$

where $\rho \geq 0$ is a sparsity-enhancing parameter. Hence, the minimization problem in (19) has a explicit solution as, for $j = 1, \ldots, p$,

$$\mathbf{w}_{t+1}^{(j)} = \begin{cases} 0, & \text{if } |\bar{\mathbf{g}}_t^{(j)}| \leq \lambda_t^{\text{RDA}}; \\ -\frac{\sqrt{t}}{\gamma} \left(\bar{\mathbf{g}}_t^{(j)} - \lambda_t^{\text{RDA}} \text{sgn}(\bar{\mathbf{g}}_t^{(j)}) \right), & \text{otherwise,} \end{cases}$$

which is equivalent to

$$\mathbf{w}_{t+1} = T(\bar{\mathbf{g}}_t, \lambda_t^{\text{RDA}}),$$

where $\lambda_t^{\text{RDA}} = \lambda + \gamma \rho / \sqrt{t}$.

The FOBOS algorithm alternates between two phases. On each iteration, it first perform an unconstrained gradient descent step as in the standard SGD algorithm, whose output is denoted as $\mathbf{w}_{t+\frac{1}{2}}$. Then it cast and solve an instantaneous optimization problems that trades off between minimization of a regularization term and a close proximity to the result of the first phase:

$$\mathbf{w}_{t+1} = \arg\min_{\mathbf{w}} \left\{ \frac{1}{2} ||\mathbf{w} - \mathbf{w}_{t+\frac{1}{2}}||^2 + \eta_{t+\frac{1}{2}} \Psi(\mathbf{w}) \right\}, \tag{20}$$

where the regularization function is scaled by an interim step size $\eta_{t+\frac{1}{2}}$.

With L_1 regularization where $\Psi(w) = \lambda ||\mathbf{w}||_1$, the second-phase update can be computed as

$$\mathbf{w}_{t+1} = T(\mathbf{w}_{t+\frac{1}{2}}, \eta_{t+\frac{1}{2}} \lambda).$$

To evaluate the stability of resulted weight vectors, we randomly permute the indices of the training samples for $B = 50$ times to produce stochastic samples that are fed to the algorithms. Such randomization helps identify the instability in learning results in terms of both error rate and the selected features.

For implementing all five stochastic methods, we allow the algorithms to run on the training data for $\{5, 10, 20, 30, 40, 50, 60\}$ passes. In the standard stochastic gradient descent algorithm, we choose the optimal learning rate between 0.1 to 0.5. The base gravity parameter in the truncated gradient algorithm is chosen from the range $[0.001, 0.01]$. For RDA, we follow the suggestions in (Xiao, 2009) which sets $\gamma = 5000$ and $\rho = 0.005$ (effectively $\gamma\rho = 25$). We tune the parameter

λ from the set of values $\{5 \times 10^{-5}, 1 \times 10^{-4}, 5 \times 10^{-4}, 1 \times 10^{-3}, 0.01, 0.05, 0.1, 0.5, 1, 5, 10\}$ for both RDA and FOBOS. As instructed by Duchi and Singer (2009), η_t is set to be $\frac{1}{\sqrt{t}}$ in FOBOS. For the proposed stabilized truncated SGD algorithm, the size of each burst (the truncation frequency) is fixed at $K = 5$ and $n_K = 5$ for all data sets. In the proposed algorithm, we initiate the rejection rate at $\beta_0 = 0.7$ with annealing rate chosen from $\{-7, -5, -3, -1, 0, 1, 3\}$. The stability selection threshold π_0 is tuned within the range $[0.5, 0.6, \ldots, 0.9]$. For multi-thread implementation in Algorithm 4, $M = 16$ is used running in parallel on a high-performance computing cluster.

6.3 Results

6.3.1 CLASSIFICATION PERFORMANCE

As shown in Table 2, the proposed algorithm shows improvement over the truncated gradient algorithm over all data sets and has better performances than RDA and FOBOS in most of the experiments. As data density increases, the truncated gradient algorithm performs better with hinge loss than with logistic loss. With hinge loss, the algorithm updates the weight vector only for samples within a small margin from the boundary. With logistic loss, the algorithm updates with continuous increments for all incoming samples and favors dense features in sparse learning. With highly sparse samples sequentially feed to the algorithm, the truncation in every K iterations is conducted with insufficient information about the true gradient due to the lack of nonzero entries in sparse features. Truncation with logistic loss leads to over selection of dense features and overfitting. The other two sparsity-inducing methods for comparison, RDA and FOBOS, also have large fluctuations across data sets with different levels of sparsity over these two loss functions, especially when data is highly sparse. In comparison, the performance of the proposed algorithm is consistent for various dimensions and sparsity levels. Our algorithm is also shown to be robust to different choices of loss function. The comparatively lower test errors, especially for highly sparse data, mainly owes to the proposed algorithm's fairer treatments of features with heterogeneous sparsity.

From Table 2 we also observe substantially lower variances in test errors under random permutations of samples. The proposed algorithm has the lowest standard deviations of test errors across all data sets and under both loss functions. Such an improvement over truncated gradient algorithm and other comparing methods comes from both informative truncation with adaptive gravity and stability selection. Based on these selection probabilities we carry out feature purging. Our selection probability is computed based on multiple bursts whose truncation is guided by fair amounts of shrinkage. Hence, the removal decisions of features from the set of stable variables are grounded in reliable information on feature importance, which is more likely to be shared across different permutations of the data. The accumulations of sufficient information for all features help the proposed algorithm to be robust to random fluctuations in online setting.

6.3.2 FEATURE SELECTION AND SPARSITY

As far as sparse learning for feature selection goes, the proposed algorithm, as shown in Table 3, is the only method that delivers sparse weight vectors across five example data sets with various sparsity levels. It is shown in Table 3 that the resulted weight vectors are far more sparse than the truncated gradient algorithm in all data sets with both loss functions. When comparing these two algorithms, the distinction in attained sparsity levels is particularly striking with logistic loss

function and when the sparsity level of the input data is low, such as the case of the Arcene data set. These results also indicate that the truncate gradient algorithm fails to extract significant features and to obtain sparse solutions, which motivates the development of techniques discussed in this paper. On the other hand, the variances in the percentage of nonzero features of the proposed algorithm are reduced by approximately a magnitude of 10. The contribution of stabilization is demonstrated again in terms of feature selection. Although RDA achieves very low sparsity in Dorothea, such a behavior is not observed in other data sets. It is shown to result in particularly denser weight vector with highly sparse data, such as RCV1, indicating its weakness in identifying truly informative features when information is scarce. FOBOS demonstrates overall poorer performance in terms of inducing sparse weight vector as compared to RDA and the proposed algorithm. Similar to its performance in terms of test error, the proposed algorithm delivers highly stable results in feature selection regardless of the choice of loss function and of random permutations of the data. We also achieve sufficient sparse result owing to stability selection which prevent noisy features from adding back to the stable set of variables in the online setting. On the other hand, the high sparsity in weight vector does not overshadow the generalizability performance as the informative truncation with unbiased shrinkage underlies a better estimation of the selection probability for the construction of the set of stable variables.

We further compare the data sparsity levels of the features selected by both sparse online learning algorithms. In Figure 3, using the Dorothea data set as an example, we show the fraction

Table 3: The average percentages (%) of nonzero features selected in the resulted weight vector and the corresponding standard deviations with hinge loss and logistic loss over 50 random permutations of the training samples.

of selected features at different data density levels. It is shown that truncated gradient algorithm is more likely to select dense features over sparse ones with both loss functions. The majority of the sparse features are truncated to zero regardless of their importance. Moreover, the fraction of selected feature exhibits a linear relationship with the level of feature density in truncated gradient algorithm. This pattern suggests that the amount of shrinkage applied to features should be approximately proportional to their data density, on the probability of having informative updates. This provides an independent justification of the informative truncation introduced in Section 3.1. In contrast, features selected by the proposed algorithm have approximately uniform distribution of sparsity levels. This improvement over the truncated gradient algorithm mostly owes to the use of informative truncation. With the crucial treatment on the heterogeneity in feature sparsity, the proposed algorithm is effective in keeping rare but important features from premature truncations.

Based on the measure of feature selection stability defined in (18), the performance of the original truncated gradient algorithm and the proposed algorithm are summarized in Table 4. The proposed algorithm demonstrates its excellent stability as compared to the truncated gradient algorithm. It shows greater overlap in selected features among different permutations of the training data. This result also echos with the lower standard deviations in the test error (Table 2) and in the number of selected features (Table 3). As discussed in Section 3, the insensitivity to data perturbation is mainly due to the fair shrinkage applied on each feature by using informative truncation and to the

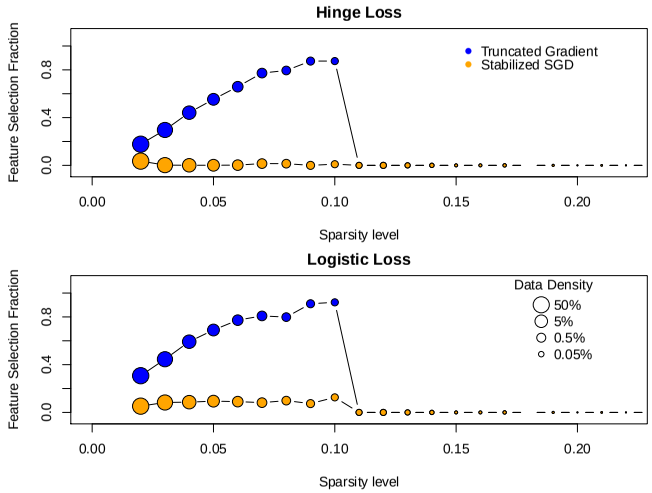

Figure 3: The fraction of features selection at different sparsity levels by the truncated gradient algorithm and the proposed algorithm respectively with the Dorothea data set as an example. The selected features are extracted as the features with nonzero entries in the resulted weight vector from the algorithms with a single fixed ordering of the training data. The x-axis represents the sparsity level, which is the proportion of nonzero entries in a feature in the training sample. The y-axis indicates the fraction of selected features among features with a discretized sparsity level. The size of each point scales with the proportion of features that fall in level of sparsity. It can be seen that the truncated gradient algorithm over-selects denser features. The proposed algorithm does not have a pre-exposed preference towards any density level.

sufficient accumulations of information in selection probabilities before applying stability selection. These measures suggest that the proposed algorithm is particularly favorable for high-dimensional sparse data.

7. Conclusion

In this paper, we address the problem of inducing sparsity in subgradient-based online learning algorithm when applied to high-dimensional sparse data. Based on the truncated gradient framework, we reduce truncation bias due to heterogeneity in feature sparsity via informative truncation. Integrated with soft-thresholding truncation, stability selection helps eliminate irrelevant features along the learning process in order to achieve stable and sufficiently sparse results. The adaptive gravity method dynamically adjusts the shrinkage at different stages of the learning process to balance between the exploration of sparse combination of nonzero weights and the exploitation of finite

updates for better convergence. This strategy also consolidates the tuning needs of the proposed algorithm into two major parameters, the annealing rate γ and the purging threshold π_0. We present a theoretical analysis of the expected regret bound, which offered a quantification of the potential improvement attained by the proposed algorithm. At last, we use extensive experimental studies to evaluate the performance of the proposed algorithm. The results demonstrate that our algorithm achieve favorable results in terms of both prediction accuracy and feature selection, compared to the original truncated gradient algorithm.

Appendices

A. Proof of Lemma 2

Proof Note that $\mathbf{w}^*$ can be written as $\mathbf{w}^* I_{\Omega^*}$. Based on the stability selection in (10), we have $\tilde{\mathbf{w}} = \hat{\mathbf{w}} I_{\hat{\Omega}}$. Let $\Omega = \{1, \ldots, p\}$. The full set Ω can be further divided into four disjoint sets: $S_1 = \Omega \setminus (\Omega^* \cup \hat{\Omega})$, $S_2 = \Omega^* \setminus \hat{\Omega}$, $S_3 = \hat{\Omega} \setminus \Omega^*$, and $S_4 = \Omega^* \cap \hat{\Omega}$, respectively.

Firstly, we consider the L_2 distance from the non-stabilized weight vector $\hat{\mathbf{w}}$ to $\mathbf{w}^*$ under Assumption 3 and the L_2 distance from the stabilized weight vector $\tilde{\mathbf{w}}$ to $\mathbf{w}^*$.

$$\begin{aligned}||\hat{\mathbf{w}} - \mathbf{w}^*||^2 &= ||\hat{\mathbf{w}} - \mathbf{w}^* I_{\Omega^*}||^2 \\ &= \sum_{j \in \Omega^*} (\hat{w}_j - w_j^*)^2 + \sum_{j \notin \Omega^*} \hat{w}_j^2, \\ &= \sum_{j \in S_2 \cup S_4} (\hat{w}_j - w_j^*)^2 + \sum_{j \in S_1 \cup S_3} \hat{w}_j^2.\end{aligned}$$

Since

$$(\hat{\mathbf{w}} I_{\hat{\Omega}} - \mathbf{w}^* I_{\Omega^*})_j^2 = \begin{cases} 0, & \text{if } j \notin \Omega^* \text{ and } j \notin \hat{\Omega}; \\ (w_j^*)^2, & \text{if } j \in \Omega^* \text{ and } j \notin \hat{\Omega}; \\ (\hat{w}_j)^2, & \text{if } j \notin \Omega^* \text{ and } j \in \hat{\Omega}; \\ (\hat{w}_j - w_j^*)^2, & \text{if } j \in \Omega^* \text{ and } j \in \hat{\Omega}, \end{cases}$$

$$\begin{aligned}||\tilde{\mathbf{w}} - \mathbf{w}^*||^2 &= \|\hat{\mathbf{w}} I_{\hat{\Omega}} - \mathbf{w}^* I_{\Omega^*}\|^2 \\ &= \sum_{j \in S_2} (w_j^*)^2 + \sum_{j \in S_3} (\hat{w}_j)^2 + \sum_{j \in S_4} (\hat{w}_j - w_j^*)^2.\end{aligned}$$

Then

$$\begin{aligned}||\hat{\mathbf{w}} - \mathbf{w}^*||^2 - ||\tilde{\mathbf{w}} - \mathbf{w}^*||^2 &= \sum_{j \in S_2} (\hat{w}_j - w_j^*)^2 + \sum_{j \in S_1} \hat{w}_j^2 - \sum_{j \in S_2} (w_j^*)^2 \\ &= \sum_{j \in S_2} \hat{w}_j^2 + \sum_{j \in S_2} (w_j^*)^2 - 2 \sum_{j \in S_2} w_j^* \hat{w}_j - \sum_{j \in S_2} (w_j^*)^2 + \sum_{j \in S_1} \hat{w}_j^2 \\ &= \sum_{j \in S_1 \cup S_2} \hat{w}_j^2 - 2 \sum_{j \in S_2} w_j^* \hat{w}_j \\ &= ||\hat{\mathbf{w}}(1 - I_{\hat{\Omega}})||^2 - 2 \sum_{j \in S_2} w_j^* \hat{w}_j. \end{aligned} \tag{21}$$

For the first part in (21), there exists a small $\varepsilon \in \left(0, \frac{\pi_0 C(p - |\hat{\Omega}|)}{|\hat{\Omega}|}\right)$ with $\hat{S}_\varepsilon = \{j : \mathbb{E}(|\hat{w}_j|) > \varepsilon\}$ such that

$$\begin{aligned}\mathbb{E}\left(||\hat{\mathbf{w}}(1 - I_{\hat{\Omega}})||^2\right) =& \mathbb{E}\left(\sum_{j=1}^p \hat{w}_j^2 I(\hat{p}_j \leq \pi_0)\right) \\ =& \mathbb{E}\left(\sum_{j=1}^p \hat{w}_j^2 I(\hat{p}_j \leq \pi_0) I(|\hat{w}_j| \leq \varepsilon)\right) + \mathbb{E}\left(\sum_{j=1}^p \hat{w}_j^2 I(\hat{p}_j \leq \pi_0) I(|\hat{w}_j| > \varepsilon)\right) \\ \geq& 0 + \varepsilon^2 \mathbb{E}\left(\sum_{j=1}^p I(\hat{p}_j \leq \pi_0) I(|\hat{w}_j| \geq \varepsilon)\right) \\ \geq& \varepsilon^2 (|\hat{S}_\varepsilon| - |\hat{\Omega}|) > 0, \end{aligned} \tag{22}$$

where the last inequality is due to $|\hat{S}_\varepsilon| > |\hat{\Omega}|$ with the specified range of ε.

For the second part in (21), recall that $S_2 = \Omega^* \setminus \hat{\Omega} = \Omega^* \setminus (\hat{\Omega} \setminus V)$. Using (13) from Lemma 1 in (Meinshausen and Bühlmann, 2010), we have

$$\begin{aligned}\mathbb{E}(|S_2|) &= \mathbb{E}(\Omega^* - (\hat{\Omega} - V)) \\ &= d^* - E(\hat{\Omega}) - \mathbb{E}(V)) \\ &= d^* - q^{\mathbf{g}} + \mathbb{E}(V) \\ &\leq d^* - q^{\mathbf{g}} + \frac{1}{2\pi_0 - 1}\frac{(q^{\mathbf{g}})^2}{p} \\ &\leq \left(\frac{q^g}{2\pi_0 p - p} - 1\right) q^g + d^*.\end{aligned} \tag{23}$$

And, since, for any $j \in \Omega \setminus \hat{\Omega}$, $\Pr(|\hat{w}_j| > 0) \leq \pi_0$,

$$\mathbb{E}(|\hat{w}_j|) = \int_0^C \Pr(|\hat{w}_j| \geq u)du \leq \Pr(|\hat{w}_j| > 0)C \leq \pi_0 C.$$

Then,

$$\mathbb{E}\left(\sum_{j \in S_2} w_j^* \hat{w}_j\right) \leq \pi_0 C^2 \mathbb{E}(|S_2|) \leq \pi_0 C^2 \mathbb{E}(|S_2|)\left[\left(\frac{q^g}{2\pi_0 p - p} - 1\right) q^g + d^*\right].$$

Thus we have

$$\mathbb{E}\left(||\hat{\mathbf{w}} - \mathbf{w}^*||^2 - ||\tilde{\mathbf{w}} - \mathbf{w}^*||^2\right) \geq \varepsilon^2(|\hat{S}_\varepsilon| - |\hat{\Omega}|) + 2\pi_0 C^2\left[\left(1 - \frac{q^g}{2\pi_0 p - p}\right) q^g - d^*\right]. \tag{24}$$

The first half of (24) is proved to be non-negative by the inequality in (22). With a sufficiently large $\pi_0 \in \left(\frac{1}{2} + \frac{(q^{\mathbf{g}})^2}{2p(q^{\mathbf{g}} - d^*)}, 1\right)$, (24) is non-negative by taking π_0 into the second half of it with $C \geq 0$ under Assumption 1.

■

B. Proof of Lemma 3

Proof Based on Algorithm 1 and Algorithm 2, we have the following relationships:

$$\bar{\mathbf{w}}_1 = T(\mathbf{h}_1, Kg_0) = \text{sign}(\mathbf{h}_1)\max(|\mathbf{h}_1| - g_0 \mathbf{1}_p K, 0), \tag{25}$$

$$\hat{\mathbf{w}}_1 = T(\mathbf{h}_1, \tilde{\mathbf{k}} g_0) = \text{sign}(\mathbf{h}_1)\max(|\mathbf{h}_t| - g_0 \tilde{\mathbf{k}}_1, 0), \tag{26}$$

where

$$\mathbf{h}_1 = \mathbf{w}_0 - \sum_{t=1}^{K} \eta L'\left(\mathbf{w}_{t-1}, z_t\right).$$

Without loss of generality, we consider the difference in the squared errors to the optimal weight vector $\mathbf{w}^*$ between$\bar{\mathbf{w}}_1$ and $\hat{\mathbf{w}}_1$:

$$\begin{aligned}&||\bar{\mathbf{w}}_1 - \mathbf{w}^*||^2 - ||\hat{\mathbf{w}}_1 - \mathbf{w}^*||^2 \\ =&||(\bar{\mathbf{w}}_1 - \mathbf{h}_1) - (\mathbf{w}^* - \mathbf{h}_1)||^2 - ||(\hat{\mathbf{w}}_1 - \mathbf{h}_1) - (\mathbf{w}^* - \mathbf{h}_1)||^2 \\ =&\left(||\bar{\mathbf{w}}_1 - \mathbf{h}_1||^2 - ||\hat{\mathbf{w}}_1 - \mathbf{h}_1||^2\right) - 2\left[(\bar{\mathbf{w}}_1 - \mathbf{h}_1)^T(\mathbf{w}^* - \mathbf{h}_1) - (\hat{\mathbf{w}}_1 - \mathbf{h}_1)^T(\mathbf{w}^* - \mathbf{h}_1)\right].\end{aligned} \tag{27}$$

In the first part of (27), based on (25) and (26), we have

$$\begin{aligned}||\bar{\mathbf{w}}_1 - \mathbf{h}_1||^2 &= pK^2 g_0^2, \\ ||\hat{\mathbf{w}}_1 - \mathbf{h}_1||^2 &= ||\tilde{\mathbf{k}}_1||^2 g_0^2,\end{aligned}$$

where $\tilde{\mathbf{k}}_1$ is the counter of informative updates in the first burst with $\tilde{k}_{1,j} \leq K$ for $j = 1, \ldots, p$. Hence,

$$||\bar{\mathbf{w}}_1 - \mathbf{h}_1||^2 - ||\hat{\mathbf{w}}_1 - \mathbf{h}_1||^2 \geq 0. \tag{28}$$

Based on (25) and (26),

$$\begin{aligned}(\bar{\mathbf{w}}_1 - \mathbf{h}_t)^T \mathbf{h}_1 &= -g_0 \sum_{j=1}^{p} \text{sign}(h_{1,j}) K \mathbf{h}_{1,j} = -g_0 K ||\mathbf{h}_t||_1, \\ (\hat{\mathbf{w}}_1 - \mathbf{h}_t)^T \mathbf{h}_1 &= -g_0 \sum_{j=1}^{p} \text{sign}(h_{1,j}) \tilde{k}_{1,j} \mathbf{h}_{1,j} = -g_0 ||\tilde{\mathbf{k}}_1 \mathbf{h}_t||_1.\end{aligned}$$

Thus in the second part of (27), we have

$$\begin{aligned}&-2\left[(\bar{\mathbf{w}}_1 - \mathbf{h}_1)^T(\mathbf{w}^* - \mathbf{h}_1) - (\hat{\mathbf{w}}_1 - \mathbf{h}_1)^T(\mathbf{w}^* - \mathbf{h}_1)\right] \\ =&\left[(\bar{\mathbf{w}}_1 - \mathbf{h}_1)^T \mathbf{h}_1 - (\hat{\mathbf{w}}_1 - \mathbf{h}_1)^T \mathbf{h}_1\right] - \left[(\bar{\mathbf{w}}_1 - \mathbf{h}_1)^T \mathbf{w}^* - (\hat{\mathbf{w}}_1 - \mathbf{h}_1)^T \mathbf{w}^*\right] \\ =&2g_0\left[\left(K\|\mathbf{h}_1\|_1 - \|\tilde{\mathbf{k}}_1 \mathbf{h}_1\|_1\right) - (\bar{\mathbf{w}}_1 - \hat{\mathbf{w}}_1)^T \mathbf{w}^*\right].\end{aligned} \tag{29}$$

Since $K \geq \tilde{k}_{1,j}$ for $j = 1, \ldots, p$, the first part of (29) is guaranteed to be nonnegative. In the second part of (29) , let $\hat{w}_{1,j} = \hat{v}_{1,j} I(|h_{1,j}| > \tilde{k}_{1,j} g_0)$ and $\bar{w}_{1,j} = \bar{v}_{1,j} I(|h_{1,j}| > K g_0)$. Denote $\delta_t = L(w_{t-1}, z_t)$ to be the gradient of the loss function at a certain iteration. Since in this paper we consider linear prediction model,

$$\delta_t = L'(\mathbf{w}_{t-1}, z_t) = G(f_{\mathbf{w_{t-1}}}(\mathbf{x}_t))\mathbf{x}_t.$$

Hence, $\delta_{t,j} = \delta_{t,j} I(|x_{t,j}| > 0)$.

Again based on relationships in (25) and (26), we consider the following two scenarios:

- When $h_{1,j} > 0$:

$$\hat{v}_{1,j} = \sum_{t=1}^{K} \left[I(|x_{t,j}| > 0)(\delta_{t,j} - g_0) \right],$$
$$\bar{v}_{1,j} = \sum_{t=1}^{K} \left[I(|x_{t,j}| > 0)\delta_{t,j} - g_0 \right].$$

Thus,

$$\begin{aligned}
\bar{v}_{1,j} - \hat{v}_{1,j} =& - \sum_{t=1}^{K} I(|x_{t,j}| = 0) g_0, \\
\bar{w}_{1,j} - \hat{w}_{1,j} =& - \sum_{t=1}^{K} I(|x_{t,j}| = 0) g_0 I(h_{1,j} > K g_0) - \sum_{t=1}^{K} (h_{1,j} \\
& - \tilde{k}_{1,j} g_0) I(\tilde{k}_{1,j} g_0 < h_{1,j} < K g_0) \\
\leq & - \sum_{t=1}^{K} I(|x_{t,j}| = 0) g_0 I(h_{1,j} > K g_0). \qquad (30)
\end{aligned}$$

- When $h_{1,j} < 0$, similarly, we get

$$\begin{aligned}
\bar{v}_{1,j} - \hat{v}_{1,j} =& \sum_{t=1}^{K} I(|x_{t,j}| = 0) g_0, \\
\bar{w}_{1,j} - \hat{w}_{1,j} =& \sum_{t=1}^{K} I(|x_{t,j}| = 0) g_0 I(h_{1,j} < -K g_0) \\
& + \sum_{t=1}^{K} (h_{1,j} + \tilde{k}_{1,j} g_0) I(-K g_0 < h_{1,j} < -\tilde{k}_{1,j} g_0) \\
\geq & \sum_{t=1}^{K} I(|x_{t,j}| = 0) g_0 I(h_{1,j} < -K g_0). \qquad (31)
\end{aligned}$$

Hence, based on jointly we have

$$\begin{aligned}
& \mathbb{E}\left((\bar{\mathbf{w}}_1 - \hat{\mathbf{w}}_1)^T \mathbf{w}^* \right) \\
=& \sum_{j=1}^{p} \mathbb{E}((\bar{w}_{1,j} - \hat{w}_{1,j}) w_j^* | h_{1,j} > 0) \Pr(h_{1,j} > 0) + \mathbb{E}((\bar{w}_{1,j} - \hat{w}_{1,j}) w_j^* | h_{1,j} < 0) \Pr(h_{1,j} < 0) \\
\leq & - g_0 \sum_{t=1}^{K} \sum_{j=1}^{p} I(|x_{t,j}| = 0) |w_j^*| \leq 0.
\end{aligned}$$

The second inequality is derived from the condition that $\lambda_j = 0$ if $\mathbf{w}_j^* = 0$ and the following fact. Since $\mathbf{h}_1$ is the sum of K stochastic gradients descent steps and each one of the stochastic gradient

which is an unbiased estimator of the true gradient (see Bottou, 1998, for analysis), we have

$$\mathbb{E}(I(h_{1,j} < 0) w_j^*) < 0,$$
$$\mathbb{E}(I(h_{1,j} > 0) w_j^*) > 0.$$

Hence, together with (28) and (29), we have

$$||\bar{\mathbf{w}}_1 - \mathbf{w}^*||^2 - ||\hat{\mathbf{w}}_1 - \mathbf{w}^*||^2 \geq 0.$$

■

C. Proof of Theorem 1

Proof At a given time t when truncation is performed, let $\mathbf{h}_t = \mathbf{w}_{t-1} - \eta \nabla_{\mathbf{w}_{t-1}} L(\mathbf{w}_{t-1}, z)$ and let $\hat{\mathbf{w}}_t$ be the truncated but non-stabilized weight vector based on the truncation in (4) that $\hat{\mathbf{w}}_t = T(\mathbf{h}_t, g_{0,t}\tilde{\mathbf{k}}_t)$ with the base gravity $g_{0,t}$. Let $\hat{\Omega}$ be the current set of stable features and the stabilized weight vector is obtained as $\bar{\mathbf{w}}_t = \hat{\mathbf{w}}_t I_{\hat{\Omega}}$.

Firstly, we have

$$\begin{aligned}
||\hat{\mathbf{w}}_t - \mathbf{w}^*||^2 \leq & ||\mathbf{w}^* - \hat{\mathbf{w}}_t||^2 + ||\hat{\mathbf{w}}_t - \mathbf{h}_t||^2 \qquad (32) \\
= & ||\mathbf{w}^* - \mathbf{h}_t||^2 - 2(\mathbf{w}^* - \hat{\mathbf{w}}_t)^T (\hat{\mathbf{w}}_t - \mathbf{h}_t).
\end{aligned}$$

In the first part of (32),

$$\begin{aligned}
||\mathbf{w}^* - \mathbf{h}_t||^2 =& ||\mathbf{w}^* - \mathbf{w}_{t-1} + \mathbf{w}_{t-1} - \mathbf{h}_t||^2 \\
=& ||\mathbf{w}^* - \mathbf{w}_{t-1}||^2 + ||\mathbf{w}_{t-1} - \mathbf{h}_t||^2 + 2(\mathbf{w}^* - \mathbf{w}_{t-1})^T (\mathbf{w}_{t-1} - \mathbf{h}_t) \\
=& ||\mathbf{w}^* - \mathbf{w}_{t-1}||^2 + ||\mathbf{w}_{t-1} - \eta \nabla_{\mathbf{w}_{t-1}} L(\mathbf{w}_{t-1}, z) - \mathbf{w}_{t-1}||^2 \\
& + 2(\mathbf{w}^* - \mathbf{w}_{t-1})^T (\mathbf{w}_{t-1} - \mathbf{w}_{t-1} + \eta \nabla_{\mathbf{w}_{t-1}} L(\mathbf{w}_{t-1}, z)) \\
=& ||\mathbf{w}^* - \mathbf{w}_{t-1}||^2 + \eta^2 ||\nabla_{\mathbf{w}_{t-1}} L(\mathbf{w}_{t-1}, z)||^2 + 2\eta (\mathbf{w}^* - \mathbf{w}_{t-1})^T \nabla_{\mathbf{w}_{t-1}} L(\mathbf{w}_{t-1}, z). \qquad (33)
\end{aligned}$$

Since $L(w, z)$ is convex,

$$(\mathbf{w}^* - \mathbf{w}_{t-1})^T \nabla_{\mathbf{w}_{t-1}} L(\mathbf{w}_{t-1}, z) \leq L(\mathbf{w}^*, z) - L(\mathbf{w}_{t-1}, z).$$

And based on Assumption 1,

$$||\nabla_{\mathbf{w}_{t-1}} L(\mathbf{w}_{t-1}, z)||^2 \leq A L(\mathbf{w}_{t-1}, z) + B.$$

Thus (33) has the upper bound

$$||\mathbf{w}^* - \mathbf{h}_t||^2 \leq ||\mathbf{w}^* - \mathbf{w}_{t-1}||^2 + \eta^2 (A L(\mathbf{w}_{t-1}, z) + B) + 2\eta \left[L(\mathbf{w}^*, z) - L(\mathbf{w}_{t-1}, z) \right].$$

In the second part of (32), since $\hat{\mathbf{w}}_t = T(\mathbf{h}_t, g_t)$, $\hat{\mathbf{w}}_t = \text{sign}(\mathbf{h}_t) \max(|\mathbf{h}_t| - g_{0,t}\tilde{\mathbf{k}}_t, 0)$ and thus

$$(\hat{\mathbf{w}}_t - \mathbf{h}_t)^T \hat{\mathbf{w}}_t = -g_{0,t} \sum_{j=1}^{p} \text{sign}(h_{t,j}) \tilde{k}_{t,j} \hat{\mathbf{w}}_{t,j} = -g_{0,t} ||\tilde{\mathbf{k}}_t \hat{\mathbf{w}}_t||_1.$$

Then

$$\begin{aligned}-(\mathbf{w}^* - \hat{\mathbf{w}}_t)^T(\hat{\mathbf{w}}_t - \mathbf{h}_t) &= -(\mathbf{w}^*)^T(\hat{\mathbf{w}}_t - \mathbf{h}_t) + \hat{\mathbf{w}}_t^T(\hat{\mathbf{w}}_t - \mathbf{h}_t) \\ &\leq -\sum_{j=1}^{p} |w_j^*||\hat{w}_{t,j} - h_{t,j}| - g_{0,t}||\tilde{\mathbf{k}}_t\hat{\mathbf{w}}_t||_1 \\ &\leq -g_{0,t}\sum_{j=1}^{p} |\tilde{k}_{t,j}w_j^*| - g_{0,t}||\tilde{\mathbf{k}}_t\hat{\mathbf{w}}_t||_1 \\ &\leq -Kg_{0,t}\sum_{j=1}^{p} |w_j^*| - Kg_{0,t}||\hat{\mathbf{w}}_t||_1 \\ &= -Kg_{0,t}\left(||\mathbf{w}^*||_1 - ||\hat{\mathbf{w}}_t||_1\right).\end{aligned}$$

The second last inequality is due to $\tilde{k}_{j,t} \leq K$ for all $j = 1, \ldots, p$.

Thus, in total, equation (32) has the upper bound

$$\begin{aligned}||\hat{\mathbf{w}}_t - \mathbf{w}^*||^2 \leq ||\mathbf{w}^* - \mathbf{w}_{t-1}||^2 + \eta^2(AL(\mathbf{w}_{t-1}, z) + B) \\ + 2\eta\left[L(\mathbf{w}^*, z) - L(\mathbf{w}_{t-1}, z)\right] + 2Kg_{0,t}\left(||\mathbf{w}^*||_1 - ||\hat{\mathbf{w}}_t||_1\right).\end{aligned} \tag{34}$$

On the other hand, from Lemma 2 we have

$$\mathbb{E}\left(||\hat{\mathbf{w}}_t - \mathbf{w}^*||^2 - ||\tilde{\mathbf{w}}_t - \mathbf{w}^*||^2\right) \geq \varepsilon^2(|\hat{S}_\varepsilon| - |\hat{\Omega}|) + 2\pi_0 C^2\left[\left(1 - \frac{q^{\mathbf{g_t}}}{2\pi_0 p - p}\right)q^{\mathbf{g}_t} - d^*\right], \tag{35}$$

where $\mathbf{g}_t = g_{0,t}\tilde{\mathbf{k}}_t$.

Since $\pi_0 \in \left(\frac{1}{2} + \frac{(q^{\mathbf{g}})^2}{2p(q^{\mathbf{g}} - d^*)}, 1\right)$ and, by Assumption 3, $q^{\mathbf{g}} > d^*$ for $t = 1, \ldots, T$, we have

$$2\pi_0 C^2\left[\left(1 - \frac{q^{\mathbf{g}_t}}{2\pi_0 p - p}\right)q^{\mathbf{g}_t} - d^*\right] \geq 0, \quad \text{for } t = 1, \ldots, T.$$

Thus, we can further write (35) as

$$\mathbb{E}\left(||\tilde{\mathbf{w}}_t - \mathbf{w}^*||^2\right) \leq \mathbb{E}\left(||\hat{\mathbf{w}}_t - \mathbf{w}^*||^2\right) - \varepsilon^2(|\hat{S}_\varepsilon| - |\hat{\Omega}|). \tag{36}$$

By rearranging (36) and combining it with (34), we get

$$\begin{aligned}&\mathbb{E}\left(\left(1 - \frac{1}{2}\eta A\right)L(\mathbf{w}_{t-1}, z_t) + \frac{Kg_{0,t}}{\eta}||\mathbf{w}_{t-1}||_1\right) \\ \leq&\mathbb{E}\left(L(\mathbf{w}^*, z_t) + \frac{Kg_{0,t}}{\eta}||\mathbf{w}^*||_1\right) + \frac{1}{2\eta}\mathbb{E}\left(||\mathbf{w}^* - \mathbf{w}_{t-1}||^2 - ||\mathbf{w}^* - \tilde{\mathbf{w}}_t||^2\right) + \frac{\eta B}{2} \\ &- \frac{\varepsilon^2}{2\eta}(|\hat{S}_{\varepsilon t}| - |\hat{\Omega}|).\end{aligned} \tag{37}$$

Based on Algorithm 3, let $\underline{\mathbf{w}}_t$ be the output weight vector at the end of time t and let $\underline{g}_t$ be the applied gravity parameter at time t, where

$$\underline{g}_{0,t} = \begin{cases} \frac{g_{0,t}}{\eta}, & \text{if } t/K \text{ is an integer;} \\ 0, & \text{otherwise.}\end{cases}$$

$$\underline{g}_t = \begin{cases} \tilde{\mathbf{k}}\frac{g_{0,t}}{\eta}, & \text{if } t/K \text{ is an integer;} \\ 0, & \text{otherwise.}\end{cases}$$

and,

$$\underline{\mathbf{w}}_t = \begin{cases} \tilde{\mathbf{w}}_t, & \text{if } t/(Kn_K) \text{ is an integer;} \\ \hat{\mathbf{w}}_t, & \text{otherwise.}\end{cases}$$

By initializing the weight vector as a vector of zeros of length p, we sum up (37) over $t = 1, \ldots, T$ with telescoping to obtain the following result:

$$\begin{aligned}&\left(1 - \frac{1}{2}\eta A\right)\mathbb{E}\left(\sum_{t=1}^{T}\left[L(\underline{\mathbf{w}}_t, z_t) + \frac{K\underline{g}_{0,t}}{1 - 1/2\eta A}||\underline{\mathbf{w}}_t||_1\right]\right) \\ \leq&\mathbb{E}\left(\sum_{t=1}^{T} L(\mathbf{w}^*, z_t) + K\underline{g}_{0,t}||\mathbf{w}^*||_1\right) + \frac{1}{2\eta}\mathbb{E}\left(||\mathbf{w}^* - \underline{\mathbf{w}}_1||^2 - ||\mathbf{w}^* - \underline{\mathbf{w}}_T||^2\right) + \frac{\eta BT}{2} \\ &- \frac{1}{2\eta}\sum_{t=1}^{T}\varepsilon_t^2 I(\frac{t}{Kn_K} \in \mathbb{Z})(|\hat{S}_{\varepsilon,t}| - |\hat{\Omega}_t|) \\ \leq&\mathbb{E}\left(\sum_{t=1}^{T} L(\mathbf{w}^*, z_t) + K\underline{g}_{0,t}||\mathbf{w}^*||_1\right) + \frac{||\mathbf{w}^*||^2}{2\eta} + \frac{\eta BT}{2} - \frac{1}{2\eta}\sum_{t=1}^{T}\varepsilon_t^2 I(\frac{t}{Kn_K} \in \mathbb{Z})(|\hat{S}_{\varepsilon,t}| - |\hat{\Omega}_t|).\end{aligned} \tag{38}$$

The theorem follows by rearrange terms in (38) and that $\tilde{k}_{t,j} \leq K$ for $j = 1, \ldots, p$ and $t = 1, \ldots, T$.

Abstract

We consider the submodular function minimization (SFM) and the quadratic minimization problems regularized by the Lovász extension of the submodular function. These optimization problems are intimately related; for example, min-cut problems and total variation denoising problems, where the cut function is submodular and its Lovász extension is given by the associated total variation. When a quadratic loss is regularized by the total variation of a cut function, it thus becomes a total variation denoising problem and we use the same terminology in this paper for "general" submodular functions. We propose a new active-set algorithm for total variation denoising with the assumption of an oracle that solves the corresponding SFM problem. This can be seen as local descent algorithm over ordered partitions with explicit convergence guarantees. It is more flexible than the existing algorithms with the ability for warm-restarts using the solution of a closely related problem. Further, we also consider the case when a submodular function can be decomposed into the sum of two submodular functions F_1 and F_2 and assume SFM oracles for these two functions. We propose a new active-set algorithm for total variation denoising (and hence SFM by thresholding the solution at zero). This algorithm also performs local descent over ordered partitions and its ability to warm start considerably improves the performance of the algorithm. In the experiments, we compare the performance of the proposed algorithms with state-of-the-art algorithms, showing that it reduces the calls to SFM oracles.

Keywords: discrete optimization, submodular function minimization, convex optimization, cut functions, total variation denoising.

1. Introduction

Submodular optimization problems such as total variation denoising and submodular function minimization are convex optimization problems which are common in computer vision, signal processing and machine learning (Bach, 2013), with notable applications to graph cut-based image segmentation (Boykov et al., 2001), sensor placement (Krause and Guestrin, 2011), or document summarization (Lin and Bilmes, 2011).

Let F be a normalized submodular function defined on $V = \{1, \dots, n\}$, i.e., $F : 2^V \to \mathbb{R}$ such that $F(\varnothing) = 0$ and an n-dimensional real vector u, i.e., $u \in \mathbb{R}^n$. In this paper, we consider the submodular function minimization (SFM) problem,

$$\min_{A \subset V} F(A) - u(A), \tag{1}$$

where we use the convention $u(A) = u^\top 1_A$ and $1_A \in \{0,1\}^n$ is the indicator vector of the set A. Note that general submodular functions can always be decomposed into a normalized submodular function, F, i.e., $F(\varnothing) = 0$ and a modular function u (see Bach, 2013).

Let f be the Lovász extension of the submodular function F. Let us consider the following continuous optimization problem

$$\min_{w \in [0,1]^n} f(w) - u^\top w. \tag{2}$$

As a consequence of submodularity, the discrete and continuous optimization problems in Eq. 1 and Eq. 2 respectively have the same optimal solutions (Lovász, 1982). Let us consider another related continuous optimization problem

$$\min_{w \in \mathbb{R}^n} f(w) - u^\top w + \tfrac{1}{2}\|w\|_2^2. \tag{3}$$

If F is a cut function in a weighted undirected graph, then f is its associated total variation, hence the denomination of *total variation denoising* (TV) problem for Eq. 3, which we use in this paper—since it is equivalent to minimizing $\frac{1}{2}\|u - w\|_2^2 + f(w)$. The unique solution of the total variation denoising in Eq. 3 can be used to obtain the solution of the SFM problem in Eq. 1 by thresholding at 0. Conversely, we may obtain the optimal solution of the total variation denoising in Eq. 3 by solving a series of SFM problems using divide-and-conquer strategy.

Relationship with existing work. Generic algorithms to optimize SFM in Eq. 1 or TV in Eq. 3 problems which only access F through function values, e.g., subgradient descent or min-norm-point algorithm (Fujishige, 1984), are too slow without any assumptions (Bach, 2013), as for signal processing applications, high precision is typically required (and often the exact solution).

For decomposable problems, i.e., when $F = F_1 + \cdots + F_r$, where each F_j is "simple", some algorithms use more powerful oracles than function evaluations, improving the running times. These powerful oracles include SFM oracles that can solve the SFM problem of simple submodular function, F_j given by

$$\min_{A \subset V} F_j(A) - u_j(A), \tag{4}$$

where $u_j \in \mathbb{R}^n$. The other set of powerful oracles are total variation or TV oracles, that solve TV problems of the form

$$\min_{w \in \mathbb{R}^n} f_j(w) - u_j^\top w + \tfrac{1}{2}\|w\|_2^2, \tag{5}$$

where $u_j \in \mathbb{R}^n$. Note that, in general, the exact total variation oracles are at most $O(n)$ times more expensive than their respective SFM oracle as they solve all SFM problems

$$\min_{A \subset V} F_j(A) - u_j(A) + \lambda|A|, \tag{6}$$

for all $\lambda \in \mathbb{R}$, which have at most $O(n)$ unique solutions. For more details refer to Fujishige (1980) and Bach (2013). Here, $|A|$ denotes the cardinality of the set A. There does exist a subclass of submodular functions (cut functions and other submodular functions that can be written in form of

cuts) whose total variation oracles are only $O(1)$ times more expensive than the corresponding SFM oracles but are still too expensive in practice.

Stobbe and Krause (2010) used SFM oracles instead of function value oracles but their algorithm remains slow in practice. However, when total variation oracles for each F_j are used, they become competitive (Komodakis et al., 2011; Kumar et al., 2015; Jegelka et al., 2013). Therefore, our goal is to design fast optimization strategies using only efficient SFM oracles for each function F_j rather than their expensive TV oracles (Kumar et al., 2015; Jegelka et al., 2013) to solve the SFM and TV denoising problems of F given by Eq. 1 and Eq. 3 respectively. An algorithm was proposed by Landrieu and Obozinski (2016) to search over partition space for solving Eq. 3 with the unary terms $(-u^\top w)$ replaced by a convex differentiable function but it applies only to functions F, which are cut functions.

In this paper, we exploit the polytope structure of these non-smooth optimization problems with exponentially many constraints, i.e., 2^n, where each face of the constraint set is indexed by an ordered partition of the underlying ground set $V = \{1, \dots, n\}$. The main insight of this paper is that given the main polytope associated with a submodular function (namely the base polytope described in Section 2) and an ordered partition, we may uniquely define a tangent cone of the polytope. Further, orthogonal projections onto the tangent cone may be done efficiently by isotonic regressions (Best and Chakravarti, 1990). The time needed is linear in the number of elements of the ordered partition used to define the tangent cone. We need SFM oracles only to check the optimality of the ordered partition. Given the orthogonal projection s onto the tangent cone, if the minimum of $F(A) - s(A)$ with respect to $A \subseteq V$ is positive then it is optimal. If it is not optimal, it gives us the violating constraints in the form of active-sets that enable us to generate a new ordered partition among the exponentially many ordered partitions.

Contributions. We make two main contributions:

- Given a submodular function F with an SFM oracle, we propose a new active-set algorithm for total variation denoising in Section 3, which is more efficient and flexible than existing ones. This algorithm may be seen as a local descent algorithm over ordered partitions. It has the additional advantage of allowing warm restarts, which will be beneficial when we have to solve a large number of total variation denoising problems as shown in Section 5.
- Given a decomposition of $F = F_1 + F_2$, with available SFM oracles for each F_j, we propose an active-set algorithm for total variation denoising in Section 4 (and hence for SFM by thresholding the solution at zero). These algorithms optimize over ordered partitions (one per function F_j). Following Jegelka et al. (2013) and Kumar et al. (2015), they are also naturally parallelizable. Given that only SFM oracles are needed, it is much more flexible than the algorithms requiring a TV oracle, and allow more applications as shown in Section 5.

2. Review of Submodular Analysis

A set-function $F : 2^V \to \mathbb{R}$ is submodular if $F(A) + F(B) \geqslant F(A \cup B) + F(A \cap B)$ for any subsets A, B of V. Our main motivating examples in this paper are cuts in a weighted undirected graph with weight function $a : V \times V \to \mathbb{R}_+$, which can be defined as

$$F(A) = \sum_{i<j} a(i,j) |1_{i \in A} - 1_{j \notin A}|, \tag{7}$$

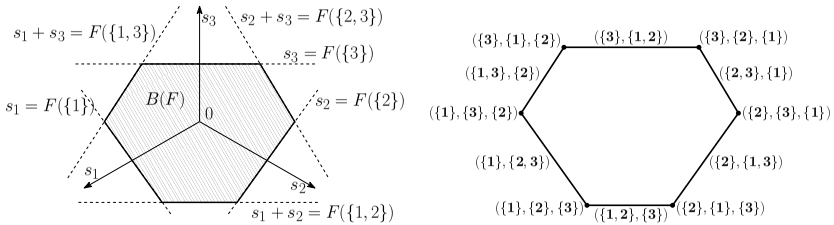

Figure 1: Base polytope for $n=3$. (a) definition from its supporting hyperplanes $\{s(A) = F(A)\}$. (b) each face (point or segment) of $B(F)$ is associated with an ordered partition.

where $i, j \in V$. Note that there are other submodular functions on which our algorithm works, e.g., concave function on the cardinality set, which *cannot* be represented in the form of Eq. 7 (Ladicky et al., 2010; Kolmogorov, 2012). However, we use cut functions as a running example to better explain our algorithm as they are most widely studied and understood among submodular functions. We now review the relevant concepts from submodular analysis (for more details, see Bach, 2013; Fujishige, 2005).

Lovász extension and convexity. The power set 2^V is naturally identified with the vertices $\{0,1\}^n$ of the hypercube in n dimensions (going from $A \subseteq V$ to $1_A \in \{0,1\}^n$). Thus, any set-function may be seen as a function f on $\{0,1\}^n$. It turns out that f may be extended to the full hypercube $[0,1]^n$ by piecewise-linear interpolation, and then to the whole vector space $\mathbb{R}^n$.

Given a vector $w \in \mathbb{R}^n$, and given its *unique* level-set representation as $w = \sum_{i=1}^m v_i 1_{A_i}$, with $(A_1, \dots, A_m)$ a partition of V and $v_1 > \cdots > v_m$, $f(w)$ is equal to $f(w) = \sum_{i=1}^m v_i \big[F(B_i) - F(B_{i-1})\big]$, where $B_i = (A_1 \cup \cdots \cup A_i)$. For cut functions, the Lovász extension happens to be equal to the *total variation*, $f(w) = \sum_{i<j} a(i,j)|w_i - w_j|$, hence our denomination total variation denoising for the problem in Eq. 3.

This extension is piecewise linear for any set-function F. It turns out that it is convex if and only if F is submodular (Lovász, 1982). Any piecewise linear convex function may be represented as the support function of a certain polytope K, i.e., as $f(w) = \max_{s \in K} w^\top s$ (Rockafellar, 1997). For the Lovász extension of a submodular function, there is an explicit description of K, which we now review.

Base polytope. We define the *base polytope* as

$$B(F) = \big\{ s \in \mathbb{R}^n,\ s(V) = F(V),\ \forall A \subset V, s(A) \leqslant F(A) \big\}.$$

Given that it is included in the affine hyperplane $\{s(V) = F(V)\}$, it is traditionally represented by the projection on that hyperplane (see Figure 1 (a)). A key result in submodular analysis is that the Lovász extension is the support function of $B(F)$, that is, for any $w \in \mathbb{R}^n$,

$$f(w) = \sup_{s \in B(F)} w^\top s. \tag{8}$$

The maximizers above may be computed in closed form from an ordered level-set representation of w using a greedy algorithm, which (a) first sorts the elements of w in decreasing order such

that $w_{\sigma(1)} \geq \ldots \geq w_{\sigma(n)}$ where σ represents the order of the elements in V; and (b) computes $s_{\sigma(k)} = F(\{\sigma(1), \ldots, \sigma(k)\}) - F(\{\sigma(1), \ldots, \sigma(k-1)\})$.

SFM as a convex optimization problem. Another key result of submodular analysis is that minimizing a submodular function F (i.e., minimizing the Lovász extension f on $\{0,1\}^n$), is equivalent to minimizing the Lovász extension f on the full hypercube $[0,1]^n$ (a convex optimization problem). Moreover, with convex duality we have

$$\begin{aligned}\min_{A \subseteq V} F(A) - u(A) &= \min_{w \in \{0,1\}^n} f(w) - u^\top w = \min_{w \in [0,1]^n} f(w) - u^\top w \\ &= \min_{w \in [0,1]^n} \max_{s \in B(F)} s^\top w - u^\top w \\ &= \max_{s \in B(F)} \min_{w \in [0,1]^n} s^\top w - u^\top w = \max_{s \in B(F)} \sum_{i=1}^n \min\{s_i - u_i, 0\}.\end{aligned}$$

This dual problem allows to obtain certificates of optimality for the primal-dual pairs $w \in [0,1]^n$ and $s \in B(F)$ using the quantity

$$\text{gap}(w,s) := f(w) - u^\top w - \sum_{i=1}^n \min\{s_i - u_i, 0\},$$

which is always non-negative. It is equal to zero only at optimality and the corresponding (w,s) form an optimal primal-dual pair.

Total variation denoising as projection onto the base polytope. A consequence of the representation of f as a support function leads to the following primal/dual pair (Bach, 2013, Sec. 8):

$$\begin{aligned}\min_{w \in \mathbb{R}^n} f(w) - u^\top w + \tfrac{1}{2}\|w\|_2^2 &= \min_{w \in \mathbb{R}^n} \max_{s \in B(F)} s^\top w - u^\top w + \tfrac{1}{2}\|w\|_2^2 \text{ using Eq. 8,} \\ &= \max_{s \in B(F)} \min_{w \in \mathbb{R}^n} s^\top w - u^\top w + \tfrac{1}{2}\|w\|_2^2, \\ &= \max_{s \in B(F)} -\tfrac{1}{2}\|s - u\|_2^2, \end{aligned} \quad (9)$$

with $w = u - s$ at optimality. Thus the TV problem is equivalent to the orthogonal projection of u onto $B(F)$.

From TV denoising to SFM. The SFM problem in Eq. 1 and the TV problem in Eq. 3 are tightly connected. Indeed, given the unique solution w of the TV problem, we obtain a solution of $\min_{A \subseteq V} F(A) - u(A)$ by thresholding w at 0, i.e., by taking $A = \{i \in V, w_i \geqslant 0\}$ (Fujishige, 1980).

Conversely, one may solve the TV problem by an appropriate sequence of SFM problems. The original divide-and-conquer algorithm may involve $O(n)$ SFM problems (Groenevelt, 1991). The extended algorithm of Jegelka et al. (2013) can reach a precision ε in $O(\log \frac{1}{\varepsilon})$ iterations but can only get the exact solution in $O(n)$ oracles. Fast efficient algorithms are proposed to solve TV problems with $O(1)$ oracles (Chambolle and Darbon, 2009; Goldfarb and Yin, 2009) but are specific to cut functions on simple graphs (chains and trees) as they exploit the weight representation given by Eq. 7. Our algorithm in Section 3 is a generalization of the divide-and-conquer strategy for solving the TV problem with general submodular functions.

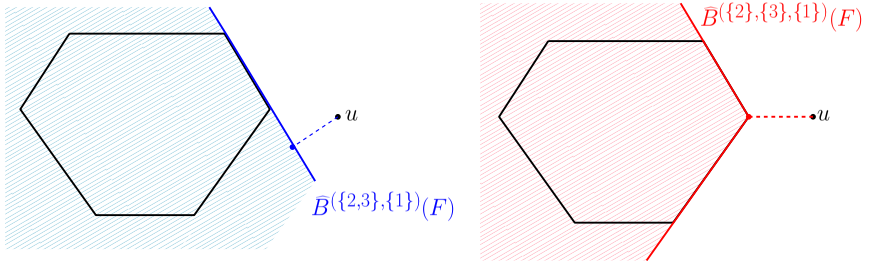

Figure 2: Projection algorithm for a single polytope: first projecting on the outer approximation $\widehat{B}^{(\{2,3\},\{1\})}(F)$, with a projected element which is not in $B(F)$ (blue), then on $\widehat{B}^{(\{2\},\{3\},\{1\})}(F)$, with a projected element being the projection of s onto $B(F)$ (red).

3. Ordered Partitions and Isotonic Regression

The main insight of this paper is (a) to consider the detailed face structure of the base polytope $B(F)$ and (b) to notice that for the outer approximation of $B(F)$ based on the tangent cone to a certain face, the orthogonal projection problem (which is equivalent to constrained TV denoising) may be solved efficiently using a simple algorithm, originally proposed to solve isotonic regression in linear time. This allows an explicit efficient local search over ordered partitions.

3.1 Outer Approximations of $B(F)$

Supporting hyperplanes. The base polytope is defined as the intersection of half-spaces $\{s(A) \leqslant F(A)\}$, for $A \subseteq V$. Therefore, faces of $B(F)$ are indexed by subsets of the power set. As a consequence of submodularity (Bach, 2013; Fujishige, 2005), the faces of the base polytope $B(F)$ are characterized by "ordered partitions" $\mathcal{A} = (A_1, \ldots, A_m)$ with $V = A_1 \cup \cdots \cup A_m$. Then, a face of $B(F)$ is such that $s(B_i) = F(B_i)$ for all $B_i = A_1 \cup \cdots \cup A_i$, $i = 1, \ldots, m$. See Figure 1 (b) for the enumeration of faces for $n = 3$ based on an enumeration of all ordered partitions. Such ordered partitions are associated to vectors $w = \sum_{i=1}^m v_i 1_{A_i}$ with $v_1 > \cdots > v_m$ with all solutions of $\max_{s \in B(F)} w^\top s$ being on the corresponding face.

From a face of $B(F)$ defined by the ordered partition $\mathcal{A}$, we may define its *tangent cone* $\widehat{B}^{\mathcal{A}}(F)$ at this face as the set

$$\widehat{B}^{\mathcal{A}}(F) = \Big\{ s \in \mathbb{R}^n, s(V) = F(V), \forall i \in \{1, \ldots, m-1\}, s(B_i) \leqslant F(B_i) \Big\}. \quad (10)$$

Since we have relaxed all the constraints unrelated to $\mathcal{A}$, these are outer approximations of $B(F)$ as illustrated in Figure 2 for two ordered partitions.

Support function. We may compute the support function of $\widehat{B}^{\mathcal{A}}(F)$, which is an upper bound on $f(w)$ since this set is an outer approximation of $B(F)$ as follows:

$$\sup_{s \in \widehat{B}^{\mathcal{A}}(F)} w^\top s = \sup_{s \in \mathbb{R}^n} \inf_{\lambda \in \mathbb{R}_+^{m-1} \times \mathbb{R}} w^\top s - \sum_{i=1}^m \lambda_i (s(B_i) - F(B_i)) \text{ , using Lagrangian duality,}$$

$$
\begin{aligned}
&= \inf_{\lambda \in \mathbb{R}_+^{m-1} \times \mathbb{R}} \sup_{s \in \mathbb{R}^n} s^\top \Big(w - \sum_{i=1}^m (\lambda_i + \cdots + \lambda_m) 1_{A_i} \Big) \\
&\qquad\qquad + \sum_{i=1}^m (\lambda_i + \cdots + \lambda_m) \big[F(B_i) - F(B_{i-1}) \big], \\
&= \inf_{\lambda \in \mathbb{R}_+^{m-1} \times \mathbb{R}} \sum_{i=1}^m (\lambda_i + \cdots + \lambda_m) \big[F(B_i) - F(B_{i-1}) \big] \\
&\qquad\qquad \text{such that } w = \sum_{i=1}^m (\lambda_i + \cdots + \lambda_m) 1_{A_i}.
\end{aligned}
$$

Thus, by defining $v_i = \lambda_i + \cdots + \lambda_m$, which are decreasing, the support function is finite for w having ordered level sets corresponding to the ordered partition $\mathcal{A}$ (we then say that w is *compatible* with $\mathcal{A}$). In other words, if $w = \sum_{i=1}^m v_i 1_{A_i}$, the support functions is equal to the Lovász extension $f(w)$. Otherwise, when w is not compatible with $\mathcal{A}$, the support function is infinite.

Let us now denote $\mathcal{W}^{\mathcal{A}}$ as a set of all weight vectors w that are compatible with the ordered partition $\mathcal{A}$. This can be defined as

$$
\mathcal{W}^{\mathcal{A}} = \Big\{ w \in \mathbb{R}^n \mid \exists v \in \mathbb{R}^m, w = \sum_{i=1}^m v_i 1_{A_i}, v_1 \geq \ldots \geq v_m \Big\}.
$$

Therefore,

$$
\sup_{s \in \widehat{B}^{\mathcal{A}}(F)} w^\top s = \begin{cases} f(w) & \text{if } w \in \mathcal{W}^{\mathcal{A}}, \\ \infty & \text{otherwise.} \end{cases} \tag{11}
$$

3.2 Isotonic Regression for Restricted Problems

Given an ordered partition $\mathcal{A} = (A_1, \ldots, A_m)$ of V, we consider the original TV problem restricted to w in $\mathcal{W}^{\mathcal{A}}$. Since on this constraint set $f(w) = \sum_{i=1}^m v_i \big[F(B_i) - F(B_{i-1}) \big]$ is a linear function, this is equivalent to

$$
\min_{v \in \mathbb{R}^m} \sum_{i=1}^m v_i \big[F(B_i) - F(B_{i-1}) - u(A_i) \big] + \tfrac{1}{2} \textstyle\sum_{i=1}^m |A_i| v_i^2 \text{ such that } v_1 \geqslant \cdots \geqslant v_m. \tag{12}
$$

This may be done by isotonic regression in complexity $O(m)$ by the weighted pool-adjacent-violator algorithm (Best and Chakravarti, 1990). Typically the solution v will have some values that are equal to each other, which corresponds to merging some sets A_i. If these merges are made, we now obtain a *basic ordered partition*[1] such that our optimal w has *strictly decreasing* values. Because none of the constraints are tight, primal stationarity leads to explicit values of v given by $v_i = u(A_i)/|A_i| - (F(B_i) - F(B_{i-1}))/|A_i|$, i.e., given $\mathcal{A}$, the exact solution of the TV problem may be obtained in closed form.

Dual interpretation. Eq. 12 is a constrained TV denoising problem that minimizes the cost function in Eq. 3 but with the constraint that weights are compatible with the ordered partition $\mathcal{A}$,

1. Given a submodular function F and an ordered partition $\mathcal{A}$, when the unique solution problem in Eq. 12 is such that $v_1 > \cdots > v_m$, we say that we $\mathcal{A}$ is a *basic ordered partition* for $F - u$. Given any ordered partition, isotonic regression allows to compute a coarser partition (obtained by partially merging some sets) which is basic.

i.e., $\min_{w \in \mathcal{W}^{\mathcal{A}}} f(w) - u^\top w + \frac{1}{2}\|w\|_2^2$. The dual of the problem can be derived in exactly the same way as shown in Eq. 9 in the previous section, using the definition of the support function defined by Eq. 11. The corresponding dual is given by $\max_{s \in \widehat{B}^{\mathcal{A}}(F)} -\frac{1}{2}\|s - u\|_2^2$, with the relationship $w = u - s$ at optimality. Thus, this corresponds to projecting u onto the outer approximation of the base polytope, $\widehat{B}^{\mathcal{A}}(F)$, which only has m constraints instead of the $2^n - 1$ constraints defining $B(F)$. See an illustration in Figure 2.

3.3 Checking Optimality of a Basic Ordered Partition

Given a basic ordered partition $\mathcal{A}$, the associated $w \in \mathbb{R}^n$ obtained from Eq. 12 is optimal for the TV problem in Eq. 3 if and only if $s = u - w \in B(F)$ due to optimality conditions in Eq. 9, which can be checked by minimizing the submodular function $F - s$. For a basic partition, a more efficient algorithm is available.

By repeated application of submodularity, we have for all sets $C \subseteq V$, if $C_i = C \cap A_i$:

$$
\begin{aligned}
F(C) - s(C) &= F(V \cap C) - \sum_{i=1}^m s(C_i) \text{ (as } s \text{ is a modular function)}, \\
&= F(B_m \cap C) - \sum_{i=1}^m s(C_i) + \sum_{i=1}^{m-1} F(B_i \cap C) - F(B_i \cap C) \text{ (as } B_m = V), \\
&= \sum_{i=1}^m F(B_i \cap C) - F(B_{i-1} \cap C) - s(C_i) \text{ (let } B_0 = \varnothing \text{ and as } F(\varnothing) = 0), \\
&= \sum_{i=1}^m F((B_{i-1} \cup A_i) \cap C) - F(B_{i-1} \cap C) - s(C_i) \text{ (since } B_i = B_{i-1} \cup A_i), \\
&= \sum_{i=1}^m F((B_{i-1} \cap C) \cup (A_i \cap C)) - F(B_{i-1} \cap C) - s(C_i), \\
&= \sum_{i=1}^m F((B_{i-1} \cap C) \cup C_i) - F(B_{i-1} \cap C) - s(C_i), \\
&\geqslant \sum_{i=1}^m \big[F(B_{i-1} \cup C_i) - F(B_{i-1}) - s(C_i) \big] \\
&\qquad\qquad \text{(as } (B_{i-1} \cap C) \subseteq B_{i-1} \text{ and due to submodularity of } F).
\end{aligned}
$$

Moreover, we have $s(A_i) = F(B_i) - F(B_{i-1})$, which implies $s(B_i) = F(B_i)$ for all $i \in \{1, \ldots, m\}$, and thus all subproblems $\min_{C_i \subseteq A_i} F(B_{i-1} \cup C_i) - F(B_{i-1}) - s(C_i)$ have non-positive values. This implies that we may check optimality by solving these m subproblems: s is optimal if and only if all of them have zero values. This leads to smaller subproblems whose overall complexity is less than a single SFM oracle call. Moreover, for cut functions, it may be solved by a single oracle call on a graph where some edges have been removed (Tarjan et al., 2006).

Given all sets C_i, we may then define a new ordered partition by splitting all A_i for which $F(B_{i-1} \cup C_i) - F(B_{i-1}) - s(C_i) < 0$. If no split is possible, the pair (w, s) is optimal for Eq. 3. Otherwise, this new strictly finer partition may not be basic, the value of the optimization problem

in Eq. 12 is strictly lower as shown in Section 3.5 (and leads to another basic ordered partition), which ensures the finite convergence of the algorithm.

3.4 Active-set Algorithm

This leads to the novel active-set algorithm below.

Data: Submodular function F with SFM oracle, $u \in \mathbb{R}^n$, ordered partition $\mathcal{A}$
Result: primal optimal: $w \in \mathbb{R}^n$ and dual optimal: $s \in B(F)$
while `True` **do**
  Solve Eq. 12 using isotonic regression and update $\mathcal{A}$ with the basic ordered partition ;
  Check optimality by solving $\min_{C_i \subseteq A_i} F(B_{i-1} \cup C_i) - F(B_{i-1}) - s(C_i)$ for $i \in \{1, \dots, m\}$;
  if *s is optimal* **then**
    `break` ;
  else
    for $i \in \{1, \dots, m\}$, split the set A_i into C_i and $A_i \setminus C_i$ in that order to get an updated ordered partition $\mathcal{A}$;
  end
end

Relationship with divide-and-conquer algorithm. When starting from the trivial ordered partition $\mathcal{A} = (V)$, then we exactly obtain a parallel version of the divide-and-conquer algorithm (Groenevelt, 1991), that is, the isotonic regression problem is always solved without using the constraints of monotonicity, i.e., there are no merges, it is not necessary to re-solve the problems where nothing has changed. This shows that the number of iterations is then less than n.

The key added benefits in our formulation is the possibility of warm-starting, which can be very useful for building paths of solutions with different weights on the total variation. This is also useful for decomposable functions where many TV oracles are needed with close-by inputs. See experiments in Section 5.

3.5 Proof of Convergence

In order to prove the convergence of the algorithm in Section 3.4, we only need to show that if the optimality check fails in step (4), then step (7) introduces splits in the partition, which ensures that the isotonic regression in step (2) of the next iteration has a strictly lower value. Let us recall the isotonic regression problem solved in step (2):

$$\min_{v \in \mathbb{R}^m} \sum_{i=1}^{m} \Big(v_i \big[F(B_i) - F(B_{i-1}) - u(A_i) \big] + \tfrac{1}{2} |A_i| v_i^2 \Big) \tag{13}$$

$$\text{such that } v_1 \geqslant \cdots \geqslant v_m. \tag{14}$$

Steps (2) ensures that the ordered partition $\mathcal{A}$ is a basic ordered partition warranting that the inequality constraints are strict, i.e., no two partitions have the same value v_i and the values v_i for each element of the partition $i = \{1, \dots, m\}$ is given through

$$v_i |A_i| = u(A_i) - (F(B_i) - F(B_{i-1})), \tag{15}$$

which can be calculated in closed form.

The optimality check in step (4) decouples into checking the optimality in each subproblem as shown in Section 3.3. If the optimality test fails, then there is a subset of C_i of A_i for some of elements of the partition $\mathcal{A}$ such that

$$F(B_{i-1} \cup C_i) - F(B_{i-1}) - s(C_i) < 0. \tag{16}$$

We will show that the splits introduced by step (7) strictly reduces the function value of isotonic regression in Eq. 13, while maintaining the feasibility of the problem. The splits modify the cost function of the isotonic regression as follows, as the objective function in Eq. 13 is equal to

$$\sum_{i=1}^{m} \Big(v_i \big[F(B_{i-1} \cup C_i) - F(B_{i-1}) - u(C_i) \big] + v_i \big[F(B_i) - F(B_{i-1} \cup C_i) - u(A_i \setminus C_i) \big] + \tfrac{1}{2} v_i^2 |C_i| + \tfrac{1}{2} v_i^2 |A_i \setminus C_i| \Big). \tag{17}$$

Let us assume a positive $t \in \mathbb{R}$, which is small enough. The direction that the isotonic regression moves is $v_i + t$ for the partition corresponding to C_i and $v_i - t$ for the partition corresponding to $A_i \setminus C_i$ maintaining the feasibility of the isotonic regression problem, i.e., $v_1 \geqslant \cdots \geqslant v_i + t > v_i - t \geqslant \cdots \geqslant v_m$. The function value is given by

$$\begin{aligned}
&\sum_{i=1}^{m} \Big((v_i + t) \big[F(B_{i-1} \cup C_i) - F(B_{i-1}) - u(C_i) \big] \\
&\quad + (v_i - t) \big[F(B_i) - F(B_{i-1} \cup C_i) - u(A_i \setminus C_i) \big] + \tfrac{1}{2} (v_i + t)^2 |C_i| + \tfrac{1}{2} (v_i - t)^2 |A_i \setminus C_i| \Big) \\
= \; &\sum_{i=1}^{m} \Big(\big(v_i \big[F(B_{i-1} \cup C_i) - F(B_{i-1}) - u(C_i) \big] + v_i \big[F(B_i) - F(B_{i-1} \cup C_i) - u(A_i \setminus C_i) \big] \\
&\quad + \tfrac{1}{2} v_i^2 |C_i| + \tfrac{1}{2} v_i^2 |A_i \setminus C_i| \big) + \tfrac{1}{2} t^2 |A_i| \\
&\quad + t \big(2F(B_{i-1} \cup C_i) - F(B_{i-1}) - F(B_i) - u(C_i) + u(A_i \setminus C_i) + v_i |C_i| - v_i |A_i \setminus C_i| \big) \Big).
\end{aligned}$$

From this we can compute the directional derivative of the function at $t = 0$, which is given by

$$\begin{aligned}
& 2F(B_{i-1} \cup C_i) - F(B_{i-1}) - F(B_i) - u(C_i) + u(A_i \setminus C_i) + |C_i| v_i - |A_i \setminus C_i| v_i \\
= \; & 2F(B_{i-1} \cup C_i) - F(B_{i-1}) - F(B_i) - 2u(C_i) + u(A_i) + 2|C_i| v_i - |A_i| v_i \\
= \; & 2\big(F(B_{i-1} \cup C_i) - F(B_{i-1}) - u(C_i) + v_i |C_i| \big) \text{ (substituting Eq. 15)} \\
= \; & 2\big(F(B_{i-1} \cup C_i) - F(B_{i-1}) - s(C_i) \big) < 0 \text{ (as } s = u - w \text{ and Eq. 16).}
\end{aligned}$$

This shows that the function strictly decreases with the splits introduced in step (7).

3.6 Discussion

Certificates of optimality. The algorithm has dual-infeasible iterates s (they only belong to $B(F)$ at convergence). Suppose that after step (3) we have $F(C) - s(C) \geqslant -\varepsilon$ for all $C \subset V$, where ε

shrinks as we run more iterations of the outer loop. This implies that $s \in B(F + \varepsilon 1_{\mathrm{Card} \in (1,n)})$, i.e., $s \in B(F_\varepsilon)$ with $F_\varepsilon = F + \varepsilon 1_{\mathrm{Card} \in (1,n)}$. Since by construction $w = u - s$, we have:

$$\begin{aligned} f_\varepsilon(w) - u^\top w + \tfrac{1}{2}\|w\|_2^2 + \tfrac{1}{2}\|s-u\|_2^2 &= \varepsilon \big| \max_{j \in V} w_j - \min_{j \in V} w_j \big| + f(w) - u^\top w + \|w\|^2 \\ &= \varepsilon \big| \max_{j \in V} w_j - \min_{j \in V} w_j \big| \\ &\quad + \sum_{i=1}^m v_i \big[F(B_i) - F(B_{i-1}) - u(A_i) \big] + \sum_{i=1}^m |A_i| v_i^2 \\ &= \varepsilon \big| \max_{j \in V} w_j - \min_{j \in V} w_j \big| \text{ (using Eq. 15)} \\ &= \varepsilon \, \mathrm{range}(w), \end{aligned}$$

where $\mathrm{range}(w) = \max_{k \in V} w_k - \min_{k \in V} w_k$. This means that w is approximately optimal for $f(w) - u^\top w + \frac{1}{2}\|w\|_2^2$ with *certified gap* less than $\varepsilon \, \mathrm{range}(w) + \varepsilon \, \mathrm{range}(w^*)$.

Maximal range of an active-set solution. For any ordered partition $\mathcal{A}$, and the optimal value of w (which we know in closed form), we have $\mathrm{range}(w) \leqslant \mathrm{range}(u) + \max_{i \in V} \big\{ F(\{i\}) + F(V \backslash \{i\}) - F(V) \big\}$. Indeed, for the u part of the expression, this is because values of w are averages of values of u; for the F part of the expression, we always have by submodularity:

$$\begin{aligned} F(B_i) - F(B_{i-1}) &\leqslant \sum_{k \in A_i} F(\{k\}) \text{ and} \\ F(B_i) - F(B_{i-1}) &\geqslant - \sum_{k \in A_i} F(V) - F(V \backslash \{k\}). \end{aligned}$$

This means that the certificate can be used in practice by replacing $\mathrm{range}(w^*)$ by its upperbound. See experimental evaluation for a 2D total variation denoising in Appendix A.

Exact solution. If the submodular function only takes integer values and we have an approximate solution of the TV problem with gap $\varepsilon \leqslant \frac{1}{4n}$, then we have the optimal solution (Chakrabarty et al., 2014).

Relationship with traditional active-set algorithm. Given an ordered partition $\mathcal{A}$, an active-set method solves the unconstrained optimization problem in Eq. 12 to obtain a value of v using the primary stationary conditions. The corresponding primal value $w = \sum_{i=1}^m v_i 1_{A_i}$ and dual value $s = u - w$ are optimal, if and only if,

$$\text{Primal feasibility : } w \in \mathcal{W}^{\mathcal{A}}, \tag{18}$$

$$\text{Dual feasibility : } s \in B(F). \tag{19}$$

If Eq. 18 is not satisfied, a move towards the optimal w is performed to ensure primal feasibility by performing line search, i.e., two consecutive sets A_i and A_{i+1} with increasing values $v_i < v_{i+1}$ are merged and a potential w is computed until primal feasibility is met. Then dual feasibility is checked and potential splits are proposed.

In our approach, we consider a different strategy which is more direct and does many merges simultaneously by using *isotonic regression*. Our method explicitly moves from ordered partitions to ordered partitions and computes an optimal vector w, which is always feasible.

4. Decomposable Problems

Many interesting problems in signal processing and computer vision naturally involve submodular functions F that decompose into $F = F_1 + \cdots + F_r$, with r "simple" submodular functions (Bach, 2013). For example, a cut function in a 2D grid decomposes into a function F_1 composed of cuts along vertical lines and a function F_2 composed of cuts along horizontal lines. For both of these functions, SFM oracles may be solved in $O(n)$ by message passing. For simplicity, in this paper, we consider the case $r = 2$ functions, but following Komodakis et al. (2011) and Jegelka et al. (2013), our framework easily extends to $r > 2$.

4.1 Reformulation as the Distance Between Two Polytopes

Following Jegelka et al. (2013), we have the primal/dual problems :

$$\begin{aligned} \min_{w \in \mathbb{R}^n} f_1(w) + f_2(w) - u^\top w + \tfrac{1}{2}\|w\|_2^2 &= \min_{w \in \mathbb{R}^n} \max_{s_1 \in B(F_1),\, s_2 \in B(F_2)} w^\top (s_1 + s_2) - u^\top w + \tfrac{1}{2}\|w\|_2^2 \\ &= \max_{s_1 \in B(F_1),\, s_2 \in B(F_2)} \min_{w \in \mathbb{R}^n} (s_1 + s_2 - u)^\top w + \tfrac{1}{2}\|w\|_2^2 \\ &= \max_{s_1 \in B(F_1),\, s_2 \in B(F_2)} -\tfrac{1}{2}\|s_1 + s_2 - u\|_2^2, \end{aligned} \tag{20}$$

with $w = u - s_1 - s_2$ at optimality.

This is the projection of u on the sum of the base polytopes $B(F_1) + B(F_2) = B(F)$. Further, this may be interpreted as finding the distance between two polytopes $B(F_1) - u/2$ and $u/2 - B(F_2)$. Note that these two polytopes typically do not intersect (they will if and only if $w = 0$ is the optimal solution of the TV problem, which is an uninteresting situation). We now review Alternating projections (AP) (Jegelka et al., 2013), Averaged alternating reflections (AAR) (Jegelka et al., 2013) and Dykstra's alternating projections (DAP) (Chambolle and Pock, 2015) to show that a large number of total variation denoising problems need to be solved to obtain an optimal solution of Eq. 20. The ability to warm start and solve these total variation denoising using our algorithm in Section 3.4 can greatly improve the performance of each of these algorithms.

Alternating projections (AP). The alternating projection algorithm (Bauschke et al., 1997) was proposed to solve the convex feasibility problem, i.e., to obtain a feasible point in the intersection of two polytopes. It is equivalent to performing block coordinate descent on the dual derived in Eq. 20. Let us denote the projection onto a polytope K as Π_K, i.e., $\Pi_K(y) = \mathrm{argmax}_{x \in K} -\|x - y\|_2^2$. Therefore, alternating projections lead to the following updates for our problem.

$$z_t = \Pi_{u/2 - B(F_2)} \Pi_{B(F_1) - u/2}(z_{t-1}),$$

where z_0 is an arbitrary starting point. Thus each of these steps require TV oracles for F_1 and F_2 since projection onto the base polytope is equivalent to performing TV denoising as shown in Eq. 9.

Averaged alternating reflections (AAR). The averaged alternating reflection algorithm (Bauschke et al., 2004), which is also known as Douglas-Rachford splitting can be used to solve convex feasibility problems. It is observed to converge quicker than alternating projection (Jegelka et al., 2013; Kumar et al., 2015) in practice. We now introduce a reflection operator for the polytope K as R_K, i.e., $R_K = 2\Pi_K - I$, where I is the identity operator. Therefore, reflection of t on a polytope K is

given by $R_K(t) = 2\Pi_K(t) - t$. The updates of each iteration of the averaged alternating reflections, which starts with an auxiliary sequence z_0 initialized to 0 vector, are given by

$$z_t = \tfrac{1}{2}(I + R_{u/2-B(F_2)} R_{B(F_1)-u/2})(z_{t-1}).$$

In the feasible case, i.e., intersecting polytopes, the sequence z_t weakly converges to a point in the intersection of the polytopes. However, in our case, we have non intersecting polytopes which leads to a converging sequence of z_t with AP but a diverging sequence of z_t with AAR. However, when we project z_t by using the projection operation, $s_{1,t} = \Pi_{B(F_1)-u/2}(z_t)$; $s_{2,t} = \Pi_{u/2-B(F_2)}(s_{1,t})$ the sequences $s_{1,t}$ and $s_{2,t}$ converge to the nearest points on the polytopes, $B(F_1) - u/2$ and $u/2 - B(F_2)$ (Bauschke et al., 2004) respectively.

Dykstra's alternating projections (DAP). Dykstra's alternating projection algorithm (Bauschke and Borwein, 1994) retrieves a convex feasible point closest to an arbitrary point, which we assume to be 0. It can also be used and has a form of primal descent interpretation, i.e., as coordinate descent for a well-formulated primal problem (Gaffke and Mathar, 1989). Let us denote ι_K as the indicator function of a convex set K. In our case we consider finding the nearest points on the polytopes $B(F_1) - u/2$ and $u/2 - B(F_2)$ closest to 0, which can be formally written as:

$$\begin{aligned}
&\min_{\substack{s\in B(F_1)-\frac{u}{2}\\ s\in \frac{u}{2}-B(F_2)}} \frac{1}{2}\|s\|_2^2 \\
= \;& \min_{s\in\mathbb{R}^n} \frac{1}{2}\|s\|_2^2 + \iota_{B(F_1)-\frac{u}{2}}(s) + \iota_{\frac{u}{2}-B(F_2)}(s) \\
= \;& \min_{s\in\mathbb{R}^n} \frac{1}{2}\|s\|_2^2 + \iota_{B(F_1)-\frac{u}{2}}(s) + \iota_{B(F_2)-\frac{u}{2}}(-s) \\
= \;& \min_{s\in\mathbb{R}^n} \left(\frac{1}{2}\|s\|_2^2 + \max_{w_1\in\mathbb{R}^n} w_1^\top s - f_1(w_1) + \frac{w_1^\top u}{2} + \max_{w_2\in\mathbb{R}^n} -w_2^\top s - f_2(w_2) + \frac{w_2^\top u}{2}\right) \\
= \;& \max_{\substack{w_1\in\mathbb{R}^n\\ w_2\in\mathbb{R}^n}} \left(- f_1(w_1) - f_2(w_2) + \frac{(w_1+w_2)^\top u}{2} + \min_{s\in\mathbb{R}^n}\left(\frac{1}{2}\|s\|_2^2 + (w_1-w_2)^\top s\right)\right) \\
= \;& \max_{\substack{w_1\in\mathbb{R}^n\\ w_2\in\mathbb{R}^n}} -f_1(w_1) - f_2(w_2) + \frac{(w_1+w_2)^\top u}{2} - \frac{1}{2}\|w_1-w_2\|_2^2 \\
= \;& \min_{\substack{w_1\in\mathbb{R}^n\\ w_2\in\mathbb{R}^n}} f_1(w_1) + f_2(w_2) - \frac{(w_1+w_2)^\top u}{2} + \frac{1}{2}\|w_1-w_2\|_2^2,
\end{aligned}$$

where $s = w_2 - w_1$ at optimality. The block coordinate descent algorithm then gives

$$\begin{aligned}
w_{1,t} &= \text{prox}_{f_1-u/2}(w_{2,t-1}) = (I - \Pi_{B(F_1)-u/2})(w_{2,t-1}), \\
s_{1,t} &= w_{2,t-1} - w_{1,t}, \\
w_{2,t} &= \text{prox}_{f_2-u/2}(w_{1,t}) = (I - \Pi_{B(F_2)-u/2})(w_{1,t}), \\
s_{2,t} &= w_{1,t} - w_{2,t},
\end{aligned}$$

where I is the identity matrix. This is exactly the same as Dykstra's alternating projection steps.

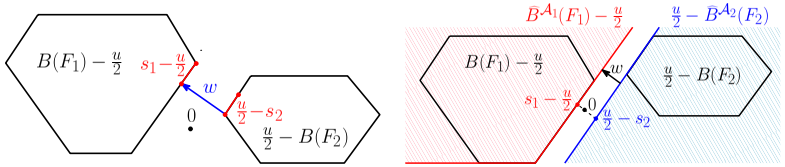

Figure 3: Closest point between two polytopes. (a) Output of Dykstra's alternating projection algorithm for the TV problem, the pair (s_1, s_2) may not be unique while $w = s_1 + s_2 - u$ is. (b) Dykstra's alternating projection output for outer approximations.

We have implemented it, and it behaves similar to alternating projections, but it still requires TV oracles for projection (see experiments in Section 5). There is however a key difference: while alternating projections and alternating reflections always converge to a pair of closest points, Dykstra's alternating projection algorithm converges to a *specific* pair of points, namely the pair closest to the initialization of the algorithm (Bauschke and Borwein, 1994); see an illustration in Figure 3-(a). This insight will be key in our algorithm to avoid cycling.

Assuming TV oracles are available for F_1 and F_2, Jegelka et al. (2013) and Kumar et al. (2015) use alternating projection (Bauschke et al., 1997) and alternating reflection (Bauschke et al., 2004) algorithms to solve dual optimization problem in Eq. 20 . Nishihara et al. (2014) gave a extensive theoretical analysis of alternating projection and showed that it converges linearly. However, these algorithms are equivalent to block *dual* coordinate descent and cannot be cast explicitly as descent algorithms for the primal TV problem. On the other hand, Dykstra's alternating projection is a descent algorithm on the primal, which enables local search over partitions. Complex TV oracles are often implemented by using SFM oracles recursively with the divide-and-conquer strategy on the individual functions. Using our algorithm in Section 3.4, they can be made more efficient using warm-starts (see experiments in Section 5).

4.2 Local Search over Partitions using Active-set Method

Given our algorithm for a single function, it is natural to perform a local search over two partitions $\mathcal{A}_1$ and $\mathcal{A}_2$, one for each function F_1 and F_2, and consider in the primal formulation a weight vector w compatible with both $\mathcal{A}_1$ and $\mathcal{A}_2$; or, equivalently, in the dual formulation, two outer approximations $\widehat{B}^{\mathcal{A}_1}(F_1)$ and $\widehat{B}^{\mathcal{A}_2}(F_2)$. That is, given the ordered partitions $\mathcal{A}_1$ and $\mathcal{A}_2$, using a similar derivation as in Eq. 20, we obtain the primal/dual pairs of optimization problems

$$\max_{\substack{s_1\in\widehat{B}^{\mathcal{A}_1}(F_1)\\ s_2\in\widehat{B}^{\mathcal{A}_2}(F_2)}} -\tfrac{1}{2}\|u - s_1 - s_2\|_2^2 = \min_{\substack{w\in\mathcal{W}^{\mathcal{A}_1}\\ w\in\mathcal{W}^{\mathcal{A}_2}}} f_1(w) + f_2(w) - u^\top w + \tfrac{1}{2}\|w\|_2^2,$$

with $w = u - s_1 - s_2$ at optimality.

Primal solution by isotonic regression. The primal solution w is unique by strong convexity. Moreover, it has to be compatible with both $\mathcal{A}_1$ and $\mathcal{A}_2$, which is equivalent to being compatible with the *coalesced* ordered partition $\mathcal{A} = \text{coalesce}(\mathcal{A}_1, \mathcal{A}_2)$ defined as the coarsest ordered partition compatible by both. As shown in Appendix B, $\mathcal{A}$ may be found in time $O(\min(m_1, m_2)n)$.

Given $\mathcal{A}$, the primal solution w of the subproblem may be found by isotonic regression like in Section 3.2 in time $O(m)$ where m is the number of sets in $\mathcal{A}$. However, finding the optimal dual variables s_1 and s_2 turns out to be more problematic. We know that $s_1 + s_2 = u - w$ and that $s_1 + s_2 \in \widehat{B}^{\mathcal{A}}(F)$, but the split of $s_1 + s_2$ into (s_1, s_2) is unknown.

Obtaining dual solutions. Given ordered partitions $\mathcal{A}_1$ and $\mathcal{A}_2$, a unique well-defined pair (s_1, s_2) could be obtained by using convex feasibility algorithms such as alternating projections (Bauschke et al., 1997) or alternating reflections (Bauschke et al., 2004). However, the result would depend in non understood ways on the initialization, and we have observed cycling of the active-set algorithm. Using Dykstra's alternating projection algorithm allows us to converge to a unique well-defined pair (s_1, s_2) that will lead to a provably non-cycling algorithm.

When running the Dykstra's alternating projection algorithm starting from 0 on the polytopes $\widehat{B}^{\mathcal{A}_1}(F_1) - u/2$ and $u/2 - \widehat{B}^{\mathcal{A}_2}(F_2)$, if w is the unique distance vector between the two polytopes, then the iterates converge to the projection of 0 onto the convex sets of elements in the two polytopes that achieve the minimum distance (Bauschke and Borwein, 1994). See Figure 3-(b) for an illustration. This algorithm is however slow to converge when the polytopes do not intersect. Note that $w \neq 0$ in most of our situations and convergence is hard to monitor because primal iterates of the Dykstra's alternating projection diverge (Bauschke and Borwein, 1994).

Translated intersecting polytopes. In our situation, we have more to work with than just the ordered partitions: *we also know the vector* w (as mentioned earlier, it is obtained cheaply from isotonic regression). Indeed, from Lemma 2.2 and Theorem 3.8 from Bauschke and Borwein (1994), given this vector w, we may translate the two polytopes and now obtain a formulation where the two polytopes do intersect; that is we aim at projecting 0 on the (non-empty) intersection of $\widehat{B}^{\mathcal{A}_1}(F_1) - u/2 + w/2$ and $u/2 - w/2 - \widehat{B}^{\mathcal{A}_2}(F_2)$. See Figure 4. We also refer to this as the *translated Dykstra problem*[2] in the rest of the paper. This is equivalent to solving the following optimization problem

$$
\begin{aligned}
&\min_{\substack{s \in \widehat{B}^{\mathcal{A}_1}(F_1) - \frac{u-w}{2} \\ s \in \frac{u-w}{2} - \widehat{B}^{\mathcal{A}_2}(F_2)}} \tfrac{1}{2}\|s\|_2^2 \qquad (21)\\
&= \min_{s \in \mathbb{R}^n} \tfrac{1}{2}\|s\|_2^2 + \iota_{\widehat{B}^{\mathcal{A}_1}(F_1) - \frac{u-w}{2}}(s) + \iota_{\frac{u-w}{2} - \widehat{B}^{\mathcal{A}_2}(F_2)}(s),\\
&= \min_{s \in \mathbb{R}^n} \tfrac{1}{2}\|s\|_2^2 + \iota_{\widehat{B}^{\mathcal{A}_1}(F_1) - \frac{u-w}{2}}(s) + \iota_{\widehat{B}^{\mathcal{A}_2}(F_2) - \frac{u-w}{2}}(-s),\\
&= \min_{s \in \mathbb{R}^n} \Big(\tfrac{1}{2}\|s\|_2^2 + \max_{w_1 \in \mathcal{W}^{\mathcal{A}_1}} w_1^\top s - f_1(w_1) + \tfrac{w_1^\top (u-w)}{2} \\
&\qquad\qquad + \max_{w_2 \in \mathcal{W}^{\mathcal{A}_2}} -w_2^\top s - f_2(w_2) + \frac{w_2^\top (u-w)}{2} \Big),\\
&= \max_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} \Big(-f_1(w_1) - f_2(w_2) + \frac{(w_1+w_2)^\top (u-w)}{2} + \min_{s \in \mathbb{R}^n} \frac{1}{2}\|s\|_2^2 + (w_1 - w_2)^\top s \Big),\\
&= \max_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} \Big(-f_1(w_1) - f_2(w_2) + \frac{(w_1+w_2)^\top (u-w)}{2} - \frac{1}{2}\|w_1 - w_2\|_2^2 \Big),
\end{aligned}
$$

2. We refer to finding a Dykstra solution for translated intersecting polytopes as translated Dykstra problem.

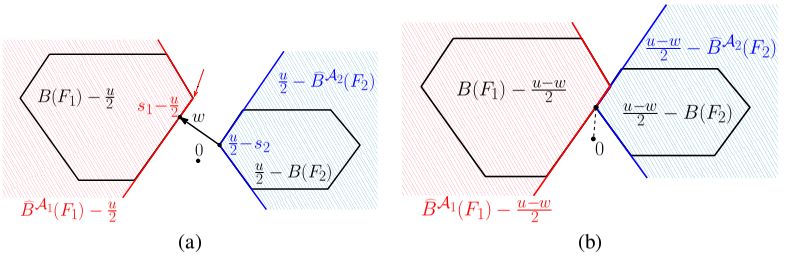

Figure 4: Translated intersecting polytopes. (a) output of our algorithm before translation. (b) Translated formulation.

$$
= \min_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} \Big(f_1(w_1) + f_2(w_2) - \frac{(w_1+w_2)^\top (u-w)}{2} + \frac{1}{2}\|w_1 - w_2\|_2^2 \Big), \qquad (22)
$$

with $s = w_2 - w_1$ at optimality.

In Section 4.4 we propose algorithms to solve the above optimization problems. Assuming that we are able to solve this step efficiently, we now present our active-set algorithm for decomposable functions below.

4.3 Active-set Algorithm for Decomposable Functions

Data: Submodular functions F_1 and F_2 with SFM oracles, $u \in \mathbb{R}^n$, ordered partitions $\mathcal{A}_1, \mathcal{A}_2$
Result: primal optimal: $w \in \mathbb{R}^n$ and dual optimal: $s_1 \in B(F_1), s_2 \in B(F_2)$

while `True` **do**
  $\mathcal{A} = \text{coalesce}(\mathcal{A}_1, \mathcal{A}_2)$;
  Estimate w by solving $\min_{w \in \mathcal{W}^{\mathcal{A}}} f(w) - u^\top w + \frac{1}{2}\|w\|_2^2$ using isotonic regression ;
  Projection step: Estimate $s_1 \in \widehat{B}^{\mathcal{A}_1}(F_1)$ and $s_2 \in \widehat{B}^{\mathcal{A}_2}(F_2)$ by projecting 0 onto the intersection of $\widehat{B}^{\mathcal{A}_1}(F_1) - u/2 + w/2$ and $u/2 - w/2 - \widehat{B}^{\mathcal{A}_2}(F_2)$ using any of the algorithms described in Section 4.4 ;
  Merge the sets in $\mathcal{A}_j$ which are tight for $s_j, j \in \{1, 2\}$;
  Check optimality of s_1 and s_2 as described in Section 3.3;
  if *s_1 and s_2 are optimal* **then**
    `break` ;
  else
    for $j \in \{1, 2\}$ and $i_j \in \{1, \dots, m_j\}$, split the set A_{j,i_j} into C_{j,i_j} and $A_{j,i_j} \setminus C_{j,i_j}$ in that order to get an updated ordered partition $\mathcal{A}_j$;
  end
end

Given two ordered partitions $\mathcal{A}_1$ and $\mathcal{A}_2$, we obtain $s_1 \in \hat{B}^{\mathcal{A}_1}(F_1)$ and $s_2 \in \hat{B}^{\mathcal{A}_2}(F_2)$ as described in the following section. The solution $w = u - s_1 - s_2$ is optimal if and only if both

$s_1 \in B(F_1)$ and $s_2 \in B(F_2)$. When checking the optimality described in Section 3.3, we split the partition. As shown in Appendix C, either (a) $\|w\|_2^2$ strictly increases at each iteration, or (b) $\|w\|_2^2$ remains constant but $\|s_1 - s_2\|_2^2$ strictly increases. This implies that the algorithm is finitely convergent.

4.4 Optimizing the "Translated Dykstra Problem"

In this section, we describe algorithms for the "projection step" of the active-set algorithm proposed in Section 4.3 that optimizes the translated Dykstra problem in Eq. 22, i.e.,

$$\min_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} f_1(w_1) + f_2(w_2) - \tfrac{(w_1+w_2)^\top (u-w)}{2} + \tfrac{1}{2}\|w_1 - w_2\|^2. \tag{23}$$

The corresponding dual optimization problem is given by

$$\min_{\substack{s \in \widehat{B}^{\mathcal{A}_1}(F_1) - \frac{u-w}{2} \\ s \in \frac{u-w}{2} - \widehat{B}^{\mathcal{A}_2}(F_2)}} \tfrac{1}{2}\|s\|_2^2, \tag{24}$$

with the optimality condition $s = w_2 - w_1$. Note that the only link to submodularity is that f_1 and f_2 are linear functions on $\mathcal{W}^{\mathcal{A}_1}$ and $\mathcal{W}^{\mathcal{A}_2}$, respectively. The rest of this section primarily deals with optimizing a quadratic program and we present two algorithms in Section 4.4.1 and Section 4.4.2.

4.4.1 ACCELERATED DYKSTRA'S ALGORITHM

In this section, we find the projection of the origin onto the intersection of the translated base polytopes obtained by solving the optimization problem in Eq. 22 given by

$$\min_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} f_1(w_1) + f_2(w_2) - \tfrac{(w_1+w_2)^\top (u-w)}{2} + \tfrac{1}{2}\|w_1 - w_2\|^2,$$

using Dykstra's alternating projection. It can be solved using the following Dykstra's iterations:

$$\begin{aligned}
s_{1,t} &= \Pi_{\widehat{B}^{\mathcal{A}_1}(F_1)}(u/2 - w/2 + w_{2,t-1}), \\
w_{1,t} &= u/2 - w/2 + w_{2,t-1} - s_{1,t}, \\
s_{2,t} &= \Pi_{\widehat{B}^{\mathcal{A}_2}(F_2)}(u/2 - w/2 + w_{1,t}), \\
w_{2,t} &= u/2 - w/2 + w_{1,t} - s_{2,t},
\end{aligned}$$

with Π_C denoting the orthogonal projection onto the sets C, solved here by isotonic regression. Note that the value of the auxiliary variable w_2 can be warm-started. The algorithm converges linearly for polyhedral sets (Shusheng, 2000).

In our simulations, we have used the recent accelerated version of Chambolle and Pock (2015), which led to faster convergence. In order to monitor convergence of the algorithm, we compute the value of $\|u - w - s_{1,t} - s_{2,t}\|_1$, which is equal to zero at convergence. Note that the algorithm is not finitely convergent and gives only *approximate* solutions. Therefore, we introduce the approximation parameters ε_1 and ε_2 such that s_1 lies in the ϵ_1-neighborhood of the base polytope of F_1, i.e., $\min_{A \subseteq V} F_1(A) - s_1(A) \geq -\varepsilon_1$ and s_2 lies in the ε_2-neighborhood of the base polytope of F_2,

i.e., $\min_{A \subseteq V} F_2(A) - s_2(A) \geq -\varepsilon_2$, respectively. See Appendix E for more details on the approximation. The optimization problem can also be decoupled into smaller optimization problems by using the knowledge of the face of the base polytopes on which s_1 and s_2 lie. This is still slow to converge in practice and therefore we present an active-set method in the next section.

4.4.2 PRIMAL ACTIVE-SET METHOD

In this section, we find the projection of the origin onto the intersection of the translated base polytopes given by Eq. 22 using the standard active-set method (Nocedal and Wright, 2006) by solving a set of linear equations. For this purpose, we derive the equivalent optimization problems using equality constraints.

The ordered partition, $\mathcal{A}_j$ is given by $(A_{j,1}, \dots, A_{j,m_j})$, where m_j is the number of elements in the ordered partitions. Let B_{j,i_j} be defined as $(A_{j,1} \cup \cdots \cup A_{j,i_j})$. Therefore,

$$f_j(w_j) = \sum_{i_j=1}^{m_j} v_{j,i_j} \Big(F_j(B_{j,i_j}) - F_j(B_{j,i_j-1}) \Big) \tag{25}$$

$$w_j = \sum_{i_j=1}^{m_j} v_{j,i_j} 1_{A_{j,i_j}} \tag{26}$$

$$\text{with the constraints, } v_{j,1} \geqslant \cdots \geqslant v_{j,m_j}. \tag{27}$$

On substituting Eq. 25, Eq. 26 and Eq. 27 in Eq. 22, we have an equivalent optimization problem:

$$\begin{aligned}
\min_{\substack{v_{1,1} \geq \ldots \geq v_{1,m_1} \\ v_{2,1} \geq \ldots \geq v_{2,m_2}}} & \sum_{i_1=1}^{m_1} \Big(F_1(B_{1,i_1}) - F_1(B_{1,i_1-1}) - \frac{u(A_{1,i_1}) - w(A_{1,i_1})}{2} \Big) v_{1,i_1} \\
+ & \sum_{i_2=1}^{m_2} \Big(F_2(B_{2,i_2}) - F_2(B_{2,i_2-1}) - \frac{u(A_{2,i_2}) - w(A_{2,i_2})}{2} \Big) v_{2,i_2} \\
+ & \sum_{i_1=1}^{m_1} \frac{1}{2}|A_{1,i_1}| v_{1,i_1}^2 + \sum_{i_2=1}^{m_2} \frac{1}{2}|A_{2,i_2}| v_{2,i_2}^2 \sum_{i_1=1}^{m_1} \sum_{i_2=1}^{m_2} v_{1,i_1} v_{2,i_2} 1_{A_{1,i_1}}^\top 1_{A_{2,i_2}}.
\end{aligned}$$

This can be written as a quadratic program in $x = \begin{pmatrix} v_1 \\ v_2 \end{pmatrix}$ with inequality constraints in the following form

$$\min_{\substack{x \in \mathbb{R}^{m_1+m_2} \\ D(\mathcal{A}_1, \mathcal{A}_2) x \gtrsim 0}} \frac{1}{2} x^\top Q(\mathcal{A}_1, \mathcal{A}_2) x + c(\mathcal{A}_1, \mathcal{A}_2)^\top x. \tag{28}$$

Here, $D(\mathcal{A}_1, \mathcal{A}_2)$ is a sparse matrix of size $(m_1 + m_2 - 2) \times (m_1 + m_2)$, which is a block diagonal matrix containing the difference or first order derivative matrices of sizes $m_1 - 1 \times m_1$ and $m_2 - 1 \times m_2$ as the blocks and $c(\mathcal{A}_1, \mathcal{A}_2)$ is a linear vector that can be computed using the function evaluations of F_1 and F_2. Note that these evaluations need to be done only once.

Computing $Q(\mathcal{A}_1, \mathcal{A}_2)$. Let us consider a bipartite graph, $G = (\mathcal{A}_1, \mathcal{A}_2, E)$, with $m_1 + m_2$ nodes representing the ordered partitions of $\mathcal{A}_1$ and $\mathcal{A}_2$ respectively. The weight of the edge between each element of ordered partitions of $\mathcal{A}_1$, represented by A_{1,i_1} and each element of ordered partitions of $\mathcal{A}_2$, represented by A_{2,i_2} is the number of elements of the ground set V that lie in both these partitions and can be written as $e(A_{1,i_1}, A_{2,i_2}) = 1_{A_{1,i_1}}^\top 1_{A_{2,i_2}}$ for all $e \in E$. The matrix $Q(\mathcal{A}_1, \mathcal{A}_2)$ represents the Laplacian matrix of the graph G. Figure 5 shows a sample bipartite graph with $m_1 = 6$ and $m_2 = 5$.

Initializing with primal feasible point. Primal active-set methods start with a primal feasible point and continue to maintain primal feasible iterates. In our case, the starting point may be obtained using the weight vector w that is estimated using isotonic regression. The vector w is compatible both with $\mathcal{A}_1$ and $\mathcal{A}_2$, i.e., $w \in \mathcal{W}^{\mathcal{A}_1}$ and $w \in \mathcal{W}^{\mathcal{A}_2}$. Therefore, we may obtain the vectors v_1 and v_2 from w and initialize the primal feasible starting point using v_1 and v_2.

Optimizing the quadratic program in Eq. 28 by using active-set methods is equivalent to finding the face of the constraint set on which the optimal solution lies. For this purpose, we need to be able to solve the quadratic program in Eq. 28 with equality constraints.

Equality constrained QP. Let us now consider the following quadratic program with equality constraints

$$\min_{\substack{p \in \mathbb{R}^{m_1+m_2} \\ D'p=0}} \frac{1}{2} p^\top Q(\mathcal{A}_1, \mathcal{A}_2) p + \big(Q(\mathcal{A}_1, \mathcal{A}_2) x_k + c(\mathcal{A}_1, \mathcal{A}_2)\big)^\top p, \tag{29}$$

where D' is the subset of the constraints in $D(\mathcal{A}_1, \mathcal{A}_2)$, i.e., indices of constraints that are tight and x_k is a primal-feasible point. We refer the indices of the tight constraints as the *working set* and represent them by the set W in the algorithm. Therefore, the set of constraints in D' is the restriction of the constraint set $D(\mathcal{A}_1, \mathcal{A}_2)$ to the working set constraints denoted by W. The vector p gives the direction of strict descent of the cost function in Eq. 28 from feasible point x_k (Nocedal and Wright, 2006).

Without loss of generality, let us assume that the equality constraints are $v_{j,k_j} = v_{j,k_j+1}$ for any k_j in $[0, m_j)$. Let $\mathcal{A}'_j$ be the new ordered partition formed by merging A_{j,k_j} and A_{j,k_j+1} as $v_{j,k_j} = v_{j,k_j+1}$. Similarly, x'_t can be computed from x_t by merging the weights v_{j,k_j} and v_{j,k_j+1} into a single weight for the merged element of the ordered partition. Finding the optimal vector p' using the quadratic program in Eq. 29 with respect to the ordered partition $\mathcal{A}'_j$ is equivalent to solving the following unconstrained quadratic problem,

$$\mathcal{Q}(\mathcal{A}'_1, \mathcal{A}'_2, x'_t) = \min_{p' \in \mathbb{R}^{m'_1+m'_2}} \left(\frac{1}{2} p'^\top Q(\mathcal{A}'_1, \mathcal{A}'_2) p' + \big(Q(\mathcal{A}'_1, \mathcal{A}'_2) x'_t + c(\mathcal{A}'_1, \mathcal{A}'_2)\big)^\top p' \right), \tag{30}$$

where m'_j is the number of elements of the ordered partition $\mathcal{A}'_j$. This can be estimated by solving a linear system using conjugate gradient descent. The complexity of each iteration of the conjugate gradient is given by $O((m'_1 + m'_2)k)$ where k is the number of non-zero elements in the sparse matrix, $Q(\mathcal{A}'_1, \mathcal{A}'_2)$ (Vishnoi, 2013). We can build p from p' by repeating the values for the elements of the partition that were merged.

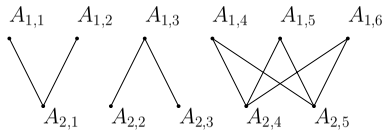

Figure 5: Bipartite graph to compute $Q(\mathcal{A}_1, \mathcal{A}_2)$ with $\mathcal{A}_1$ having $m_1 = 6$ components and $\mathcal{A}_2$ having $m_2 = 5$.

Primal active-set algorithm. We now can describe the standard primal active-set method.

Data: Laplacian matrix, $Q(\mathcal{A}_1, \mathcal{A}_2)$ and vector, $c(\mathcal{A}_1, \mathcal{A}_2)$, ordered partitions $\mathcal{A}_1, \mathcal{A}_2$
Result: $x^* \in \mathbb{R}^{m_1+m_2}$

Initialize: $t = 0$;
Primal feasible x_0 using the solution of isotonic regression w;
W_0 with indices of rows of $D(\mathcal{A}_1, \mathcal{A}_2)$ that are equal to 0;
while `True` **do**
  Estimate primal: Solve equality constrained QP in Eq. 29 with equality constraints indexed by working set W_t to find optimal p ;
  if *p == 0* **then**
    Estimate dual: $\lambda = D(\mathcal{A}_1, \mathcal{A}_2)^{-\top}\big(Q(\mathcal{A}_1, \mathcal{A}_2) x_t + c(\mathcal{A}_1, \mathcal{A}_2)\big)$;
    if $\lambda_i \geq 0$ *for all* $i \in W_t$ **then**
      `break` ;
    else
      update $j = \operatorname{argmin}_{j \in W_t} \lambda_j$;
      update $W_{t+1} = W_t \setminus \{j\}$;
      update $x_{t+1} = x_t$;
    end
  else
    Line search: Find least β that retains feasibility of $x_{t+1} = x_t + \beta p$ and find the blocking constraints B_t ;
    $W_{t+1} = W_t \cup B_t$;
  end
  $t = t + 1$
end
return $x^* = x_t$

We can estimate w_1 and w_2 from x^*, which will enable us to estimate s feasible in Eq. 24. Therefore we can estimate the dual variable $s_1 \in B^{\mathcal{A}_1}(F_1)$ and $s_2 \in B^{\mathcal{A}_2}(F_2)$ using s.

4.5 Decoupled Problem

In our context, the quadratic program in Eq. 28 can be decoupled into smaller optimization problems. Let us consider the bipartite graph $G = (\mathcal{A}_1, \mathcal{A}_2, E)$ of which Q is the Laplacian matrix. The number of connected components of the graph, G, is equal to the number of level-sets of w.

Let m be the total number of connected components in G. These connected components define a partition on the ground set V and a total order on elements of the partition can be obtained using the levels sets of w. Let k denote the index of each bipartite subgraph of G represented by $G_k = (\mathcal{A}_{1,k}, \mathcal{A}_{2,k}, E_k)$, where $k = 1, 2, \ldots, m$. Let J_k denote the indices of the nodes of G_k in G.

$$x^*_{J_k} = \operatorname*{argmin}_{\substack{x \in \mathbb{R}^{m_{1,k}+m_{2,k}} \\ D(\mathcal{A}_1,\mathcal{A}_2)_k x \succcurlyeq 0}} \frac{1}{2} x^\top Q(\mathcal{A}_1, \mathcal{A}_2)_{J_k J_k} x + c(\mathcal{A}_1, \mathcal{A}_2)^\top_{J_k} x, \tag{31}$$

where $m_{j,k}$ is size of $\mathcal{A}_{j,k}$. Therefore, $m_{1,k} + m_{2,k}$ is the total number of nodes in the subgraph G_k. Note that this is exactly equivalent to decomposition of the base polytope of F_j into base polytopes of submodular functions formed by contracting F_j on each individual component representing the connected component k. See Appendix D for more details.

5. Experiments

In this section, we show the results of the algorithms proposed on various problems. We first consider the problem of solving total variation denoising for a non decomposable function using active-set methods in Section 5.1, specifically cut functions. Here, our experiments mainly focus on the time comparisons with state-of-art methods and also show an important setting where we show the gain due to the ability to warm-start our algorithm. In Section 5.2, we consider cut functions on a 3D grid decomposed into a function of the 2D grid and a function of chains. We then consider a 2D grid and a concave function on cardinality, which is not a cut function. Our algorithm leads to marginal gains for the usual non decomposable functions. However, in the non decomposable case there are many total variation problems to be solved. The ability to warm-start lends to huge improvements when compared to the usage of standard total variation oracles in this setting.

5.1 Non-decomposable Total Variation Denoising

Our experiments consider images, which are 2-dimensional grids with vertex neighborhood of size 4. The data set comprises of 6 different images of varying sizes. We consider a large image of size 5616×3744 and recursively scale into a smaller image of half the width and half the height maintaining the aspect ratio. Therefore, the size of each image is four times smaller than the size of the previous image. We restrict to anisotropic uniform-weighted total variation to compare with Chambolle and Darbon (2009) but our algorithms work as well with weighted total variation, which is standard in computer vision, and on any graph with SFM oracles. Therefore, the unweighted total variation is

$$f(w) = \lambda \sum_{i \sim j} |w_i - w_j|,$$

where λ is a regularizing constant for solving the total variation problem in Eq. 3.

Maxflow (Boykov and Kolmogorov, 2004) is used as the SFM oracle for checking the optimality of the ordered partitions. Figure 6(a) shows the number of SFM oracle calls required to solve the TV problem for images of various sizes. Note that for the algorithm of Chambolle and Darbon (2009) each SFM oracle call optimizes smaller problems sequentially, while each SFM oracle call in our method optimizes several independent smaller problems in parallel. Therefore, our method has lesser number of oracle calls than Chambolle and Darbon (2009). However, oracle complexity of

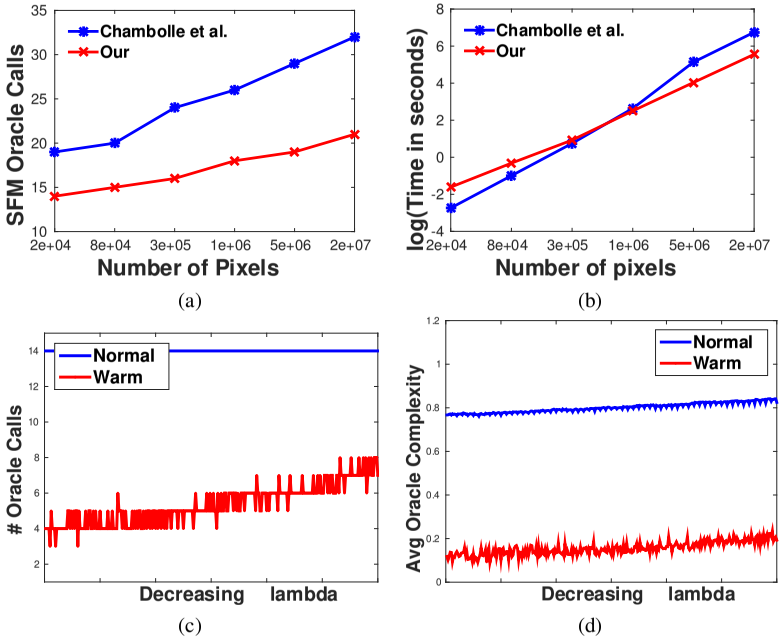

Figure 6: (a) Number of SFM oracle calls for images of various sizes, (b) Time taken for images of various sizes, (c) Number of iterations with and without warm start, (d) Average complexity of the oracle with and without warm start.

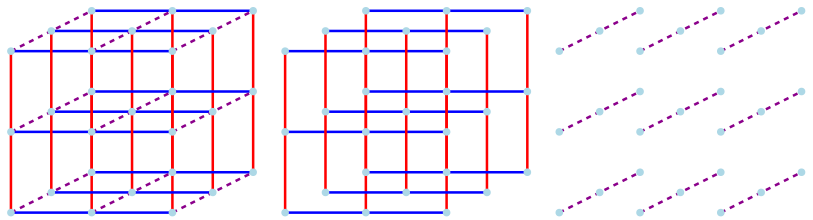

each call is higher for the our method when compared to Chambolle and Darbon (2009). Figure 6(b) shows the time required for each of the methods to solve the TV problem to convergence. We have an optimized code and only use the oracle as plugin which takes about 80-85 percent of the running time. This is primarily the reason our approach takes more time than (Chambolle and Darbon, 2009) despite having fewer oracle calls for small images.

Figure 6(c) also shows the ability to warm start by using the output of a related problem, i.e., when computing the solution for several values of λ (which is typical in practice). In this case, we use optimal ordered partitions of the problem with larger λ to warm start the problem with smaller λ. It can be observed that warm start of the algorithm requires lesser number of oracle calls to converge than using the initialization with trivial ordered partition. Warm start also largely helps in reducing the burden on the SFM oracle. With warm starts the number of ordered partitions does not change much over iterations. Hence, it suffices to query only ordered partitions that have changed. To analyze this we define *oracle complexity* as the fraction of pixels in the elements of the partitions that need to be queried. Oracle complexity is averaged over iterations to understand the average burden on the oracle per iteration. With warm starts this reduces drastically, which can be observed in Figure 6(d).

5.2 Decomposable Total Variation Denoising and SFM

Cut functions. In the decomposable case, we consider the SFM and TV problems on a cut function defined on a 3D-grid. The 3D-grid consists of lines parallel lines in each dimension as shown in Figure 7. It can be decomposed into two functions F_1 and F_2, where F_1 is composed on parallel 2D-grids and F_2 is composed of parallel chains. From Figure 7, the function F_1 represents all the solid edges(red and blue) whereas the function F_2 represents the dashed edges(magenta). For brevity, we refer to each 2D-grid of the function F_1 as a *frame*. The SFM oracle for the function F_1 is the maxflow-mincut (Boykov and Kolmogorov, 2004) algorithm, which may run in parallel for all frames. Similarly the SFM oracle for the function F_2 is the message passing algorithm, which may run in parallel for all chains. The corresponding TV oracles, i.e., *projection algorithm* for F_1 and F_2 may be solved using the algorithm described in Section 3.4 due to availability of the respective SFM oracles. We consider averaged alternating reflection (AAR) (Bauschke et al., 2004) by solving each projection without warm-start and counting the total number of SFM oracle calls of F_1 to solve the SFM and TV on the 3D-grid as our baseline. (SGD-P) denotes the dual subgradient based method (Komodakis et al., 2011) modified with Polyak's rule (Poljak, 1987) to solve SFM on the 3D-grid. We show the performance of alternating projection (AP-WS), averaged alternating reflection (AAR-WS) (Bauschke et al., 2004) and Dykstra's alternating projection (DAP-WS) (Bauschke and Borwein, 1994) using warm start of each projection with the ordered partitions. WS denotes warm start variant of each of the algorithm. The performance of the active-set algorithm proposed in Section 4.3 with inner loop solved using the primal active-set method proposed in Section 4.4.2 is represented by (ACTIVE).

In our experiments, we consider the 3D volumetric data set of the Stanford bunny (max) of size $102 \times 100 \times 79$. The function F_1 represents 102 frames while F_2 represents the 7900 chains. The dimension of each frame in F_1 is 100×79, while the length of each chain in F_2 is 102. Figure 8 (a) and (b) show that (AP-WS), (AAR-WS), (DAP-WS) and (ACTIVE) require relatively less number of oracle calls when compared to when compared to AAR or SGD-P. Note that we count 2D SFM oracle calls as they are more expensive than the SFM oracles on chains.

(a) (b) (c)

Figure 7: (a) Cut function F defined on a 3D-grid may be decomposed into: (b) F_1 represented by solid edges (red and blue) and (c) F_2 represented by dashed lines (magenta)

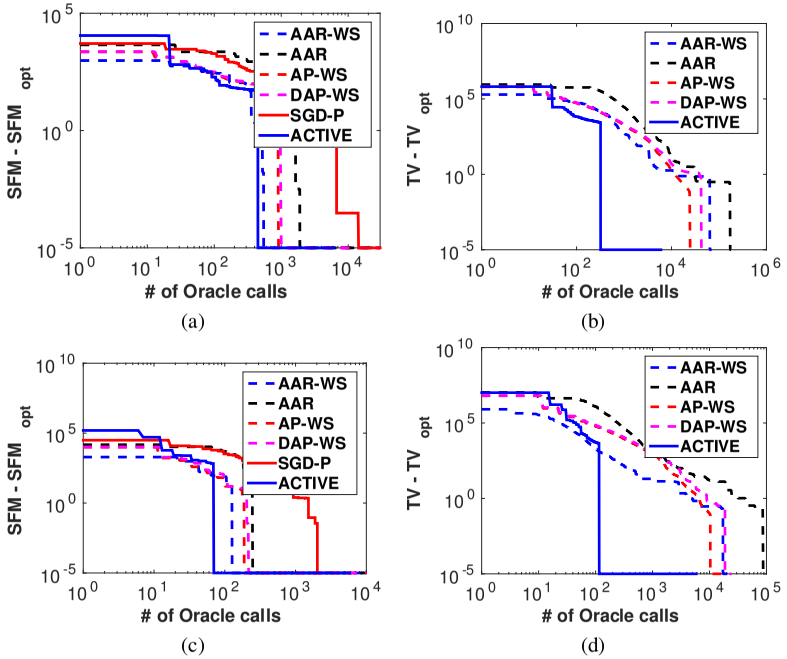

Figure 8: (a) Number of 2D SFM calls to obtain 3D SFM, (b) Number of 2D SFM calls to obtain 3D TV, (c) Number of 2D SFM calls to obtain SFM of 2D + concave function, (d) Number of 2D SFM calls to obtain TV of 2D + concave function.

Time comparisons. We also performed time comparisons between the iterative methods and the combinatorial methods on standard data sets. The standard mincut-maxflow (Boykov and Kolmogorov, 2004) on the 3D volumetric data set of the Standard bunny (max) of size $102 \times 100 \times 79$ takes 0.11 seconds while averaged alternating reflections (AAR) without warm start takes 0.38 seconds. The averaged alternating reflections with warm start (AAR-WS) takes 0.21 seconds and the active-set method (ACTIVE) takes 0.38 seconds. The main bottleneck in the active-set method is the inversion of the Laplacian matrix and it could considerably improve by using methods suggested by Vishnoi (2013). Note that the projection on the base polytopes of F_1 and F_2 can be parallelized by projecting onto each of the 2D frame of F_1 and each line of F_2 respectively (Kumar et al., 2015). The times for (AAR), (AAR-WS) and (ACTIVE) use parallel multi-core architectures[3] while the combinatorial algorithm only uses a single core. Note that cut functions on grid structures are only a small subclass of submodular functions with such efficient combinatorial algorithms. In contrast, our algorithm works on more general class of sum of submodular functions than just with cut functions.

Concave functions on cardinality. In this experiment we consider our SFM problem of sum of a 2D cut on a graph of size 5616×3744 and a super pixel based concave function on cardinality (Stobbe and Krause, 2010; Jegelka et al., 2013). The unary potentials of each pixel is calculated using the Gaussian mixture model of the color features. The edge weight $a(i, j) = \exp(-\|y_i - y_j\|^2)$, where y_i denotes the RGB values of the pixel i. In order to evaluate the concave function, regions R_j are extracted via superpixels and, for each R_j, defining the function $F_2(S) = |S||R_j \setminus S|$. We use 200 and 500 regions. Figure 8 (c) and (d) shows that (AP-WS), (AAR-WS), (DAP-WS) and (ACTIVE) algorithms converge for solving TV quickly by using only SFM oracles and relatively less number of oracle calls. Note that we count 2D SFM oracle calls.

6. Conclusion

In this paper, we present an efficient active-set algorithm for optimizing quadratic losses regularized by Lovász extension of a submodular function using the SFM oracle of the function. We also present an active-set algorithms to minimize sum of "simple" submodular functions using SFM oracles of the individual "simple" functions. We also show that these algorithms are competitive to the existing state-of-art algorithms to minimize submodular functions.

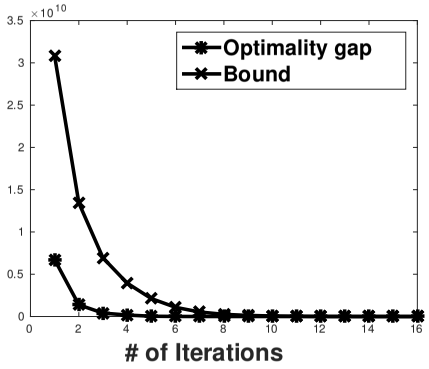

Figure 9: Certified gap vs. bound for TV denoising on a 2D image using the algorithm in Section 3.4.

Appendix A. Certificates of Optimality

We consider a total variation denoising problem on an 2D image of dimensions 384×288 using the algorithm proposed in Section 3.4 for non-decomposable functions, where we assume a 2D SFM oracle. Here, we plot the optimality gap given by $(f(w) - u^\top w + \frac{1}{2}\|w\|_2^2) - (f(w^*) - u^\top w^* + \frac{1}{2}\|w^*\|_2^2)$ and the bound, $\varepsilon \operatorname{range}(w) + \varepsilon \operatorname{range}(w^*)$, proposed in Section 3.6. Here, w is the solution at the end of each iteration of the algorithm and w^* is the optimal solution.

Appendix B. Algorithms for Coalescing Partitions

The basic interpretation in coalescing two ordered partitions is as follows. Given an ordered partition $\mathcal{A}_1$ and $\mathcal{A}_2$ with m_1 and m_2 elements in the partitions respectively, we define for each $j = 1, 2$, $\forall i_j = (1, \ldots, m_j)$, $B_{j,i_j} = (A_{j,1} \cup \ldots \cup A_{j,i_j})$. The inequalities defining the outer approximation of the base polytopes are given by hyperplanes defined by

$$\forall i_j = (1, \ldots, m_j), s_j(B_{j,i_j}) \leq F_j(B_{j,i_j}).$$

The hyperplanes defined by common sets of both these partitions, defines the coalesced ordered partitions. The following algorithm performs coalescing between these partitions.

- **Input**: Ordered partitions $\mathcal{A}_1$ and $\mathcal{A}_2$.
- **Initialize**: $x = 1, y = 1, z = 1$ and $C = \varnothing$.
- **Algorithm**: Iterate until $x = m_1$ and $y = m_2$
  1. If $|B_{1,x}| > |B_{2,y}|$ then $y := y + 1$.
  2. If $|B_{1,x}| < |B_{2,y}|$ then $x := x + 1$.

3. If $B_{1,x} == B_{2,y}$ then
   - $A_z = (B_{1,x} \setminus C)$,
   - $C = B_{1,x}$, and
   - $z := z + 1$.

– **Output**: $m = z$, ordered partitions $\mathcal{A} = (A_1, \ldots, A_m)$.

Running time. The algorithm terminates in $\min(m_1, m_2)$ iterations and the checking condition for step (3) takes n iterations. Therefore, the algorithm overall takes a time of $O(\min(m_1, m_2)n)$.

Appendix C. Optimality of Algorithm for Decomposable Problems

In step (10) of the algorithms, when we split partitions, the value of the primal/dual pair of optimization algorithms

$$\max_{\substack{s_1 \in \widehat{B}^{\mathcal{A}_1}(F_1) \\ s_2 \in \widehat{B}^{\mathcal{A}_2}(F_2)}} -\tfrac{1}{2}\|u - s_1 - s_2\|_2^2 = \min_{\substack{w \in \mathcal{W}^{\mathcal{A}_1} \\ w \in \mathcal{W}^{\mathcal{A}_2}}} f_1(w) + f_2(w) - u^\top w + \tfrac{1}{2}\|w\|_2^2,$$

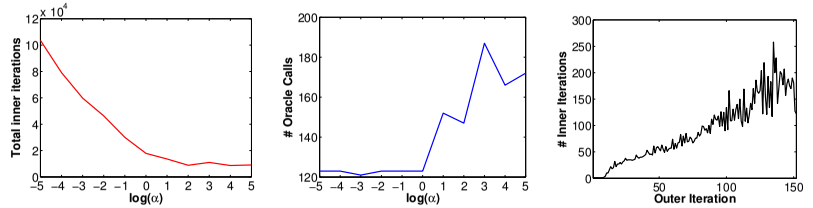
cannot increase. This is because, when splitting, the constraint set for the minimization problem only gets bigger. Since at optimality, we have $w = u - s_1 - s_2$, $\|w\|_2$ cannot decrease, which shows the first statement.

Now, if $\|w\|_2$ remains constant after an iteration, then it has to be the same (and not only have the same norm), because the optimal s_1 and s_2 can only move in the direction orthogonal to w.

In step (4) of the algorithm, we project 0 on the (non-empty) intersection of $\widehat{B}^{\mathcal{A}_1}(F_1) - u/2 + w/2$ and $u/2 - w/2 - \widehat{B}^{\mathcal{A}_2}(F_2)$. This corresponds to minimizing $\frac{1}{2}\|s_1 - u/2 + w/2\|^2$ such that $s_1 \in \widehat{B}^{\mathcal{A}_1}(F_1)$ and $s_2 = u - w - s_1 \in \widehat{B}^{\mathcal{A}_2}(F_2)$. This is equivalent to minimizing $\frac{1}{8}\|s_1 - s_2\|^2$. We have:

$$\begin{aligned}
\max_{\substack{s_1 \in \widehat{B}^{\mathcal{A}_1}(F_1) \\ s_2 \in \widehat{B}^{\mathcal{A}_2}(F_2) \\ s_1 + s_2 = u - w}} -\frac{1}{8}\|s_1 - s_2\|_2^2 &= \min_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} \max_{\substack{s_1 \in \mathbb{R}^n, s_2 \in \mathbb{R}^n \\ s_1 + s_2 = u - w}} \Big(-\frac{1}{8}\|s_1 - s_2\|_2^2 + f_1(w_1) + f_2(w_2) \\
&\qquad\qquad -w_1^\top s_1 - w_2^\top s_2 \Big) \\
&= \min_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} \max_{s_2 \in \mathbb{R}^n} \Big(-\frac{1}{8}\|u - w - 2s_2\|_2^2 + f_1(w_1) + f_2(w_2) \\
&\qquad\qquad -w_1^\top (u - w - s_2) - w_2^\top s_2 \Big) \\
&= \min_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} \max_{s_2 \in \mathbb{R}^n} \Big(-\frac{1}{8}\|u - w\|_2^2 - \frac{1}{2}\|s_2\|_2^2 + \frac{1}{2} s_2^\top (u - w) \\
&\qquad\qquad + f_1(w_1) + f_2(w_2) - w_1^\top (u - w - s_2) - w_2^\top s_2 \Big) \\
&= \min_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} -w_1^\top (u - w) + f_1(w_1) + f_2(w_2) - \frac{1}{8}\|u - w\|_2^2 \\
&\qquad\qquad + \max_{s_2 \in \mathbb{R}^n} -\frac{1}{2}\|s_2\|_2^2 + s_2^\top \big(\tfrac{u-w}{2} + w_1 - w_2\big) \\
&= \min_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} \Big(-w_1^\top (u - w) + f_1(w_1) + f_2(w_2) - \frac{1}{8}\|u - w\|_2^2 \\
&\qquad\qquad + \frac{1}{2}\|\tfrac{u-w}{2} + w_1 - w_2\|_2^2 \Big) \\
&= \min_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} \Big(-w_1^\top (u - w) + f_1(w_1) + f_2(w_2) + \frac{1}{2}\|w_1 - w_2\|_2^2 \\
&\qquad\qquad + \frac{1}{2}(u - w)^\top (w_1 - w_2) \Big) \\
&= \min_{\substack{w_1 \in \mathcal{W}^{\mathcal{A}_1} \\ w_2 \in \mathcal{W}^{\mathcal{A}_2}}} \Big(f_1(w_1) + f_2(w_2) - \frac{1}{2}(u - w)^\top (w_1 + w_2) \\
&\qquad\qquad + \frac{1}{2}\|w_1 - w_2\|_2^2 \Big),
\end{aligned}$$

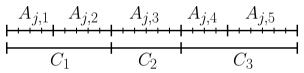
Thus s_1 and s_2 are dual to certain vectors w_1 and w_2, which minimize a decoupled formulation in f_1 and f_2. To check optimality, like in the single function case, it decouples over the constant sets of w_1 and w_2, which is exactly what step (5) is performing.



If the check is satisfied, it means that w_1 and w_2 are in fact optimal for the problem above without the restriction in compatibilities, which implies that they are the Dykstra solutions for the TV problem.

If the check is not satisfied, then the same reasoning as for the one function case, leads directions of descent for the new primal problem above. Hence it decreases; since its value is equal to $-\frac{1}{8}\|s_1 - s_2\|_2^2$, the value of $\|s_1 - s_2\|_2^2$ must increase, hence the second statement.

Appendix D. Decoupled Problems.



Given that we deal with polytopes, knowing w implies that we know the faces on which we have to looked for. It turns outs that for base polytopes, these faces are products of base polytopes for modified functions (a similar fact holds for their outer approximations).

Given the ordered partition $\mathcal{A}'$ defined by the level sets of w (which have to be finer than $\mathcal{A}_1$ and $\mathcal{A}_2$), we know that we may restrict $\widehat{B}^{\mathcal{A}_j}(F_j)$ to elements s such that $s(B) = F(B)$ for all sup-level sets B of w (which have to be unions of contiguous elements of A_j); see an illustration below.

(a) (b) (c)

Figure 10: (a) Total number of inner iterations for varying α. (b) Total number of outer iterations for varying α. and (c) Number of inner iterations per each outer iteration for the $\alpha = 10^1$.

More precisely, if $C_1, \dots, C_{m'}$ are constant sets of w ordered with decreasing values. Then, we may search for s_j independently for each subvector $(s_j)_{C_k} \in \mathbb{R}^{C_k}$, $k \in \{1, \dots, m'\}$ and with the constraint that

$$(s_j)_{C_k} \in \hat{B}^{\mathcal{A}_j \cap C_k}\big[(F_j)_{C_k | C_1 \cup \dots \cup C_{k-1}}\big],$$

where $\mathcal{A}_j \cap C_k$ is the ordered partition obtained from $\mathcal{A}_j$ once restricted onto C_k and the submodular function is the so-called contraction of F on C_k given $C_1 \cup \dots \cup C_{k-1}$, defined as $S \mapsto F_j(S \cup C_1 \cup \dots \cup C_{k-1}) - F(C_1 \cup \dots \cup C_{k-1})$. Thus this corresponds to solving m different smaller subproblems.

Appendix E. Approximate Dykstra Steps

The Dykstra step, i.e., step (4) of the algorithm proposed in Section 4.4.1 is not finitely convergent. Therefore, it needs to be solved approximately. For this purpose, we introduce a parameter α to approximately solve the Dykstra step such that $\|s_1 + s_2 - u + w\|_1 \leq \alpha(\epsilon_1 + \epsilon_2)$. Let ϵ be defined as $\alpha(\epsilon_1 + \epsilon_2)$. This shows that the s_1 and s_2 are ϵ-accurate. Therefore, α must be chosen in such a way that we avoid cycling in our algorithm. However, another alternative is to warm start the Dykstra step with w_1 and w_2 of the previous iteration. This ensures we don't go back to the same w_1 and w_2, which we have already encountered and avoid cycling. Figure 10 shows the performance of our algorithm for a simple problem of 100×100 2D-grid with 4-neighborhood and uniform weights on the edges with varying α. Figure 10-(a) shows the total number of inner iterations required to solve the TV problem. Figure 10-(b) gives the total number of SFM oracle calls required to solve the TV problem. In Figure 10-(c), we show the number of inner iterations in every outer iteration for the best α we have encountered.

Abstract

We propose a generic Bayesian mixed-effects model to estimate the temporal progression of a biological phenomenon from observations obtained at multiple time points for a group of individuals. The progression is modeled by continuous trajectories in the space of measurements. Individual trajectories of progression result from spatiotemporal transformations of an average trajectory. These transformations allow for the quantification of changes in direction and pace at which the trajectories are followed. The framework of Riemannian geometry allows the model to be used with any kind of measurements with smooth constraints. A stochastic version of the Expectation-Maximization algorithm is used to produce maximum *a posteriori* estimates of the parameters. We evaluated our method using a series of neuropsychological test scores from patients with mild cognitive impairments, later diagnosed with Alzheimer's disease, and simulated evolutions of symmetric positive definite matrices. The data-driven model of impairment of cognitive functions illustrated the variability in the ordering and timing of the decline of these functions in the population. We showed that the estimated spatiotemporal transformations effectively put into correspondence significant events in the progression of individuals.

Keywords: longitudinal model, spatiotemporal analysis, Riemannian geometry, stochastic expectation-maximization algorithm

1. Introduction

The study of the temporal progression of a biological or natural phenomenon is central to several scientific fields. For instance, the study of progressive diseases plays a crucial role in the diagnosis and prognosis of patients. In computer vision, the dynamics of facial expressions in video sequences may be important in automatic detection and characterization of emotions.

For a given individual or object, the evolution of the observed phenomenon can be measured by several characteristics or features, which describe the state of the individual at a given time point. In medicine, these features may be blood markers, height, or weight, but also structured multivariate data such as medical images. The shape of a human face may be described by the position of characteristic points on the nose, mouth or brows. These features may be represented, at a given time point, by a point in a high-dimensional space. The temporal evolution of these features may be modeled therefore as a smooth parametric curve in the space of measurements, i.e. a spatiotemporal trajectory. These trajectories vary across individuals in two possible ways. Firstly, the position and direction of the trajectory differ because the measurements have intrinsically different values and different trajectory of changes for different individuals. Secondly, the pace at which the trajectory is followed (i.e. the way the curve is parametrized) varies because some individuals may follow the same progression pattern but at a different age and possibly at a different speed. We refer to the first type of variability as a *spatial* variability, and the second type as a *temporal* variability, leading together to the concept of *spatiotemporal* variability.

The goal of this paper is to automatically estimate the typical trajectory of changes and its spatiotemporal variability within a group of individuals. We aim to infer such spatiotemporal patterns from longitudinal data sets, which consist of repeated observations of the same biological phenomenon at several time points for a group of individuals. The time points and their number may vary for different individuals.

In the literature, *mixed-effects models* (Eisenhart, 1947; Laird and Ware, 1982) and (Verbeke and Molenberghs, 2009) appear as a popular method for the analysis of longitudinal data. These statistical models include *fixed* and *random effects* which provide these models with a hierarchical structure, where fixed effects described the data at the population (or group) level, and the random effects at the individual level. By fitting a mixed-effects model, one can learn an average trajectory as well as individual-specific trajectories. Moreover, mixed-effects models enforce conditions on the distribution of the random effects, thus opening up the possibility to learn a distribution of trajectories in the space of observations.

Linear Mixed Effects (LME) models are the most simple mixed-effects models introduced in Laird and Ware (1982). A particular, but yet informative case of the LME models for analysing longitudinal data is the *random slope and intercept model*. This model writes: $\mathbf{y}_{i,j} = (t_{i,j}-t_0)(\overline{\mathbf{A}}+\mathbf{A}_i)+(\overline{\mathbf{B}}+\mathbf{B}_i)+\boldsymbol{\varepsilon}_{i,j}$, where $t_0 \in \mathbb{R}$ and $(t_{i,j})_{1\leq j\leq k_i}$ denotes the time points at which the observations $\mathbf{y}_{i,j} \in \mathbb{R}^n$ of the ith individual were obtained. The population parameters (or fixed effects) of the model are the slope $\overline{\mathbf{A}}$ and the intercept $\overline{\mathbf{B}}$. The random effects are the subject-specific slopes $(\mathbf{A}_i)_{1\leq i\leq p}$ and intercepts $(\mathbf{B}_i)_{1\leq i\leq p}$, which are assumed to be normally distributed and independent of each other. This random slope and intercept model estimates an average trajectory $\overline{\mathbf{D}}(t) = (t-t_0)\overline{\mathbf{A}} + \overline{\mathbf{B}}$. The random effects of the model allows us to estimate individual trajectories $\mathbf{D}_i(t) = (t-t_0)(\overline{\mathbf{A}}+\mathbf{A}_i) + (\overline{\mathbf{B}}+\mathbf{B}_i)$, which are obtained by adjusting the slope and intercept of the average trajectory. This model is essentially built on the idea of regressing the measurements against time. The parameter t_0 can be understood as a *reference time*. If the longitudinal dataset arises from animal breeding studies, developmental studies or pharmacological studies, the reference time t_0 may be chosen to be the date of birth or the time at which a drug was administered.

However, there are many situations in which there is no obvious reference time t_0 at which observations may be compared. In ageing, for instance, different individuals of the same age may be at different stages of ageing, or stages of disease progression. Therefore, it does not make sense to regress the measurements against age, or, in other words, to statistically compare measurements at a given age. In video sequences, there is no obvious way to find the frames corresponding to the same event in two different sequences. By contrast, we would like this temporal alignment of the trajectories to be automatically estimated from the data. Adding the reference time t_0 as a new parameter of the model is not a solution as the model becomes non-identifiable: an infinite number of triplets $(\overline{A}, \overline{B}, t_0)$ parametrize the same trajectory.

In Yang et al. (2011) and Delor et al. (2013), the authors addressed this problem by introducing *time shifts* in their statistical analysis. In Durrleman et al. (2009, 2013), time reparametrizations called *time warps* (smooth monotonic transformations of the real line) are considered to address this point in the context of longitudinal shape analysis, and parameters were estimated by optimizing an uncontrolled approximation of the likelihood. In Hong et al. (2014), the authors used parametric time warps with a regression model for shape analysis. In Lorenzi et al. (2015), the authors used Riemannian manifold techniques to estimate a model of normal brain ageing from MR images. The model was used to compute a time shift, called *morphological age shift*, which corresponds to the actual anatomical age of the subject with respect to an estimated reference age. In (Fonteijn et al., 2012; Young et al., 2015), the authors developed a statistical model called *the Event-Based Model*, which estimates an ordering of categorical variables. The model is used to estimate the progression of a series of events. However, these models do not allow for the estimation of the relative timing between two consecutive events. In Jedynak et al. (2012), the authors modeled the progression of biomarkers using a nonlinear mixed-effects model for univariate observations. This model estimates individual trajectories which are defined using individual-specific time reparametrizations of an average trajectory. However, the proposed model is not identifiable unless some conditions are imposed on the parameters of the model. Therefore, generalizing the model to multivariate observations is not straightforward. Also, the model is specific to univariate observations whereas our generic model, presented below, allows analysing any kind of observations defined by smooth constraints. This work offers pragmatic solutions to include the idea of time raparametrization in the estimation of trajectories of changes for some specific applications. Nevertheless, we are still lacking a principle and generic approach to deal with the estimation of spatiotemporal variability in longitudinal data sets.

Structured multivariate data such as images, graphs, shapes, or positive definite matrices add further difficulty as these data do not lie in Euclidean spaces. Algebraic operations such as addition or scaling are not defined or do not yield an output of the same type. The spaces in which they live are defined by smooth constraints and may be considered in general as *Riemannian manifolds*. There is no natural extension of LME models on Riemannian manifolds. In Fletcher (2011), the authors proposed an extension of linear regression for Riemannian manifolds, which was later extended for longitudinal data in a group of diffeomorphisms (Singh et al., 2013, 2014). Nevertheless, this longitudinal model strongly depends on a choice of reference time-point to define random effects, therefore making difficult its coupling with time raparametrization. In Su et al. (2014), trajectories are defined by the quotient with a time raparametrization group. This approach allowed

for the definition of statistics in the quotient space, but as a consequence did not yield any estimate of the temporal variability.

This paper proposes a Bayesian mixed-effects model, called *generic spatiotemporal model*, defined for any longitudinal observations on a Riemannian manifold. The fixed effects of the model are used to define an average trajectory and the random effects are used to define individual-specific trajectories. In order to define such individual trajectories, we introduce the notion of "exp-parallelization" of a curve on a Riemannian manifold, based on the idea of "variations of a curve". This construction allows the definition of random effects to account for the spatial variability, the distribution of which (up to an isometric transform) does not depend on a reference time-point. It allows us, therefore, to easily include random time raparametrization to account for the temporal variability in the model. All in one, the model defines distributions of spatiotemporal trajectories for data on any Riemannian manifolds. It gives a systematic way to derive specific nonlinear mixed-effects models for a large variety of observations and Riemannian manifolds.

These models need to then be fitted to given longitudinal data sets. Given their strong non-linear nature, we propose to use a stochastic version of the Expectation-Maximization (EM) (Dempster et al., 1977) algorithm, called the Monte Carlo Markov Chain Stochastic Approximation EM (MCMC-SAEM) algorithm. Theoretical results regarding the convergence of the MCMC-SAEM have been proven in Kuhn and Lavielle (2004), Allassonnière et al. (2010) and ensure that the algorithm maximizes the observed likelihood. This technique allows us to propose a generic algorithm for the estimation of the model parameters. We will instantiate this method for a set of multivariate bounded measurements and for positive definite matrices.

The paper is organized as follows: in Section 2, we give the key mathematical tools and define the generic mixed-effects model with spatiotemporal transformations for manifold-valued measurements. Particular cases of the generic model are given and discussed in Section 3. Section 4 is focused on the MCMC-SAEM which is used to estimate the parameters of the statistical model. Finally, Sections 5.2 and 5 are dedicated to empirical and experimental validations of our generic model.

2. A Bayesian Mixed-Effects Model for Longitudinal Observations on a Riemannian Manifold

This section aims at introducing a notion of Riemannian geometry called "exp-parallelization". Given a group-average trajectory on a Riemannian manifold, the notion of exp-parallelization is used to define individual trajectories. For a comprehensive review of basic concepts of Riemannian geometry, see Do Carmo Valero (1992); Petersen (2006). In this section, we assume that $\mathbb{M}$ is an open subset of $\mathbb{R}^N$ equipped with a Riemannian metric $g^{\mathbb{M}}$.

2.1 Exp-parallelization on a Riemannian Manifold

This section introduces the notion of "exp-parallelization" of a curve on a Riemannian manifold $(\mathbb{M}, g^{\mathbb{M}})$. The notion of "variation of a differentiable curve" on a manifold is defined in Do Carmo Valero (1992) (Chapter 9). It allows defining *neighbouring* curves to a given curve c. In the next section, this construction will be used to define individual trajecto-

ries. Let $(\mathbb{M}, g^{\mathbb{M}})$ denotes a *geodesically complete* Riemannian manifold equipped with its Levi-Civita connection $\nabla^{\mathbb{M}}$.

Definition 1 *Let $c : I \subset \mathbb{R} \to \mathbb{M}$ a differentiable curve on $\mathbb{M}$, $t_0 \in I$ and $\mathbf{w} \in \mathrm{T}_{c(t_0)}\mathbb{M}$ a tangent vector to $\mathbb{M}$ at $c(t_0)$. An* exp-parallelization of c in the direction of $\mathbf{w}$ *is a curve $\boldsymbol{\eta}^{\mathbf{w}}(c, \cdot) : I \to \mathbb{M}$ defined by:*

$$\forall t \in I,\ \boldsymbol{\eta}^{\mathbf{w}}(c, t) = \mathrm{Exp}^{\mathbb{M}}_{c(t)}\big(\mathrm{P}_{c,t_0,t}(\mathbf{w})\big). \tag{1}$$

This construction is illustrated in Fig. 1. Given $t \in I$, parallel transport carries the tangent vector $\mathbf{w}$ from $\mathrm{T}_{c(t_0)}\mathbb{M}$ to $\mathrm{T}_{c(t)}\mathbb{M}$ along the curve c. At the point $c(t)$, a new point on $\mathbb{M}$ is obtained by taking the Riemannian exponential of the tangent vector $\mathrm{P}_{c,t_0,t}(\mathbf{w})$. This new point is denoted by $\boldsymbol{\eta}^{\mathbf{w}}(c, t)$. As t varies, one describes a curve $\boldsymbol{\eta}^{\mathbf{w}}(c, \cdot)$ on $\mathbb{M}$, which can be understood as a "parallel" to the curve c. Note that if $\mathbb{M}$ is the Euclidean space $\mathbb{R}^N$, an exp-parallelization of a curve c, in the direction of a tangent vector $\mathbf{w}_i$, is the translation of c by the vector $\mathbf{w}_i$.

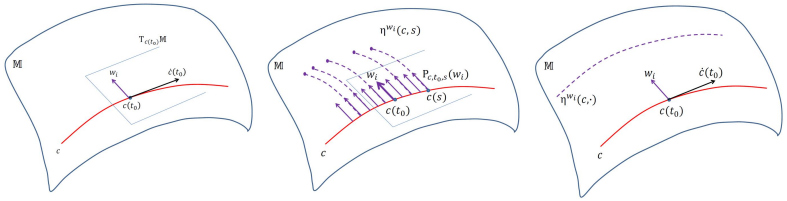

Figure 1: Exp-parallelization on a schematic manifold. Left: a non-zero vector $\mathbf{w}_i$ is chosen in $\mathrm{T}_{c(t_0)}\mathbb{M}$. Middle: the tangent vector $\mathbf{w}_i$ is transported continuously along the curve c. Then, a point $\eta^{\mathbf{w}_i}(c, s)$ is constructed at time s by use of the Riemannian exponential. Right: The curve $\eta^{\mathbf{w}_i}(c, \cdot)$ is the "parallel" resulting from the construction.

2.2 Hierarchical Structure of the Model

In this section, we consider a longitudinal dataset $(\mathbf{y}_{i,j})_{1\leq i\leq p,\, 1\leq j\leq k_i}$. The observations are obtained for a group of p individuals. For the ith individual, the observations $(\mathbf{y}_{i,j})_{1\leq j\leq k_i}$ are obtained at times $t_{i,1} < \ldots < t_{i,k_i}$. The number k_i of observations may vary from one individual to another.

The *generic spatiotemporal* model is a nonlinear mixed-effects model. As emphasized in the introduction, mixed-effects models include fixed and random effects. The *fixed-effects* are parameters which are shared by all the individuals and allow for the description of the model at the population level. *Random effects* are individual-specific random variable which describe the model at the individual level. These two types of effects provide the model with a hierarchical structure. The generic spatiotemporal model is constructed as follows. To begin with, a group-average trajectory $\boldsymbol{\gamma}_0$ is defined on the manifold $\mathbb{M}$. Given the average trajectory, subject-specific trajectories are obtained by spatiotemporal transformations,

which consist of *exp-parallelizations* of the average trajectory $\boldsymbol{\gamma}_0$ and *time reparametrization*. The data points $\mathbf{y}_{i,j}$ are seen as samples along these individual trajectories. If $\boldsymbol{\gamma}_i$ denotes the trajectory of the ith individual, the model writes: $\mathbf{y}_{i,j} = \boldsymbol{\gamma}_i(t_{i,j}) + \varepsilon_{i,j}$, where $\varepsilon_{i,j}$ is a Gaussian noise. The observation $\mathbf{y}_{i,j}$ is therefore considered as a small perturbation of a quantity which lies in a Riemannian manifold.

The group-average trajectory $\boldsymbol{\gamma}_0$ is chosen to be the unique geodesic $\boldsymbol{\gamma}_0 = \boldsymbol{\gamma}_{\mathbf{p}_0,t_0,\mathbf{v}_0}$ of $\mathbb{M}$ which goes through the point $\mathbf{p}_0 \in \mathbb{M}$ at time t_0 and with velocity $\mathbf{v}_0 \in T_{\mathbf{p}_0}\mathbb{M}$. Let $i \in \{1, \ldots, p\}$ denote the ith individual. The subject-specific trajectory $\boldsymbol{\gamma}_i$ is defined in two steps. The first step consists in constructing the curve $\eta^{\mathbf{w}_i}(\boldsymbol{\gamma}_0, \cdot)$, which is an *exp-parallelization* of the average trajectory $\boldsymbol{\gamma}_0$ in the direction of a tangent vector $\mathbf{w}_i \in T_{\mathbf{p}_0}\mathbb{M}$. This tangent vector is chosen orthogonal, for the inner product $g^{\mathbb{M}}_{\mathbf{p}_0}$, to $\dot{\boldsymbol{\gamma}}_0(t_0) = \mathbf{v}_0$. The tangent vectors $(\mathbf{w}_i)_{1\leq i\leq p}$ are random effects of the model, called *space shifts*. The orthogonality condition on the space shifts is discussed below. The second step consists of *reparametrizing in time* the exp-parallelization $\eta^{\mathbf{w}_i}(\boldsymbol{\gamma}_0, \cdot)$. We consider a subject-specific affine mapping ψ_i of the form $\psi_i(t) = \alpha_i(t - t_0 - \tau_i) + t_0$, where $\alpha_i > 0$ and $\tau_i \in \mathbb{R}$ are random effects of our model. The trajectory $\boldsymbol{\gamma}_i$ of the ith individual is $\boldsymbol{\gamma}_i(t) = \boldsymbol{\eta}^{\mathbf{w}_i}(\boldsymbol{\gamma}_0, \psi_i(t))$. The mapping ψ_i is called *time reparametrization* and the random effects α_i (respectively τ_i) are called *acceleration factor* (respectively *time shift*).

2.3 Definition of the Space Shifts

As mentioned above, the space shifts $(\mathbf{w}_i)_{1\leq i\leq p}$ are required to be orthogonal to $\dot{\boldsymbol{\gamma}}_0(t_0) = \mathbf{v}_0$ for the inner product $g^{\mathbb{M}}_{\mathbf{p}_0}$ induced by the Riemannian metric on $\mathbb{M}$. This section discusses different methods which allow to impose this orthogonality condition on the space shifts into a statistical model. The methodological challenge raised by this section consists of defining a (nonlinear) mixed-effects model with smooth constraints on some random effect of the model.

In order to ensure the interpretability of the space shifts, we consider an Independent Component Analysis (ICA) (Hyvärinen et al., 2004) decomposition of each tangent vector $\mathbf{w}_i$ as a linear combination of $N_s < N$ statistically independent tangent vectors $(\mathbf{A}_l)_{1\leq l\leq N_s}$ which are called *independent components* or *independent directions*. As a consequence, the space shifts $(\mathbf{w}_i)_{1\leq i\leq p}$ are defined as follows: $\forall i \in \{1, \ldots, p\}$, $\mathbf{w}_i = \mathbf{A}\mathbf{s}_i = \sum_{l=1}^{N_s} s_{l,i}\mathbf{A}_l$ where $\mathbf{A} = (\mathbf{A}_l)_{1\leq l\leq N_s}$ is such that each $\mathbf{A}_i$ is a vector in $\mathrm{T}_{\dot{\boldsymbol{\gamma}}_0(t_0)}\mathbb{M}$. In this definition, the weights $(s_{l,i})_{1\leq l\leq N_s}$ are random effects of the model called *sources*. By defining the space shifts this way, the generic spatiotemporal model will estimate an ICA decomposition of the space shifts. However, this definition does not ensure the orthogonality of the space shifts. A possible solution to make the vectors $\mathbf{w}_i$ orthogonal to $\mathbf{v}_0 = \dot{\boldsymbol{\gamma}}_0(t_0)$ consists of decomposing each vector $(\mathbf{A}_l)_{1\leq l\leq N_s}$ in an orthonormal basis of $\mathrm{Span}\big(\dot{\boldsymbol{\gamma}}_0(t_0)\big)^{\perp} \subset \mathrm{T}_{\mathbf{p}_0}\mathbb{M}$. Indeed, if $(\mathcal{B}_k)_{1\leq k\leq (N-1)N_s}$ is an orthonormal basis of $\mathrm{Span}\big(\dot{\boldsymbol{\gamma}}_0(t_0)\big)^{\perp}$, we assume that: $\forall l \in \{1, \ldots, N_s\}$, $A_l = \sum_{k=1}^{(N-1)N_s} \beta_{l,k}\mathcal{B}_k$. By construction, each independent component $\mathbf{A}_l$ $(1 \leq l \leq N_s)$ is orthogonal, for the inner product $g^{\mathbb{M}}_{\mathbf{p}_0}$, to $\mathbf{v}_0$. Therefore, each space shift $(\mathbf{w}_i)_{1\leq i\leq p}$ is orthogonal to $\mathbf{v}_0$ since we assumed that it writes as a linear combination of these independent components. In the following, the orthonormal basis is computed using the Gram-Schmidt algorithm or the Householder method (Coleman and Sorensen, 1984).

Moreover, it is important to note that the choice of the form of the distribution of the space-shifts does not depend on the reference time-point t_0. Indeed, the $\mathbf{w}_i = \mathbf{A}\mathbf{s}_i$ are defined in the tangent space of the curve at point $\mathbf{p}_0 = \gamma_0(t_0)$. At another point $\mathbf{p}'_0 = \gamma_0(t'_0)$, space-shifts become $\mathbf{w}'_i = \mathrm{P}_{\gamma_0,t_0,t'_0}\mathbf{w}_i$, where $\mathrm{P}_{\gamma_0,t_0,t'_0}$ is an orthogonal matrix. They are therefore distributed according to $\mathbf{w}'_i = P_{\gamma_0,t_0,t}\mathbf{A}\mathbf{s}_i$: the distribution of the sources $\mathbf{s}_i$ does not change and the independent components (i.e. the columns of $\mathbf{A}$) are adjusted to the new position on the average trajectory. In particular, the variance of the $\mathbf{w}'_i$ is invariant. This property holds for isometric invariant distributions. For instance, if $\mathbf{w}_i \sim \mathcal{N}(\mathbf{0}, \mathbf{\Sigma})$, then $\mathbf{w}'_i \sim \mathcal{N}(\mathbf{0}, \mathrm{P}_{\gamma_0,t_0,t'_0}\,\mathbf{\Sigma}\,\mathrm{P}^{\top}_{\gamma_0,t_0,t'_0})$.

2.4 The Statistical Model

The generic spatiotemporal model assumes that the jth observation of the ith individual derives from:

$$\mathbf{y}_{i,j} = \eta^{\mathbf{w}_i}(\boldsymbol{\gamma}_0, \psi_i(t_{i,j})) + \boldsymbol{\varepsilon}_{i,j}. \tag{2}$$

With the notations introduced above, let $\mathbf{z}_{\mathrm{pop}} = (\mathbf{p}_0, t_0, \mathbf{v}_0, (\beta_{l,k})_{l,k})$ denote the *population variables* and $(\mathbf{z}_i)_{1\leq i\leq p}$ denote the set of *individual variables* with: $\mathbf{z}_i = (\xi_i, \tau_i, (s_{l,i})_{l,i})$. Both $\mathbf{z}_{\mathrm{pop}}$ and $(\mathbf{z}_i)_{1\leq i\leq p}$ are *latent* (or random) variables assumed independent of each other and distributed as follows:

$$\begin{aligned} &\mathbf{p}_0 \sim \mathcal{N}(\overline{\mathbf{p}_0}, \sigma^2_{\mathbf{p}_0}), \quad t_0 \sim \mathcal{N}(\overline{t_0}, \sigma^2_{t_0}),\\ &\mathbf{v}_0 \sim \mathcal{N}(\overline{v_0}, \sigma^2_{v_0}), \quad \beta_{l,k} \overset{\text{i.i.d.}}{\sim} \mathcal{N}(\overline{\beta}_{l,k}, \sigma^2_{\beta}), \end{aligned} \tag{3}$$

and $\psi_i(t) = \alpha_i(t - t_0 - \tau_i) + t_0$ with $\alpha_i = \exp(\xi_i)$ and :

$$\xi_i \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, \sigma^2_{\xi}), \quad \tau_i \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, \sigma^2_{\tau}), \quad s_{l,i} \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, 1). \tag{4}$$

where $\sigma^2_{\mathbf{p}_0}$, $\sigma^2_{t_0}$, $\sigma^2_{\mathbf{v}_0}$ and σ^2_{β} are fixed variance parameters. The noise variables $(\boldsymbol{\varepsilon}_{i,j})_{i,j}$ are assumed independent of the other random variables and identically distributed:

$$\boldsymbol{\varepsilon}_{i,j} \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, \sigma^2). \tag{5}$$

Let $\boldsymbol{\theta}_{\mathrm{var}} = (\sigma^2_{\xi}, \sigma^2_{\tau}, \sigma^2)$ denote the variance parameters which are not fixed and $\boldsymbol{\theta} = \left(\overline{\mathbf{p}_0}, \overline{t_0}, \overline{\mathbf{v}_0}, (\overline{\beta}_{l,k}), \boldsymbol{\theta}_{\mathrm{var}}\right)$ be the *parameters* of the model. The domain of $\boldsymbol{\theta}$ is denoted by Θ and defined by:

$$\begin{aligned} \Theta = \big\{\boldsymbol{\theta} = &(\overline{\mathbf{p}_0}, \overline{\mathbf{v}_0}, \overline{t_0}, (\overline{\beta}_{l,k})_{l,k}, \boldsymbol{\theta}_{\mathrm{var}}) \,/\, (\overline{\mathbf{p}_0}, \overline{\mathbf{v}_0}) \in \mathrm{T}\mathbb{M},\\ &\overline{t_0} \in \mathbb{R}, (\overline{\beta}_{l,k})_{l,k} \in \mathbb{R}^{(N-1)N_s},\, \boldsymbol{\theta}_{\mathrm{var}} \in]0, +\infty[^3\big\}. \end{aligned} \tag{6}$$

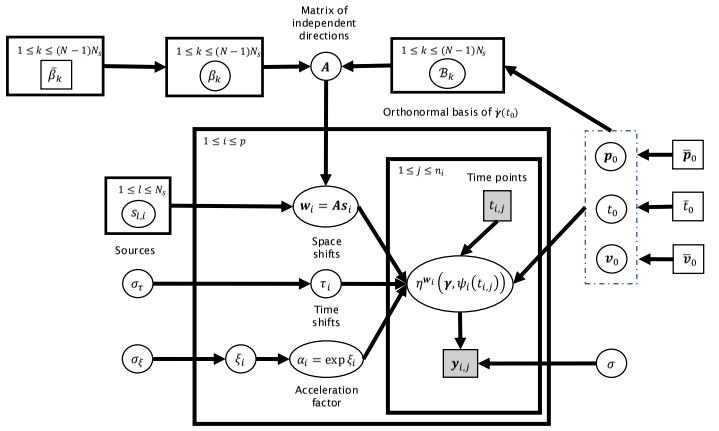

Figure 2: Graphical representation of the generic spatiotemporal model. Round shapes indicate latent variables of the model. Boxes with indexes in the upper left corner indicate a repetition. Shaded boxes indicate that the quantity is observed. This figure illustrates the dependence between the variables of the generic spatiotemporal model.

2.4.1 Discussion

The additive, or *extrinsic*, noise model in Eq. (2) makes sense because we assumed that $\mathbb{M}$ is a subset of the Euclidean space $\mathbb{R}^N$. The term $\eta^{\mathbf{w}_i}(\boldsymbol{\gamma}_0, \psi_i(t_{i,j}))$ belongs to the manifold $\mathbb{M}$ while the noise term $\boldsymbol{\varepsilon}_{i,j}$ is added in the underlying Euclidean space. However, the noise model is not *intrinsic* in the sense that the noise term $\boldsymbol{\varepsilon}_{i,j}$ is not added on the manifold. In Fletcher (2011), the author have considered an intrinsic noise model which would write: $\mathbf{y}_{i,j} = \mathrm{Exp}_{\eta^{\mathbf{w}_i}(\boldsymbol{\gamma}_0,\psi_i(t_{i,j}))}(\boldsymbol{\varepsilon}_{i,j})$. This noise model allows for it to remain on the manifold. Still, obtaining maximum *a posteriori* estimates of the parameters with this intrinsic noise model is more difficult as the model likelihood might not be available in closed-form.

We assume a centred log-normal distribution for the acceleration factors α_i. Indeed, this choice of probability distribution ensures the positiveness of the acceleration factors. With this assumption, the individual time reparametrizations do not reverse time. Other probability distributions, such as the exponential distribution, could have been considered.

3. Particular Cases of the Generic Spatiotemporal Model

The generic spatiotemporal model, introduced in the previous section, is a statistical tool which allows, given a Riemannian manifold $\mathbb{M}$ equipped with a Riemannian metric $g^{\mathbb{M}}$, to instantiate a large variety of nonlinear mixed-effects models. This section aims at describing the generic spatiotemporal model for classical Riemannian manifolds. The models for one-dimensional geodesically complete Riemannian manifolds given in Section 3.1 were introduced in Schiratti et al. (2015c). The progression models, given in Section 3.3 were introduced in Schiratti et al. (2015b).

3.1 The case of One-Dimensional Geodesically Complete Riemannian Manifolds

Let M be an open interval of $\mathbb{R}$ equipped with a Riemannian metric g^M, for which it is geodesically complete. The case of one dimensional manifolds is particular because, for all $p_0 \in M$, $\mathrm{T}_p M \simeq \mathbb{R}$ and given $v_0 \in \mathrm{T}_{p_0} M$, there is only one tangent vector w at p_0 which is orthogonal (for the inner product $g^M_{p_0}$) to v_0 : $w = 0$. As a result, if γ_0 is a geodesic of M, $t_0 \in \mathbb{R}$ and $w = 0$, then for all $s \in \mathbb{R}$, $\eta^w(\gamma_0, s) = \gamma_0(s)$. Therefore, the generic spatiotemporal model writes: $y_{i,j} = \gamma_0\big(\psi_i(t_{i,j})\big) + \varepsilon_{i,j}$, with, for all $i \in \{1, \ldots, p\}$, $\psi_i(t) = \alpha_i(t - t_0 - \tau_i) + t_0$ and $\alpha_i = \exp(\xi_i)$.

We show that, in this one-dimensional framework, a different presentation of the generic spatiotemporal model is possible. This presentation provides a different insight on the role of the latent variables $(\alpha_i, \tau_i)_{1 \leq i \leq p}$. Let $p_0 \in M$, $t_0 \in \mathbb{R}$ and $v_0 \in \mathrm{T}_{p_0} M \simeq \mathbb{R}$. Let γ_0 be the group-average trajectory defined as the geodesic which goes through the point p_0 at time t_0 and with velocity v_0. Let $1 \leq i \leq p$. The trajectory γ_i of the ith individual is defined as the geodesic γ_i which goes through the point p_0 at time $t_0 + \tau_i$ and with velocity $\alpha_i v_0$. Having defined individual trajectories of progression, the observations are seen as random samples along these trajectories: $y_{i,j} = \gamma_i(t_{i,j}) + \varepsilon_{i,j}$. In this definition, the acceleration factor α_i allows characterizing whether the ith individual is progressing faster ($\alpha_i > 1$) or slower ($\alpha_i < 1$) than the average trajectory. The time shift τ_i allows determining whether the ith individual is evolving ahead ($\tau_i < 0$) or behind ($\tau_i > 0$) the average trajectory. Moreover, it follows from a unicity property of the geodesics that, for all $i \in \{1, \ldots, p\}$, $\gamma_i(t) = \gamma_0\big(\psi_i(t)\big)$. This result legitimises the choice of affine time reparametrizations of the form $\psi_i : t \mapsto \alpha_i(t - t_0 - \tau_i) + t_0$.

3.1.1 The "Straight Lines Model"

Unbounded observations can be considered as points on the real line. The real line $M = \mathbb{R}$ equipped with its canonical metric is a geodesically complete one-dimensional Riemannian manifold. For the canonical metric, the geodesics are of the form $t \in \mathbb{R} \mapsto at + b$ with $(a, b) \in \mathbb{R}^2$. The generic spatiotemporal model writes: $y_{i,j} = p_0 + \alpha_i v_0(t_{i,j} - t_0 - \tau_i) + \varepsilon_{i,j}$. This model is referred to as the *univariate straight lines model*. Note that, even though the average and individual trajectories are straight lines, the model is *not* linear due to the multiplication between the random effects α_i and τ_i.

We propose to compare the nonlinear straight lines model to the random slope and intercept model, discussed in the introduction. This linear mixed-effects model writes: $y_{i,j} = (\overline{a} + a_i)(t_{i,j} - t_0) + (\overline{b} + b_i) + \varepsilon_{i,j}$, where $(A_i, B_i)_{1 \leq i \leq p}$ are random effects of the model which are assumed to be independent of each other and normally distributed with mean 0 and variance-covariance matrix $\mathbf{D}$. The fixed effects of this model are $(\overline{a}, \overline{b}, t_0)$. This linear model analyzes the distribution of the observations at a fixed reference time t_0. In comparison, the straight lines model analyzes the distribution of the times at which the observations reach a given value of the measurements. The two models illustrated in Fig. 3 are not equivalent because the observations generated by these two models are different. Indeed, the *random slope and intercept model* generates straight lines whose slope $\overline{a} + a_i$ and intercept $\overline{b} + b_i - t_0(\overline{a} + a_i)$ both follow Gaussian distributions. With the straight lines model, only the slope $\overline{a}a_i$ follows a Gaussian distribution. The intercept $\overline{b} - (t_0 + \tau_i)\overline{a}a_i$ actually does not follow a Gaussian distribution. It is the sum of two random variables, one following a Gaussian distribution, and the other one being the product of two independent Gaussian random variables, a_i and τ_i. The distribution of $a_i\tau_i$ is that of a (weighted) sum of two chi-square random variables (which are, in general, not independent).

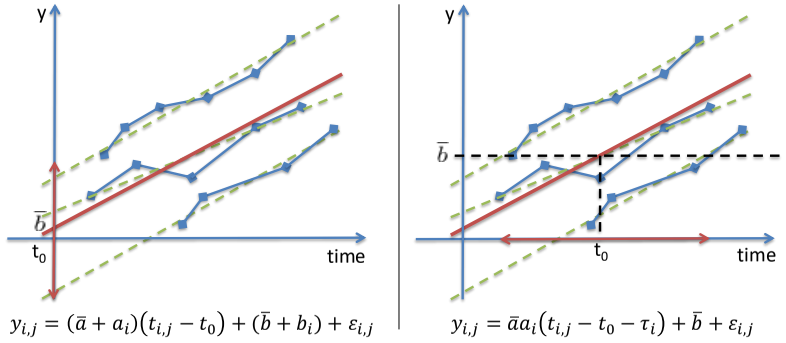

Figure 3: Schematic example of a random slope and intercept linear mixed-effects model (left) and straight lines model (right).

3.2 The "Logistic Curves Model"

If the observations are bounded, such as percentages or scores to a test, the measurements can be normalized to produce new observations in the open interval $M =]0, 1[$. We consider that this open interval of the real line is equipped with the Riemannian metric $g = (g_p)_{p \in]0,1[}$ where : $\forall p \in \mathbb{M} =]0, 1[$, $\forall (u, v) \in T_p\mathbb{M} \times T_p\mathbb{M}$, $g_p(u, v) = uM(p)v$, where $M(p) = 1/\big(p^2(1-p)^2\big)$. This Riemannian metric on $]0, 1[$ is obtained as the push-forward of the Euclidean metric on $\mathbb{R}$ by the logit transform. In Schiratti et al. (2015c), it is proven that $\mathbb{M} =]0, 1[$ is a geodesically complete Riemannian manifold and that the generic spatiotemporal model

writes:

$$y_{i,j} = \left(1 + \left(\frac{1}{p_0} - 1\right)\exp\Big(-\frac{v_0\alpha_i(t_{i,j} - t_0 - \tau_i)}{p_0(1-p_0)}\Big)\right)^{-1} + \varepsilon_{i,j}. \tag{7}$$

In this framework, the Riemannian logarithm at $p = 1/2$, which corresponds to the inflexion point of the logistics, is given by: $\forall q \in]0,1[$, $\mathrm{Log}_{1/2}(q) = (1/4)\mathrm{logit}(q)$. However, in (7), the point p_0 is not fixed to $1/2$, but is estimated as a fixed effect. The model estimates the p_0, and therefore the best tangent space, which best describes the observations. Furthermore, even if one fixes $p = 1/2$, the model lifted up on the tangent space remains nonlinear due to the multiplication between the random effects α_i and τ_i. Therefore, the logistic curves model is not equivalent to a linear model on the logit transform of the observations.

3.3 A Progression Model

The generic spatiotemporal model can be used to study the temporal progression of a family of features which characterize the evolution of a biological phenomenon. We assume that each feature is described by repeated *univariate* observations, which are random perturbations of quantities lying in a one-dimensional geodesically complete Riemannian manifold (M, g^M), open subset of $\mathbb{R}$. For each individual, at each time point, the observations $(\mathbf{y}_{i,j})_{1\leq i\leq p,\, 1\leq j\leq k_i}$ consist of a N-dimensional vector of univariate features. Hence, for this progression model, the observations $(\mathbf{y}_{i,j})_{1\leq i\leq p,\, 1\leq j\leq k_i}$ are considered as random perturbations of quantities which belong to the product manifold $\mathbb{M} = M \times \ldots \times M = M^N$. Since each Riemannian manifold (M, g^M) is geodesically complete, $\mathbb{M}$ equipped with the product metric is also geodesically complete.

On the product manifold $\mathbb{M} = M^N$, equipped with the product metric, a geodesic is of the form $t \mapsto \big(\gamma_1(t), \ldots, \gamma_N(t)\big)$, where $\gamma_1, \ldots, \gamma_N$ are geodesics of the one-dimensional Riemannian manifold M. Because we would like to model the joint temporal progression of N features, we propose to choose the group-average trajectory among a parametric family of geodesics of $\mathbb{M}$. This family is of the form:

$$\Big\{\boldsymbol{\gamma}_{0,\boldsymbol{\delta}} : t \in \mathbb{R} \mapsto \big(\gamma_0(t), \gamma_0(t+\delta_1), \ldots, \gamma_0(t+\delta_{N-1})\big)\Big\}, \tag{8}$$

with $\boldsymbol{\delta} = (0, \delta_1, \ldots, \delta_{N-1})^\top$, $\delta_i \in \mathbb{R}$ and γ_0 denotes a geodesic of the one-dimensional Riemannian manifold g^M which goes through a point $p_0 \in M$ at time t_0 with velocity v_0. The relative delay between two consecutive biomarkers is given by the parameters δ_i $(1 \leq i \leq N-1)$. The vector $\boldsymbol{\delta}$ is to be estimated as a fixed effect of the model. The first component of the vector $\boldsymbol{\delta}$ is chosen to be equal to zero in order to ensure the identifiability of the model. Note that assuming that the group average belongs to this parametric family of geodesics is equivalent to assuming that the progression of each feature is described by trajectories which have the same shape but are shifted in time.

Lemma 2 *Let $\boldsymbol{\gamma}$ be a geodesic of the product manifold $\mathbb{M} = M^N$ and let $t_0 \in \mathbb{R}$. If $\eta^{\mathbf{w}}(\boldsymbol{\gamma}, \cdot)$ denotes an exp-parallelization of the geodesic $\boldsymbol{\gamma}$ using $\mathbf{w} = (w_1, \ldots, w_N) \in \mathrm{T}_{\boldsymbol{\gamma}(t_0)}\mathbb{M}$ and with $\boldsymbol{\gamma}(t) = (\gamma_1(t), \ldots, \gamma_N(t))$, we have $\eta^{\mathbf{w}}(\boldsymbol{\gamma}, s) = \big(\gamma_1\big(\frac{w_1}{\dot{\gamma}_1(t_0)} + s\big), \ldots, \gamma_N\big(\frac{w_N}{\dot{\gamma}_N(t_0)} + s\big)\big)$, $s \in \mathbb{R}$.*

In this framework, an exp-parallelization of the group-average trajectory $\boldsymbol{\gamma}_{0,\boldsymbol{\delta}}$ can be computed using the result given in Lemma 2. Indeed, it follows from Lemma 2 that the generic spatiotemporal model 2 writes :

$$y_{i,j,k} = \gamma_0\left(\frac{w_{i,k}}{\dot{\gamma}_0(t_0 + \delta_{k-1})} + \psi_i(t_{i,j}) + \delta_{k-1}\right) + \varepsilon_{i,j,k}, \tag{9}$$

where, for all $k \in \{1, \ldots, N\}$, $(\mathbf{y}_{i,j})_k$ denotes the kth component of $\mathbf{y}_{i,j}$. In other words, $(\mathbf{y}_{i,j})_k$ is the observation associated to the kth biomarker, for the ith individual, at the jth time point. Similarly, $(\mathbf{w}_i)_k$ denotes the kth component of the space shift $\mathbf{w}_i$. For all $i \in \{1, \ldots, p\}$, $\psi_i(t) = \alpha_i(t - t_0 - \tau_i) + t_0$ is the individual specific time reparametrization. This model is referred to as the *progression model*. For this model, the latent variables are: $\mathbf{z}_{\mathrm{pop}} = \big(p_0, t_0, v_0, (\delta_k)_{1\leq k\leq N-1}, (\beta_{l,k})_{l,k}\big)$ and, for all $i \in \{1, \ldots, p\}$, $\mathbf{z}_i = \big(\xi_i, \tau_i, (s_{l,i})_{l,i}\big)$. The definition of the individual latent variables $(\mathbf{z}_i)_{1\leq i\leq p}$ remains unchanged. For the population latent variables $\mathbf{z}_{\mathrm{pop}}$, the variables $(\delta_k)_{1\leq k\leq N-1}$ are added. We assume that the latent variables $\mathbf{z}_{\mathrm{pop}}$ are distributed as follows:

$$p_0 \sim \mathcal{N}(\overline{p_0}, \sigma^2_{p_0}),\ t_0 \sim \mathcal{N}(\overline{t_0}, \sigma^2_{t_0}),\ v_0 \sim \mathcal{N}(\overline{v_0}, \sigma^2_{v_0}), \tag{10}$$

and

$$\beta_{l,k} \overset{\text{i.i.d.}}{\sim} \mathcal{N}(\overline{\beta}_{l,k}, \sigma^2_\beta),\ \delta_k \overset{\text{i.i.d.}}{\sim} \mathcal{N}(\overline{\delta}_k, \sigma^2_\delta), \tag{11}$$

where $\sigma^2_{p_0}$, $\sigma^2_{t_0}$, $\sigma^2_{v_0}$ and σ^2_δ are *fixed* variance parameters. Similarly to the generic spatiotemporal model, the latent variables are assumed independent of each other and independent of the noise variables $\boldsymbol{\varepsilon}_{i,j} \overset{\text{i.i.d.}}{\sim} \mathcal{N}(\mathbf{0}, \sigma^2\mathrm{I}_N)$.

3.4 The Symmetric Positive Definite (SPD) Matrices Model

In this section, we describe how the generic spatiotemporal model can be used to analyze longitudinal datasets of symmetric positive definite matrices. Such datasets may arise in Diffusion Tensor Imaging (DTI) or when observing the temporal evolution of covariance matrices.

The space of 3×3 symmetric positive definite matrices is usually denoted by SDP(3), which is an open subset of the vector space of $(3,3)$ symmetric real matrices, denoted by Sym(3). By identifying Sym(3) with $\mathbb{R}^6$, $\mathbb{M} = \mathrm{SDP}(3)$ can be considered as an open submanifold of $\mathbb{R}^6$. Indeed, $\mathbb{M}$ can be equipped with a Riemannian metric. In Pennec et al. (2006), the authors defined an *affine-invariant* Riemannian metric on SDP(3). Equipped with this metric, the space of symmetric positive definite matrices is a geodesically complete Riemannian manifold, without boundaries (matrices with null eigenvalues are at infinity). The results presented below are obtained with the affine-invariant metric on SDP(3).

If $\boldsymbol{\Sigma} \in \mathrm{SDP}(3)$, $\boldsymbol{\Sigma}^{1/2}$ denotes the unique symmetric positive definite matrix $\mathbf{S}$ such that : $\mathbf{S}^2 = \boldsymbol{\Sigma}$ and $\boldsymbol{\Sigma}^{-1/2}$ denotes its inverse. Let $\mathrm{T}_{\boldsymbol{\Sigma}}\mathbb{M}$ denote the tangent space to $\mathbb{M}$ at the point $\boldsymbol{\Sigma}$. $\mathrm{T}_{\boldsymbol{\Sigma}}\mathbb{M}$ can be identified with Sym(3) and is equipped with the inner product $\langle\cdot,\cdot\rangle_{\boldsymbol{\Sigma}}$ defined by : $\forall(\mathbf{W}_1, \mathbf{W}_2) \in \mathrm{T}_{\boldsymbol{\Sigma}}\mathbb{M}$, $\langle \mathbf{W}_1, \mathbf{W}_2\rangle_{\boldsymbol{\Sigma}} = \mathrm{tr}\big(\boldsymbol{\Sigma}^{-1/2}\mathbf{W}_1^\top\boldsymbol{\Sigma}^{-1}\mathbf{W}_2\boldsymbol{\Sigma}^{-1/2}\big)$. In order to describe exp-parallelization in the Riemannian manifold $\mathrm{SPD}(n)$ equipped with

the affine invariant metric, we give a closed-form expression of the parallel transport. The result given in Lemma 3 is based in the work of Lenglet et al. (2006). For $\mathbf{P}_0 \in \mathrm{SPD}(n)$, $t_0 \in \mathbb{R}$, $\mathbf{V}_0 \in \mathrm{T}_{\mathbf{P}_0}\mathrm{SPD}(n) \simeq \mathrm{SYM}(n)$, the geodesic $\boldsymbol{\gamma}_0$, defined by $\boldsymbol{\gamma}_0(t) = \mathrm{Exp}_{\mathbf{P}_0,t_0}(\mathbf{V}_0)(t)$ for all $t \in \mathbb{R}$, is given by : $\boldsymbol{\gamma}_0(t) = \mathbf{P}_0^{1/2} \exp\big(t\mathbf{P}_0^{-1/2}\mathbf{V}_0\mathbf{P}_0^{-1/2}\big)\mathbf{P}_0^{1/2}$, where $\mathbf{P}_0^{1/2}$ (respectively $\mathbf{P}_0^{-1/2}$) denotes the unique symmetric positive definite square root of $\mathbf{P}_0$ (respectively its inverse). The proof of Lemma 3 can be adapted to obtain the expression of the geodesics. One can also obtain this expression by noting that the geodesic starting at I_n with velocity $\mathbf{V} \in \mathrm{SYM}(n)$ is given by $\exp(t\mathbf{V})$ and use the invariance of the affine-invariant metric under congruent transformations. Finally, the expression of the parallel transport along such a geodesic is given by the following lemma.

Lemma 3 *Let $\mathbf{P}_0 \in \mathrm{SPD}(n)$, $t_0 \in \mathbb{R}$ and $\mathbf{V}_0 \in \mathrm{T}_{\mathbf{P}_0}\mathrm{SPD}(n) \simeq \mathrm{SYM}(n)$. Let $\boldsymbol{\gamma}_0$ be the geodesic defined as above. If $\mathbf{W}$ is a tangent vector in $\mathrm{T}_{\mathbf{P}_0}\mathrm{SPD}(n)$, the parallel transport $\mathrm{P}_{\boldsymbol{\gamma}_0,t_0,t}(\mathbf{W})$ is given by:*

$$\forall t \in \mathbb{R},\ \mathrm{P}_{\boldsymbol{\gamma}_0,t_0,t}(\mathbf{W}) = \exp\Big(\frac{t-t_0}{2}\mathbf{V}_0\mathbf{P}_0^{-1}\Big)\mathbf{W}\exp\Big(\frac{t-t_0}{2}\mathbf{P}_0^{-1}\mathbf{V}_0\Big). \tag{12}$$

The proof of Lemma 3 is given in Appendix A.2. It follows from this lemma that the generic spatiotemporal model writes :

$$\mathbf{Y}_{i,j} = \mathbf{P}_i(t_{i,j})^{1/2}\exp\big(\mathbf{P}_i(t_{i,j})^{-1/2}\mathbf{V}_i(t_{i,j})\mathbf{P}_i(t_{i,j})^{-1/2}\big)\mathbf{P}_i(t)^{1/2} + \boldsymbol{\varepsilon}_{i,j}, \tag{13}$$

with, for all $t \in \mathbb{R}$,

$$\mathbf{P}_i(t) = \mathbf{P}_0^{1/2}\exp\big(\alpha_i(t-t_0-\tau_i)\mathbf{P}_0^{-1/2}\mathbf{V}_0\mathbf{P}_0^{-1/2}\big)\mathbf{P}_0^{1/2}, \tag{14}$$

and:

$$\mathbf{V}_i(t) = \exp\Big(\frac{\alpha_i(t-t_0-\tau_i)}{2}\mathbf{V}_0\mathbf{P}_0^{-1}\Big)\mathbf{W}_i\exp\Big(\frac{\alpha_i(t-t_0-\tau_i)}{2}\mathbf{P}_0^{-1}\mathbf{V}_0\Big). \tag{15}$$

The prior distribution for the matrices $\mathbf{P}_0$, $\mathbf{V}_0$ and $(\boldsymbol{\varepsilon}_{i,j})_{i,j}$ are defined as follows: $\mathbf{P}_0 \sim \mathcal{SN}(\overline{\mathbf{P}_0}, \sigma_{P_0}^2)$, $\mathbf{V}_0 \sim \mathcal{SN}(\overline{\mathbf{V}_0}, \sigma_{V_0}^2)$ and $\boldsymbol{\varepsilon}_{i,j} \overset{\text{i.i.d.}}{\sim} \mathcal{SN}(\mathbf{0}, \sigma^2)$, where $\mathcal{SN}$ denotes the Gaussian distribution on the vector space $\mathrm{Sym}(n)$. Given $\overline{\mathbf{M}} \in \mathrm{SYM}(n)$, the probability distribution $\mathcal{SN}(\overline{\mathbf{M}}, \sigma^2)$ on $\mathrm{Sym}(n)$ is defined by the density function q such that: $q(\mathbf{M}) = \frac{1}{(2\pi)^{m/2}\sigma^m}\exp\big(-\frac{1}{2\sigma^2}\mathrm{tr}\big[(\overline{\mathbf{M}}-\mathbf{M})^2\big]\big)$ with $\mathbf{M} \in \mathrm{Sym}(n)$ and with $m = n(n+1)/2$. The "standard" distribution $\mathcal{SN}(\mathbf{0}, 1)$ is used in physics and in the theory of random matrices. It is sometimes called *Gaussian Orthogonal Ensemble*. The probability distribution of the other random effects of the model are defined as in Section 2.2. This model will be referred to as the *symmetric positive definite matrices model* or $\mathrm{SPD}(n)$ *matrices model*. In Arsigny et al. (2006), the authors considered the space $\mathrm{SPD}(n)$ equipped with the log-Euclidean metric. This metric provides the space of symmetric positive definite matrices with a structure of Riemannian manifold. Unlike with the affine-invariant metric, the space $\mathrm{SPD}(n)$ endowed with the Log-Euclidean metric is a *flat* Riemannian manifold, meaning that its sectional curvature is null everywhere. By contrast, the space $\mathrm{SPD}(n)$ equipped with the affine-invariant metric is a Riemannian manifold of non-positive curvature (Skovgaard, 1984; Moakher and

Zéraï, 2011) with no cut-locus. Within the Log-Euclidean framework, the geodesics are of the form: $\exp(\mathbf{V}_1 + t\mathbf{V}_2)$ with $\mathbf{V}_1, \mathbf{V}_2 \in \mathrm{SYM}(n)$. As expected, the geodesics are the image of a straight line in $\mathrm{SYM}(n)$ by the matrix exponential map. Future developments should include comparisons with the log-euclidean metric on the space $\mathrm{SPD}(3)$.

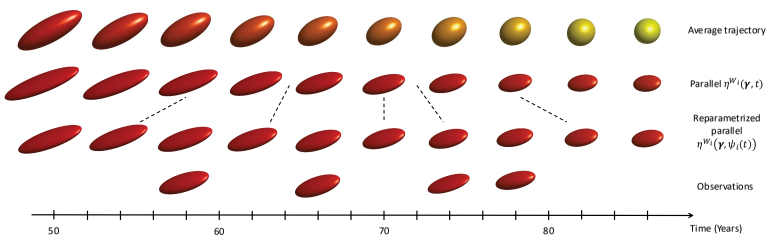

Figure 4: Simulated evolutions of diffusion tensors. First row : average trajectory from a highly anisotropic diffusion tensor to a sphere. Second row : a parallel to the average trajectory obtained using a random space shift $\mathbf{W}_i$. Third row : the reparametrization of the exp-parallelization with $\alpha_i = 0.7$ and $\tau_i = -4$ (years). Fourth row : the observations are samples from the reparametrized exp-parallelization. Each diffusion tensor is colored according to its fractional anisotropy (red for a highly anisotropic tensors, yellow for a sphere).

4. Parameters Estimation

The generic spatiotemporal model (Eq. (2)) is a nonlinear mixed-effects model for which the *observed* likelihood is not available in closed-form. Indeed, it writes as an intractable integral which could only be approximated. In order to produce maximum likelihood estimates, we could use the Expectation Maximization (EM) algorithm (Dempster et al., 1977). The first step of the EM algorithm, usually called "E-step", requires us to compute the expectation of the log-complete likelihood (the likelihood of the observations $\mathbf{y} = (\mathbf{y}_{i,j})_{1\leq i\leq p, 1\leq j\leq k_i}$ and the latent variables $\mathbf{z}$) with respect to the conditional distribution of the latent variables knowing the observations and the current values of the parameters. In the case of our model, this expectation cannot be computed in closed-form.

Therefore, we choose to estimate the parameters of the generic spatiotemporal model by using a stochastic version of the EM algorithm, in which this step is replaced by a stochastic approximation. This algorithm is the Monte Carlo Markov Chains (MCMC) Stochastic Approximation EM (MCMC-SAEM) algorithm (Allassonnière et al., 2010). The MCMC-SAEM iterates, until convergence, between three steps: simulation, stochastic approximation and maximization.

4.1 Simulation Step

Algorithm 1 The Block Metropolis-Hastings-within-Gibbs sampler

Require: Set of latent variables $\mathbf{z}^{(k-1)} = \big(\mathbf{z}_{\text{pop}}^{(k-1)}, (\mathbf{z}_i^{(k-1)})_{1\leq i\leq p}\big)$, current estimate of the parameters $\boldsymbol{\theta}^{(k-1)}$, variance-covariance matrices $\mathbf{D}_{\text{pop}}$ and $(\mathbf{D}_i)_{1\leq i\leq p}$ and $\boldsymbol{\theta}_{\text{hyper}}$

Ensure: Set of latent variables $\mathbf{z}^{(k)}$

Block $\mathbf{z}_{\text{pop}}^{(k)}$ of population latent variables:

Draw a candidate $\mathbf{z}_{\text{pop}}^* \sim \mathcal{N}\big(\mathbf{z}_{\text{pop}}^{(k-1)}, \mathbf{D}_{\text{pop}}\big)$

Compute the acceptance ratio $\alpha(\mathbf{z}_{\text{pop}}^{(k-1)}, \mathbf{z}_{\text{pop}}^*)$ defined by:

$$\alpha(\mathbf{z}_{\text{pop}}^{(k-1)}, \mathbf{z}_{\text{pop}}^*) = \frac{q(\mathbf{y} \mid \mathbf{z}_{\text{pop}}^*, (\mathbf{z}_i^{(k-1)})_{1\leq i\leq p}, \boldsymbol{\theta}^{(k-1)}) q_{\text{pop}}(\mathbf{z}_{\text{pop}}^* \mid \boldsymbol{\theta}^{(k-1)})}{q(\mathbf{y} \mid \mathbf{z}_{\text{pop}}^{(k-1)}, (\mathbf{z}_i^{(k-1)})_{1\leq i\leq p}, \boldsymbol{\theta}^{(k-1)}) q_{\text{pop}}(\mathbf{z}_{\text{pop}}^{(k-1)} \mid \boldsymbol{\theta}^{(k-1)})} \wedge 1.$$

Draw $U \sim \text{Uniform}\big([0,1]\big)$

Set: $\mathbf{z}_{\text{pop}}^{(k)} = \mathbf{z}_{\text{pop}}^*$ if $U \leq \alpha(\mathbf{z}_{\text{pop}}^{(k-1)}, \mathbf{z}_{\text{pop}}^*)$ and $\mathbf{z}_{\text{pop}}^{(k)} = \mathbf{z}_{\text{pop}}^{(k-1)}$ otherwise.

for $i = 1 \dots p$ **do**

  Blocks $(\mathbf{z}_i^{(k)})_{1\leq i\leq p}$ of individual latent variables:

  Draw a candidate $\mathbf{z}_i^* \sim \mathcal{N}\big(\mathbf{z}_i^{(k-1)}, \mathbf{D}_{\text{indiv}}\big)$

  Compute the acceptance ratio $\alpha(\mathbf{z}_i^{(k-1)}, \mathbf{z}_i^*)$ defined by:

$$\alpha(\mathbf{z}_i^{(k-1)}, \mathbf{z}_i^*) = \frac{q(\mathbf{y} \mid \mathbf{z}_{\text{pop}}^{(k)}, \mathbf{z}_{-i}^{(k-1),(k)}, \mathbf{z}_i^*, \boldsymbol{\theta}^{(k-1)}) q_i(\mathbf{z}_i^* \mid \boldsymbol{\theta}^{(k-1)})}{q(\mathbf{y} \mid \mathbf{z}_{\text{pop}}^{(k)}, \mathbf{z}_{-i}^{(k-1),(k)}, \mathbf{z}_i^{(k-1)}, \boldsymbol{\theta}^{(k-1)}) q_i(\mathbf{z}_i^{(k-1)} \mid \boldsymbol{\theta}^{(k-1)})} \wedge 1.$$

  Draw $U \sim \text{Uniform}([0,1])$

  Set: $\mathbf{z}_i^{(k)} = \mathbf{z}_i^*$ if $U \leq \alpha(\mathbf{z}_i^{(k-1)}, \mathbf{z}_i^*)$ or $\mathbf{z}_i^{(k)} = \mathbf{z}_i^{(k-1)}$ otherwise.

end for

Return: $\mathbf{z}^{(k)} = \big(\mathbf{z}_{\text{pop}}^{(k)}, (\mathbf{z}_i^{(k)})_{1\leq i\leq p}\big)$.

If $\tilde{\boldsymbol{\theta}}^{(k-1)}$ denotes the current estimate of $\tilde{\boldsymbol{\theta}}$ at the beginning of the kth iteration of the MCMC-SAEM, the simulation step consists of drawing a sample $\mathbf{z}^{(k)}$ from the transition kernel $\boldsymbol{\pi}_{\boldsymbol{\theta}^{(k-1)},\mathbf{y}}(\mathbf{z}^{(k-1),\cdot})$ of an ergodic Markov chain whose stationary distribution is the conditional distribution $q(\mathbf{z} \mid \mathbf{y}, \tilde{\boldsymbol{\theta}}^{(k-1)})$, the distribution of the latent variables $\mathbf{z}$ knowing the observations $\mathbf{y}$ and $\tilde{\boldsymbol{\theta}}^{(k-1)}$. This step is achieved using a Monte Carlo Markov Chain (MCMC) sampler. We chose to use a Block Metropolis-Hastings-within-Gibbs (Block MHwG) sampler for the sampling step of the MCMC-SAEM. Each Metropolis-Hastings step of the algorithm consists in a multivariate symmetric random walk. The Block MHwG sampler updates simultaneously *block* (or sets) of latent variables then, at each iteration, each block is updated conditionally on the others. Even though the latent variables can be grouped in several ways, we chose to group the latent variables as follows: $\{\mathbf{z}_{\text{pop}}\}$ and $\{\mathbf{z}_i\}_{1\leq i\leq p}$. This grouping being

given by the hierarchical structure of the model. Note that the latent variables also could have been grouped as follows: $\{\mathbf{p}_0, t_0, \mathbf{v}_0\}$, $\{(\beta_{l,k})_{l,k}\}$ and $\{\mathbf{z}_i\}_{1\leq i\leq p}$. In the case of the progression models, the delay variables $(\delta_k)_{1\leq k\leq N-1}$ were grouped with $\mathbf{z}_{\text{pop}}$, although they could also be considered as a block in itself.

For each block, the proposal in the Metropolis-Hastings step is chosen to be a multivariate Gaussian distribution centred at the current state of the block. Each variance-covariance matrix of a proposal distribution is chosen to be diagonal matrix: $\mathbf{D}_{\text{pop}} = \text{Diag}\big(\zeta_{\mathbf{p}_0}^2 \text{I}_N, \zeta_{t_0}^2, \zeta_{\mathbf{v}_0}^2 \text{I}_N, \zeta_{\boldsymbol{\beta}}^2 \text{I}_{(N-1)N_s}\big)$ for the proposal distribution associated to $\mathbf{z}_{\text{pop}}$ and $\mathbf{D}_{\text{indiv}} = \text{Diag}\big(\zeta_\xi^2, \zeta_\tau^2, \zeta_s^2\big)$ for the proposal distribution associated to $\mathbf{z}_i$ $(1 \leq i \leq p)$. The variances parameters $\zeta_{\mathbf{p}_0}^2, \zeta_{t_0}^2, \zeta_{\mathbf{v}_0}^2, \zeta_{\boldsymbol{\beta}}^2$ and $\zeta_\xi^2, \zeta_\tau^2$ are adjusted by hand to ensure an average acceptance rate for each block around 23% (Roberts et al., 1997). The Block MHwG sampler is described in Algorithm 1.

Let $\boldsymbol{\theta}_{\text{hyper}} = (\sigma_{\mathbf{p}_0}^2, \sigma_{t_0}^2, \sigma_{\mathbf{v}_0}^2, \sigma_{\boldsymbol{\beta}}^2)$ denote the fixed hyperparameters which appear in the probability distribution of the latent variables in $\mathbf{z}_{\text{pop}}$. Let $i \in \{1, \dots, p\}$ and $q_{\text{pop}}\big(\cdot \mid \boldsymbol{\theta}\big)$ (respectively $q_i(\cdot \mid \boldsymbol{\theta})$ denote the density function of the joint distribution of the latent variables $\mathbf{z}_{\text{pop}}$ (respectively $\mathbf{z}_i$) as specified in the generative model (equations (3) and (4)):

$$\begin{aligned} q_{\text{pop}}(\mathbf{z}_{\text{pop}} \mid \boldsymbol{\theta}) \propto \exp\Big(-\frac{1}{2\sigma_{\mathbf{p}_0}^2}\|\mathbf{p}_0 - \overline{\mathbf{p}_0}\|^2\Big) \exp\Big(-\frac{1}{2\sigma_{t_0}^2}(t_0 - \overline{t_0})^2\Big) \\ \exp\Big(-\frac{1}{2\sigma_{\mathbf{v}_0}^2}\|\mathbf{v}_0 - \overline{\mathbf{v}_0}\|^2\Big) \exp\Big(-\frac{1}{2\sigma_{\boldsymbol{\beta}}^2}\|\boldsymbol{\beta} - \overline{\boldsymbol{\beta}}\|^2\Big), \end{aligned} \tag{16}$$

and

$$q_i(\mathbf{z}_i \mid \boldsymbol{\theta}) \propto \exp\Big(-\frac{1}{2\sigma_\xi^2}\xi_i^2\Big) \exp\Big(-\frac{1}{2\sigma_\tau^2}\tau_i^2\Big) \exp\Big(-\frac{1}{2}\|\mathbf{s}_i\|^2\Big), \tag{17}$$

with: $\boldsymbol{\beta} = [\beta_{l,k}]_{1\leq l\leq N_s, 1\leq k\leq N-1}$ and for all $i \in \{1, \dots, p\}$, $\mathbf{s}_i = [s_{l,i}]_{1\leq l\leq N_s}$. The probability distributions q_{pop} and q_i $(1 \leq i \leq p)$ are given up to a constant. Indeed, the normalizing constant of q_{pop} or q_i $(1 \leq i \leq p)$ depends only on the parameters $\boldsymbol{\theta}$. Therefore, these constants can be omitted for the computation of the acceptance ratio in Algorithm 1.

4.1.1 Discussion

In order to avoid tuning by hand the parameters $\zeta_{\mathbf{p}_0}^2$, $\zeta_{t_0}^2$, $\zeta_{\mathbf{v}_0}^2$ and $\zeta_{\boldsymbol{\beta}}^2$ of the proposal distribution in the Block MHwG sampler, a possible solution would consist of using an *adaptive* (Atchadé, 2006) version of the Block MHwG sampler, where the algorithm automatically adjusts these variance parameters.

4.2 Stochastic Approximation

The convergence of the MCMC-SAEM was proven in Kuhn and Lavielle (2004) (for bounded latent variables) and in Allassonnière et al. (2010) (for unbounded latent variables) for statistical models which belong to the *curved exponential family*. That is to say, models for which the log complete likelihood $q(\mathbf{y}, \mathbf{z}, \boldsymbol{\theta})$ writes: $\forall \boldsymbol{\theta} \in \Theta$, $\log q(\mathbf{y}, \mathbf{z}, \boldsymbol{\theta}) = -\Phi(\boldsymbol{\theta}) + \langle \mathbf{S}(\mathbf{y}, \mathbf{z}), \Psi(\boldsymbol{\theta}) \rangle$, where Φ, Ψ are smooth functions of the parameters, $\mathbf{S}(\mathbf{y}, \mathbf{z})$ is a measurable function of the observations and latent variables called *sufficient statistic of the model* and

$\langle \cdot, \cdot \rangle$ is an inner product on a product space. The generic spatiotemporal model belongs to the curved exponential family.

Because the generic spatiotemporal model belongs to the curved exponential family, the stochastic approximation can be done on the sufficient statistics of the model. At the kth iteration of the MCMC-SAEM, we have: $\mathbf{S}_k = \mathbf{S}_{k-1} + \varepsilon_k\big(\mathbf{S}(\mathbf{y}, \mathbf{z}^{(k)}) - \mathbf{S}_{k-1}\big)$, where $(\varepsilon_k)_{k\geq 1}$ is a sequence of positive step sizes such that $\sum_k \varepsilon_k = +\infty$ and $\sum_k \varepsilon_k^2 < +\infty$. If $\varepsilon_k = 1$, then $\mathbf{S}_k$ does not depend on $\mathbf{S}_{k-1}$. Intuitively, the sequence $(\mathbf{S}_k)_{k\geq 0}$ has "no memory" as long as $\varepsilon_k = 1$ and the MCMC-SAEM freely explores the parameters space during this period. In practice, we choose $\varepsilon_k = 1$ as long as $k \leq N_b$ and $\varepsilon_k = (k - N_b)^{-0.65}$ if $k > N_b$.

4.2.1 Maximization Step

The maximization step consists of solving the following optimization problem : $\boldsymbol{\theta}^{(k)} = \underset{\boldsymbol{\theta}\in\Theta}{\text{argmax}} \big(-\Phi(\boldsymbol{\theta}) + \langle \mathbf{S}_k, \Psi(\boldsymbol{\theta}) \rangle \big)$, where $\mathbf{S}_k$ denotes the stochastic approximation on the sufficient statistics of the model, obtained in the "stochastic approximation step" of the algorithm. For the generic spatiotemporal model, this optimization problem is solved in closed-form.

4.3 Computational Aspects

For the progression model (9), the MCMC-SAEM would have to estimate the following parameters : $\boldsymbol{\theta} = (\overline{p_0}, \overline{t_0}, \overline{v_0}, \overline{\delta}_1, \ldots, \overline{\delta}_{N-1}, \overline{\beta}_1, \ldots, \overline{\beta}_{(N-1)N_s}, \sigma_\eta, \sigma_\tau, \sigma)$. In this example, we see that the number of parameters to estimate is $6 + (N-1)(N_s+1)$. As the dimension N of the manifold $\mathbb{M}$ increases, the number of parameters increases linearly. Moreover, as N increases, the number N_s of independent sources has a greater impact on the number of parameters to estimate.

The number p of individuals also impacts on the runtime of the MCMC-SAEM. As the number p of individuals increases, the cost of a single computation of the observed likelihood increases. This step is the most expensive step of the MCMC-SAEM algorithm. The overall runtime of the MCMC-SAEM could be improved by sampling the blocks $(\mathbf{z}_i)_{1\leq i\leq p}$ (in the Block MHwG sampler) in parallel.

5. Experiments

The section on numerical experiments begins with a comparison of our implementation of the MCMC-SAEM algorithm with other state-of-the-art algorithms. It is followed by a section entitled "Validation Procedure" which presents an evaluation criteria designed to quantify how well the time reparametrizations of the generic spatiotemporal model allowed to temporally align the progression of individuals. Finally, results obtained on a synthetic dataset of Symmetric Positive Definite (SPD) matrices and on a real dataset of neuropsychological tests scores are given. These datasets are analyzed using the particular cases of the generic spatiotemporal model described in Section 3.

5.1 Convergence of the Algorithm

In this section, we aim to compare our implementation of the MCMC-SAEM with state-of-the-art algorithms. Our algorithm, implemented in MATLAB, is compared with STAN and

Table 1: Relative error on the parameters estimated with the different algorithms. First row: results obtained with our implementation of the MCMC-SAEM. Second row: results obtained with STAN. Third row: results obtained with MONOLIX.

$\lvert\widehat{p_0} - p_0^*\rvert/p_0^*$	$\lvert\widehat{t_0} - t_0^*\rvert/t_0^*$	$\lvert\widehat{v_0} - v_0^*\rvert/v_0^*$	$\lvert\widehat{\sigma_\xi} - \sigma_\xi^*\rvert/\sigma_\xi^*$	$\lvert\widehat{\sigma_\tau} - \sigma_\tau^*\rvert/\sigma_\tau^*$	$\lvert\widehat{\sigma} - \sigma^*\rvert/\sigma^*$
0.0150	0.0050	0.0176	0.0600	0.0545	0.010
0.0917	0.0191	0.1088	0.0600	0.0386	0.010
0.0417	0.0086	0.0412	0.0400	0.0286	0.008

MONOLIX. STAN is a R/C++ library which implements an adaptive Hamiltonian Monte Carlo sampler called "the No U-Turns Sampler" (NUTS, Hoffman and Gelman (2014)). MONOLIX is a software developed by Marc Lavielle and the Lixoft company. It implements the MCMC-SAEM algorithm with some technical improvements (such as a simulated annealing scheme). Note that our implementation of the MCMC-SAEM algorithm differs from MONOLIX in the sense that it can be used with any particular case of the generic spatiotemporal model presented in Section 3. In particular, our implementation can be used to analyze univariate, as well as multivariate (such as covariance matrices), longitudinal observations. In its current version (2016R1), MONOLIX does not allow observations to be passed as matrices or vectors, which is not convenient for the analysis multivariate longitudinal observations.

In order to compare these algorithms, we consider a synthetic longitudinal dataset of observations in $]0, 1[$. The open set $]0, 1[$ is equipped with the Riemannian metric defined in Section 3.2, which generates logistic shaped geodesics. This dataset is generated for $p = 250$ individuals, with an average of 5 time points per individual. Each algorithm is run with the same initialization and the logistic curves model (7) was used to generate the data.

The experimental results given in Table 1 consist in relative errors on the parameters estimated with the different algorithms. The runtime and number of iteration needed for each method to converge are reported in Table 2. The results presented in the first table show that all the different methods succeeded in estimating the parameters which were used to generate the data. The corresponding number of iterations show that STAN is, by far, the most computationally intensive method. Even though our implementation of the MCMC-SAEM requires more iterations to converge than MONOLIX, the overall runtime is similar. The fact that MONOLIX requires fewer iterations to converge can be explained by the fact that the MCMC-SAEM is coupled with a simulated annealing procedure Lavielle and Mentré (2007), which allows for a better and faster exploration of the parameters space.

The results presented in these tables show that the performance of our implementation of the MCMC-SAEM is similar to the one of state-of-the-art methods. Still, the number of iterations needed to converge could be further reduced, for example, by combining several MCMC samplers in the sampling step of the MCMC-SAEM.

Table 2: Number of iterations and runtime corresponding to the experimental results given in Table 1. First row: results obtained with our implementation of the MCMC-SAEM. Second row: results obtained with STAN. Third row: results obtained with MONOLIX.

Iterations	Runtime (for 1000 iterations)	Overall runtime
3500	30 s	90 s
15000	15 min	$\simeq 3,75$ h
400	110 s	45 s

5.2 Validation Procedure

The idea is to assess how well the estimated individual time reparametrizations put in correspondence the progression of the individuals. To this end, we will use additional information which is not used in the model: the time at which a particular event occurs in the life of an individual. For example, the event could be the time at which a disease is diagnosed, or at which a metabolic change occurred for instance. Such an event occurs at a different time point (or age) for each individual.

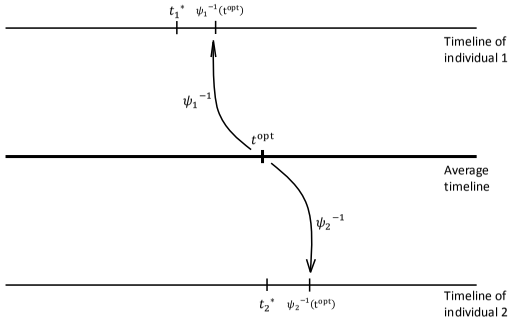

Figure 5: The average time of event t^{opt} is mapped to the individual timelines using ψ_i^{-1}.

The individual time reparametrization ψ_i are supposed to put into correspondence the time at which similar spatiotemporal patterns are found in the individual data. To assess how well this is achieved, we will test whether the time at which a particular event occur in the life of the individuals are mapped to the same time-point in the average trajectory of the model.

For the ith individual, ψ_i maps the timeline of this individual to the "average timeline", namely the one of the average trajectory. Let t_i^* be the time point at which the event occurs in the timeline of the ith individual. We estimate the time-point t^{opt} that corresponds to

the occurrence of the event in the average trajectory $\boldsymbol{\gamma}_0$ by minimizing the sum of errors $E(t) = \sum_i |t_i^* - \psi_i^{-1}(t)|$. Note that t^{opt} can be interpreted as a median of the normalized ages $(\psi_i(t_i^*))_i$, and could therefore not be unique. Then we map t^{opt} back to the individual timelines by using the mappings ψ_i^{-1}, as illustrated in Fig. 5. The value $\psi_i^{-1}(t^{\text{opt}})$ may be thought of as a prediction of the model of the time-point (or age) at which the event occurred for the i*th* individual. Without errors, this time-point would be exactly t_i^*. In practice, the difference $|t_i^* - \psi_i^{-1}(t^{\text{opt}})|$ allows quantifying how well the events the timeline of the ith individual and the average timeline have been put into correspondence.

In the following experiments, the median t^{opt} of $\left(\psi_i(t_i^*)\right)_{1\leq i\leq p}$ is computed unambiguously. To assess how well the individual trajectories and the average trajectory are put into correspondence, we plot an histogram of the errors $\left(|t_i^* - \psi_i^{-1}(t^{\text{opt}})|\right)_{1\leq i\leq p}$.

5.3 Tensors : a Synthetic Dataset

We start by presenting the synthetic dataset of SPD matrices used for this experiment and then present the results obtained with the particular case of the generic spatiotemporal model for SPD matrices (see Section 3.4).

5.3.1 Data

We consider a synthetic dataset, in which we simulate repeated observations of a a symmetric definite positive matrix (also called a diffusion tensor in medical imaging) for one hundred individuals. The observations were not generated from the model. The observations were obtained instead by prescribing an ad hoc hierarchical model on the eigenvalues of the diffusion tensors. At the level of the population, the eigenvalues of the diffusion tensors follow a decreasing piecewise linear evolution with a change point at 50 years old. Observations for a given individual were simulated by randomly shifting the change point (time at which a change occurs in the speed at which eigenvalues decrease) and randomly increasing or decreasing the slopes of each eigenvalue (see Fig.6, left). In this synthetic dataset, the individuals have, on average, five time points.

5.3.2 Results

The results presented below were obtained with $N_s = 1$ source. A greater number of independent sources would have been possible but many more iterations would have been necessary for the MCMC-SAEM to converge. The Bayesian tensor model with the MCMC-SAEM allows estimating an average trajectory of progression in the space SDP(3). This average trajectory is the geodesic which goes through the point $\overline{\mathbf{P}_0}$, at time $\overline{t_0}$, with velocity $\overline{\mathbf{V}_0}$, given by :

$$\overline{\mathbf{P}_0} = \begin{pmatrix} 11.30 & 0.96 & 0.68 \\ 0.96 & 9.53 & 1.21 \\ 0.68 & 1.21 & 10.19 \end{pmatrix}, \quad \overline{t_0} = 53.83 \text{ years},$$

and

$$\overline{\mathbf{V}_0} = \begin{pmatrix} -0.99 & -0.17 & -0.20 \\ -0.17 & -0.75 & -0.27 \\ -0.20 & -0.27 & -0.85 \end{pmatrix} \text{ unit per year.}$$

The evolution of the eigenvalues of the average trajectory, plotted in Fig. 6, is similar to the model used to generate the observations. However, the MCMC-SAEM tends to underestimate the first eigenvalue and overestimate the third eigenvalue. The variability in speed and delay of progression is captured by the estimated parameters $\sigma_\eta = 0.07$ and $\sigma_\tau = 0.5$ year. Fig. 6 (left) shows that the eigenvalues of each individual decrease at a similar pace before and after the change point. This may explain why the model captured small variations in speed of progression. The standard deviation σ_τ on the parameter t_0 is much smaller. The individual acceleration factor, time shift and space shift allow fitting the average trajectory to the observations of an individual. As shown in Fig. 6 (right), the estimated individual trajectory is well-adjusted to the observations of the individual.

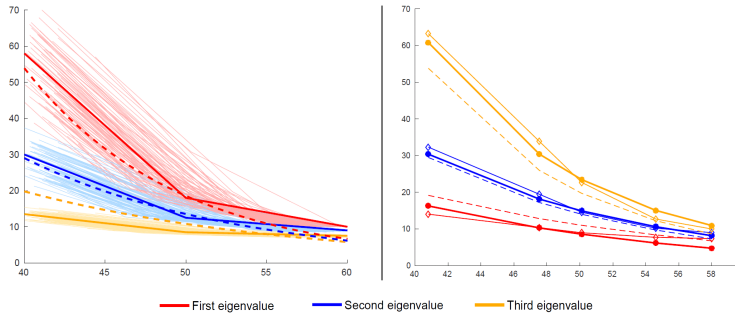

Figure 6: Left : In solid bold line, the average model of eigenvalues evolution for the synthetic dataset of tensors. In solid lines, the evolution of the eigenvalues for all the individuals in the dataset. In dotted line, the evolution of the eigenvalues of the average trajectory, given by the MCMC-SAEM. Right : the evolution of the eigenvalues of an individual. In dotted line, the eigenvalues of the average trajectory estimated by the MCMC-SAEM. With square markers, the eigenvalues of the observations for this individual. With round markers, the eigenvalues of the estimated individual trajectory.

The eigenvalues of the average estimated trajectory are smooth functions of time. Therefore, it would not have been possible to obtain a piecewise-linear progression of the eigenvalues for the average trajectory. Nevertheless, we can still validate the ability of the tensor model to put into correspondence the dynamic of each individual following Sec. 5.2 by using the individual change point t_i^*. For this dataset, the sum of errors $\sum_i |t_i^* - \psi_i^{-1}(t)|$ has a unique minimum at $t^{\text{opt}} = 49.73$ years. This minimum t^{opt} is close to 50 years, the time at which the change point occurs in the average model used to generate the data. Fig. 7 shows that the model made an error of less than 2 years for almost 60% of the population by predicting the individual change point with $\psi_i^{-1}(t^{\text{opt}})$, and less than 4 years for 90% of the population. The change point was generated using a Gaussian distribution centred at

50 years with a standard deviation of 2 years. Therefore, the error is of the same order as the standard deviation of the change point.

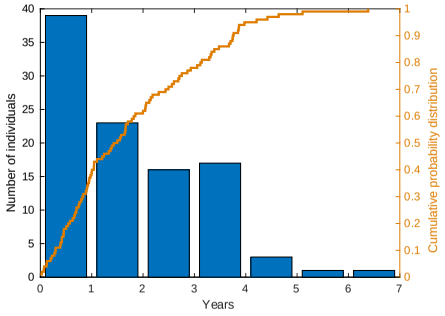

Figure 7: Histogram of $\left(|t_i^* - \psi_i^{-1}(t^{\text{opt}})|\right)_{1 \leq i \leq 100}$ superimposed with the cumulative distribution of this error. Here, t_i^* represents the age of the change point for the ith individual.

5.4 Neuropsychological Tests

This section starts by presenting the real dataset of neuropsychological tests scores from the ADNI database. Then, we present results obtained using the progression model (see Eq. (9)) with logistic curves.

5.4.1 Data

The dataset consists of scores to the modified "ADAS-Cog" test (Mohs et al., 1997) obtained from the ADNI1, ADNIGO and ADNI2 cohorts of the Alzheimer's Disease Neuroimaging Initiative. The 13 items were grouped into 4 categories according to the cognitive function they assess: memory, language, concentration and praxis. For each cognitive function, the scores were added and normalized by the maximum possible value therefore producing measurements in $]0, 1[$. As a consequence, each observation is a point on the manifold $\mathbb{M} =]0, 1[^4$ (note that results without item pooling are presented in Schiratti et al. (2015a)). We use 248 individuals who were included in the study as mild cognitive impaired (MCI) subjects and later converted to Alzheimer's disease (AD). Each individual was observed on average 6 times.

5.4.2 Results

This data set was analyzed using the *progression model* given in Eq. (9) with logistic curves. The number of independent components could be either $1, 2$ or 3, as the manifold is of dimension 4. The model with one independent component estimated a residual noise variance

$\sigma^2 = 0.012$ and explained 79% of the total variance. The model with two (resp. three) independent components estimated a noise variance $\sigma^2 = 0.008$ (resp. $\sigma^2 = 0.0084$) and explained 84% (resp. 85%) of the total variance. Because the results obtained with three independent components are similar to the results obtained with two independent components, we choose, for the sake of clarity, to report the results obtained with two components ($N_s = 2$).

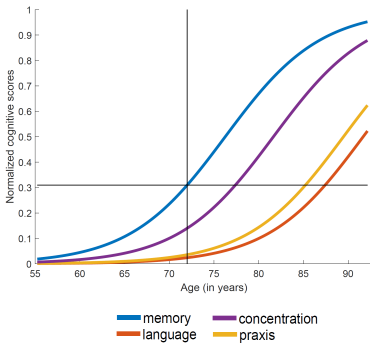

Figure 8: The estimated average trajectory. The estimated parameters p_0 (resp. t_0) are represented by an horizontal (resp. vertical line) at $p_0 = 0.3$ (resp. $t_0 = 72$ years).

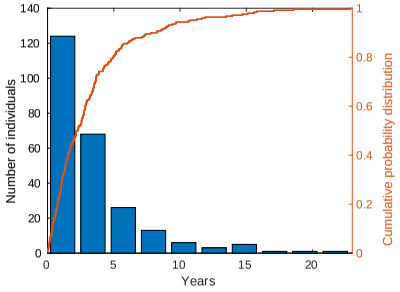

Figure 9: Histogram of $\left(|t_i^{\text{conv}} - \psi_i^{-1}(t^{\text{opt}})|\right)_{1 \leq i \leq 248}$ superimposed with the cumulative distribution of this error.

The average trajectory estimated by the progression model, plotted in Fig. 8, is characterized by the fixed effects $p_0 = 0.3$, $t_0 = 72$ years, $v_0 = 0.04$ unit per year and $\boldsymbol{\delta} = [0; -15; -13; -5]$ years. The first biomarker (memory) reaches the value $p_0 = 0.3$ at 72 years on average, the second one (concentration), at $t_0 + 5 = 77$ years, followed by praxis and language. The fixed effects provide an ordering of the biomarkers and the relative delay between them. The random effects characterize the spatiotemporal variability of the average trajectory among the population. The estimated standard deviation of the time-shift is $\sigma_\tau = 7.5$ years, meaning that age of disease onset ranges between 72 ± 7.5 years for 95% of the individuals. A positive (resp. negative) time-shift means that the individual is evolving behind (resp. ahead) the average trajectory. The estimated standard deviation of the acceleration factors is $\sigma_\eta = 0.9$. As a consequence, most of the individuals are progressing between $e^{\sigma_\eta} \simeq 2.4$ times faster or $e^{-\sigma_\eta} \simeq 0.4$ times slower than the average trajectory (see Fig. 11, first row). Estimates of the individual time-shits and log-acceleration factors are plotted in Fig. 10. This figure shows a clear correspondence between the time shifts and

the estimated age at which individuals were diagnosed with the disease. This fact shows that the normalized age $\psi_i(t)$ is a better temporal marker of disease progression than age. This is confirmed by our validation procedure (Fig. 9), which shows an error in the prediction of age at diagnosis of less than 2.5 years in 50% of the cases.

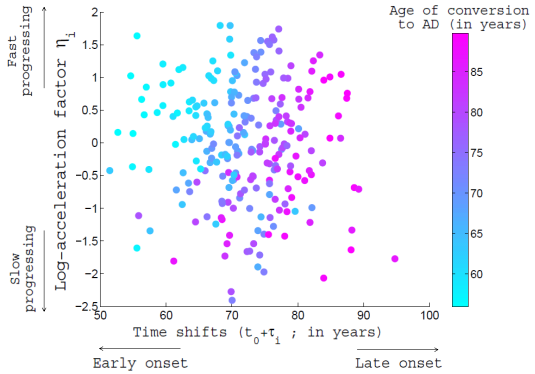

Figure 10: Plot of $t_0 + \tau_i$ with respect to the log-acceleration factor η_i. Each point is colored with respect to the estimated age of conversion to AD.

In this multivariate setting, random effects also include space shifts, which are a combination of two independent components denoted here $\mathbf{c}_1(\mathbf{A})$ and $\mathbf{c}_2(\mathbf{A})$. As shown in lemma 2, these space-shifts perturb the relative delay and the ordering in the progression of biomarkers. Fig. 11 shows that individuals with a space shift of the form $\mathbf{w}_i = \sigma_{s_i}\mathbf{c}_1(\mathbf{A})$ have memory and concentration impaired at nearly the same time, while the language and praxis remains nearly constant. In the opposite direction, impairment in language and praxis nearly coincide for individuals with a space-shift of the form $\mathbf{w}_i = -\sigma_{s_i}\mathbf{c}_1(\mathbf{A})$. The second independent component almost does not change memory and concentration but changes the delay and the ordering between language and praxis. These results show that the biomarkers tend to evolve in pairs : memory & concentration, language & praxis. Space shifts capture here the variability in the profile of cognitive decline at the individual level during the onset of the disease.

5.5 Body Mass Index in Adolescent Girls

We analyzed a longitudinal dataset of body fat percentages from 162 adolescent girls. This dataset is taken from the MIT Growth and Development Study Bandini et al. (2002); Phillips et al. (2003). The data is analyzed using the univariate logistic model (see supplementary material for the details and results). The analysis of this data in
Fitzmaurice et al. (2012) requires the use of the time at menarche to temporally align the data across individuals before the statistical analysis. By contrast, our approach is able to include such an alignment as a random effect of the model. The estimated parameters

produced an error of less than one year for 50% of the individuals in the alignment of the age at which the menarche occurred.

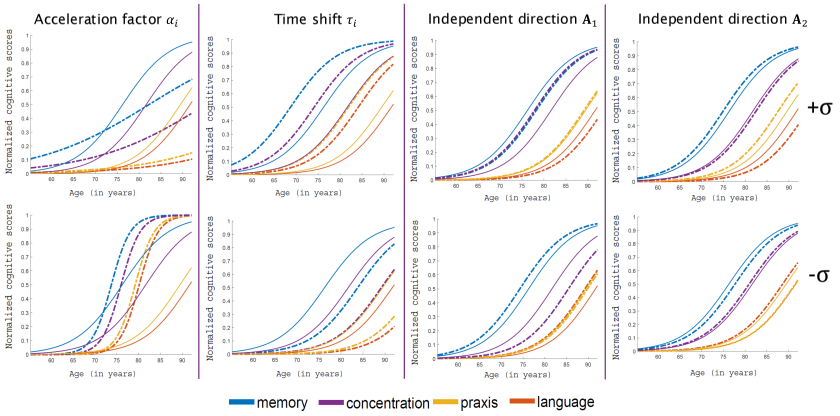

Figure 11: Variability of the average trajectory γ_δ in terms of space shift, time shift and acceleration factor. The solid lines represent the average trajectory, while the dotted lines represent the variability of this average trajectory among the population.

6. Conclusion

We proposed a mixed-effects model for the spatiotemporal analysis of manifold-valued measurements. This generic model can be used to automatically learn the temporal progression of a biological phenomenon from repeated observations of several samples. The model accounts for the fact that each sample has a different appearance, has different trajectory of changes and different pace of changes. This is enabled by the introduction of a hierarchical statistical model whose fixed effects define a group-average trajectory in the space of measurements and random effects account for the spatiotemporal variability of the trajectories of changes at the individual level.

Building the model in the framework of Riemannian geometry allowed us to identify the key orthogonality condition to uniquely decompose temporal and spatial variability across trajectories of changes. Our particular use of parallel transport ensures the invariance of the form of the distribution of spatial random effects in time. Finally, it allows the instantiation of the model for a large variety of data types, as shown by our experiments with univariate and multivariate bounded measurements, as well as symmetric definite positive matrices. This framework is also well suited for analysing data with smooth constraints or highly structured data such as images, networks(Koval et al. (2017)), or shapes for instance.

We rely on the stochastic approximation of the Expectation-Maximization algorithm to estimate model parameters. This algorithm is proven to converge asymptotically, and our experiments confirmed this convergence in several practical situations. This algorithm is very generic and allows a modular implementation of the method which eases its instantiation for any kind of manifold-valued observations. Note, nevertheless, that specific optimizations were needed to match, and even outperform state-of-the-art implementations for real-valued measurements.

The model is particularly useful to analyze biological phenomenon, for which there is no obvious way to temporally align individual data time series. Temporal realignment introduced as random-effect allowed us to automatically predict the age at which patients were diagnosed with Alzheimer's disease or at which menarche occurred in adolescent girls. Although the model assumed a monotonic progression of body fat with age, this hypothesis could be relaxed by replacing the distribution of the acceleration factors and space shifts with a mixture of Gaussian distributions. This could also be achieved by considering non-affine time reparametrizations of the average trajectory. Improvements in prediction and goodness of fit might result from extensions of the model, for instance by introducing mixture models to identify population clusters or by adding a drift in the parallel transport so that individual trajectories do not always remains parallel to the average trajectory.

Appendix A. Proof of Lemma 2 and Lemma 3

In this appendix, we will first give a proof of Lemma 2 and we shall then give a proof of Lemma 3.

A.1 Proof of Lemma 2

The definitions and properties given above are useful to prove the result given in 2. Before proving this result, we recall its context. We consider a product manifold $\mathbb{M} = M^N$ where $M \subset \mathbb{R}$ is an open interval. M is equipped with a Riemannian metric g and is geodesically complete. The product manifold $\mathbb{M}$ is equipped with the product metric.

Proof Let $t_0 \in \mathbb{R}$, $\boldsymbol{\gamma} = (\gamma_1, \dots, \gamma_N)$ be a geodesic of $\mathbb{M}$ and $\mathbf{w} = (w_1, \dots, w_N) \in \mathrm{T}_{\boldsymbol{\gamma}(t_0)}\mathbb{M}$. Using the previous proposition on product manifolds, the computation of $\eta^{\mathbf{w}}(\boldsymbol{\gamma}, t)$ boils down to the computation of $\mathrm{Exp}_{\gamma_i(t)}\big(\mathrm{P}_{\gamma_i,t_0,t}(w_i)\big)$. This term is computed in three steps.

Let $i \in \{1, \dots, N\}$. The parallel transport $\mathrm{P}_{\gamma_i,t_0,t}(w_i)$ is computed as follows. First, note that M is an open interval of $\mathbb{R}$. Therefore, for all $p \in M$, $\mathrm{T}_pM \simeq \mathbb{R}$. The Riemannian metric g of M is necessarily of the form $p \in M \mapsto g_p$ with : $\forall (u, v) \in \mathrm{T}_pM$, $g_p(u, v) = uvf(p)$ where $f : M \to]0, +\infty[$ is a smooth function.

It follows from the definition of parallel transport along the curve $t \mapsto \gamma_i$ that : $\forall t$, $\mathrm{P}_{\gamma_i,t_0,t}(w_i) \in \mathrm{T}_{\gamma_i(t)}M$. Since, for all t, $\mathrm{T}_{\gamma_i(t)}M$ is a one-dimensional vector space, the tangent vector $\dot\gamma_i(t) \neq 0$ spans this space. As a consequence, there exist a smooth function $\xi_i : \mathbb{R} \to \mathbb{R}$ such that : $\forall t \in \mathbb{R}$, $\mathrm{P}_{\gamma_i,t_0,t}(w_i) = \xi_i(t)\dot\gamma_i(t)$. Because the parallel transport is an isometry and because γ_i is a geodesic, we have :

$$\forall t \in \mathbb{R},\ g_{\gamma_i(t)}\big(\mathrm{P}_{\gamma_i,t_0,t}(w_i), \dot\gamma_i(t)\big) = g_{\gamma_i(t_0)}(w_i, \dot\gamma_i(t_0)). \tag{18}$$

The bilinearity of $g_{\gamma_i(t)}$ gives :

$$\begin{aligned} g_{\gamma_i(t)}\big(\mathrm{P}_{\gamma_i,t_0,t}(w_i), \dot\gamma_i(t)\big) &= g_{\gamma_i(t)}\big(\xi_i(t)\dot\gamma_i(t), \dot\gamma_i(t)\big) \\ &= \xi_i(t) g_{\gamma_i(t)}\big(\dot\gamma_i(t), \dot\gamma_i(t)\big). \end{aligned} \tag{19}$$

Using that $\dot\gamma_i$ is parallel along γ_i, we have :

$$\forall t \in \mathbb{R},\ g_{\gamma_i(t)}\big(\dot\gamma_i(t), \dot\gamma_i(t)\big) = g_{\gamma_i(t_0)}\big(\dot\gamma_i(t_0), \dot\gamma_i(t_0)\big). \tag{20}$$

As a consequence, (18), (19) and (20) give :

$$\forall t \in \mathbb{R},\ \xi_i(t) g_{\gamma_i(t_0)}\big(\dot\gamma_i(t_0), \dot\gamma_i(t_0)\big) = g_{\gamma_i(t_0)}\big(w_i, \dot\gamma_i(t_0)\big). \tag{21}$$

Using the form of the metric on M, (21) writes :

$$\forall t \in \mathbb{R},\ \xi_i(t)\big(\dot\gamma_i(t_0)\big)^2 f\big(\gamma_i(t_0)\big) = w_i \dot\gamma_i(t_0) f\big(\gamma_i(t_0)\big). \tag{22}$$

This last equation gives : $\forall t$, $\xi_i(t) = w_i/\dot\gamma_i(t_0)$. Finally,

$$\forall i \in \{1, \dots, N\},\ \forall t \in \mathbb{R},\ \mathrm{P}_{\gamma_i,t_0,t}(w_i) = \frac{w_i}{\dot\gamma_i(t_0)} \dot\gamma_i(t). \tag{23}$$

The last step consist in computing $\mathrm{Exp}_{\gamma_i(t)}\big(\mathrm{P}_{\gamma_i,t_0,t}(w_i)\big)$ with $t \in \mathbb{R}$ fixed. This is done by introducing the curves

$$c : s \in [0, 1] \mapsto \mathrm{Exp}_{\gamma_i(t)}\big(s\mathrm{P}_{\gamma_i,t_0,t}(w_i)\big),$$

and

$$\tilde c : s \in [0, 1] \mapsto \gamma_i\Big(t + s\frac{w_i}{\dot\gamma_i(t_0)}\Big).$$

Both curves c and $\tilde c$ are geodesics of M which satisfy to : $c(0) = \tilde c(0) = \gamma_i(t)$ and $\dot c(0) = \dot{\tilde c}(0) = \frac{w_i}{\dot\gamma_i(t_0)}\dot\gamma_i(t)$. By unicity, the two curves are equal. As a consequence, for all $i \in \{1, \dots, N\}$ and all $t \in \mathbb{R}$,

$$\mathrm{Exp}_{\gamma_i(t)}\big(\mathrm{P}_{\gamma_i,t_0,t}(w_i)\big) = \gamma_i\Big(t + \frac{w_i}{\dot\gamma_i(t_0)}\Big). \tag{24}$$

This last equation completes the proof of the lemma. ■

A.2 Proof of Lemma 3

First, some notations need to be introduced. Let $m = n(n+1)/2$ denote the dimension of the linear space SYM(n), $(\mathbf{E}_i)_{1\leq i\leq m}$ be the canonical basis of SYM(n) and $(\mathbf{E}_i^*)_{1\leq i\leq m}$ its *dual basis*. The matrices are indexed by a single index, which corresponds to an enumeration of the pairs of integers $\{(k, l),\ 1 \leq k, l \leq n,\ k \leq l\}$. A matrix $\mathbf{V}$ in SYM(n) will be identified to the vector $(v_1, \dots, v_m)$ of its coefficients from the upper triangular part. Using the expression of the Christoffel symbols in terms of the canonical basis of SYM(n) and its dual basis, Lenglet and collaborators prove that if $t \mapsto \boldsymbol{\Sigma}(t) = (\sigma_1(t), \dots, \sigma_m(t))$ is a smooth curve in SPD(n) and $t \mapsto \mathbf{V}(t) = (v_1(t), \dots, v_m(t))$ a vector field along Σ, the *covariant derivative* of $\mathbf{V}$ along $\boldsymbol{\Sigma}$ is given by the expression:

$$D\mathbf{V}/dt = \sum_i^m \frac{dv_i}{dt}(t)\mathbf{E}_i + \sum_{i,j=1}^m v_i(t)\frac{d\sigma_j}{dt}(t)\nabla_{\mathbf{E}_i}\mathbf{E}_j. \tag{25}$$

Taking the Frobenius inner product of the previous equality (on both sides) with $\mathbf{E}_k^*$ ($1 \leq k \leq m$), together with the expression of the Christoffel symbols (see Lenglet et al. (2006), Eq.(3) and Eq.(4)), one gets that the vector field $\mathbf{V}$ is parallel along the curve $\boldsymbol{\Sigma}$ if and only if:

$$\frac{d\mathbf{V}}{dt}(t) - \frac{1}{2}\mathbf{V}(t)\boldsymbol{\Sigma}(t)^{-1}\frac{d\boldsymbol{\Sigma}}{dt}(t) - \frac{1}{2}\frac{d\boldsymbol{\Sigma}(t)}{dt}(t)\boldsymbol{\Sigma}(t)^{-1}\mathbf{V}(t) = 0. \tag{26}$$

We can now give the proof of Lemma 3.

Proof With the expression of the geodesic $\boldsymbol{\gamma}_0$, given in Section 3.4, one can easily see that:

$$\forall t \in \mathbb{R},\ \frac{d\boldsymbol{\gamma}_0(t)}{dt}\boldsymbol{\gamma}_0^{-1}(t) = \mathbf{V}_0\mathbf{P}_0^{-1}. \tag{27}$$

Let $t \mapsto \mathbf{V}(t)$ be a vector field parallel along $\boldsymbol{\gamma}_0$. Eq. (26) is equivalent to:

$$\frac{d\mathbf{V}(t)}{dt} = \frac{1}{2}\mathbf{V}(t)\mathbf{P}_0^{-1}\mathbf{V}_0 - \frac{1}{2}\mathbf{V}_0\mathbf{P}_0^{-1}\mathbf{V}(t). \tag{28}$$

Note that Eq. (28) is a *differential Lyapunov equation*. It can be solved by considering the matrix-valued function $t \mapsto \exp(-t\mathbf{M}^\top)\mathbf{R}(t)\exp(-t\mathbf{M})$, with $\mathbf{M} = -(1/2)\mathbf{P}_0^{-1}\mathbf{V}_0$ and $\mathbf{R}$, any differentiable matrix-valued function. Given that $\mathbf{V}(t_0) = \mathbf{W}$, one has that the parallel transport in $\mathrm{SPD}(n)$ is given by:

$$\mathbf{V}(t) = \exp\Big(\frac{t-t_0}{2}\mathbf{V}_0\mathbf{P}_0^{-1}\Big)\mathbf{W}\exp\Big(\frac{t-t_0}{2}\mathbf{P}_0^{-1}\mathbf{V}_0\Big). \tag{29}$$

Abstract

Stochastic Gradient Descent with a constant learning rate (constant SGD) simulates a Markov chain with a stationary distribution. With this perspective, we derive several new results. (1) We show that constant SGD can be used as an approximate Bayesian posterior inference algorithm. Specifically, we show how to adjust the tuning parameters of constant SGD to best match the stationary distribution to a posterior, minimizing the Kullback-Leibler divergence between these two distributions. (2) We demonstrate that constant SGD gives rise to a new variational EM algorithm that optimizes hyperparameters in complex probabilistic models. (3) We also show how to tune SGD with momentum for approximate sampling. (4) We analyze stochastic-gradient MCMC algorithms. For Stochastic-Gradient Langevin Dynamics and Stochastic-Gradient Fisher Scoring, we quantify the approximation errors due to finite learning rates. Finally (5), we use the stochastic process perspective to give a short proof of why Polyak averaging is optimal. Based on this idea, we propose a scalable approximate MCMC algorithm, the Averaged Stochastic Gradient Sampler.

Keywords: approximate Bayesian inference, variational inference, stochastic optimization, stochastic gradient MCMC, stochastic differential equations

1. Introduction

Stochastic gradient descent (SGD) has become crucial to modern machine learning. SGD optimizes a function by following noisy gradients with a decreasing step size. The classical result of Robbins and Monro (1951) is that this procedure provably reaches the optimum of the function (or local optimum, when it is nonconvex) (Bouleau and Lepingle, 1994). Recent studies investigate the merits of adaptive step sizes (Duchi et al., 2011; Tieleman and Hinton, 2012), gradient or iterate averaging (Toulis et al., 2016; Défossez and Bach, 2015), and constant step-sizes (Bach and Moulines, 2013; Flammarion and Bach, 2015). Stochastic gradient descent has enabled efficient optimization with massive data, since one can often obtain noisy-but-unbiased gradients very cheaply by randomly subsampling a large dataset.

Recently, stochastic gradients (SG) have also been used in the service of scalable Bayesian Markov Chain Monte Carlo (MCMC) methods, where the goal is to generate samples from a conditional distribution of latent variables given a data set. In Bayesian inference, we assume a probabilistic model $p(\theta, \mathbf{x})$ with data $\mathbf{x}$ and hidden variables θ; our goal is to approximate the posterior

$$p(\theta \,|\, \mathbf{x}) = \exp\{\log p(\theta, \mathbf{x}) - \log p(\mathbf{x})\}. \tag{1}$$

These so-called stochastic gradient MCMC algorithms—such as SG Langevin dynamics (Welling and Teh, 2011), SG Hamiltonian Monte Carlo (Chen et al., 2014), SG thermostats (Ding et al., 2014), and SG Fisher scoring (Ahn et al., 2012)—employ stochastic gradients of $\log p(\theta, \mathbf{x})$ to improve convergence and computation of existing sampling algorithms. Also see Ma et al. (2015) for a complete classification of these algorithms.

The similarities between SGD as an optimization algorithm and stochastic gradient MCMC algorithms raise the question of how exactly these two types of algorithms relate to each other. The main questions we try to address in this paper are:

- What is the simplest modification to SGD that yields an efficient approximate Bayesian sampling algorithm?
- How can we construct other sampling algorithms based on variations of SGD such as preconditioning (Duchi et al., 2011; Tieleman and Hinton, 2012), momentum (Polyak, 1964) or Polyak averaging (Polyak and Juditsky, 1992)?

To answer these questions, we draw on the theoretical analysis tools of continuous-time stochastic differential equations (Bachelier, 1900; Gardiner et al., 1985) and variational inference (Jordan et al., 1999).

As a simple example, consider SGD with a constant learning rate (constant SGD). Constant SGD first marches toward an optimum of the objective function and then bounces around its vicinity. (In contrast, traditional SGD converges to the optimum by decreasing the learning rate.) Our analysis below rests on the idea that constant SGD is a stochastic process with a stationary distribution, one that is centered on the optimum and that has a certain covariance structure. The main idea is that we can use this stationary distribution to approximate a posterior. In contrast, stochastic gradient MCMC algorithms take precautions to sample from an asymptotically exact posterior, but at the expense of slower mixing. Our inexact approach enjoys minimal implementation effort and typically faster mixing. It is a hybrid of Monte Carlo and variational algorithms, and complements the toolbox of approximate Bayesian inference.

Here is how it works. We apply constant SGD as though we were trying to minimize the negative log-joint probability $-\log p(\theta, \mathbf{x})$ over the model parameters θ. Constant SGD has several tunable parameters: the constant learning rate, the minibatch size, and the preconditioning matrix (if any) that we apply to the gradient updates. These tuning parameters all affect the stationary distribution of constant SGD; depending on how they are set, this stationary distribution of θ will be closer to or farther from the posterior distribution $p(\theta|\mathbf{x})$. If we set these parameters appropriately, we can perform approximate Bayesian inference by simply running constant SGD.

In more detail, we make the following contributions:

1. First, we develop a variational Bayesian view of stochastic gradient descent. Based on its interpretation as a continuous-time stochastic process—specifically a multivariate Ornstein-Uhlenbeck (OU) process (Uhlenbeck and Ornstein, 1930; Gardiner et al., 1985)—we compute stationary distributions for a large class of SGD algorithms, all of which converge to a Gaussian distribution with a non-trivial covariance matrix. The stationary distribution is parameterized by the learning rate, minibatch size, and preconditioning matrix.

   Results about the multivariate OU process make it easy to minimize the KL divergence between the stationary distribution and the posterior analytically. We can thus relate the optimal step size or preconditioning matrix to the Hessian and noise covariances near the optimum. The optimal preconditioners relate to AdaGrad (Duchi et al., 2011), RMSProp (Tieleman and Hinton, 2012), and classical Fisher scoring (Longford, 1987). We demonstrate how these different optimization methods compare when used for approximate inference.

2. We show that constant SGD gives rise to a new variational EM algorithm (Bishop, 2006) which allows us to use SGD to optimize hyperparameters while performing approximate inference in a Bayesian model. We demonstrate this by fitting a posterior to a Bayesian multinomial regression model.

3. We use our formalism to derive the stationary distribution for SGD with momentum (Polyak, 1964). Our results show that adding momentum only changes the scale of the covariance of the stationary distribution, not its shape. This scaling factor is a simple function of the damping coefficient. Thus we can also use SGD with momentum for approximate Bayesian inference.

4. Then, we analyze scalable MCMC algorithms. Specifically, we use the stochastic-process perspective to compute the stationary distribution of Stochastic-Gradient Langevin Dynamics (SGLD) by Welling and Teh (2011) when using constant learning rates, and analyze stochastic gradient Fisher scoring (SGFS) by Ahn et al. (2012). The view from the multivariate OU process reveals a simple justification for this method: we confirm that the preconditioning matrix suggested in SGFS is indeed optimal. We also derive a criterion for the free noise parameter in SGFS that can enhance numerical stability, and we show how the stationary distribution is modified when the preconditioner is approximated with a diagonal matrix (as is often done in practice for high-dimensional problems).

5. Finally, we analyze iterate averaging (Polyak and Juditsky, 1992), where one successively averages the iterates of SGD to obtain a lower-variance estimator of the optimum. Based on the stochastic-process methodology, we give a shorter derivation of a known result, namely that the convergence speed of iterate averaging cannot be improved by preconditioning the stochastic gradient with any matrix. Furthermore, we show that (under certain assumptions), Polyak iterate averaging can yield an *optimal* stochastic-gradient MCMC algorithm, and that this optimal sampler can generate exactly one effectively independent sample per pass through the dataset. This result is both positive and negative; it suggests that iterate averaging can be used as a powerful Bayesian sampler, but it also argues that no SG-MCMC algorithm can generate more than one useful sample per pass through the data, and so the cost of these algorithms must scale linearly with dataset size.

Our paper is organized as follows. In Section 3 we review the continuous-time limit of SGD, showing that it can be interpreted as an OU process. In Section 4 we present consequences of this perspective: the interpretation of SGD as variational Bayes and results around preconditioning and momentum. Section 5 discusses SG Langevin Dynamics and SG Fisher Scoring. In Section 6 we discuss Polyak averaging for optimization and sampling. In the empirical study (Section 7), we show that our theoretical assumptions are satisfied for different models, that we can use SGD to perform gradient-based hyperparameter optimization, and that iterate averaging gives rise to a Bayesian sampler with fast mixing.

2. Related Work

Our paper relates to Bayesian inference and stochastic optimization.

Scalable MCMC. Recent work in Bayesian statistics focuses on making MCMC sampling algorithms scalable by using stochastic gradients. In particular, Welling and Teh (2011) developed stochastic-gradient Langevin dynamics (SGLD). This algorithm samples from a Bayesian posterior by adding artificial noise to the stochastic gradient which, as the step size decays, comes to dominate the SGD noise. Also see Sato and Nakagawa (2014) for a detailed convergence analysis of the algorithm. Though elegant, one disadvantage of SGLD is that the step size must be decreased to arrive at the correct sampling regime, and as step sizes get small so does mixing speed. Other research suggests improvements to this issue, using Hamiltonian Monte Carlo (Chen et al., 2014) or thermostats (Ding et al., 2014). Shang et al. (2015) build on thermostats and use a similar continuous-time formalism as used in this paper.

Ma et al. (2015) give a complete classification of possible stochastic gradient-based MCMC schemes.

Below, we will analyze properties of stochastic gradient Fisher scoring (SGFS; Ahn et al., 2012), an extention to SGLD. This algorithm speeds up mixing times in SGLD by preconditioning gradients with the inverse gradient noise covariance. Ahn et al. (2012) show that (under some assumptions) SGFS can eliminate the bias associated with running SGLD with non-vanishing learning rates. Our approach to analysis can extend and sharpen the results of Ahn et al. (2012). For example, they propose using a diagonal approximation to the gradient noise covariance as a heuristic; in our framework, we can analyze and rigorously justify this choice as a variational Bayesian approximation.

Maclaurin et al. (2016) also interpret SGD as a non-parametric variational inference scheme, but with different goals and in a different formalism. The paper proposes a way to track entropy changes in the implicit variational objective, based on estimates of the Hessian. As such, the authors mainly consider sampling distributions that are not stationary, whereas we focus on constant learning rates and distributions that have (approximately) converged. Note that their notion of hyperparameters does not refer to model parameters but to parameters of SGD.

Stochastic Optimization. Stochastic gradient descent is an active field (Zhang, 2004; Bottou, 1998). Many papers discuss constant step-size SGD. Bach and Moulines (2013); Flammarion and Bach (2015) discuss convergence rate of averaged gradients with constant step size, while Défossez and Bach (2015) analyze sampling distributions using quasi-martingale techniques. Toulis et al. (2014) calculate the asymptotic variance of SGD for the case of decreasing learning rates, assuming that the data is distributed according to the model. None of these papers consider the Bayesian setting. Dieuleveut et al. (2017) also analyzed SGD with constant step size and its relation to

Markov chains. Their analysis resulted in a novel extrapolation scheme to improve the convergence behavior of iterate averaging.

The fact that optimal preconditioning (using a decreasing Robbins-Monro schedule) is achieved by choosing the inverse noise covariance was first shown in (Sakrison, 1965), but here we derive the same result based on different arguments and suggest a scalar prefactor. Note the optimal scalar learning rate of $2/\mathrm{Tr}(BB^\top)$, where $BB^\top$ is the SGD noise covariance (as discussed in Section 4 or this paper), can also be derived based on stability arguments. This was done in the context of least mean square filters (Widrow and Stearns, 1985).

Finally, Chen et al. (2016) also draw analogies between SGD and scalable MCMC. They suggest annealing the posterior over time to use scalable MCMC as a tool for global optimization. We follow the opposite idea and suggest to use constant SGD as an approximate sampler by choosing appropriate learning rate and preconditioners.

Stochastic differential equations. The idea of analyzing stochastic gradient descent with stochastic differential equations is well established in the stochastic approximation literature (Kushner and Yin, 2003; Ljung et al., 2012). Recent work focuses on dynamical aspects of the algorithm. Li et al. (2015) discuss several one-dimensional cases and momentum. Li et al. (2017) give a mathematically rigorous justification of the continuous-time limit. Chen et al. (2015) analyze stochastic gradient MCMC and study their convergence properties using stochastic differential equations.

Our work makes use of the same formalism but has a different focus. Instead of analyzing dynamical properties, we focus on stationary distributions. Further, our paper introduces the idea of minimizing KL divergence between multivariate sampling distributions and the posterior.

Variational Inference. Variational Inference (VI) denotes a set of methods which aim at approximating a Bayesian posterior by a simpler, typically factorized distribution. This is done by minimizing Kullback-Leibler divergence or related divergences between these distributions (Jordan et al., 1999; Opper and Saad, 2001). For the class of models where the conditional distributions are in the exponential family, the variational objective can be optimized by closed-form updates (Ghahramani and Beal, 2000), but this is a restricted class of models with conjugate priors. A scalable version of VI, termed Stochastic Variational Inference (SVI), relies on stochastic gradient descent for data subsampling (Hoffman et al., 2013). For non-conjugate models, Black-Box variational inference (Ranganath et al., 2014) has enabled SVI for a large class of models, but this approach may suffer from high-variance gradients. A modified form of black-box variational inference relies on re-parameterization gradients (Salimans and Knowles, 2013; Kingma and Welling, 2014; Rezende et al., 2014; Kucukelbir et al., 2015; Ruiz et al., 2016). This version is limited to continuous latent variables but typically has much lower-variance gradients.

In this paper, we compare against the Gaussian reparameterization gradient version of black-box variational inference as used in Kingma and Welling (2014); Rezende et al. (2014); Kucukelbir et al. (2015) which we refer to as BBVI. We find that our approach performs similarly in practice, but it is different in that it does not optimize the parameters of a simple variational distribution. Rather, it controls the shape of the approximate posterior via the parameters of the optimization algorithm, such as the learning rate or preconditioning matrix.

3. Continuous-Time Limit Revisited

We first review the theoretical framework that we use throughout the paper. Our goal is to characterize the behavior of SGD when using a constant step size. To do this, we approximate SGD with a continuous-time stochastic process (Kushner and Yin, 2003; Ljung et al., 2012).

3.1 Problem Setup

Consider loss functions of the following form:

$$\mathcal{L}(\theta) = \frac{1}{N}\sum_{n=1}^{N}\ell_n(\theta), \quad g(\theta) \equiv \nabla_\theta \mathcal{L}(\theta). \tag{2}$$

Such loss functions are common in machine learning, where $\mathcal{L}(\theta) \equiv \mathcal{L}(\theta, \mathbf{x})$ is a loss function that depends on data $\mathbf{x}$ and parameters θ. Each $\ell_n(\theta) \equiv \ell(\theta, \mathbf{x}_n)$ is the contribution to the overall loss from a single observation $\mathbf{x}_n$. For example, when finding a maximum-a-posteriori estimate of a model, the contributions to the loss may be

$$\ell_n(\theta) = -\log p(x_n \,|\, \theta) - \frac{1}{N}\log p(\theta), \tag{3}$$

where $p(x_n \,|\, \theta)$ is the likelihood and $p(\theta)$ is the prior. For simpler notation, we will suppress the dependence of the loss on the data.

From this loss we construct stochastic gradients. Let $\mathcal{S}$ be a set of S random indices drawn uniformly at random from the set $\{1, \ldots, N\}$. This set indexes functions $\ell_n(\theta)$, and we call $\mathcal{S}$ a "minibatch" of size S. Based on the minibatch, we used the indexed functions to form a stochastic estimate of the loss and a stochastic gradient,

$$\hat{\mathcal{L}}_S(\theta) = \frac{1}{S}\sum_{n\in\mathcal{S}}\ell_n(\theta), \quad \hat{g}_S(\theta) = \nabla_\theta \hat{\mathcal{L}}_S(\theta). \tag{4}$$

In expectation the stochastic gradient is the full gradient, i.e., $g(\theta) = \mathbb{E}[\hat{g}_S(\theta)]$. We use this stochastic gradient in the SGD update

$$\theta(t+1) = \theta(t) - \epsilon\,\hat{g}_S(\theta(t)). \tag{5}$$

Above and for what follows, we assume a constant (non-decreasing) learning rate ϵ.

Eqs. 4 and 5 define the discrete-time process that SGD simulates from. We will approximate it with a continuous-time process that is easier to analyze.

3.2 SGD as an Ornstein-Uhlenbeck Process

We now show how to approximate the discrete-time Eq. 5 with a continuous-time Ornstein-Uhlenbeck process (Uhlenbeck and Ornstein, 1930). This leads to the stochastic differential equation below in Eq. 11. To justify the approximation, we make four assumptions. We verify its accuracy empirically in Section 7.

Assumption 1 *Observe that the stochastic gradient is a sum of S independent, uniformly sampled contributions. Invoking the central limit theorem, we assume that the gradient noise is Gaussian with covariance $\frac{1}{S}C(\theta)$, hence*

$$\hat{g}_S(\theta) \approx g(\theta) + \frac{1}{\sqrt{S}}\Delta g(\theta), \quad \Delta g(\theta) \sim \mathcal{N}(0, C(\theta)). \tag{6}$$

Assumption 2 *We assume that the covariance matrix $C(\theta)$ is approximately constant with respect to θ. As a symmetric positive-semidefinite matrix, this constant matrix C factorizes as*

$$C(\theta) \approx C = BB^\top. \tag{7}$$

Assumption 2 is justified when the iterates of SGD are confined to a small enough region around a local optimum of the loss (e.g. due to a small ϵ) that the noise covariance does not vary significantly in that region.

We now define $\Delta\theta(t) = \theta(t+1) - \theta(t)$ and combine Eqs. 5, 6, and 7 to rewrite the process as

$$\Delta\theta(t) = -\epsilon\, g(\theta(t)) + \tfrac{\epsilon}{\sqrt{S}} B\, \Delta W, \quad \Delta W \sim \mathcal{N}(0, \mathbf{I})\,. \tag{8}$$

This can be interpreted as a finite-difference equation that approximates the following continuous-time stochastic differential equation:

$$d\theta(t) = -\epsilon g(\theta) dt + \tfrac{\epsilon}{\sqrt{S}} B\, dW(t). \tag{9}$$

Assumption 3 *We assume that we can approximate the finite-difference equation (8) by the stochastic differential equation (9).*

This assumption is justified if either the gradients or the learning rates are small enough that the discretization error becomes negligible.

Assumption 4 *We assume that the stationary distribution of the iterates is constrained to a region where the loss is well approximated by a quadratic function,*

$$\mathcal{L}(\theta) = \tfrac{1}{2}\, \theta^\top A \theta. \tag{10}$$

(Without loss of generality, we assume that a minimum of the loss is at $\theta = 0$.) We also assume that A is positive definite.

The symmetric matrix A is thus the Hessian at the optimum. Assumption 4 makes sense when the loss function is smooth and the stochastic process reaches a low-variance quasi-stationary distribution around a deep local minimum. The exit time of a stochastic process is typically exponential in the height of the barriers between minima, which can make local optima very stable even in the presence of noise (Kramers, 1940).

SGD as an Ornstein-Uhlenbeck process. The four assumptions above result in a specific kind of stochastic process, the multivariate *Ornstein-Uhlenbeck* process (Uhlenbeck and Ornstein, 1930):

$$d\theta(t) = -\epsilon A\, \theta(t) dt + \tfrac{1}{\sqrt{S}} \epsilon B\, dW(t) \tag{11}$$

This connection helps us analyze properties of SGD because the Ornstein-Uhlenbeck process has an analytic stationary distribution $q(\theta)$ that is Gaussian. This distribution will be the core analytic tool of this paper:

$$q(\theta) \propto \exp\left\{-\tfrac{1}{2}\theta^\top \Sigma^{-1} \theta\right\}. \tag{12}$$

The covariance Σ satisfies

$$\Sigma A + A\Sigma = \tfrac{\epsilon}{S} BB^\top. \tag{13}$$

(More details are in Appendix B.) Without explicitly solving this equation, we see that the resulting covariance Σ is proportional to the learning rate ϵ and inversely proportional to the magnitude of A and minibatch size S. This characterizes the stationary distribution of running SGD with a constant step size.

Discussion of Assumptions 1–4. Our analysis suggests that constant SGD and Langevin-type diffusion algorithms (Welling and Teh, 2011) are very similar. Both types of algorithms can be characterized by three regimes. First, there is a search phase where the algorithm approaches the optimum. In this early phase, assumptions 1–4 are often violated and it is hard to say anything general about the behavior of the algorithm. Second, there is a phase where SGD has converged to the vicinity of a local optimum. Here, the objective already looks quadratic, but the gradient noise is small relative to the average gradient $g(\theta)$. Thus SGD takes a relatively directed path towards the optimum. This is the regime where our assumptions should be approximately valid, and where our formalism reveals its use. Finally, in the third phase the iterates are near the local optimum. Here, the average gradient $g(\theta)$ is small and the sampling noise becomes more important. In this final phase, constant SGD begins to sample from its stationary distribution.

Finally, we note that if the gradient noise covariance C does not have full rank, then neither will the stationary covariance Σ. This scenario complicates the analysis in Section 4, so below we will assume that C has full rank. This could be enforced easily by adding very low-magnitude isotropic artificial Gaussian noise to the stochastic gradients.

4. SGD as Approximate Inference

We discussed a continuous-time interpretation of SGD with a constant step size (constant SGD). We now discuss how to use constant SGD as an approximate inference algorithm. To repeat the set-up from the introduction, consider a probabilistic model $p(\theta, \mathbf{x})$ with data $\mathbf{x}$ and hidden variables θ; our goal is to approximate the posterior $p(\theta \mid \mathbf{x})$ in Eq. 1.

We set the loss to be the negative log-joint distribution (Eqs. 2 and 3), which equals the negative log-posterior up to an additive constant. The classical goal of SGD is to minimize this loss, leading us to a maximum-a-posteriori point estimate of the parameters. This is how SGD is used in many statistical models, including logistic regression, linear regression, matrix factorization, and neural networks. In contrast, our goal here is to tune the parameters of SGD so that its stationary distribution approximates the posterior.

Fig. 1 shows an example. Here we illustrate two Bayesian posteriors—from a linear regression problem (top) and a logistic regression problem (bottom)—along with iterates from a constant SGD algorithm. In these figures, we set the parameters of the optimization to values that minimize the Kullback-Leibler (KL) divergence between the stationary distribution of the OU process and the posterior—these results come from our theorems below. The left plots optimize both a preconditioning matrix and the step size; the middle plots optimize only the step size (both are outlined in Section 4.1). We can see that the stationary distribution of constant SGD can be made close to the exact posterior.

Fig. 2 also compares the empirical covariance of the iterates with the predicted covariance in terms of Eq. 13. The close match supports the assumptions of Section 3.

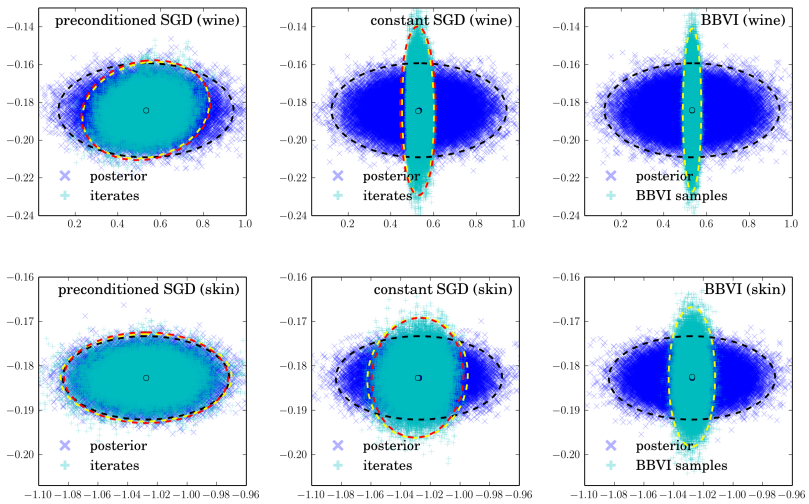

Figure 1: Posterior distribution $f(\theta) \propto \exp\{-N\mathcal{L}(\theta)\}$ (blue) and stationary sampling distributions $q(\theta)$ of the iterates of SGD (cyan) or black box variational inference (BBVI) based on reparameterization gradients. Rows: linear regression (top) and logistic regression (bottom) discussed in Section 7. Columns: full-rank preconditioned constant SGD (left), constant SGD (middle), and BBVI (Kucukelbir et al., 2015) (right). We show projections on the smallest and largest principal component of the posterior. The plot also shows the empirical covariances (3 standard deviations) of the posterior (black), the covariance of the samples (yellow), and their prediction (red) in terms of the Ornstein-Uhlenbeck process, Eq. 13.

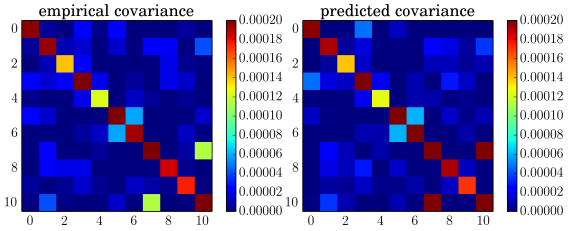

Figure 2: Empirical and predicted covariances of the iterates of stochastic gradient descent, where the prediction is based on Eq. 13. We used linear regression on the wine quality data set as detailed in Section 7.1.

We will use this perspective in three ways. First, we develop optimal conditions for constant SGD to best approximate the posterior, connecting to well-known results around adaptive learning rates and preconditioners (Duchi et al., 2011; Tieleman and Hinton, 2012). Second, we propose an algorithm for hyperparameter optimization based on constant SGD. Third, we use it to analyze the stationary distribution of stochastic gradient descent with momentum (Polyak, 1964).

4.1 Constant Stochastic Gradient Descent

First, we show how to tune constant SGD's parameters to minimize KL divergence to the posterior; this is a type of variational inference (Jordan et al., 1999). The analysis leads to three versions of constant SGD—one with a constant step size, one with a full preconditioning matrix, and one with a diagonal preconditioning matrix. Each yields samples from an approximate posterior, and each reflects a different tradeoff between efficiency and accuracy. Finally, we show how to use these algorithms to learn hyperparameters.

Assumption 4 from Section 3 says that the posterior is approximately Gaussian in the region that the stationary distribution focuses on,

$$f(\theta) \propto \exp\left\{-\tfrac{N}{2}\theta^\top A\theta\right\}. \tag{14}$$

The scalar N corrects the averaging in equation 2. Furthermore, in this section we will consider a more general SGD scheme that may involve a *preconditioning matrix* H instead of a scalar learning rate ϵ:

$$\theta_{t+1} = \theta_t - H\hat{g}_S(\theta(t)).$$

We will set the parameters of SGD to minimize the KL divergence between the stationary distribution $q(\theta)$ (Eqs. 12 and 13) and the posterior $f(\theta)$ (Eq. 14). This involves the the learning rate ϵ or more generally the preconditioning matrix H and the minibatch size S:

$$\{H^*, S^*\} = \arg\min_{H,S} KL(q \mid\mid f).$$

First, consider a scalar learning rate ϵ (or a trivial preconditioner $H = \epsilon\mathbf{I}$). The distributions $f(\theta)$ and $q(\theta)$ are both Gaussians. Their means coincide, at the minimum of the loss, and so their KL divergence is

$$\begin{aligned} KL(q \,||\, f) &= -\mathbb{E}_q[\log f(\theta)] + \mathbb{E}_q[\log q(\theta)] \\ &= \tfrac{1}{2}\left(N\mathbb{E}_q[\theta^\top A\theta] - \log|NA| - \log|\Sigma| - D\right) \\ &= \tfrac{1}{2}\left(N\mathrm{Tr}(A\Sigma) - \log|NA| - \log|\Sigma| - D\right), \end{aligned}$$

where $|\cdot|$ is the determinant and D is the dimension of θ.

We suggest three variants of constant SGD that generate samples from an approximate posterior.

Theorem 1 (Constant SGD) *Under Assumptions A1-A4, the constant learning rate that minimizes KL divergence from the stationary distribution of constant SGD to the posterior is*

$$\epsilon^* = 2\tfrac{S}{N}\tfrac{D}{\mathrm{Tr}(BB^\top)}. \tag{15}$$

Proof To prove this claim, we face the problem that the covariance of the stationary distribution depends indirectly on ϵ through Eq. 13. Inspecting this equation reveals that $\Sigma_0 \equiv \frac{S}{\epsilon}\Sigma$ is independent of S and ϵ. This simplifies the entropy term $\log|\Sigma| = D\log(\epsilon/S) + \log|\Sigma_0|$. Since Σ_0 is constant, we can neglect it when minimizing KL divergence.

We also need to simplify the term $\mathrm{Tr}(A\Sigma)$, which still depends on ϵ and S through Σ. To do this, we again use Eq. 13, from which follows that $\mathrm{Tr}(A\Sigma) = \frac{1}{2}(\mathrm{Tr}(A\Sigma) + \mathrm{Tr}(\Sigma A)) = \frac{\epsilon}{2S}\mathrm{Tr}(BB^\top)$. The KL divergence is therefore, up to constant terms,

$$KL(q||f) \overset{c}{=} \frac{\epsilon N}{2S}\mathrm{Tr}(BB^\top) - D\log(\epsilon/S). \tag{16}$$

Minimizing KL divergence over ϵ/S results in Eq. 15 for the optimal learning rate. ■

Theorem 1 suggests that the learning rate should be chosen inversely proportional to the average of diagonal entries of the noise covariance, and proportional to the ratio between the minibatch size and dataset size.

Since both the posterior f and the variational distribution q are Gaussian, one might wonder if also the reverse KL divergence is viable. While the KL divergence can be computed up to a constant, we cannot remove its dependence on the unknown stationary distribution Σ using Eq. 13, unless A and Σ commute. This setup is discussed in Appendix C.

Instead of using a scalar learning rate, we now consider a positive-definite preconditioning matrix H. This gives us more tuning parameters to better approximate the posterior.

Theorem 2 (Preconditioned constant SGD) *The preconditioner for constant SGD that minimizes KL divergence from the stationary distribution to the posterior is*

$$H^* = \frac{2S}{N}(BB^\top)^{-1}. \tag{17}$$

Proof To prove this, we need the Ornstein-Uhlenbeck process which corresponds to preconditioned SGD. Replacing the constant learning rate in Eq. 11 with a positive-definite preconditioning matrix H results in

$$d\theta(t) = -HA\,\theta(t)dt + \frac{1}{\sqrt{S}}HB\,dW(t).$$

All our results carry over after substituting $\epsilon A \leftarrow HA,\ \epsilon B \leftarrow HB$. Eq. 13, after the transformation and multiplication by H^{-1} from the left, becomes

$$A\Sigma + H^{-1}\Sigma AH = \frac{1}{S}BB^\top H. \tag{18}$$

Using the cyclic property of the trace, this implies that

$$\mathrm{Tr}(A\Sigma) = \frac{1}{2}(\mathrm{Tr}(A\Sigma) + \mathrm{Tr}(H^{-1}A\Sigma H)) = \frac{1}{2S}\mathrm{Tr}(BB^\top H). \tag{19}$$

Consider now the log determinant term, $\log|\Sigma|$, which still has an implicit dependence on H. We first define $Q = \Sigma H^{-1}$, hence $Q^\top = H^{-1}\Sigma$ since Σ, H and H^{-1} are symmetric. Eq. 18 can be written as $A\Sigma H^{-1} + H^{-1}\Sigma A = \frac{1}{S}BB^\top$, which is equivalent to $QA + AQ^\top = \frac{1}{S}BB^\top$.

Thus, we see that Q is independent of H. The log determinant term is up to a constant $\log|\Sigma| = \log|H| + \log|Q|$. Combining Eq. 19 with this term, the KL divergence is up to a constant

$$KL(q||f) \overset{c}{=} \frac{N}{2S}\mathrm{Tr}(BB^\top H) + \log|H| + \log|Q|. \tag{20}$$

Taking derivatives with respect to the entries of H results in Eq. 17. ■

In high-dimensional applications, working with large dense matrices is impractical. In those settings we can constrain the preconditioner to be diagonal. The following corollaries are based on the proof of Theorem 2:

Corollary 3 *The optimal diagonal preconditioner for SGD that minimizes KL divergence to the posterior is* $H^*_{kk} = \frac{2S}{NBB^\top_{kk}}$.

Proof This follows from Eq. 20, where we restrict the preconditioning matrix to be diagonal. ■

Corollary 4 *Under assumptions A1-A4, preconditioning with the full inverse noise covariance as in Theorem 2 results in samples from the exact posterior.*

Proof Consider Eq. 18. Inserting $H = \frac{2S}{N}(BB^\top)^{-1}$ results in $A\Sigma + H^{-1}\Sigma AH = \frac{2}{N}\mathbf{I}$ which is solved by $\Sigma = A^{-1}/N$ which is the posterior covariance. ■

We showed that the optimal diagonal preconditioner is the inverse of the diagonal part of the noise matrix. Similar preconditioning matrices have been suggested earlier in optimal control theory based on very different arguments, see (Widrow and Stearns, 1985). Our result also relates to AdaGrad and its relatives (Duchi et al., 2011; Tieleman and Hinton, 2012), which also adjust the preconditioner based on the square root of the diagonal entries of the noise covariance. In Appendix F we derive an optimal global learning rate for AdaGrad-style diagonal preconditioners. In Section 7, we compare three versions of constant SGD for approximate posterior inference: one with a scalar step size, one with a dense preconditioner, and one with a diagonal preconditioner.

Remark on estimating the noise covariance. In order to use our theoretical insights in practice, we need to estimate the stochastic gradient noise covariance $C \equiv BB^\top$. We do this in an online manner. As before, let g_t be the full gradient, $\hat{g}_{S,t}$ be the stochastic gradient of the full minibatch, and $\hat{g}_{1,t}$ be the stochastic gradient of the first sample in the minibatch at time t (which has a much larger variance if $S \gg 1$). For large S, we can approximate $g_t \approx \hat{g}_{S,t}$, and thus obtain an estimator of the noise covariance by $(\hat{g}_{1,t} - \hat{g}_{S,t})(\hat{g}_{1,t} - \hat{g}_{S,t})^\top$. Following Ahn et al. (2012), we can now build an online estimate C_t that approaches C by the following recursion,

$$C_t = (1 - \kappa_t)C_{t-1} + \kappa_t(\hat{g}_{1,t} - \hat{g}_{S,t})(\hat{g}_{1,t} - \hat{g}_{S,t})^\top. \tag{21}$$

Above, κ_t is a decreasing learning rate. Ahn et al. (2012) have proven that such an online average converges to the noise covariance in the optimum at long times (provided that $\kappa_t \sim 1/t$ and that N is sufficiently large). We found that this online estimator works well in practice, even though our theoretical assumptions would require preconditioning SGD with the true noise covariance in finite

time. Regarding the computational overhead of this procedure, note that similar online estimates of the gradient noise are carried out in adaptive SGD schemes such as AdaGrad (Duchi et al., 2011) or RMSProp (Tieleman and Hinton, 2012). When using a diagonal approximation to the noise covariance, the costs are proportional in the number of dimensions and mini-batch size; this efficiency means that the online estimate does not spoil the efficiency of SGD. Full preconditioning scales quadratically in the dimension and is therefore impractical in many real-word setups.

4.2 Constant SGD as Variational EM

Consider a supervised probabilistic model with joint distribution $p(y, \theta|x, \lambda) = p(y|x, \theta)p(\theta|\lambda)$ that factorizes into a likelihood and prior, respectively. Our goal is to find optimal hyperparameters λ. Jointly point-estimating θ and λ by following gradients of the log joint leads to overfitting or degenerate solutions. This can be prevented in a Bayesian approach, where we treat the parameters θ as latent variables. In Empirical Bayes (or type-II maximum likelihood), we maximize the *marginal* likelihood of the data, integrating out the main model parameters:

$$\lambda^\star = \arg\max_\lambda \log p(y|x, \lambda) = \arg\max_\lambda \log \textstyle\int_\theta p(y, \theta|x, \lambda) d\theta.$$

When this marginal log-likelihood is intractable, a common approach is to use *variational expectation-maximization (VEM)* (Bishop, 2006), which iteratively optimizes a variational lower bound on the marginal log-likelihood over λ. If we approximate the posterior $p(\theta|x, y, \lambda)$ with some distribution $q(\theta)$, then VEM tries to find a value for λ that maximizes the expected log-joint probability $\mathbb{E}_q[\log p(\theta, y|x, \lambda)]$.

Constant SGD gives rise to a simple VEM algorithm that applies to a large class of differentiable models. Define $\mathcal{L}(\theta, \lambda) = -\log p(y, \theta \,|\, x, \lambda)$. If we interpret the stationary distribution of SGD as a variational approximation to a model's posterior, we can justify following a stochastic gradient descent scheme on both θ and λ:

$$\theta_{t+1} = \theta_t - \epsilon^* \nabla_\theta \mathcal{L}(\theta_t, \lambda_t); \quad \lambda_{t+1} = \lambda_t - \rho_t \nabla_\lambda \mathcal{L}(\theta_t, \lambda_t). \tag{22}$$

While the update for θ uses the optimal constant learning rate ϵ^* and therefore samples from an approximate posterior, the λ update uses a decreasing learning rate ρ_t and therefore converges to a local optimum. The result is a type of VEM algorithm.

We stress that the optimal constant learning rate ϵ^* is not unknown, but can be estimated based on an online estimate of the noise covariance $C \equiv BB^\top$, as given in Eq. 21. In Section 7 we show that gradient-based hyperparameter learning is a cheap alternative to cross-validation.

4.3 Stochastic Gradient with Momentum

The continuous-time formalism also allows us to explore extensions of classical SGD. One of the most popular methods is stochastic gradient with momentum (Polyak, 1964; Sutskever et al., 2013). Here, we give a version of this algorithm that allows us to sample from an approximate posterior.

SGD with momentum doubles the dimension of parameter space in introducing an additional *momentum* variable v that has the same dimension as θ. Position and momentum are coupled in such a way that the algorithm keeps memory of some of its past gradients. The updates of SGD with momentum are

$$\begin{aligned} \mathrm{v}(t+1) &= (1-\mu)\mathrm{v}(t) - \epsilon\, \hat{g}_S(\theta(t)) \\ \theta(t+1) &= \theta(t) + \mathrm{v}(t+1). \end{aligned}$$

This involves the damping coefficient $\mu \in [0, 1]$. For $\mu = 1$ (infinite damping or overdamping), the momentum information gets lost and we recover SGD.

As before we assume a quadratic objective $\mathcal{L} = \frac{1}{2}\theta^\top A\theta$. Going through the same steps A1-A4 of Section 3 that allowed us to derive the Ornstein-Uhlenbeck process for SGD, we find

$$\begin{aligned} d\mathrm{v} &= -\mu\mathrm{v}dt - \epsilon A\theta dt + \tfrac{1}{\sqrt{S}}\epsilon B\, dW, \\ d\theta &= \mathrm{v}dt. \end{aligned} \tag{23}$$

We solve this set of stochastic equations asymptotically for the long-time limit. We reformulate the stochastic equation in terms of coupled equations for the moments. (This strategy was also used by Li et al. (2015) in a more restricted setting). The first moments of the set of coupled stochastic differential equations give

$$d\mathbb{E}[\mathrm{v}] = -\mu\mathbb{E}[\mathrm{v}]dt - \epsilon A\mathbb{E}[\theta]dt, \quad d\mathbb{E}[\theta] = \mathbb{E}[\mathrm{v}]dt.$$

Note we used that expectations commute with the differential operators. These deterministic equations have the simple solution $\mathbb{E}[\theta] = 0$ and $\mathbb{E}[\mathrm{v}] = 0$, which means that the momentum has expectation zero and the expectation of the position variable converges to the optimum (at 0).

In order to compute the stationary distribution, we derive and solve similar equations for the second moments. These calculations are carried out in Appendix D, where we derive the following conditions:

$$\begin{aligned} \mathbb{E}[\mathrm{v}\mathrm{v}^\top] &= \tfrac{\epsilon}{2}\mathbb{E}[\theta\theta^\top]A + \tfrac{\epsilon}{2}A\mathbb{E}[\theta\theta^\top], \\ \mu\mathbb{E}[\mathrm{v}\mathrm{v}^\top] &= \tfrac{\epsilon^2}{2S}BB^\top. \end{aligned} \tag{24}$$

Eq. 25 relate to equilibrium thermodynamics, where $\mathbb{E}[\mathrm{v}\mathrm{v}^\top]$ is a matrix of expected kinetic energies, while $\frac{1}{2}(\mathbb{E}[\theta\theta^\top]A + A\mathbb{E}[\theta\theta^\top])$ has the interpretation of a matrix of expected potential energies. The first equation says that energy conservation holds in expectation, which is the case for an equilibrium system which exchanges energy with its environment. The second equation relates the covariance of the velocities with $BB^\top$, which plays the role of a matrix-valued temperature. This is known as the fluctuation-dissipation theorem (Nyquist, 1928). Combining both equations and using $\Sigma = \mathbb{E}[\theta\theta^\top]$ yields

$$\Sigma A + A\Sigma = \tfrac{\epsilon}{\mu S}BB^\top. \tag{25}$$

This is exactly Eq. 13 of SGD without momentum, however, with the difference that the noise covariance is re-scaled by a factor $\frac{\epsilon}{\mu S}$ instead of $\frac{\epsilon}{S}$.

We have shown that ϵ, S, and μ play similar roles: only the combination $\frac{\epsilon}{\mu S}$ affects the KL divergence to the posterior. Thus, no single optimal constant learning rate exists—many combinations of ϵ, μ, and S can yield the same stationary distribution. But different choices of these parameters will affect the dynamics of the Markov chain. For example, Sutskever et al. (2013) observe that, for a given effective learning rate $\frac{\epsilon}{\mu S}$, using a smaller μ sometimes makes the *discretized* dynamics of SGD more stable. Also, using very small values of μ while holding $\frac{\epsilon}{\mu}$ fixed will eventually increase the autocorrelation time of the Markov chain (but this effect is often negligible in practice).

5. Analyzing Stochastic Gradient MCMC Algorithms

We have analyzed well-known stochastic optimization algorithms such as SGD, preconditioned SGD and SGD with momentum. We now investigate Bayesian sampling algorithms. A large class of modern MCMC methods rely on stochastic gradients (Welling and Teh, 2011; Ahn et al., 2012; Chen et al., 2014; Ding et al., 2014; Ma et al., 2015). The central idea is to add artificial noise to the stochastic gradient to asymptotically sample from the true posterior.

In practice, however, the algorithms are used in combination with several heuristic approximations, such as non-vanishing learning rates or diagonal approximations to the Hessian. In this section, we use the variational perspective to quantify these biases and help understanding these algorithms better under more realistic assumptions.

5.1 SGLD with Constant Rates

To begin with, we we analyze the well-known Stochastic Gradient Langevin Dynamics by Welling and Teh (2011). This algorithm has been carefully analyzed in the long time limit where the stochastic gradient noise vanishes as the learning rate goes to zero, and where mixing becomes infinitely slow (Sato and Nakagawa, 2014). Here we analyze an approximate version of the algorithm, SGLD with a constant learning rate. We are interested in the stationary distribution of this approximate inference algorithm.

The discrete-time process that describes Stochastic Gradient Langevin dynamics is

$$\theta_{t+1} \quad = \quad \theta_t - \tfrac{\epsilon}{2} N \hat{\nabla}_\theta \mathcal{L}(\theta_t) + \sqrt{\epsilon}\, V(t),$$

where $V(t) \sim \mathcal{N}(0, \mathbf{I})$ is a vector of independent Gaussian noises. Following assumptions 1–4 of Section 3, V becomes the Wiener noise dV and the corresponding continuous-time process is

$$d\theta \quad = \quad -\tfrac{1}{2}\epsilon N A \theta dt + \sqrt{\epsilon} dV + \epsilon \tfrac{1}{\sqrt{S}} N B\, dW.$$

Above, dV and dW are vectors of independent Wiener noises, i.e. $\mathbb{E}[dW dV^\top] = \mathbb{E}[dV dW^\top] = 0$. The analog of Eq. 13 is then

$$\tfrac{1}{2} N (A\Sigma + \Sigma A) \quad = \quad \mathbf{I} + \tfrac{\epsilon N}{2S} B B^\top.$$

In the limit of $\epsilon \to 0$, we find that $\Sigma^{-1} = NA$, meaning the stationary distribution becomes identical to the posterior. However, for non-zero ϵ, there are discrepancies. These correction-terms are positive. This shows that the posterior covariance is generally overestimated by Langevin dynamics, which can be attributed to non-vanishing learning rates at long times.

5.2 Stochastic Gradient Fisher Scoring

We now investigate Stochastic Gradient Fisher Scoring (Ahn et al., 2012), a scalable Bayesian MCMC algorithm. We use the variational perspective to rederive the Fisher scoring update and identify it as optimal. We also analyze the sampling distribution of the truncated algorithm, one with diagonal preconditioning (as it is used in practice), and quantify the bias that this induces.

The basic idea here is that the stochastic gradient is preconditioned and additional noise is added to the updates such that the algorithm approximately samples from the Bayesian posterior. More precisely, the update can be cast into the following form:

$$\theta(t+1) = \theta(t) - \epsilon H\, \hat{g}(\theta(t)) + \sqrt{\epsilon} H E\, W(t). \tag{26}$$

The matrix H is a preconditioner and $EW(t)$ is Gaussian noise; we control the preconditioner and the covariance $EE^\top$ of the noise. Stochastic gradient Fisher scoring suggests a preconditioning matrix H that leads to samples from the posterior even if the learning rate ϵ is not asymptotically small. We show here that this preconditioner follows from our variational analysis.

Theorem 5 (Stochastic Gradient Fisher Scoring) *Under Assumptions A1-A4, the positive-definite preconditioner H in Eq. 26 that minimizes KL divergence from the stationary distribution of SGFS to the posterior is*

$$H^* = \tfrac{2}{N}(\epsilon B B^\top + E E^\top)^{-1}. \tag{27}$$

Proof To prove the claim, we go through the steps of Section 3 to derive the corresponding Ornstein-Uhlenbeck process, $d\theta(t) = -\epsilon H A \theta(t) dt + H\left[\epsilon B + \sqrt{\epsilon} E\right] dW(t)$. For simplicity, we have set the minibatch size S to 1. In Appendix E, we derive the following KL divergence between the posterior and the sampling distribution:

$$KL(q||p) = -\tfrac{N}{4}\mathrm{Tr}(H(\epsilon B B^\top + E E^\top)) + \tfrac{1}{2}\log|T| + \tfrac{1}{2}\log|H| + \tfrac{1}{2}\log|NA| + \tfrac{D}{2}.$$

(T is constant with respect to H, ϵ, and E.) We can now minimize this KL divergence over the parameters H and E. When E is given, minimizing over H gives Eq. 27. ■

Eq. 27 not only minimizes the KL divergence, but makes it 0, meaning that the stationary sampling distribution *is* the posterior. This solution corresponds to the suggested Fisher Scoring update in the idealized case when the sampling noise distribution is estimated perfectly (Ahn et al., 2012). Through this update, the algorithm thus generates posterior samples without decreasing the learning rate to zero. (This is in contrast to Stochastic Gradient Langevin Dynamics by Welling and Teh (2011).)

In practice, however, SGFS is often used with a diagonal approximation of the preconditioning matrix (Ahn et al., 2012; Ma et al., 2015). However, researchers have not explored how the stationary distribution is affected by this truncation, which makes the algorithm only approximately Bayesian. We can quantify its deviation from the exact posterior and we derive the optimal diagonal preconditioner, which follows from the KL divergence in Theorem 5:

Corollary 6 *When approximating the Fisher scoring preconditioner by a diagonal matrix H^*_{kk} or a scalar H^*_{scalar}, respectively, then*

$$H^*_{kk} = \frac{2}{N}(\epsilon B B^\top_{kk} + E E^\top_{kk})^{-1} \quad \textit{and} \quad H^*_{scalar} = \frac{2D}{N}(\sum_k [\epsilon B B^\top_{kk} + E E^\top_{kk}])^{-1}.$$

Note that we have not made any assumptions about the noise covariance E. We can adjust it in favor of a more stable algorithm. For example, in the interests of stability we might want to set a maximum step size h^{max}, so that $H_{kk} \leq h^{max}$ for all k. We can adjust E such that $H_{kk} \equiv h^{max}$ in Eq. 27 becomes independent of k. Solving for E yields $E E^\top_{kk} = \frac{2}{h^{max} N} - \epsilon B B^\top_{kk}$.

Hence, to keep the learning rates bounded in favor of stability, one can inject noise in dimensions where the variance of the gradient is too small. This guideline is opposite to the advice of Ahn et al. (2012) to choose B proportional to E, but follows naturally from the variational analysis.

An additional benefit of SGFS over simple constant SGD is that the sum of gradient noise and Gaussian noise will always look "more Gaussian" than the gradient noise on its own. An extreme case is when the gradient covariance $BB^\top$ is not full rank; in this situation injecting full-rank Gaussian noise could prevent degenerate behavior.

6. A Bayesian View on Iterate Averaging

We now apply our continuous-time analysis to the technique of iterate averaging (Polyak and Juditsky, 1992). Iterate averaging was derived as an optimization algorithm, and we analyze this algorithm in Section 6.1 from this perspective. In Section 6.2 we show that iterate averaging can also be used as a Bayesian sampling algorithm.

6.1 Iterate Averaging for Optimization

Iterate averaging further refines SGD's estimate of the optimal parameters by averaging the iterates produced by a series of SGD steps. Polyak and Juditsky (1992) proved the remarkable result that averaged SGD achieves the best possible convergence rate among stochastic gradient algorithms[1], including those that use second-order information such as Hessians. This implies that the convergence speed of iterate averaging cannot be improved when premultiplying the stochastic gradient with any preconditioning matrix. We use stochastic calculus to show that the stationary distribution of iterate averaging is the same for any constant preconditioner. Based on slightly stronger-than-usual assumptions, we give a short proof on why this result holds.

To eliminate asymptotic biases, iterate averaging usually requires a slowly decreasing learning rate. We consider a simplified version with a constant rate, also analyzed in (Zhang, 2004; Nemirovski et al., 2009).

Algorithm. Before we begin iterate averaging, we assume that we have run ordinary constant SGD for long enough that it has reached its stationary distribution and forgotten its intialization. In this scenario, we use iterate averaging to "polish" the results obtained by SGD.

Iterate averaging estimates the location of the minimum of $\mathcal{L}$ using a sequence of stochastic gradients $\hat{g}_S$, and then computes an average of the iterates in an online manner,

$$\begin{aligned} \theta_{t+1} &= \theta_t - \epsilon \hat{g}_S(\theta_t), \\ \hat{\mu}_{t+1} &= \tfrac{t}{t+1}\,\hat{\mu}_t + \tfrac{1}{t+1}\,\theta_{t+1}. \end{aligned} \tag{28}$$

After T stochastic gradient steps and going over to continuous times, this average is

$$\hat{\mu} \approx \tfrac{1}{T}\int_0^T \theta(t)\,dt \equiv \hat{\mu}'. \tag{29}$$

The average $\hat{\mu}$ and its approximation $\hat{\mu}'$ are random variables whose expected value is the minimum of the objective. (Again, this assumes $\theta(0)$ is drawn from the SGD process's stationary distribution.)

The accuracy of this estimator $\hat{\mu}'$ after a fixed number of iterations T is characterized by its covariance matrix D. Using stochastic calculus, we can compute D from the autocorrelation matrix of the stationary distribution of the OU process, shown in Appendix G. We prove that

$$D \equiv \mathbb{E}\left[\hat{\mu}'\hat{\mu}'^\top\right] \approx \tfrac{1}{\epsilon T}\left(\Sigma(A^{-1})^\top + A^{-1}\Sigma\right). \tag{30}$$

1. To be more precise, averaged SGD is optimal among methods that only have access to a stochastic gradient oracle—if more is known about the source of the noise then sometimes better rates are possible (e.g., Johnson and Zhang, 2013; Defazio et al., 2014).

This approximation ignores terms of order $1/(T\epsilon)^2$. This term is small since we assume that the number of iterations T is much larger than the inverse learning rate $1/\epsilon$. The covariance shrinks linearly over iterations as we expect from Polyak and Juditsky (1992). We use Eq. 13 to derive

$$D \approx \tfrac{1}{TS} A^{-1} BB^\top (A^{-1})^\top.$$

Note that this covariance depends only on the number of iterations T times the minibatch size S, not on the step size ϵ. Since TS is the total number of examples that are processed, this means that this iterate averaging scheme's efficiency does not depend on either the minibatch size or the step size, proven first in (Polyak and Juditsky, 1992).

We can make a slightly stronger statement. If we precondition the stochastic gradients with a positive-definite matrix H (for example, the inverse of the Hessian evaluated at the minimum), it turns out that the covariance of the estimator remains unchanged. The resulting Ornstein-Uhlenbeck process is $d\theta = -HA\theta(t)dt + \frac{1}{\sqrt{S}} HB\,dW(t)$. The resulting stationary covariance D' of preconditioned iterate averaging is the same as above:

$$\begin{aligned} D' &\approx \tfrac{1}{T}(HA)^{-1}(\tfrac{1}{\sqrt{S}}HB)(\tfrac{1}{\sqrt{S}}HB)^\top((HA)^\top)^{-1} \\ &= \tfrac{1}{TS} A^{-1}H^{-1}HBB^\top HH^{-1}A^{-1} \\ &= \tfrac{1}{TS} A^{-1}BB^\top A^{-1}. \end{aligned} \tag{31}$$

Both the stationary distribution and the autocorrelation matrix change as a result of the preconditioning, and these changes exactly cancel each other out.

This optimality of iterate averaging was first derived by Polyak and Juditsky (1992), using quasi-martingales. Our derivation is based on stronger assumptions, but is shorter.

6.2 Finite-Window Iterate Averaging for Posterior Sampling

Above, we used the continuous-time formalism to quickly rederive known results about the optimality of iterate averaging as an optimization algorithm. Next, as in Section 4, we will analyze iterate averaging as an algorithm for approximate posterior inference.

We will show that (under some optimistic assumptions), iterate averaging requires exactly N gradient calls to generate one sample drawn from the exact posterior distribution, where N is the number of observations. That is, there exist conditions under which iterate averaging generates one true posterior sample per pass over the data. This result is both exciting and discouraging; it implies that, since our assumptions are all optimistic and iterate averaging is known to saturate the Cramér-Rao bound, *no* black-box stochastic-gradient MCMC algorithm can generate samples in time sublinear in the number of data points.

In addition to Assumptions 1–4 of Section 3, we need an additional assumption for our theoretical considerations to hold:

Assumption 5 *Assume that the sample size N is large enough that the Bernstein-von Mises theorem (Le Cam, 1986) applies (hence the posterior is Gaussian). Also assume that the observed dataset was drawn from the model $p(y\,|\theta)$ with parameter $\theta = 0$. Then $A = BB^\top$, that is, the Fisher information matrix equals the Hessian.*

This simplifies equation 13:

$$A\Sigma + \Sigma A = \tfrac{\epsilon}{S} BB^\top \overset{A5}{\Longrightarrow} \Sigma = \frac{\epsilon}{2S}\mathbf{I}. \tag{32}$$

Algorithm 1 The Iterate Averaging Stochastic Gradient sampler (IASG)

input: averaging window $T = N/S$, number of samples M, input for SGD.
for $t = 1$ *to* $M * T$ **do**
  $\theta_t = \theta_{t-1} - \epsilon\, \hat{g}_S(\theta_{t-1})$; // perform an SGD step;
  if $t \bmod T = 0$ **then**
    $\mu_{t/T} = \frac{1}{T} \sum_{t'=0}^{T-1} \theta_{t-t'}$; // average the T most recent iterates
  end
end
output: return samples $\{\mu_1, \ldots, \mu_M\}$.

That is, the sampling distribution of SGD is isotropic.

Stationary distribution. We will consider the sampling distribution of the *average* of T successive samples from the stationary SGD process with step size ϵ. Going to the continuous-time OU formalism, we show in Appendix G that the stationary covariance of the iterate averaging estimator defined in Eq. 30 is

$$D = \frac{1}{ST} A^{-1} + \frac{1}{\epsilon S T^2} U \Lambda^{-2} (e^{-\epsilon T \Lambda} - \mathbf{I}) U^\top, \tag{33}$$

where U is orthonormal, Λ is diagonal, and $U \Lambda U^\top = A$ is the eigendecomposition of the Hessian A. We have previously assumed that the posterior has covariance $\frac{1}{N} A^{-1}$. Thus, to leading order in the ratio $1/(\epsilon T \Lambda)$, the stationary distribution of fixed-window iterate averaging is a scaled version of the posterior.

If we choose $T = N/S$, so that we average the iterates of a single pass through the dataset, then the iterate-averaging sampling distribution will have approximately the same covariance as the posterior,

$$\begin{aligned} D^\star &= \frac{1}{N} A^{-1} + \frac{S}{\epsilon} \frac{1}{N^2} U \Lambda^{-2} (e^{-\frac{\epsilon}{S} N \Lambda} - \mathbf{I}) U^\top \\ &= \frac{1}{N} U \Lambda^{-1} \left(\mathbf{I} + \frac{S}{\epsilon} \frac{1}{N} \Lambda^{-1} (e^{-\frac{\epsilon}{S} N \Lambda} - \mathbf{I}) \right) U^\top. \end{aligned} \tag{34}$$

$D^\star$ and A^{-1} have identical eigenvectors, and their eigenvalues differ by a factor that goes to zero as $\frac{\epsilon}{S}$ becomes large. Conversely, as $\frac{\epsilon}{S}$ approaches zero, all of these eigenvalues approach $\frac{\epsilon}{2S}$ as in Eq. 32. (This can be shown by taking a second-order Maclaurin approximation of $e^{-\frac{\epsilon N}{S} \Lambda}$.)

Our analysis gives rise to the Iterate Averaging Stochastic Gradient sampler (IASG), described in Algorithm 1. We now investigate its approximation error and efficiency.

Approximation error, step size, and minibatch size. We now focus on the correction terms that lead to deviations between the iterate averaging estimator's covariance D^* and the posterior covariance $\frac{1}{N} A^{-1}$.

The analysis above tells us that we can ignore these correction terms if we choose a large enough $\frac{\epsilon}{S}$. But the analysis in previous chapters assumes that $\frac{\epsilon}{S}$ is small enough that assumptions 1–4 hold. These considerations are in tension.

When is $\frac{\epsilon}{S}$ "large enough"? Eq. 34 shows that the relative error is largest in the direction of the smallest eigenvalue $\lambda_{\min} \equiv \min_k \Lambda_{kk}$ of A (corresponding to the least-constrained direction in the posterior). We will focus our analysis on the relative error in this direction, which is given by

$$\mathrm{err}_{\max} \equiv \frac{S}{\epsilon} \frac{1}{N \lambda_{\min}} (e^{-\frac{S}{\epsilon} N \lambda_{\min}} - 1).$$

We are given N and $\lambda_{\min}$, but we can control $\frac{\epsilon}{S}$. To make $\mathrm{err}_{\max}$ small, we must therefore choose $\frac{\epsilon}{S} > \frac{c}{N \lambda_{\min}}$ for some constant c. So larger datasets and lower-variance posteriors let us use smaller stepsizes.

It is hard to say in general how small $\frac{\epsilon}{S}$ needs to be to satisfy assumptions 1–4. But if assumption 4 is satisfied (i.e., the cost is approximately quadratic), then assumption 3 (no discretization error) cannot hold if $\epsilon > \frac{2}{\lambda_{\max}}$. This is the step size at which the discretized noise-free gradient descent process becomes unstable for quadratic costs. (We define $\lambda_{\max} \equiv \max_k \Lambda_{kk}$ analogous to $\lambda_{\min}$.)

Combining this observation with the analysis above, we see that this iterate averaging scheme will not work unless

$$\frac{2}{S \lambda_{\max}} > \frac{\epsilon}{S} > \frac{c}{N \lambda_{\min}} \Rightarrow \frac{2}{c} > \frac{S}{N} \frac{\lambda_{\max}}{\lambda_{\min}}.$$

That is, we need the dataset size N to be large enough relative to the condition number $\frac{\lambda_{\max}}{\lambda_{\min}}$ of the Hessian A if this simple iterate-averaging scheme is to generate good posterior samples. If the condition number is large relative to N, then it may be necessary to replace the scalar step size ϵ with a preconditioning matrix $H \approx A^{-1}$ to reduce the effective condition number of the Hessian A.

Efficiency. Next, we theoreticaly analyze the efficiency with which iterate averaging can draw samples from the posterior, and compare this method to other approaches. We assume that the cost of analyzing a minibatch is proportional to S. We have shown above that we need to average over $T = N/S$ samples of SGD to create a sample of iterate averaged SGD. Since this averaging induces a strong autocorrelation, we can only use every Tth sample of the chain of averaged iterates. Furthermore, every sample of SGD incurs a cost at least proportional to D where D is the dimensionality of θ. This means that we cannot generate an independent sample from the posterior in less than $O(S * T * D) = O(ND)$ time; we must analyze at least N observations per posterior sample.

We compare this result with the more classical strategy of estimating the posterior mode via Newton's method (which has an $O(ND^2 + D^3)$ cost) and then estimating the posterior covariance by computing the inverse-Hessian at the mode, again incurring an $O(ND^2 + D^3)$ cost. By contrast, getting an unbiased full-rank estimate of the covariance using MCMC requires generating at least D samples, which again costs $O(ND^2)$. If $N > D$, then this is within a constant cost of the classical approach.

However, it is conceivable that Polyak averaging (Section 6.2) could be used to estimate the first few principal components of the posterior relatively quickly (i.e., in $O(ND)$ time). This corresponds to finding the smallest principal components of A, which cannot be done efficiently in general. A related question is investigated experimentally in Section 7.2.

The analysis above implies an upper bound on the efficiency of stochastic-gradient MCMC (SGMCMC) methods. The argument is this: given that assumptions 1–5 hold, suppose that there exists an SGMCMC method that, for large N, is able to generate effectively independent posterior samples using $d < O(N)$ operations. Then, if we wanted to estimate the posterior mode, we could simply average some large number M of those samples to obtain an estimator whose covariance would be $\frac{1}{M} A^{-1}$. This approach would require dM operations, whereas iterate averaging would require $O(MN) > dM$ operations to obtain an estimator with the same covariance. But this contradicts the result of Polyak and Juditsky (1992) that *no* stochastic-gradient-oracle algorithm can

Method	Wine	Skin	Protein
constant SGD	18.7	0.471	1000.9
constant SGD-d	14.0	0.921	678.4
constant SGD-f	0.7	0.005	1.8
SGLD (Welling and Teh, 2011)	2.9	0.905	4.5
SGFS-d (Ahn et al., 2012)	12.8	0.864	597.4
SGFS-f (Ahn et al., 2012)	0.8	0.005	1.3
BBVI (Kucukelbir et al., 2015)	44.7	5.74	478.1

Table 1: KL divergences between the posterior and stationary sampling distributions applied to the data sets discussed in Section 7.1. To estimate the KL divergence, we fitted a multivariate Gaussian to the iterates of our sampling algorithms and used a Laplace approximation for the posterior. We compared constant SGD without preconditioning and with diagonal (-d) and full rank (-f) preconditioning against Stochastic Gradient Langevin Dynamics and Stochastic Gradient Fisher Scoring (SGFS) with diagonal (-d) and full rank (-f) preconditioning, and BBVI.

outperform iterate averaging. Thus, the optimality of iterate averaging as an optimization algorithm, taken with assumptions 1–5, implies that *no SGMCMC algorithm can generate posterior samples in sublinear time*[2].

This argument relies on assumptions 1–5 being true, but one can easily construct scenarios in which they are violated. However, these assumptions are all optimistic; there seems (to us) little reason to think that problems that violate assumptions 1–5 will be easier than those that do not.

7. Experiments

We test our theoretical assumptions from Section 3 and find good experimental evidence that they are reasonable in some settings. We also investigate iterate averaging and show that the assumptions outlined in 6.2 result in samples from a close approximation to the posterior. We also compare against other approximate inference algorithms, including SGLD (Welling and Teh, 2011), NUTS (Hoffman and Gelman, 2014), and black-box variational inference (BBVI) using Gaussian reparametrization gradients (Kucukelbir et al., 2015). In Section 7.3 we show that constant SGD lets us optimize hyperparameters in a Bayesian model.

7.1 Confirming the Stationary Distribution's Covariance

In this section, we confirm empirically that the stationary distributions of SGD with KL-optimal constant learning rates are as predicted by the Ornstein-Uhlenbeck process.

Real-world data. We first considered the following data sets.

- The *Wine Quality Data Set*[3], containing $N = 4,898$ instances, 11 features, and one integer output variable (the wine rating).

2. At least, not without exploiting additional knowledge about the source of gradient noise as do methods like SVRG and SAGA (Johnson and Zhang, 2013; Defazio et al., 2014).
3. P. Cortez, A. Cerdeira, F. Almeida, T. Matos and J. Reis, 'Wine Quality Data Set', UCI Machine Learning Repository.

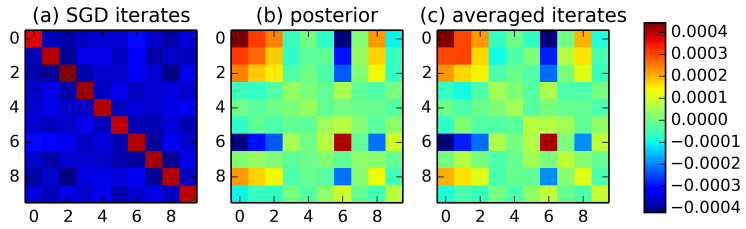

Figure 3: Iterate averaging on linear regression, where we generated artificial data as generated from the model. (a) shows the empirical covariance of the iterates of SGD, whereas (c) shows the averaged iterates with optimally chosen time window. The resulting covariance strongly resembles the true posterior covariance in (b). This shows that iterate averaging may result in posterior sampling.

- A data set of *Protein Tertiary Structure*[4], containing $N = 45,730$ instances, 8 features and one output variable.
- The *Skin Segmentation Data Set*[5], containing $N = 245,057$ instances, 3 features, and one binary output variable.

We applied linear regression on data sets 1 and 2 and applied logistic regression on data set 3. We rescaled the feature to unit length and used a mini-batch of size $S = 100$, $S = 100$ and $S = 10000$ for the three data sets, respectively. The quadratic regularizer was 1. The constant learning rate was adjusted according to Eq. 15.

Fig. 1 shows two-dimensional projections of samples from the posterior (blue) and the stationary distribution (cyan), where the directions were chosen two be the smallest and largest principal component of the posterior. Both distributions are approximately Gaussian and centered around the maximum of the posterior. To check our theoretical assumptions, we compared the covariance of the sampling distribution (yellow) against its predicted value based on the Ornstein-Uhlenbeck process (red), where very good agreement was found. Since the predicted covariance is based on approximating SGD as a multivariate Ornstein-Uhlenbeck process, we conclude that our modeling assumptions are satisfied to a very good extent. Since the wine dataset is smaller than the skin segmentation data set, it has a broader posterior and therefore requires a larger learning rate to match it. For this reason, discretization effects play a bigger role and the stationary distribution of preconditioned SGD on wine does not exactly match the posterior. The unprojected 11-dimensional covariances on wine data are also compared in Fig. 2. The rightmost column of Fig. 1 shows the sampling distributions of black box variational inference (BBVI) using the reparametrization trick (Kucukelbir et al., 2015). Our results show that the approximation to the posterior given by constant SGD is not worse than the approximation given by BBVI.

We also computed KL divergences between the posterior and stationary distributions of various algorithms: constant SGD with KL-optimal learning rates and preconditioners, Stochastic Gradient Langevin Dynamics, Stochastic Gradient Fisher Scoring (with and without diagonal approximation)

4. Prashant Singh Rana, 'Protein Tertiary Structure Data Set', UCI Machine Learning Repository.
5. Rajen Bhatt, Abhinav Dhall, 'Skin Segmentation Dataset', UCI Machine Learning Repository.

and BBVI. For SG Fisher Scoring, we set the learning rate to ϵ^* of Eq. 15, while for Langevin dynamics we chose the largest rate that yielded stable results ($\epsilon = \{10^{-3}, 10^{-6}, 10^{-5}\}$ for data sets 1, 2 and 3, respectively). Table 1 summarizes the results. We found that constant SGD can compete in approximating the posterior with the MCMC algorithms under consideration. This suggests that the most important factor is not the artificial noise involved in scalable MCMC, but rather the approximation of the preconditioning matrix.

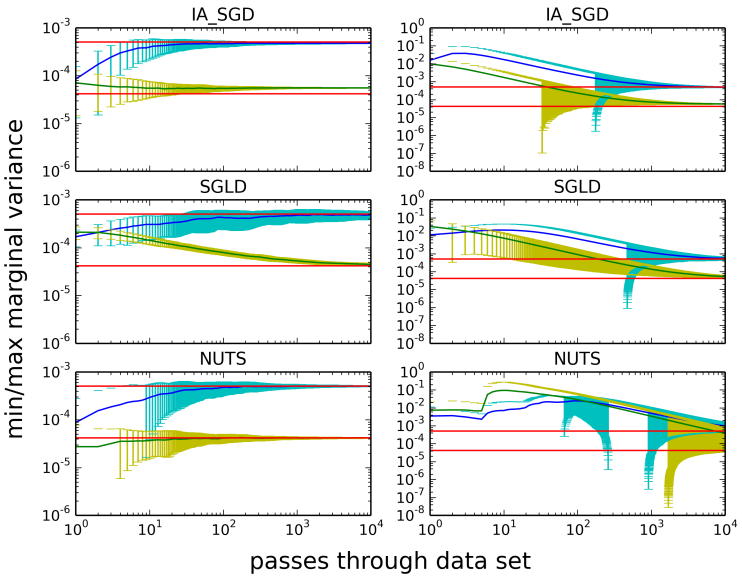

Figure 4: Convergence speed comparison between IASG (top), SGLD (middle), and NUTS (bottom) on linear regression. The plots show minimal (yellow) and maximal (blue) posterior marginal variances, respectively, as a function of iterations, measured in units of passes through the data. Error bars denote one standard deviation. Red solid lines show the ground truth. Left plots were initialized in the posterior maximum, whereas in the right column, we initialized randomly.

7.2 Iterate Averaging as Approximate MCMC

In the following, we show that under the assumptions specified in Section 6.2, iterate averaging with a constant learning rate and fixed averaging window results in samples from the posterior.

Synthetic data. In order to strictly satisfy the assumptions outlined in Section 6.2, we generated artificial data that came from the model. We chose a linear regression model with a Gaussian prior with precision $\lambda = 1$. We first generated $N = 10,000$ covariates by drawing them from a $D = 10$

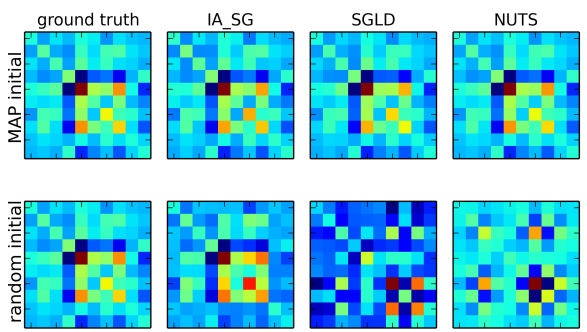

Figure 5: Posterior covariances as estimated by different methods, see also Fig. 4. The top row shows results where we initialized the samplers in the maximum posterior mode. The bottom rows were initialized randomly. For MAP initialization, all samplers find a good estimate of the posterior. When initializing randomly, IASG performs better than NUTS and SGLD.

dimensional Gaussian with unit covariance. We drew the true weight vector from the prior. We then generated the corresponding response variables from the linear regression model.

In a first experiment, we confirmed that iterate averaging may result in samples from the exact posterior, shown in Fig. 3. The left panel shows the empirical covariance matrix of the iterates of SGD. The middle and right panel show the posterior covariance and empirical covariance of the averaged iterates, respectively. As predicted by our theory, there is a very strong resemblance which demonstrates that constant-rate iterate averaging with the right rates and averaging windows may actually result in samples from the posterior. To generate this plot, we then ran constant SGD with a constant learning rate $\epsilon = 0.005$ for $10 * D * N = 10^6$ iterations and a minibatch size $S = 1$ and used an averaging window of $N/S = 10^4$, as predicted by the theory presented earlier in order to achieve samples from the posterior.

Next, we analyzed the convergence speed of Iterate-Averaged Stochastic Gradients (IASG, see Algorithm 1) compared to related methods. Fig. 4 shows these comparisons for three modern scalable MCMC algorithms: SGLD (Welling and Teh, 2011) and NUTS (Hoffman and Gelman, 2014). We investigated how quickly these algorithms could give us estimates of the posterior covariances. To better visualize the convergence behavior, we focussed on diagonal entries of the posterior covariance, the marginal variances. As before, the data were generated from the model such the theoretical assumptions of 6.2 applied. We then ran the samplers for up to $10^3 * D$ effective passes through the data. For IASG and SGLD we used a minibatch size of $S = 10$ and an averaging window of $N/S = 1000$. The constant learning rate of IASG was $\epsilon = 0.003$ and for SGLD we decreased the learning rate according to the Robbins-Monro schedule of $\epsilon_t = \frac{\epsilon_0}{\sqrt{1000+t}}$ where we found $\epsilon_0 = 10^{-3}$ to be optimal. NUTS automatically adjusts its learning rate and uses non-stochastic gradients.

The left column of Fig. 4 shows the results of these experiments. We found the convergence speeds of the samplers to be highly dependent on whether we optimized the samplers in the maximum posterior mode (termed MAP-initialization: this partially eleminates the initial bias and burn-in phase) or whether the samplers were initialized randomly, as in a real-world application. Thus, we show both results: while the the right column shows random initializations, the left one shows MAP-initialization. The rows of Fig. 4 show results of IASG (top), SGLD (middle), and NUTS (bottom). Each entry shows the smallest and largest marginal variance of the posterior over iterations, as estimated from these methods, where we excluded the first 10 iterations to avoid large biases. We also give the standard deviations for these estimates based on 100 independent Markov chains. The solid red lines show the ground truth of these marginal variances. Fig. 5 shows additional results on the same experiments, where we display the posterior estimates of the three different samplers under the two different initializations.

We found that in both initializations, IASG can find a fast approximate solution to the posterior. It uses stochastic gradients which gives it a competitive advantage over NUTS (which uses full gradients) in particular in the early search phase of the sampler. Langevin dynamics behaves similarly at early iterations (it also employs stochastic gradients). However, compared to IASG, we see that the Langevin algorithm has a much larger standard error when estmating the posterior covariances. This is because it uses a decreasing Robbins-Monro learning rate that slows down equilibration at long times. In contrast, IASG uses a constant learning rate and therefore converges fast. Note that in practice a large variance may be as bad as a large bias, especially if posterior estimates are based on a single Markov chain. This is also evident in Fig. 5, which shows that for random initialization, both NUTS and SGLD reveal less of the structure of the true posterior covariance compared to IASG.

When initialized in the posterior maximum, we see that all algorithms perform reasonably well (though SGLD's estimates are still highly variable even after $10,000$ sweeps through the dataset). IASG converges to a stable estimate much faster than SGLD or NUTS, but produces slightly biased estimates of the smallest variance.

7.3 Optimizing Hyperparameters

We test the hypothesis of Section 4.2, namely that constant SGD as a variational algorithm gives rise to a variational EM algorithm where we jointly optimize hyperparameters using gradients while drawing samples form an approximate posterior. To this end, we experimented with a Bayesian multinomial logistic (a.k.a. softmax) regression model with normal priors. The negative log-joint is

$$\begin{aligned}\mathcal{L} \equiv -\log p(y, \theta|x) = \tfrac{\lambda}{2}\textstyle\sum_{d,k}\theta_{dk}^2 - \tfrac{DK}{2}\log(\lambda) + \tfrac{DK}{2}\log 2\pi \\ + \textstyle\sum_n \log \sum_k \exp\{\sum_d x_{nd}\theta_{dk}\} - \sum_d x_{nd}\theta_{dy_n},\end{aligned} \tag{35}$$

where $n \in \{1, \ldots, N\}$ indexes examples, $d \in \{1, \ldots, D\}$ indexes features and $k \in \{1, \ldots, K\}$ indexes classes. $x_n \in \mathbb{R}^D$ is the feature vector for the nth example and $y_n \in \{1, \ldots, K\}$ is the class for that example. Eq. 35 has the degenerate maximizer $\lambda = \infty$, $\theta = 0$, which has infinite posterior density which we hope to avoid in our approach.

Real-world data. In all experiments, we applied this model to the MNIST dataset ($60,000$ training examples, $10,000$ test examples, 784 features) and the cover type dataset ($500,000$ training examples, $81,012$ testing examples, 54 features).

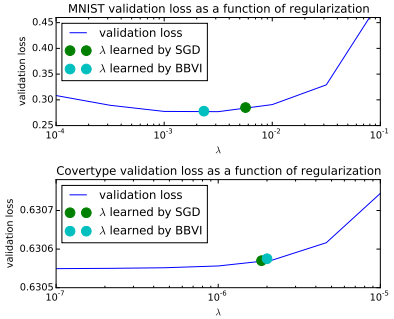

Figure 6: Validation loss as a function of L2 regularization parameter λ. Circles show the values of λ that were automatically selected by SGD and BBVI.

Fig. 6 shows the validation loss achieved by maximizing equation 35 over θ for various values of λ. This gives rise to the continuous blue curve. The value for constant SGD was obtained using Eq. 22, hence using constant learning rates for θ and decreasing learning rates for λ. BBVI was carried out by optimizing a variational lower bound in mean-field variational inference, and optimizing hyperparameters based on this lower bound.

The results suggest that BBVI and constant SGD yield similar results. Thus, constant SGD can be used as an inexpensive alternative to cross-validation or other VEM methods for hyperparameter selection.

8. Conclusions

In this paper, we built on a stochastic process perspective of stochastic gradient descent and various extensions to derive several new results. Under specified assumptions, SGD is approximated by a multivariate Ornstein-Uhlenbeck process, which possesses an analytic solution. We computed the stationary distribution of constant SGD and analyzed its properties.

We analyzed SGD together with several extensions, such as momentum, preconditioning, and iterate averaging. The shape of the stationary distribution is controlled by the parameters of the algorithm such as the constant learning rate, preconditioning matrix, or averaging period. We can thus tune these parameters to minimize the Kullback-Leibler divergence between the stationary distribution and a Bayesian posterior. This view uses these stochastic optimization algorithms as approximate inference. We also analyzed stochastic gradient Langevin dynamics and stochastic gradient Fisher scoring and were able to analyze approximation errors for these algorithms.

The Bayesian view on constant-rate SGD allows us to use this algorithm as a new variational EM algorithm. We suggested and tested a double SGD scheme which uses decreasing learning rates on the hyperparameters and constant learning rates on the main parameters. We showed that this is both easy to implement and prevents us from finding degenerate solutions; it is a cheap alternative to cross-validation for many complex models.

Last, our analysis suggests the many similarities between sampling and optimization algorithms that can be explored using the stochastic process perspective. A future direction might be to explore

similarities in the noise characteristics of black-box variational inference algorithms and Langevin-type MCMC. Further exploring the use of iterate averaging as a Bayesian algorithm is another interesting avenue for further studies.

Acknowledgments

We would like to thank Yingzhen Li and Thomas Hofmann for their valuable feedback on our manuscript.

Appendix A. Examples: Ornstein-Uhlenbeck Formalism

Let us illustrate the Ornstein-Uhlenbeck formalism based on two simple examples. First, consider the following quadratic loss,

$$\mathcal{L}(\theta) = -\tfrac{1}{2N}\sum_{n=1}^{N}||x_n - \theta||^2. \tag{36}$$

Let us define $\bar{x} = \frac{1}{N}\sum_{n=1}^{N} x_n$ as the empirical mean of the data points. The gradient is $g(\theta) = (\bar{x}-\theta)$, and the stochastic gradient is $\hat{g}(\theta) = \frac{1}{S}\sum_{s=1}^{S}(x_s-\theta)$. Because the gradient is linear in x, the noise covariance is just the covariance of the data: $\Sigma_x \equiv C/S = \frac{1}{S^2}\mathbb{E}\left[\sum_{s,s'}(x_s-\bar{x})(x_{s'}-\bar{x})^\top\right] = \frac{1}{S}\mathbb{E}[(x_n-\bar{x})(x_n-\bar{x})^\top]$. We can shift the parameter $\theta \to \theta + \bar{x}$, resulting in $\theta^* = 0$. Note that the Hessian $A \equiv \mathbf{I}$ is just unity. According to Eq. 38,

$$q(\theta) \;\propto\; \exp\left\{-\tfrac{S}{2\epsilon}(\theta-\bar{x})^\top\Sigma_x^{-1}(\theta-\bar{x})\right\}.$$

as the resulting stationary distribution. Next, consider linear regression, where we minimize

$$\mathcal{L}(\theta) \;=\; -\tfrac{1}{2N}\textstyle\sum_n (y_n - x_n^\top\theta)^2. \tag{37}$$

We can write the stochastic gradient as $\hat{g} = \hat{A}\theta - \hat{\mu}$, where $\hat{\mu} = \frac{1}{S}\sum_s x_s y_s$ and $\hat{A} = \frac{1}{S}\sum_s x_s x_s^\top$ are estimates based on a mini-batch of size S. The sampling noise covariance is $C(\theta) = \mathbb{E}[(\hat{g}-g)(\hat{g}-g)^\top] = \mathbb{E}[\hat{g}\hat{g}^\top] - gg^\top$, where $\mathbb{E}[\hat{g}\hat{g}^\top] = \mathbb{E}[(\hat{A}\theta-\hat{\mu})(\hat{A}\theta-\hat{\mu})^\top]$. We see that the noise covariance is quadratic, but unfortunately it cannot be further simplified.

Fig. 1 shows the objective function of linear regression (blue) and the sampling distribution of stochastic gradient descent (yellow) on simulated data. We see that both distributions do not coincide, because the sampling distribution is also affected by the noise covariance.

Appendix B. Stationary Covariance

The Ornstein-Uhlenbeck process has an analytic solution in terms of the stochastic integral (Gardiner et al., 1985),

$$\theta(t) = \exp(-At)\theta(0) + \sqrt{\tfrac{\epsilon}{S}}\int_0^t \exp[-A(t-t')]B dW(t') \tag{38}$$

Following Gardiner's book and using $A = A^\top$, we derive an algebraic relation for the stationary covariance of the multivariate Ornstein-Uhlenbeck process. Define $\Sigma = \mathbb{E}[\theta(t)\theta(t)^\top]$. Using the

formal solution for $\theta(t)$ given in the main paper, we find

$$\begin{aligned}
A\Sigma + \Sigma A &= \tfrac{\epsilon}{S}\int_{-\infty}^{t} A\exp[-A(t-t')]BB^\top\exp[-A(t-t')]dt' \\
&+ \tfrac{\epsilon}{S}\int_{-\infty}^{t}\exp[-A(t-t')]BB^\top\exp[-A(t-t')]dt'A \\
&= \tfrac{\epsilon}{S}\int_{-\infty}^{t}\frac{d}{dt'}\left(\exp[-A(t-t')]BB^\top\exp[-A(t-t')]\right) \\
&= \tfrac{\epsilon}{S}BB^\top.
\end{aligned}$$

We used that the lower limit of the integral vanishes by the positivity of the eigenvalues of A.

Appendix C. Reverse KL Divergence Setup

It is interesting to also consider the case of trying to minimize the reverse KL divergence, i.e. $KL(f||q)$ instead of $KL(q||f)$. One might assume that this is possible since both the variational distribution and the posterior are assumed to be Gaussian. This turns out to lead only to a feasible algorithm in the special case where the Hessian in the optimum A and the stationary covariance Σ commute. In more detail, the KL-divergence between the posterior and the stationary distribution is (up to constants):

$$\begin{aligned}
KL(f||q) &= \mathbb{E}_f[\log f] - \mathbb{E}_f[\log q] \\
&= \tfrac{1}{2}\mathbb{E}_f\left[\theta^\top\Sigma^{-1}\theta\right] + \tfrac{1}{2}\log|\Sigma| + \text{const.} \\
&= \tfrac{1}{2N}\mathrm{Tr}(A^{-1}\Sigma^{-1}) + \tfrac{1}{2}\log|\Sigma| + \text{const.}
\end{aligned} \tag{39}$$

While we were able to derive this divergence, it turns out that we cannot in general eliminate its dependence in the stationary covariance and re-express it in terms of $BB^\top$, using Eq. 13. However, if A and Σ commute, we can proceed as follows:

$$\begin{aligned}
\mathrm{Tr}(A^{-1}\Sigma^{-1}) &= \mathrm{Tr}((\Sigma A)^{-1}) \\
&\overset{A\Sigma=\Sigma A}{=} 2\mathrm{Tr}((\Sigma A + A\Sigma)^{-1}) \\
&\overset{Eq.\ 13}{=} \tfrac{2S}{\epsilon}\mathrm{Tr}((BB^\top)^{-1})
\end{aligned} \tag{40}$$

Following the logic of Theorems 1 and 2, we find the following result for the optimal learning rate:

$$\epsilon^* = \frac{2S}{ND}\mathrm{Tr}((BB^\top)^{-1}). \tag{41}$$

Interestingly, when comparing Eq. 15 with Eq. 41, we find that the inverse of the trace of the noise covariance gets replaced by the trace of the inverse noise covariance. While $KL(q||f)$ suggests to choose the learning rate inversely proportional to the largest Eigenvalue of the noise, $KL(f||q)$ thus suggests to choose the learning rate proportional to the inverse of the smallest Eigenvalue of the noise. Both approaches have thus a different emphasis on how to fit the posterior mode, in a similar fashion as variational inference and expectation propagation. Note, however, that A and Σ rarely commute in practice, and thus $KL(q||f)$ is the only viable option.

Appendix D. SGD With Momentum

Here, we give more details on the deviations of the results on SGD with momentum. In order to compute the stationary distribution of Eq. 23, we need to solve the equations for the second moments:

$$\begin{aligned}
d\mathbb{E}[\theta\theta^\top] &= \mathbb{E}[d\theta\theta^\top + \theta d\theta^\top] \\
&= (\mathbb{E}[\mathrm{v}\theta^\top] + \mathbb{E}[\theta\mathrm{v}^\top])dt, && (42)\\
d\mathbb{E}[\theta\mathrm{v}^\top] &= \mathbb{E}[d\theta\mathrm{v}^\top + \theta d\mathrm{v}^\top] \\
&= \mathbb{E}[\mathrm{v}\mathrm{v}^\top]dt - \mu\mathbb{E}[\theta\mathrm{v}^\top]dt - \epsilon\mathbb{E}[\theta\theta^\top]Adt, && (43)\\
d\mathbb{E}[\mathrm{v}\theta^\top] &= \mathbb{E}[d\mathrm{v}\theta^\top + \mathrm{v}d\theta^\top] \\
&= \mathbb{E}[\mathrm{v}\mathrm{v}^\top]dt - \mu\mathbb{E}[\mathrm{v}\theta^\top]dt - \epsilon A\mathbb{E}[\theta\theta^\top]dt, && (44)\\
d\mathbb{E}[\mathrm{v}\mathrm{v}^\top] &= \mathbb{E}[d\mathrm{v}\mathrm{v}^\top + \mathrm{v}d\mathrm{v}^\top] + \mathbb{E}[d\mathrm{v}d\mathrm{v}^\top] \\
&= -2\mu\mathbb{E}[\mathrm{v}\mathrm{v}^\top]dt - \epsilon A\mathbb{E}[\theta\mathrm{v}^\top]dt - \epsilon\mathbb{E}[\mathrm{v}\theta^\top]Adt + \tfrac{\epsilon^2}{S}BB^\top dt. && (45)
\end{aligned}$$

In the last equation we used the fact that according to Ito's rule, there is an additional non-vanishing contribution due to the noise, $\mathbb{E}[d\mathrm{v}d\mathrm{v}^\top] = \frac{\epsilon^2}{S}\mathbb{E}[B\,dW dW^\top B^\top] = \frac{\epsilon^2}{S}BB^\top dt$. This contribution does not exist for the other correlators; for more details see e.g. (Gardiner et al., 1985).

Since we are looking for a stationary solution, we set the left hand sides of all equations to zero. Eq. 42 implies that $\mathbb{E}[\mathrm{v}\theta^\top] + \mathbb{E}[\theta\mathrm{v}^\top] = 0$, hence the cross-correlation between momentum and position is anti-symmetric in the stationary state. We can thus add Eqs. 43 and 44 to find $0 = d\mathbb{E}[\mathrm{v}\theta^\top + \theta\mathrm{v}^\top] = 2\mathbb{E}[\mathrm{v}\mathrm{v}^\top]dt - \epsilon A\mathbb{E}[\theta\theta^\top]dt - \epsilon\mathbb{E}[\theta\theta^\top]Adt$. Combining this with Eq. 45 yields

$$\begin{aligned}
\mathbb{E}[\mathrm{v}\mathrm{v}^\top] &= \tfrac{\epsilon}{2}\mathbb{E}[\theta\theta^\top]A + \tfrac{\epsilon}{2}A\mathbb{E}[\theta\theta^\top] \\
\mu\mathbb{E}[\mathrm{v}\mathrm{v}^\top] &= \tfrac{\epsilon^2}{2S}BB^\top - \underbrace{\tfrac{1}{2}\epsilon(A\mathbb{E}[\theta\mathrm{v}^\top] + \mathbb{E}[\mathrm{v}\theta^\top]A)}_{=0}.
\end{aligned}$$

Last, we show that the underbraced term is zero, which gives Eq. 25 in the main paper. Denote $\xi = \mathbb{E}[\theta\mathrm{v}^\top] = -\xi^\top$ which is antisymmetric due to Eq. 42. First of all, $A\xi + \xi^\top A$ is obviously symmetric. It is simultaneously antisymmetric due to the following calculation: $\sum_k A_{ik}\xi_{kj} + \sum_k \xi_{ik}^\top A_{kj}^\top = \sum_k A_{ik}\xi_{kj} - \sum_k \xi_{ki}A_{jk} = \sum_k A_{ik}\xi_{kj} - \sum_k A_{jk}\xi_{ki}$. This term swaps the sign as i and j are interchanged. Being both symmetric and antisymmetric, it is zero.

Appendix E. Stochastic Gradient Fisher Scoring

We start from the Ornstein-Uhlenbeck process with minibatch size $S = 1$,

$$\begin{aligned}
d\theta(t) &= -\epsilon HA\theta(t)dt + H\left[\epsilon B dW(t) + \sqrt{\epsilon}E dV(t)\right] \\
&\Leftrightarrow \\
d\theta(t) &= -A'\theta(t)dt + B'dW(t),
\end{aligned}$$

where we define $A' \equiv \epsilon HA$ and $B' \equiv H\sqrt{\epsilon^2 BB^\top + \epsilon EE^\top}$, and use the fact that the dynamics of $CdW(t) + DdV(t)$ are equivalent to $\sqrt{CC^\top + DD^\top}dW(t)$. Here we are using matrix square roots, so $B'B'^\top = \epsilon H(\epsilon BB^\top + EE^\top)H$.

As derived in the paper, the variational bound is (up to a constant)

$$KL \stackrel{c}{=} \frac{N}{2}\mathrm{Tr}(A\Sigma) - \tfrac{1}{2}\log(|\Sigma|).$$

To evaluate it, the task is to remove the unknown covariance Σ from the bound. To this end, as before, we use the identity for the stationary covariance $A'\Sigma + \Sigma A'^\top = B'B'^\top$. The criterion for the stationary covariance is equivalent to

$$HA\Sigma + \Sigma AH = \epsilon HBB^\top H + HEE^\top H.$$

We can further simplify this expression as follows:

$$\begin{aligned}
A\Sigma + H^{-1}\Sigma AH &= \epsilon BB^\top H + EE^\top H \\
\Rightarrow \mathrm{Tr}(A\Sigma) &= \frac{1}{2}\mathrm{Tr}(H(\epsilon BB^\top + EE^\top)).
\end{aligned}$$

As above, we can also reparameterize the covariance as $\Sigma = TH$, so that T does not depend on H:

$$\begin{aligned}
HA\Sigma + \Sigma AH &= \epsilon HBB^\top H + HEE^\top H \\
A\Sigma H^{-1} + H^{-1}\Sigma A &= \epsilon BB^\top + EE^\top \\
AT + T^\top A &= \epsilon BB^\top + EE^\top.
\end{aligned}$$

The KL divergence is therefore

$$\begin{aligned}
KL &= \frac{N}{2}\mathrm{Tr}(A\Sigma) - \frac{D}{2} - \frac{1}{2}\log(N|A|) - \frac{1}{2}\log|\Sigma| \\
&= \frac{N}{4}\mathrm{Tr}(H(\epsilon BB^\top + EE^\top)) - \frac{D}{2} - \frac{1}{2}\log(N|A|) - \frac{1}{2}\log|T| - \frac{1}{2}\log|H|, \quad (46)
\end{aligned}$$

which is the result we give in the main text.

Appendix F. Square Root Preconditioning

We analyze the case where we precondition with a matrix that is proportional to the square root of the diagonal entries of the noise covariance.

We define

$$G = \sqrt{\mathrm{diag}(BB^\top)}$$

as the diagonal matrix that contains square roots of the diagonal elements of the noise covariance. We use an additional scalar learning rate ϵ .

Theorem 7 (Taking square roots) *Consider SGD preconditioned with G^{-1} as defined above. Under the previous assumptions, the constant learning rate which minimizes KL divergence between the stationary distribution of this process and the posterior is*

$$\epsilon^* = \frac{2DS}{N\mathrm{Tr}(BB^\top G^{-1})}. \quad (47)$$

Proof We read off the appropriate KL divergence from the proof of Theorem 2 with $G^{-1} \equiv H$:

$$KL(q||f) \stackrel{c}{=} \frac{\epsilon N}{2S}\mathrm{Tr}(BB^\top G^{-1}) - \mathrm{Tr}\log(G) + \frac{D}{2}\log\frac{\epsilon}{S} - \frac{1}{2}\log|\Sigma|$$

Minimizing this KL divergence over the learning rate ϵ yields Eq. 47. ■

Appendix G. Iterage Averaging

We now prove our result for the covariance of the averaged iterates. We first need an identity for the non-equal-time covariance in the stationary state:

$$\mathbb{E}[\theta(t)\theta(s)^\top] = \begin{cases} \Sigma e^{-\epsilon A(s-t)} & t < s \\ e^{-\epsilon A(t-s)}\Sigma & t \geq s. \end{cases} \tag{48}$$

To derive it, one uses the formal solution of the Ornstein-Uhlenbeck process for $\theta(t)$ in combination with Eq. 29, see also (Gardiner et al., 1985) for more details. Note that for $t = s$, it simplifies to $\mathbb{E}[\theta(t)\theta(t)^\top] = \Sigma$, as one would expect.

We are averaging over T time steps. Going to the continuous-time OU formalism, we are interested in the following quantity, which is the equal-time covariance of the time-averaged iterates:

$$D \equiv \mathbb{E}\left[\left(\frac{1}{T}\int_0^T \theta(t)dt\right)\left(\frac{1}{T}\int_0^T \theta(s)ds\right)^\top\right].$$

This can be further broken down to two contributions:

$$\begin{aligned} D &= \frac{1}{T^2}\int_0^T\int_0^T \mathbb{E}[\theta(t)\theta(s)^\top]dsdt \\ &= \frac{1}{T^2}\int_0^T\int_0^t \mathbb{E}[\theta(t)\theta(s)^\top]dsdt + \frac{1}{T^2}\int_0^T\int_t^T \mathbb{E}[\theta(t)\theta(s)^\top]dsdt \end{aligned}$$

We now use the eigendecomposition $A = U\Lambda U^\top$ of the Hessian, the autocorrelation Eq. 48, as well as the identity $e^{cA} = Ue^{c\Lambda}U^\top$. The first term becomes

$$\begin{aligned} \frac{1}{T^2}\int_0^T\int_0^t \mathbb{E}[\theta(t)\theta(s)^\top]dsdt &= \frac{1}{T^2}\int_0^T\int_0^t e^{-\epsilon A(t-s)}\Sigma dsdt \\ &= \frac{1}{T^2}\int_0^T\int_0^t Ue^{-\epsilon\Lambda(t-s)}U^\top\Sigma dsdt \\ &= \frac{1}{\epsilon T^2}\int_0^T U\Lambda^{-1}(\mathbf{I} - e^{-\epsilon t\Lambda})U^\top\Sigma dt \\ &= \frac{1}{\epsilon T}A^{-1}\Sigma + \frac{1}{\epsilon^2 T^2}U\Lambda^{-2}(e^{-\epsilon T\Lambda} - \mathbf{I})U^\top\Sigma. \end{aligned} \tag{49}$$

The calculation for the second term goes analogously and yields

$$\frac{1}{T^2}\int_0^T\int_t^T \mathbb{E}[\theta(t)\theta(s)^\top]dsdt = \frac{1}{\epsilon T}\Sigma A^{-1} + \frac{1}{\epsilon^2 T^2}\Sigma U\Lambda^{-2}(e^{-\epsilon T\Lambda} - \mathbf{I})U^\top.$$

Both equations combined give us

$$\begin{aligned} D = &\frac{1}{\epsilon T}(A^{-1}\Sigma + \Sigma A^{-1}) \\ &+ \frac{1}{\epsilon^2 T^2}(U\Lambda^{-2}(e^{-\epsilon T\Lambda} - \mathbf{I})U^\top\Sigma + \Sigma U\Lambda^{-2}(e^{-\epsilon T\Lambda} - \mathbf{I})U^\top). \end{aligned} \tag{50}$$

When $\epsilon T\Lambda \gg 1$ (valid for sufficiently long averaging periods T), we obtain

$$D \approx \frac{1}{\epsilon T}(A^{-1}\Sigma + \Sigma A^{-1}),$$

which is Eq. 30 in the main text. We can also simplify the expression for $\Sigma = \frac{\epsilon}{2S}I$, as motivated in Section 6.2. In this case, Eq. 50 results in

$$D = \frac{1}{ST}A^{-1} + \frac{1}{\epsilon ST^2}(U\Lambda^{-2}(e^{-\epsilon T\Lambda} - \mathbf{I})U^\top).$$

This is exactly Eq. 33 in the main text.

Abstract

Motivated by applications in neuroimaging analysis, we propose a new regression model, Sparse TensOr REsponse regression (STORE), with a tensor response and a vector predictor. STORE embeds two key sparse structures: element-wise sparsity and low-rankness. It can handle both a non-symmetric and a symmetric tensor response, and thus is applicable to both structural and functional neuroimaging data. We formulate the parameter estimation as a non-convex optimization problem, and develop an efficient alternating updating algorithm. We establish a non-asymptotic estimation error bound for the actual estimator obtained from the proposed algorithm. This error bound reveals an interesting interaction between the computational efficiency and the statistical rate of convergence. When the distribution of the error tensor is Gaussian, we further obtain a fast estimation error rate which allows the tensor dimension to grow exponentially with the sample size. We illustrate the efficacy of our model through intensive simulations and an analysis of the Autism spectrum disorder neuroimaging data.

Keywords: Functional connectivity analysis, High-dimensional statistical learning, Magnetic resonance imaging, Non-asymptotic error bound, Tensor decomposition

1. Introduction

In this article, we study a class of high-dimensional regression models with a tensor response and a vector predictor. Tensor, a.k.a. multidimensional array, is now frequently arising in a wide range of scientific and business applications (Yuan and Zhang, 2016). Our motivation comes from neuroimaging analysis. One example is anatomical magnetic resonance imaging (MRI), where the data takes the form of a three-dimensional array, and image voxels correspond to brain spatial locations. Another example is functional magnetic resonance imaging (fMRI), where the goal is to understand brain functional connectivity that is encoded by a symmetric matrix, with rows and columns corresponding to brain regions, and entries corresponding to interaction between those regions. In both examples, it is of keen scientific interest to compare the scans of brains, or the brain connectivity patterns, between the subjects with neurological disorder and the healthy controls, after adjusting for additional covariates such as age and sex. Both can be more generally formulated as a regression problem, with image tensor or connectivity matrix serving as a response, and the group indicator and other covariates forming a predictor vector.

1.1 Our Proposal

We develop a general class of tensor response regression models, namely STORE, and embed two key sparse structures: element-wise sparsity and low-rankness. Both structures serve to greatly reduce the computational complexity of the estimation procedure. Meanwhile, both are scientifically plausible in plenty of applications, and have been widely employed in high-dimensional multivariate regressions (e.g., Tibshirani, 1996; Zou, 2006; Yuan and Lin, 2006; Peng et al., 2010; Zhou et al., 2013; Raskutti and Yuan, 2016). A unique feature of STORE is that, it can not only handle a non-symmetric tensor response, but also a symmetric tensor response, and thus is applicable to both structural and functional neuroimaging analysis.

We formulate the learning of STORE as a non-convex optimization problem, and accordingly develop an efficient alternating updating algorithm. Our algorithm consists of two major steps, and each step iteratively updates a subset of the unknown parameters while fixing the others. In Step 1, we reformulate the estimation as a sparse tensor decomposition problem and then employ a decomposition algorithm, the truncated tensor power method (Sun et al., 2017), for solution. In Step 2, we utilize the bi-convex structure of the problem to obtain a closed-form solution.

We carry out a non-asymptotic theoretical analysis for the actual estimator obtained from our optimization algorithm. Based upon a set of our newly developed techniques to tackle the non-convexity in estimation, we obtain an explicit error bound of the actual minimizer. Specifically, let $\mathcal{E}_i, i = 1, \ldots, n$, denote the error tensor, and $\mathbf{\Theta}^*$ denote the set of all true parameters. Given an initial parameter with an initialization error ϵ, the finite sample error bound of the t-th step solution $\widehat{\mathbf{\Theta}}^{(t)}$ consists of two parts:

$$D\left(\widehat{\mathbf{\Theta}}^{(t)}, \mathbf{\Theta}^*\right) \leq \underbrace{\kappa^t \epsilon}_{\text{computational error}} + \underbrace{\frac{1}{1-\kappa} \max\left\{C \cdot \eta\left(\frac{1}{n}\sum_{i=1}^{n} \mathcal{E}_i, s\right), \frac{\widetilde{C}}{\sqrt{n}}\right\}}_{\text{statistical error}},$$

with a high probability. Here $\kappa \in (0,1)$ is a contraction coefficient, C and $\widetilde{C}$ are some positive constants, and $\eta\left(n^{-1}\sum_{i=1}^{n} \mathcal{E}_i, s\right)$ represents the s-sparse spectral norm of the averaged error tensor; see (8) for a formal definition of this norm. This error bound portrays the estimation error in each iteration, and reveals an interesting interplay between the computational efficiency and the statistical rate of convergence. Note that the computational error decays geometrically with the iteration number t, whereas the statistical error remains the same when t grows. Therefore, this bound provides a meaningful guidance for the maximal number of iterations T. That is, we stop when the computational error becomes dominated by the statistical error. The resulting estimator falls within the statistical precision of the true parameter $\mathbf{\Theta}^*$. Additionally, this finite sample error bound provides a general theoretical guarantee of our estimator, and the result holds for any distribution of the error tensor $\mathcal{E}_i$, by noting that it relies on $\mathcal{E}_i$ only through its sparse spectral norm $\eta\left(n^{-1}\sum_{i=1}^{n} \mathcal{E}_i, s\right)$. In Sections 4.3 and 4.4, we obtain explicit forms of statistical errors when the distribution of

$\mathcal{E}_i$ is available. In particular, when the third-order error tensor $\mathcal{E}_i \in \mathbb{R}^{d_1 \times d_2 \times d_3}$, $i = 1, \cdots, n$, follows an i.i.d. Gaussian distribution, we have

$$D\left(\widehat{\mathbf{\Theta}}^{(T)}, \mathbf{\Theta}^*\right) = O_p\left(\sqrt{\frac{s^3 \log(d_1 d_2 d_3)}{n}}\right),$$

where s is the cardinality parameter of the decomposed components in the tensor coefficients. This fast estimation error rate allows the tensor dimension to grow exponentially with the sample size. When the order of the tensor is one, STORE reduces to the d-dimensional vector regression and our statistical error reduces to $O_p(\sqrt{s \log d/n})$, which is known to be minimax optimal (Wang et al., 2014).

1.2 Related Works and Our Contributions

Our work is related to but also clearly distinct from a number of recent development in high-dimensional statistical models involving tensor data.

The first is a class of tensor decomposition methods (Chi and Kolda, 2012; Liu et al., 2012; Anandkumar et al., 2014a,b; Yuan and Zhang, 2016; Sun et al., 2017). Tensor decomposition is an *unsupervised* learning method that aims to find the best low-rank approximation of a single tensor. Our proposed tensor response regression, however, is a *supervised* learning method, which aims to estimate the coefficient tensor that characterizes the association between the tensor response and the vector predictor. Although we utilize the sparse tensor decomposition step of Sun et al. (2017) as part of our estimation algorithm, our objective and technical tools involved are completely different. Particularly, because we work with *multiple* tensor samples, the consistency of our estimator is indexed by both the tensor dimension and the sample size. This is different from the sparse tensor decomposition estimator in Sun et al. (2017) that works with a *single* tensor only. Consequently, new large deviation inequalities are needed and derived in our theoretical investigation. Moreover our algorithm is not restricted to any particular decomposition procedure but can be coupled with other decomposition solutions, e.g., Chi and Kolda (2012); Liu et al. (2012).

The second related line of research tackles tensor regression where the response is a scalar and the predictor is a tensor (Zhou et al., 2013; Wang and Zhu, 2017; Yu and Liu, 2016). In those papers, a low-rank structure is often imposed on the coefficient tensor, which is similar to the low-rank principle we also employ. However, they all treated the tensor as a *predictor*, whereas we treat it as a *response*. This difference in modeling approach leads to different focus and interpretation. The tensor predictor regression focuses on understanding the change of a biological outcome as the tensor image varies, while the tensor response regression aims to study the change of the image as the predictors such as the disease status and age vary. When it comes to theoretical analysis, the two models involve utterly different techniques. In a way, their difference is in analogous to that between multi-response regression and multi-predictor regression in the classical vector-valued regression context.

The third and more relevant line of works directly studies regression with a tensor response (Zhu et al., 2009; Li et al., 2011; Rabusseau and Kadri, 2016; Li and Zhang, 2017; Raskutti and Yuan, 2016). Although aiming to address the same type of problem, our proposal is analytically different in several ways. We also numerically compare with some of those alternative solutions in simulations and real data analysis.

In particular, Zhu et al. (2009) considered a 3×3 symmetric positive definite matrix arising from diffusion tensor imaging as a response, and developed an intrinsic regression model by mapping the Euclidean space of covariates to the Riemannian manifold of positive-definite matrices. Unlike their solution, we consider a non-symmetric or symmetric tensor response in the Euclidean space, and allow the dimension of the tensor response to increase with the sample size. Li et al. (2011) estimated regression parameters by building iteratively increasing neighbors around each voxel and smoothing observations within the neighbors with weights. By contrast, we model all the voxels in an image tensor in a joint fashion.

Rabusseau and Kadri (2016) considered a tensor response model with a low-rank structure. However, no sparsity is enforced in their estimator, and thus their method is not directly applicable for selecting brain subregions affected by the disorder. Our approach instead is capable of region selection, and the resulting estimator is much easier to interpret.

Li and Zhang (2017) proposed an envelope-based tensor response model that is notably different from our proposal. First, they utilized a generalized sparsity principle to exploit the redundant information in the tensor response, by seeking linear combinations of the response that are irrelevant to the regression. Our method instead utilizes the element-wise sparsity in terms of the individual entries. As such our method can achieve region selection, whereas their approach cannot. Second, they obtained the $\sqrt{n}$-convergence rate for the *global* minimizer of their objective function when the tensor dimension is fixed. However, their objective function is non-convex and there is no guarantee that the optimization algorithm can find this global minimizer. By contrast, we derive the error rate of the *actual* minimizer of our algorithm at each iteration, and we also permit an increasing tensor dimension. Third, their approach could not directly incorporate the symmetry constraint when the tensor response is symmetric, which is often encountered in functional imaging analysis. To the best of our knowledge, our solution is the first that can simultaneously tackle both a non-symmetric and a symmetric tensor response in a regression setup.

Raskutti and Yuan (2016) developed a class of sparse regression models, under the assumption of Gaussian error, when either or both the response and predictor are tensors. When the error distribution is Gaussian, our error bound matches theirs. However, our bound is obtained for a general error distribution, where the normality is not necessarily required. In addition, they required another crucial condition that the regularizer must be convex and weakly decomposable. We do not impose this assumption, but instead tackle a non-convex optimization problem, and employ a different set of proof techniques. Finally, they achieved the low-rankness of the estimator through a tensor nuclear norm, which is known to be computationally NP-hard (Friedland and Lim, 2014). By contrast, our rate is established for the actual estimator obtained from our optimization algorithm, which we show later is both feasible and scalable.

Our major contribution is two-fold. First, we propose a new class of regression models with tensor as a response. This model is useful for a wide range of scientific applications, but has received only limited attention in the statistics literature, especially for the symmetric tensor response case. Our proposal is shown to exhibit numerous advantages compared to the existing solutions. Second, we develop a set of new tools for the theoretical analysis of non-convex optimization, which is notably different from recent development in this area (Wang et al., 2014; Yi and Caramanis, 2015; Sun et al., 2015; Balakrishnan et al., 2017). A common technique used in the non-convex optimization analysis is to separately

establish the convergence for the population and sample optimizers then combine the two. By contrast, our analysis hinges on exploitation of the bi-convex structure of the objective function, as well as a careful characterization of the impact of the intermediate sparse tensor decomposition step on the estimation error in each iteration step. The bi-convex structure frequently arises in many optimization problems. As such tools we develop are also of independent interest, and enrich the current toolbox of non-convex optimization analysis.

1.3 Notations and Structure

Throughout the article we adopt the following notations. Denote $[d] = \{1, \ldots, d\}$, and $\mathbf{I}_d$ the $d \times d$ identity matrix. Denote $1(\cdot)$ the indicator function, and $\circ$ the outer product between vectors. For a vector $\mathbf{a} = \mathbb{R}^d$, $\|\mathbf{a}\|$ denotes its Euclidean norm, and $\|\mathbf{a}\|_0$ the L_0 norm, i.e., the number of nonzero entries in $\mathbf{a}$. For a matrix $\mathbf{A} \in \mathbb{R}^{d\times d}$, $\|\mathbf{A}\|$ denotes its spectral norm. For a tensor $\mathcal{A} \in \mathbb{R}^{d_1\times\ldots\times d_m}$, and a set of vectors $\mathbf{a}_j \in \mathbb{R}^{d_j}, j = 1, \ldots, m$, the multilinear combination of the tensor entries is defined as $\mathcal{A} \times_1 \mathbf{a}_1 \times_2 \ldots \times_m \mathbf{a}_m := \sum_{i_1\in[d_1]} \cdots \sum_{i_m\in[d_m]} a_{i_1} \ldots a_{i_m} \mathcal{A}_{i_1,\ldots,i_m} \in \mathbb{R}$. The tensor spectral norm is defined as $\|\mathcal{A}\| := \sup_{\|\mathbf{a}_1\|=\ldots=\|\mathbf{a}_m\|=1} |\mathcal{A} \times_1 \mathbf{a}_1 \times_2 \ldots \times_m \mathbf{a}_m|$, and the tensor Frobenius norm as $\|\mathcal{A}\|_F := \sqrt{\sum_{i_1,\ldots,i_m} \mathcal{A}^2_{i_1,\ldots,i_m}}$. For two tensors $\mathcal{A}, \mathcal{B} \in \mathbb{R}^{d_1\times\ldots\times d_m}$, their inner product is $\langle \mathcal{A}, \mathcal{B}\rangle = \sum_{i_1,\ldots,i_m} \mathcal{A}_{i_1,\ldots,i_m} \mathcal{B}_{i_1,\ldots,i_m}$. See Kolda and Bader (2009) for more tensor operations. We say $a_n = o(b_n)$ if a_n/b_n converges to 0 as n increases to infinity.

The rest of the article is organized as follows. Section 2 introduces the proposed sparse tensor response regression model, and Section 3 presents the optimization algorithm. Section 4 establishes the estimation error bound. Section 5 presents the simulation results, and Section 6 applies our method to an analysis of the Autism spectrum disorder imaging data. The appendix collects all technical proofs.

2. Model

For an mth-order tensor response $\mathcal{Y}_i \in \mathbb{R}^{d_1\times\cdots\times d_m}$, and a vector of predictors $\mathbf{x}_i \in \mathbb{R}^p$, $i = 1, \ldots, n$, we consider the tensor response regression model of the form,

$$\mathcal{Y}_i = \mathcal{B}^* \times_{m+1} \mathbf{x}_i + \mathcal{E}_i, \tag{1}$$

where $\mathcal{B}^* \in \mathbb{R}^{d_1\times\cdots\times d_m\times p}$ is an $(m+1)$th-order tensor coefficient, and $\mathcal{E}_i \in \mathbb{R}^{d_1\times\cdots\times d_m}$ is an error tensor independent of $\mathbf{x}_i$. Without loss of generality, the intercept is set to zero, by centering the samples $\mathbf{x}_i$ and $\mathcal{Y}_i$. We also use $d_{m+1} := p$ to represent the dimension of $\mathbf{x}_i$. Our goal is to estimate $\mathcal{B}^*$ given n i.i.d. observations $\{(\mathbf{x}_i, \mathcal{Y}_i), i = 1, \ldots, n\}$.

To facilitate estimation of the ultrahigh dimensional unknown parameters under a limited sample size, it is crucial to introduce some sparse structures. Two most commonly used structures are element-wise sparsity and low-rankness (Raskutti and Yuan, 2016). In the context of tensor response regression, we assume that $\mathcal{B}^*$ admits the following rank-K decomposition structure (Kolda and Bader, 2009),

$$\mathcal{B}^* = \sum_{k\in[K]} w^*_k \boldsymbol{\beta}^*_{k,1} \circ \cdots \circ \boldsymbol{\beta}^*_{k,m} \circ \boldsymbol{\beta}^*_{k,m+1}, \quad w^*_k \in \mathbb{R},\ \boldsymbol{\beta}^*_{k,j} \in \mathbb{S}^{d_j}, \tag{2}$$

where $\mathbb{S}^d = \{\mathbf{v} \in \mathbb{R}^d \,|\, \|\mathbf{v}\| = 1\}$, $\|\boldsymbol{\beta}^*_{k,j}\|_0 \le d_{j0} < d_j$, and d_{j0} represents the true sparsity of the individual components $\boldsymbol{\beta}^*_{k,j}$, for $k \in [K]$, $j \in [m+1]$. Consequently, when coupling with the low-rank structure of (2), the element-wise sparsity of $\boldsymbol{\beta}^*_{k,j}$ implies that some individual entries of $\mathcal{B}^*$ are zero. Moreover, we assume $w^*_{\max} = w^*_1 \ge \cdots \ge w^*_K = w^*_{\min} > 0$, and assume each w^*_i to be bounded away from 0 and ∞. Under the structure of (2), estimating $\mathcal{B}^*$ reduces to the estimation of $w^*_k, \beta^*_{k,1}, \ldots, \beta^*_{k,m+1}$ for any $k \in [K]$, and the corresponding parameter space becomes $\mathbb{B} := \{w_k \in \mathbb{R}, \boldsymbol{\beta}_{k,j} \in \mathbb{R}^{d_j}, k \in [K], j \in [m+1] \,|\, c_1 \le |w_k| \le c_2, \|\boldsymbol{\beta}_{k,j}\|_2 = 1, \|\boldsymbol{\beta}_{k,j}\|_0 \le d_{j0}\}$. Accordingly, the number of unknown parameters is reduced from $p\prod_{j=1}^m d_j$ to $K(\sum_{j=1}^m d_j + p)$. To estimate those unknown parameters, we propose to solve the following constrained optimization problem,

$$\min_{\substack{w_k,\boldsymbol{\beta}_{k,1},\ldots,\boldsymbol{\beta}_{k,m+1}\\ k\in[K],j\in[m+1]}} \frac{1}{n}\sum_{i=1}^n \Big\|\mathcal{Y}_i - \sum_{k\in[K]} w_k(\boldsymbol{\beta}^\top_{k,m+1}\mathbf{x}_i)\boldsymbol{\beta}_{k,1} \circ \cdots \circ \boldsymbol{\beta}_{k,m}\Big\|_F^2, \tag{3}$$
$$\text{subject to } \|\boldsymbol{\beta}_{k,j}\|_2 = 1, \|\boldsymbol{\beta}_{k,j}\|_0 \le s_j,$$

where s_j is the cardinality parameter of the j-th component. Here we encourage the sparsity of the decomposed components via a hard-thresholding penalty to control $\|\boldsymbol{\beta}_{k,j}\|_0$. Compared to the lasso type penalized approach in sparse learning, the hard-thresholding method avoids bias and has been shown to be more appealing in numerous high-dimensional learning problems (Shen et al., 2012, 2013; Wang et al., 2014).

3. Estimation

The problem in (3) is a non-convex optimization. The key of our estimation procedure is to explore its *bi-convex* structure. In particular, the objective function in (3) is bi-convex in $(\boldsymbol{\beta}_{k,1}, \ldots, \boldsymbol{\beta}_{k,m+1})$, $k \in [K]$, in that it is convex in $\boldsymbol{\beta}_{k,j}$ when all other parameters are fixed. Utilizing this property, we propose an efficient alternating updating algorithm to solve (3).

3.1 Algorithm

We first summarize our estimation procedure in Algorithm 1, then present the two key alternative steps.

Step 1: The first core step of our algorithm is to update $w_k, \boldsymbol{\beta}_{k,1}, \ldots, \boldsymbol{\beta}_{k,m}$ for each $k = 1, \ldots, K$, given $\boldsymbol{\beta}_{j,m+1}$, $j = 1, \ldots, K$ and $w_{k'}, \beta_{k',1}, \ldots, \beta_{k',m}$, $k' \ne k$. Letting $\alpha_{ik} := \boldsymbol{\beta}^\top_{k,m+1}\mathbf{x}_i$, $i = 1, \ldots, n$, we note that (3) is equivalent to

$$\min_{\substack{w_k,\boldsymbol{\beta}_{k,1},\ldots,\boldsymbol{\beta}_{k,m}\\ \|\boldsymbol{\beta}_{k,j}\|_2=1,\|\boldsymbol{\beta}_{k,j}\|_0\le s_j,j\in[m]}} \frac{1}{n}\sum_{i=1}^n \alpha^2_{ik}\Big\|\mathcal{R}_i - w_k\boldsymbol{\beta}_{k,1} \circ \cdots \circ \boldsymbol{\beta}_{k,m}\Big\|_F^2, \tag{4}$$

where the residual tensor term $\mathcal{R}_i$ is of the form,

$$\mathcal{R}_i := \Big[\mathcal{Y}_i - \sum_{k'\ne k, k'\in[K]} w_{k'}\alpha_{ik'}\boldsymbol{\beta}_{k',1} \circ \cdots \circ \boldsymbol{\beta}_{k',m}\Big]/\alpha_{ik}. \tag{5}$$

The next lemma shows that (4) can be solved via a sparse tensor decomposition procedure.

Algorithm 1 Alternating updating algorithm for STORE.

1: **Input:** data $\{(\mathbf{x}_i, \mathcal{Y}_i), i = 1, \ldots, n\}$, rank K, cardinality vector $(s_1, \ldots, s_m)$.
2: **Initialize** $w_k = 1$ and random unit-norm vectors $\boldsymbol{\beta}_{k,1}, \ldots, \boldsymbol{\beta}_{k,m+1}$ for each $k \in [K]$.
3: **Until** the termination condition is met, **Do**
4: Step 1: For $k = 1$ to K, obtain $\widehat{w}_k, \widehat{\boldsymbol{\beta}}_{k,1}, \ldots, \widehat{\boldsymbol{\beta}}_{k,m}$ by solving (6) via the sparse tensor decomposition procedure of Sun et al. (2017) with parameters K and $(s_1, \ldots, s_m)$.
5: Step 2: For $k = 1$ to K, obtain $\widehat{\boldsymbol{\beta}}_{k,m+1}$ using Lemma 2.
6: **Output:** $\widehat{w}_k, \widehat{\boldsymbol{\beta}}_{k,1}, \ldots, \widehat{\boldsymbol{\beta}}_{k,m+1}$ for each $k \in [K]$.

Lemma 1 *Denote $(\widehat{w}_k, \widehat{\boldsymbol{\beta}}_{k,1}, \ldots, \widehat{\boldsymbol{\beta}}_{k,m})$ as the solution of (4), and denote $(\widetilde{w}_k, \widetilde{\boldsymbol{\beta}}_{k,1}, \ldots, \widetilde{\boldsymbol{\beta}}_{k,m})$ as the solution of*

$$\min_{\substack{w_k, \boldsymbol{\beta}_{k,1}, \ldots, \boldsymbol{\beta}_{k,m} \\ \|\boldsymbol{\beta}_{k,j}\|_2 = 1, \|\boldsymbol{\beta}_{k,j}\|_0 \le s_j, j \in [m]}} \left\| \bar{\mathcal{R}} - w_k \boldsymbol{\beta}_{k,1} \circ \cdots \circ \boldsymbol{\beta}_{k,m} \right\|_F^2, \tag{6}$$

where $\bar{\mathcal{R}} := \frac{1}{n} \sum_{i=1}^n \alpha_{ik}^2 \mathcal{R}_i$. Then it satisfies that $\widehat{w}_k = n \widetilde{w}_k / \sum_{i=1}^n \alpha_{ik}^2$ and $\widehat{\boldsymbol{\beta}}_{k,l} = \widetilde{\boldsymbol{\beta}}_{k,l}$, for $l = 1, \ldots, m$ and $k = 1, \ldots, K$.

Lemma 1 implies that the optimization problem in (4) reduces to a sparse rank-one tensor decomposition on the averaged tensor $\bar{\mathcal{R}}$. To efficiently solve (6), in this paper we employ a truncation-based sparse tensor decomposition procedure (Sun et al., 2017), by first solving the non-sparse tensor decomposition components and then truncating them to achieve the desirable sparsity. It is also noteworthy that our method is flexible in the choice of optimization algorithm for solving (6), and Algorithm 1 can be coupled with many other sparse tensor decomposition algorithms, e.g., Chi and Kolda (2012); Liu et al. (2012).

When the tensor response $\mathcal{Y}_i$ is symmetric, the resulting coefficient $\mathcal{B}$ should be symmetric too. Our algorithm can easily adapt to this scenario, by setting $\boldsymbol{\beta}_{k,1} = \cdots = \boldsymbol{\beta}_{k,m} = \boldsymbol{\beta}_k$ for each $k \in [K]$, and the cardinality parameters $s_1 = \cdots = s_m = s$. That is, we slightly modify Step 1 in Algorithm 1 as: for $k = 1$ to K, compute $\mathcal{R}_i$ in (5) and solve $\widehat{w}_k, \widehat{\boldsymbol{\beta}}_k$ via the symmetric sparse tensor decomposition with parameters K and s.

Step 2: The second core step of our algorithm is to update $\boldsymbol{\beta}_{k,m+1}$ for each $k = 1, \ldots, K$, given $w_j, \beta_{j,1}, \ldots, \boldsymbol{\beta}_{j,m}$, $j = 1, \ldots, K$ and $\boldsymbol{\beta}_{k',m+1}$, $k' \neq k$. Letting $\mathcal{A}_k = w_k \beta_{k,1} \circ \cdots \circ \boldsymbol{\beta}_{k,m}$, then (3) is equivalent to

$$\min_{\alpha} \frac{1}{n} \sum_{i=1}^n \left\| \mathcal{T}_i - \alpha^\top \mathbf{x}_i \mathcal{A}_k \right\|_F^2, \tag{7}$$

where the residual tensor $\mathcal{T}_i = \mathcal{Y}_i - \sum_{k' \neq k, k' \in [K]} w_{k'} (\boldsymbol{\beta}_{k',m+1}^\top \mathbf{x}_i) \boldsymbol{\beta}_{k',1} \circ \cdots \circ \boldsymbol{\beta}_{k',m}$. The next lemma gives a closed-form solution of (7).

Lemma 2 *The solution of (7) is given by*

$$\widehat{\boldsymbol{\beta}}_{k,m+1} = \left(\frac{1}{n} \sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i^\top \right)^{-1} \frac{n^{-1} \sum_{i=1}^n \langle \mathcal{T}_i, \mathcal{A}_k \rangle \mathbf{x}_i}{\|\mathcal{A}_k\|_F^2}.$$

In our neuroimaging example in Section 6, the dimension of the predictor vector is $p = 3$. For such a small value of p, the sample size n is generally much larger, and we can directly invert the sample covariance matrix $n^{-1} \sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i^\top$. If $n < p$, this matrix is not invertible. Then one may employ sparse graphical model estimation (Yuan and Lin, 2007; Friedman et al., 2008; Zhang and Zou, 2014) and replace this inverse with a sparse precision matrix estimator. Alternatively, one may also introduce additional sparsity constraint on the parameter $\boldsymbol{\beta}_{k,m+1}$ and resort to a regularized estimation approach to update $\boldsymbol{\beta}_{k,m+1}$.

Finally, we terminate the alternating update of Steps 1 and 2 when the new estimates are close to the ones from the previous iteration. The termination condition is set as

$$\max_{j \in [m+1], k \in [K]} \min \left\{ \|\widehat{\boldsymbol{\beta}}_{k,j}^{(t)} - \widehat{\boldsymbol{\beta}}_{k,j}^{(t-1)}\|, \|\widehat{\boldsymbol{\beta}}_{k,j}^{(t)} + \widehat{\boldsymbol{\beta}}_{k,j}^{(t-1)}\| \right\} \le 10^{-4}.$$

3.2 Tuning Parameter Selection

In Algorithm 1, the rank K and the cardinality $s_1, \ldots, s_m$ are tuning parameters. We propose to select those parameters via a BIC-type criterion. Specifically, given a pre-specified set of rank values $\mathcal{K}$ and a pre-specified set of cardinality values $\mathcal{S}_1, \ldots, \mathcal{S}_m$, we choose the combination of parameters $(\widehat{K}, \widehat{s}_1, \ldots, \widehat{s}_m)$ that minimizes

$$\mathrm{BIC} = \log \left(\sum_{i=1}^n \|\mathcal{Y}_i - \widehat{\mathcal{B}} \times_{m+1} \mathbf{x}_i\|_F^2 \right) + \frac{\log(n \prod_{j=1}^m d_m)}{n \prod_{j=1}^m d_m} \sum_{k=1}^K \sum_{j=1}^m \|\widehat{\boldsymbol{\beta}}_{k,j}\|_0.$$

This criterion balances between model fitting and model sparsity, and a similar version has been commonly employed in rank estimation (Zhou et al., 2013).

4. Theory

Next we establish the error bound of the actual STORE estimator obtained from our Algorithm 1. The resulting error bound consists of two quantities: a computational error and a statistical error. The computational error captures the error caused by the non-convexity of the optimization, whereas the statistical error measures the error due to finite samples.

In order to compute the distance between the estimator and the truth, we define the distance measure between two unit vectors $\mathbf{u}, \mathbf{v} \in \mathbb{R}^d$ as $D(\mathbf{u}, \mathbf{v}) := \sqrt{1 - (\mathbf{u}^\top \mathbf{v})^2}$. We then have $D(\mathbf{u}, \mathbf{v}) \le \min\{\|\mathbf{u} - \mathbf{v}\|, \|\mathbf{u} + \mathbf{v}\|\} \le \sqrt{2} D(\mathbf{u}, \mathbf{v})$. The distance function $D(\mathbf{u}, \mathbf{v})$ resolves the sign issue in the decomposition components since changing the signs of any two component vectors does not affect the generated tensor.

4.1 Assumptions

We first introduce the technical assumptions required to guarantee the desirable error bound. The first assumption is about the structure of the true model.

Assumption 3 (Model Assumption) *In model (1), we assume the true coefficient $\mathcal{B}^*$ is sparse and low-rank satisfying (2) and such decomposition is unique up to a permutation. Assume $\|\mathcal{B}^*\| \le C_1 w_{\max}^*$, and for each i, assume $\|\mathbf{x}_i\| \le C_2$ and $|\boldsymbol{\beta}_{k,m+1}^{*\top} \mathbf{x}_i| \ge C_3$ almost surely, for some positive constants C_1, C_2, C_3. Furthermore, we require the eigenvalues of*

the sample covariance $\Sigma := n^{-1}\sum_{i=1}^n \mathbf{x}_i\mathbf{x}_i^\top$ *to satisfy* $c_0 < \lambda_{\min}(\Sigma) \le \lambda_{\max}(\Sigma) < \widetilde{c}_0$ *for some constants* $c_0, \widetilde{c}_0$.

The above unique decomposition condition is to ensure the identifiability of tensor decomposition. Kruskal (1976, 1977) provided the classical conditions for such identifiability if the sum of the Kruskal ranks of the m decomposed component matrices is larger than $2K+2$. In our model, the rank K is fixed, and hence the identifiability of our tensor decomposition (2) is guaranteed when the decomposed components are not highly dependent. Moreover, the conditions on the predictor vector $\mathbf{x}_i$ are mild and trivially hold when the dimension of $\mathbf{x}_i$ is fixed. In Section 6, the dimension of $\mathbf{x}_i$ is 3 in our neuroimaging data example.

The second assumption is about the initialization in Algorithm 1.

Assumption 4 (Initialization Assumption) *Define the initialization error*

$$\epsilon := \max\left\{\max_k \|\widehat{w}_k^{(0)} - w_k^*\|_2, \max_{k,j} D\left(\widehat{\boldsymbol{\beta}}_{k,j}^{(0)}, \boldsymbol{\beta}_{k,j}^*\right)\right\}.$$

We assume that

$$\epsilon < \min\left\{\sqrt{\frac{w_{\min}^*}{2(w_{\min}^* + w_{\max}^* C_1)}}, \frac{w_{\min}^{*2}}{8\sqrt{5}w_{\max}^* C_1(6\sqrt{2}w_{\min}^* + 2)}, \frac{C_3}{2C_2}, \frac{w_{\min}^*}{2}\right\},$$

where the constants C_1, C_2, C_3 *are as defined in Assumption 3.*

Note that our assumption on the initialization parameters only requires the error to be bounded by some constant; i.e., the initial estimators are not too far away from the true parameters. This assumption is necessary to handle the non-convexity of the optimization, and has been commonly imposed in non-convex optimization (Wang et al., 2014; Balakrishnan et al., 2017). It is also noteworthy that this assumption is satisfied by the estimators from sparse singular value decomposition of the unfolding matrix from the original tensor in Step 1 of Algorithm 1; see Sun et al. (2017) for more discussion on the theoretical guarantee of such an initialization procedure.

The third assumption requires that the error tensor $\mathcal{E}_i$ is controlled. Before stating the assumption, we introduce a critical concept to measure the noise level in the tensor response regression. In particular, we define the sparse spectral norm of $\mathcal{E}$ as

$$\eta(\mathcal{E}, d_{01}, \cdots, d_{0m}) := \sup_{\substack{\|\mathbf{u}_1\|=\cdots=\|\mathbf{u}_m\|=1 \\ \|\mathbf{u}_1\|_0\le d_{01},\ldots,\|\mathbf{u}_m\|_0\le d_{0m}}} \left|\mathcal{E}\times_1\mathbf{u}_1\times_2\cdots\times_m\mathbf{u}_m\right|. \tag{8}$$

This quantifies the perturbation error in a sparse scenario, and in the sparse case with $d_{0j} \ll d_j$ $(j = 1, \ldots, m)$, it is much smaller than the spectral norm $\|\mathcal{E}\|$, i.e., $\eta(\mathcal{E}, d_1, \cdots, d_m)$. Denoting $d_0 = \max_j d_{0j}$, we have $\eta(\mathcal{E}, d_{01}, \cdots, d_{0m}) \le \eta(\mathcal{E}, d_0, \cdots, d_0)$. We write $\eta(\mathcal{E}, d_0) := \eta(\mathcal{E}, d_0, \cdots, d_0)$.

Assumption 5 (Error Assumption) *Let* $s := \max\{s_1, \ldots, s_m\}$, *with* s_j *being the cardinality parameter in Algorithm 1. We assume the error tensor* $\mathcal{E}_i$, $i = 1, \ldots, n$, *satisfies*

$$\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right) \le \frac{C_3 w_{\min}^*}{8},$$

where C_3 *is as defined in Assumption 3.*

This assumption requires that the observed tensor responses, $\mathcal{Y}_i$, $i = 1, \ldots, n$, are not too noisy. It is a minor condition, since we only require the spectral norm of the error tensor to be bounded. As we later show in Section 4.3, when $\mathcal{E}_i$ is a standard Gaussian tensor, its spectral norm converges to zero when the sample size n increases.

4.2 Main Result

Next we present our main theorem that describes the estimation error of the actual estimator at each iteration from Algorithm 1.

Theorem 6 *Assuming Assumptions 3, 4, and 5, the estimator in the t-th iteration of Algorithm 1, with* $s \ge d_0 := \max_j d_{j0}$, *satisfies that*

$$\begin{aligned}&\max\left\{\max_k \|\widehat{w}_k^{(t)} - w_k^*\|_2, \max_{k,j} D\left(\widehat{\boldsymbol{\beta}}_{k,j}^{(t)}, \boldsymbol{\beta}_{k,j}^*\right)\right\} \\ \le\ & \underbrace{\kappa^t\epsilon}_{\text{computational error}} + \underbrace{\frac{1}{1-\kappa}\max\left\{\frac{4\sqrt{5}}{C_3 w_{\min}^*}\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right), \frac{\widetilde{C}}{\sqrt{n}}\right\}}_{\text{statistical error}},\end{aligned} \tag{9}$$

where the contraction coefficient $\kappa = (\kappa_1 + \kappa_2)\kappa_3 \in (0, 1)$, *with* $\kappa_1 := 4\sqrt{5}w_{\max}^* C_3\epsilon/w_{\min}^*$, $\kappa_2 := 2C_2\eta\left(\bar{\mathcal{E}}, s\right)/C_3^2$, *and* $\kappa_3 := 2/w_{\min}^* + 6\sqrt{2}$. *Here* C_1, C_2, C_3 *are constants as defined in Assumption 3, and* $\widetilde{C}$ *is some positive constant.*

Theorem 6 reveals the interplay between the computational error and the statistical error for our estimator, and has some interesting implications. First, it provides a theoretical guidance to terminate the iterations of the alternating updating algorithm. That is, when the computational error is dominated by the statistical error, in that

$$t \ge T := \log_{1/\kappa}\left(\frac{(1-\kappa)\epsilon}{\max\left\{\frac{4\sqrt{5}}{C_3 w_{\min}^*}\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right), \frac{\widetilde{C}}{\sqrt{n}}\right\}}\right), \tag{10}$$

the estimator from our algorithm achieves an error at the rate

$$O_p\left(\max\left\{\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right), \frac{1}{\sqrt{n}}\right\}\right). \tag{11}$$

The constants C_3 and $\widetilde{C}$ in (10) are unknown in practice. However, due to the fact both constants are independent of the sample size, the sparsity parameters, and the dimensionality, the expression (10) gives an order of the optimal termination T in terms of the parameters that go to infinity. Second, Theorem 6 also provides a general theoretical guarantee for our estimator for any distribution of the error tensor $\mathcal{E}_i$, as the error rate depends on the distribution of the error tensor only through $\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right)$. Later we obtain the explicit forms of the error rates for some special error distributions.

We also remark that, Theorem 6 is obtained assuming the true rank K is known. This is a common assumption in theoretical analysis in the tensor literature (Zhou et al., 2013; Li and Zhang, 2017). To our knowledge, none of the exiting works has provided a provable estimation of the rank, due to that the exact tensor rank calculation is NP hard (Kolda and Bader, 2009). The theory of rank estimation will be our future research.

4.3 Gaussian Tensor Error

We derive the explicit form of the statistical error in Theorem 6 when $\mathcal{E}_i, i = 1, \ldots, n$, are i.i.d. Gaussian tensors; i.e., the entries of $\mathcal{E}_i$ are i.i.d. standard Gaussian random variables.

Corollary 7 *Under the assumptions of Theorem 6, and assuming $\mathcal{E}_i \in \mathbb{R}^{d_1 \times d_2 \times d_3}, i = 1, \ldots, n$, are i.i.d. Gaussian tensors, we have*

$$\eta\left(\frac{1}{n}\sum_{i=1}^{n}\mathcal{E}_i, s\right) = O_p\left(\sqrt{\frac{s^3\log(d_1d_2d_3)}{n}}\right).$$

Consequently the estimator at the T-th iteration of Algorithm 1 satisfies

$$\max\left\{\max_k \|\widehat{w}_k^{(T)} - w_k^*\|_2, \max_{k,j} D\left(\widehat{\boldsymbol{\beta}}_{k,j}^{(T)}, \boldsymbol{\beta}_{k,j}^*\right)\right\} = O_p\left(\sqrt{\frac{s^3\log(d_1d_2d_3)}{n}}\right).$$

We provide some insight about the statistical error $O_p(\sqrt{s^3\log(d_1d_2d_3)/n})$. Note that, s is the maximal cardinality of vectors $\widehat{\boldsymbol{\beta}}_{k,j}$ for $k \in [K]$ and $j \in [m]$, and hence there are at most $O(s^3)$ non-zero elements and $O(d_1d_2d_3)$ free parameters in the true tensor coefficient $\mathcal{B}^*$. This error rate allows the tensor dimension to grow exponentially with the sample size and matches the one established by Raskutti and Yuan (2016) for sparse tensor regression. When the order of tensor is one, i.e., $m = 1$, it reduces to the statistical error $O_p(\sqrt{s\log d/n})$ for the high-dimensional vector regression $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \epsilon$ with $\boldsymbol{\beta} \in \mathbb{R}^d$ and $\|\boldsymbol{\beta}\|_0 \le s$, and is known to be minimax optimal (Wang et al., 2014).

4.4 Symmetric Matrix Error

Next we consider the case when the response $\mathcal{Y}_i$ is a symmetric matrix ($m = 2$). Such a scenario is often encountered in functional neuroimaging analysis, where the target of interest is the brain connectivity pattern encoded in the form of a symmetric correlation matrix. The symmetry of the coefficient $\mathcal{B}^*$ requires that $\boldsymbol{\beta}_{k,1}^* = \boldsymbol{\beta}_{k,2}^* = \boldsymbol{\beta}_k^*$. Henceforth, $\mathcal{B}^* = \sum_{k\in[K]} w_k^* \cdot \boldsymbol{\beta}_k^* \circ \boldsymbol{\beta}_k^* \circ \boldsymbol{\beta}_{k,3}^*$, where $w_k^* \in \mathbb{R}$, $\|\boldsymbol{\beta}_k^*\|_2 = 1, \|\boldsymbol{\beta}_k^*\|_0 \le d_0$, and $\boldsymbol{\beta}_{k,3}^* \in \mathbb{S}^p$. To facilitate the derivation of the explicit form of $\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right)$, we assume that the error matrix $\mathcal{E}_i$ satisfies

$$\mathcal{E}_i = (\widetilde{\mathcal{E}}_i + \widetilde{\mathcal{E}}_i^\top)/2, \tag{12}$$

where $\widetilde{\mathcal{E}}_i \in \mathbb{R}^{d\times d}$ is a matrix whose entries are i.i.d. standard Gaussian. This assumption is mainly for technical reasons, and the theoretical analysis of a more general symmetric tensor response is left as future work.

Corollary 8 *Under the assumptions of Theorem 6, and assuming $\mathcal{E}_i, i = 1, \ldots, n$ are i.i.d. and of the form* (12)*, we have*

$$\eta\left(\frac{1}{n}\sum_{i=1}^{n}\mathcal{E}_i, s\right) = O_p\left(\sqrt{\frac{s^2\log(d^2)}{n}}\right).$$

5. Simulations

In this section, we investigate the numerical performance of our method, and demonstrate its superior performance when compared to some alternative solutions.

To evaluate the estimation accuracy, we report the estimation error $\|\widehat{\mathcal{B}} - \mathcal{B}\|_F$. To evaluate the variable selection accuracy, we compute the true positive rate, $\text{TPR} := m^{-1}\sum_{j=1}^m \text{TPR}_j$, and the false positive rate, $\text{FPR} := m^{-1}\sum_{j=1}^m \text{FPR}_j$, where $\text{TPR}_j := K^{-1}\sum_{k=1}^K\sum_i 1([\beta_{k,j}]_i \neq 0, [\widehat{\beta}_{k,j}]_i \neq 0)/\sum_i 1([\beta_{k,j}]_i \neq 0)$, $\text{FPR}_j := K^{-1}\sum_{k=1}^K\sum_i 1([\beta_{k,j}]_i = 0, [\widehat{\beta}_{k,j}]_i \neq 0)/\sum_i 1([\beta_{k,j}]_i = 0)$. We also report the F1 score, $F_1 := 2(\text{recall}^{-1} + \text{precision}^{-1})^{-1}$, where $\text{precision} = m^{-1}K^{-1}\sum_{j=1}^m\sum_{k=1}^K\sum_i 1([\beta_{k,j}]_i \neq 0, [\widehat{\beta}_{k,j}]_i \neq 0)/\sum_i 1([\widehat{\beta}_{k,j}]_i = 0)$ and recall = TPR. The TPR, FPR and F1 score are all between 0 and 1, with a larger value of TPR and F1 and a smaller value of FPR indicating a better selection performance.

We compare our STORE method with four alternative solutions. The first is ordinary least squares (OLS) that fits one response variable at a time. Although a naive solution, OLS is widely used in neuroimaging analysis due to its simplicity. The second is the sparse ordinary least squares method (Sparse OLS) of Peng et al. (2010) that first vectorizes the tensor response then fits a regularized multivariate regression with the lasso penalty. The third is the envelope-based tensor response regression method (ENV) of Li and Zhang (2017) that utilizes a generalized sparsity principle. It is noteworthy that, in Li and Zhang (2017), ENV has been shown to clearly outperform the tensor predictor regression method of Zhou et al. (2013). Hence, we directly compare with ENV but no longer with Zhou et al. (2013). The fourth is the higher-order low-rank regression method (HOLRR) of Rabusseau and Kadri (2016) that imposes a low-rank tensor structure. We also comment that, OLS and sparse OLS both ignore the tensor structure of the data, whereas neither of OLS, ENV, and HOLRR performs region selection.

5.1 3D Tensor Response Example

We first consider an example of a third-order tensor response ($m = 3$). The data was generated from model (1) with x_i a scalar taking values 0 or 1 with an equal probability, and the coefficient tensor $\mathcal{B} \in \mathbb{R}^{d_1\times d_2\times d_3}$ of the form, $\mathcal{B} = \sum_{k\in[K]} w_k\beta_{k,1}\circ\beta_{k,2}\circ\beta_{k,3}\circ\beta_{k,4}$, $w_k \in \mathbb{R}$, $\beta_{k,j} \in \mathbb{S}^{d_j}$. For each $k \in [K]$, we first generated i.i.d. standard Gaussian entries of the three vectors $\beta_{k,1}, \beta_{k,2}, \beta_{k,3}$, then truncated each vector with the cardinality parameters s_{01}, s_{02}, s_{03} accordingly. Next we normalized each vector and aggregated the coefficients as w_k. We set $\beta_{k,4}$ as one. In all simulations, we fixed the tensor dimensions $d_1 = 100, d_2 = 50, d_3 = 20$. We set the true cardinality $s_{0j} = s * d_j$ ($j = 1, 2, 3$), and varied the sparsity level $s \in \{0.3, 0.5\}$ and rank $K \in \{2, 5\}$. We considered the sample size $n \in \{20, 100\}$. Based on our theoretical finding, a larger sample size leads to a better estimation performance. We have chosen a relatively small sample size to mimic the situation where the number of subjects is limited. Such a situation is commonly encountered in neuroimaging studies. In total, there are 8 combinations of different scenarios. For STORE, the tuning parameters were chosen according to the BIC criterion in Section 3.2 by setting $\mathcal{K} = \{1, 2, \ldots, 10\}$ and $\mathcal{S} = \{0.1, 0.2, \ldots, 0.9\}$. The tunings for Sparse OLS and HOLRR were conducted based on their recommended approaches.

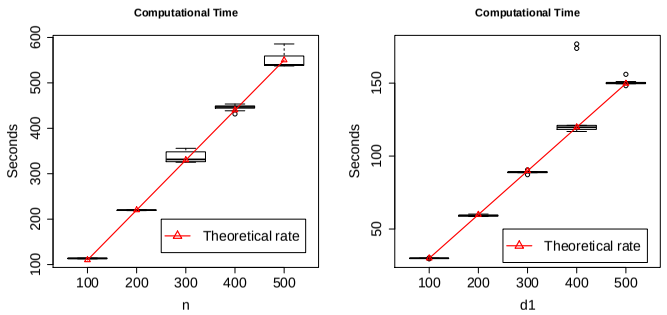

Figure 1: The computational time of our algorithm as the sample size and the tensor dimension varies. The theoretical linear rate is shown in red triangle.

Table 1 reports simulation results based on 20 replications. It is seen that our STORE method clearly achieves a superior performance than all the competing methods in terms of both estimation accuracy and variable selection accuracy. The same pattern holds for different sample size n, rank K, and sparsity level s. It is also noted that, since OLS, ENV, and HOLRR do not incorporate entry-wise sparsity, their corresponding TPR and FPR values are always one, and their F1 scores are undefined due to zero in the denominator of the precision.

We also studied the computational time of our algorithm when the sample size and the tensor dimension increase. The code is written in R and is implemented on a laptop with 2.5 GHz Intel Core i7 processor. Figure 5.1 reports the results based on 20 replications. Specifically, we fixed the rank $K = 2$ and the sparsity $s = 0.3$. In the left panel, we fixed the tensor dimensions $d_1 = 100, d_2 = 50, d_3 = 20$, but varied the sample size $n \in \{100, 200, 300, 400, 500\}$. In the right panel, we fixed $n = 20$, $d_2 = 50$, $d_3 = 20$, but varied the dimension $d_1 \in \{100, 200, 300, 400, 500\}$. This scale of sample size and tensor dimension is typical in neuroimaging applications. From the plot we see that the computational time of our Algorithm 1 is roughly linear in terms of the sample size and the tensor dimension when other parameters are fixed. This shows that our algorithm is scalable and feasible with moderate to large sample size and dimensionality. Meanwhile, it is possible to further improve our current algorithm. For instance, in each iteration, one could employ the recently developed parallel tensor decomposition (Papalexakis et al., 2012), or the sketching tensor decomposition (Wang et al., 2015), to accelerate the computation.

5.2 2D Symmetric Matrix Response Example

Next we considered an example of a second-order symmetric tensor (matrix, $m = 2$). This type of problem is commonly encountered in functional neuroimaging and brain connectivity analysis. The data was generated from the model, $\mathcal{Y}_i = \mathcal{B} \times_{m+1} x_i + \mathcal{E}_i$, where $\mathcal{Y}_i \in \mathbb{R}^{100 \times 100}$

n	K	s	Method	Error	TPR	FPR	F1

Table 1: Third-order tensor response example with different sample size n, rank K, and sparsity s. Reported are the average estimation error, TPR, FPR, and F1 score, with the standard error shown in the parenthesis. The minimal error in each case is shown in boldface.

is the symmetric matrix response, x_i is a scalar taking values 0 or 1, and the error term $\mathcal{E}_i$ is a symmetric matrix whose upper triangle entries are generated randomly from a standard normal distribution. The sample size is $n = 20$. To mimic some common connectivity patterns, we have simulated three symmetric coefficient matrices $\mathcal{B}$ that lead to three graph patterns: a randomly generated sparse and low-rank graph (random), a hub graph (hub),

Graph Pattern	Method	Estimation Error	TPR	FPR	F1
random	OLS	22.168 (0.560)	1 (0)	1 (0)	NA

and a small-world graph (small-world). Note that the coefficient tensor $\mathcal{B}$ is symmetric, though the corresponding graph pattern is not necessarily so. The random and hub graphs are both of a low-rank structure, with the true rank $K = 2$ and $K = 10$, respectively. The small-world graph is not of an exact low-rank structure, and our method essentially provides a low-rank *approximation*. This scenario also allows us to investigate the performance of our method under potential model mis-specification. Besides, as none of the competitive solution enforces the symmetry property of the estimator $\widehat{\mathcal{B}}$, for comparison, we symmetrized their final estimators by $(\widehat{\mathcal{B}} + \widehat{\mathcal{B}}^\top)/2$.

Table 2 reports the results over 20 data replications. Figure 2 further illustrates the estimated graph patterns of all methods in one replicate. The first column shows the true graphs. The second column shows the estimates from OLS, ENV, and HOLRR. Note that, although those three methods yield different numerical estimates, none of them impose any sparsity. As such, their estimated graph patterns look the same. The third column shows the estimate from Sparse OLS, and the last column from our method STORE. In the first scenario where the true graph is sparse and low-rank, our method substantially outperforms the competing solutions, with a much smaller estimation error and perfect selection accuracy. By contrast, OLS, ENV, and HOLRR yield much larger estimation error and could only generate dense graph estimates. Sparse OLS, on the other hand, produce many false positive links and a large error too. In the second scenario where the truth is a hub graph, our method again outperforms the alternative solutions. This time Sparse OLS misses many true positive links, which again results in a much larger estimation error. In the third scenario of the small-world graph, our model assumption is not satisfied. However our method still manages to achieve a reasonable estimation error and graph recovery. Although HOLRR obtains the smallest estimation error for this

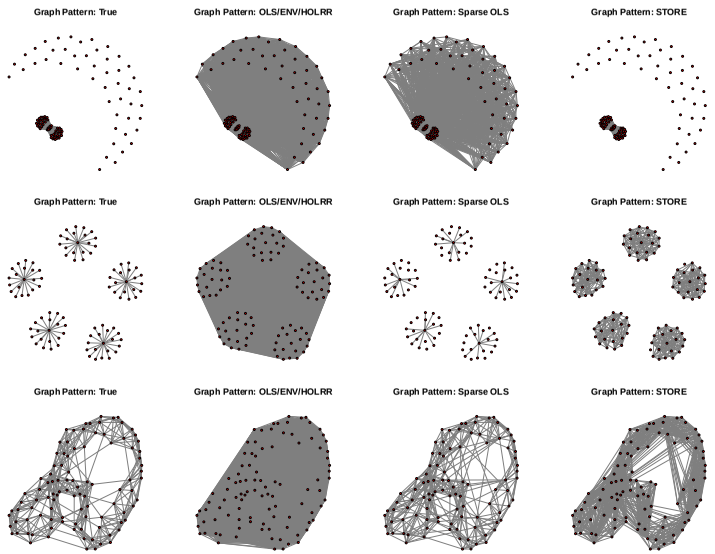

Figure 2: Symmetric matrix response example. Top row: the random graph, middle row: the hub graph, bottom row: the small-world graph. The first column: the true graph pattern; The second column: the estimated graph from OLS, ENV, and HOLRR; The third column: the estimated graph from Sparse OLS; The forth column: the estimated graph from our method STORE.

example, its graph estimate is completely dense and the corresponding FPR is one. Sparse OLS recoveres the graph pattern reasonably well, but still misses many true positive links, and yields a smaller TPR than our method.

6. Real Data Analysis

In this section, we analyze a real neuroimaging data to illustrate our proposed method. The data is from the Autism Brain Imaging Data Exchange (ABIDE), a study for autism spectrum disorder (ASD) (Di Martino et al., 2014). ASD is an increasingly prevalent neurodevelopmental disorder. It is characterized by symptoms such as social difficulties, communication deficits, stereotyped behaviors and cognitive delays (Rudie et al., 2013). It is of scientific importance to understand how brain functional architecture and brain connectivity pattern differ between subjects with ASD and the normal controls. After removing those with missing values and poor image quality, the data set consists of the resting-state

functional magnetic resonance imaging (fMRI) of 795 subjects, of which 362 have ASD, and 433 are the normal controls. We took the fMRI image as the response, and the ASD status indicator (1 = ASD and 0 = normal control), age and sex as covariates. For each fMRI image, there are two forms of data: one is a 3D tensor and another is a 2D symmetric matrix. Correspondingly, we have fitted two separate tensor response regression models.

6.1 3D FALFF Tensor Response

The first form of the fMRI data is a third-order tensor of fractional amplitude of low-frequency fluctuations (fALFF). fALFF is a metric reflecting the percentage of power spectrum within low-frequency domain ($0.01 - 0.1$ Hz). It characterizes the intensity of spontaneous brain activities, and provides a measure of functional architecture of the brain (Shi and Kang, 2015). It is calculated at each individual image voxel, and forms a 3D tensor with dimension $91 \times 109 \times 91$. We applied our STORE method as well as four competing methods (OLS, Sparse OLS, ENV, and HOLRR) to this general 3D tensor response.

Figure 3 shows the estimated coefficient tensors, overlaid on a brain image of a randomly selected subject, by all five methods. Among those, OLS, ENV, and HOLRR perform no region selection, whereas Sparse OLS yields a sparse estimate that is difficult to interpret. By contrast, the STORE estimate reveals a small number of brain regions that exhibit a clear difference between the ASD and normal control groups. Furthermore, we mapped those nonzero entries of our estimate to the AAL atlas. Table 3 reports the names of those identified regions and the corresponding coefficient entries in each region. Our results in general agree with the autism literature. For instance, we have found that multiple cerebellum (`Cerebellum`) regions show distinctive patterns between the ASD and control groups. The cerebellum has long been known for its importance in motor learning, coordination, and more recently, cognitive functions and affective regulation. It has emerged as one of the key brain regions affected in autism (Becker and Stoodley, 2013). Moreover, we identified the superior parietal lobule (`Parietal_Sup`) and precuneus (`Precuneus`), which agrees with Travers et al. (2015), in that they found individuals with ASD showed decreased activation in the superior parietal lobule and precuneus relative to individuals with typical development, suggesting that the superior parietal lobule may play an important role in motor learning and repetitive behavior in individuals with ASD.

6.2 2D Symmetric Partial Correlation Matrix Response

The second form of the fMRI data is a second-order symmetric partial correlation matrix. The partial correlation between brain regions reveals the synchronization of brain systems, and offers an alternative measure of the intrinsic brain functional architecture. It is evaluated, however, at a different scale from fALFF. Specifically, it is computed between pairs of pre-specified brain regions, each of which is a collection of brain voxels. It forms a 2D symmetric matrix with dimension 116×116, which corresponds to 116 regions-of-interest under the commonly used Anatomical Automatic Labeling (AAL) atlas (Tzourio-Mazoyer et al., 2002). We applied our STORE method to this 2D symmetric matrix response. As none of those competing methods incorporates the symmetry, we chose not to apply them in this analysis.

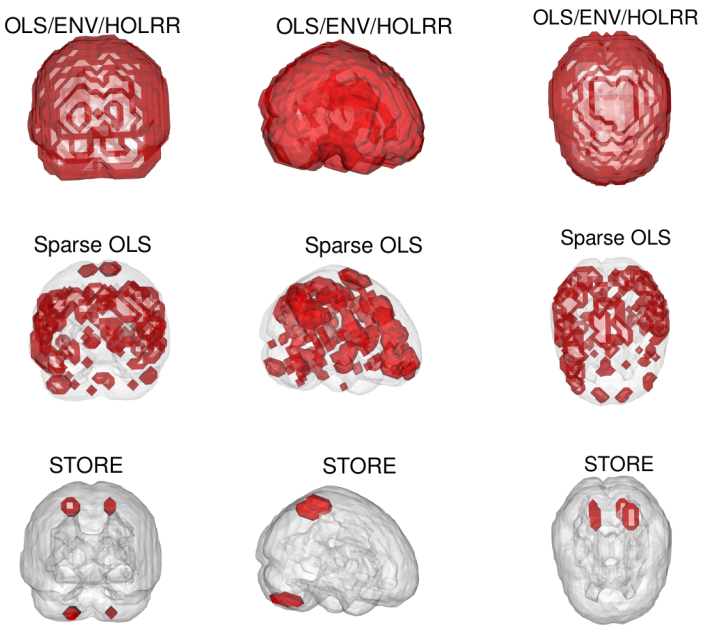

Figure 3: Analysis of the ABIDE data. The response is a 3D brain image tensor. Shown are the estimated coefficient tensor overlaid on a randomly selected brain image. Top row: OLS/ENV/HOLRR, middle row: Sparse OLS, bottom row: STORE. Left column: front view, middle column: side view, right column: top view.

Figure 4 reports top 20 identified links from our method. The red links correspond to those that are more likely to be absent in the ASD group, whereas the black ones are those more likely to be present in ASD. Table 4 reports the names of those links and their relative connection strengthens in the network, as reflected by the corresponding entries in the matrix coefficient $\widehat{\mathcal{B}}$. Many different connectivity patterns concentrate on the left middle frontal gyrus (`Frontal_Mid_L`) and the temporal lobe (`Temporal`), and such findings again agrees with the literature (Kana et al., 2006; Di Martino et al., 2014; Ha et al., 2015).

Acknowledgments

We would like to thank the Action Editor Animashree Anandkumar and the anonymous referees for helpful comments on an earlier manuscript. Li's research was partially supported by NSF grant DMS-1613137 and NIH grant AG034570.

Appendix A.

We divide the appendix into three parts. First we begin with a number of auxiliary lemmas. Next we provide detailed proofs of the main theorem. Then we present the technical proofs of all lemmas and corollaries.

A1 Auxiliary Lemmas

Lemma 9 *For any matrix $\mathbf{Y}_i \in \mathbb{R}^{d_1 \times d_2}$, with $i = 1, \ldots, n$, and vectors $\gamma = (\gamma_1, \ldots, \gamma_n)^\top \in \mathbb{R}^n$, $\alpha \in \mathbb{R}^{d_1}$ and $\beta \in \mathbb{R}^{d_2}$, we have*

$$\arg \min_{\beta, \|\beta\|_2=1} \frac{1}{n} \sum_{i=1}^n \gamma_i^2 \left\| \mathbf{Y}_i - \alpha\beta^\top \right\|_F^2 = \arg \min_{\beta, \|\beta\|_2=1} \left\| \frac{1}{n} \sum_{i=1}^n \gamma_i^2 \mathbf{Y}_i - \alpha\beta^\top \right\|_F^2.$$

The proof of Lemma 9 is provided in Section A3.3 in the online supplement.

We next introduce the Slepian's lemma (Slepian, 1962), which provides a comparison between the supremums of two Gaussian processes.

Lemma 10 *(Slepian, 1962, Slepian's Lemma) Denote two centered Gaussian processes $\{G_s, s \in \mathcal{S}\}$ and $\{H_s, s \in \mathcal{S}\}$. Assume that both processes are almost surely bounded and for each $s, t \in \mathcal{S}$, $\mathbb{E}(G_s - G_t)^2 \leq E(H_s - H_t)^2$, then we have*

$$\mathbb{E}\left[\sup_{s \in \mathcal{S}} G_s\right] \leq \mathbb{E}\left[\sup_{s \in \mathcal{S}} H_s\right].$$

Moreover, if $\mathbb{E}(G_s^2) = E(H_s^2)$ for all $s \in \mathcal{S}$, then we have, for each $x > 0$,

$$\mathbb{P}\left[\sup_{s \in \mathcal{S}} G_s > x\right] \leq \mathbb{P}\left[\sup_{s \in \mathcal{S}} H_s > x\right].$$

The next result provides a concentration of Lipschitz functions of Gaussian random variables (Massart, 2003) .

Lemma 11 *(Massart, 2003, Theorem 3.4) Let $\mathbf{v} \in \mathbb{R}^d$ be a Gaussian random variable such that $\mathbf{v} \sim N(0, \mathbf{I}_d)$. Assuming $g(\mathbf{v}) \in \mathbb{R}$ to be a Lipschitz function such that $|g(\mathbf{v}_1) - g(\mathbf{v}_2)| \leq L\|\mathbf{v}_1 - \mathbf{v}_2\|_2$ for any $\mathbf{v}_1, \mathbf{v}_2 \in \mathbb{R}^d$, then we have, for each $t > 0$,*

$$\mathbb{P}\left[|g(\mathbf{v}) - \mathbb{E}[g(\mathbf{v})]| \geq t\right] \leq 2 \exp\left(-\frac{t^2}{2L^2}\right).$$

The next lemma provides an upper bound of the Gaussian width of the unit ball for the sparsity regularizer (Raskutti and Yuan, 2016).

Lemma 12 *(Raskutti and Yuan, 2016, Lemma 2) For a tensor $\mathcal{T} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$, denote its regularizer $R(\mathcal{T}) = \sum_{j_1} \sum_{j_2} \sum_{j_3} |\mathcal{T}_{j_1, j_2, j_3}|$. Define the unit ball of this regularizer as $B_R(1) := \{\mathcal{T} \in \mathbb{R}^{d_1 \times d_2 \times d_3} | R(\mathcal{T}) \leq 1\}$. For a Gaussian tensor $\mathcal{G} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ whose entries are independent standard normal random variables, we have*

$$\mathbb{E}\left[\sup_{\mathcal{T} \in B_R(1)} \langle \mathcal{T}, \mathcal{G} \rangle\right] \leq c\sqrt{\log(d_1 d_2 d_3)},$$

for some bounded constant $c > 0$.

The next lemma links the hard thresholding sparsity and the L_1-penalized sparsity.

Lemma 13 *For any vectors $\mathbf{u} \in \mathbb{R}^{d_1}, \mathbf{v} \in \mathbb{R}^{d_2}, \mathbf{w} \in \mathbb{R}^{d_3}$ satisfying $\|\mathbf{u}\|_2 = \|\mathbf{v}\|_2 = \|\mathbf{w}\|_2 = 1$, $\|\mathbf{u}\|_0 \leq s, \|\mathbf{v}\|_0 \leq s$, and $\|\mathbf{w}\|_0 \leq s$, denoting $\mathcal{A} := \mathbf{u} \circ \mathbf{v} \circ \mathbf{w}$, we have the bound of the L_1-norm regularizer*

$$\|\mathcal{A}\|_1 := \sum_{j_1} \sum_{j_2} \sum_{j_3} |\mathcal{A}_{j_1 j_2 j_3}| \leq s^{3/2}.$$

A2 Proof of Theorem 6

We divide the proof of Theorem 6 into two major steps: characterization of the estimation error in Step 1 in Algorithm 1, then the estimation error in Step 2. Each leads to a new theorem. Then we complete the proof of Theorem 6 by iteratively applying those results.

A2.1 Estimation Error in Step 1 of Algorithm 1

We first derive the estimation error in Step 1 of our Algorithm 1. The key idea is to transform the problem into a standard sparse tensor decomposition problem, then incorporate the existing contracting results obtained in Sun et al. (2017) to derive the final error bound of the estimator in Step 1. In the following derivation, for simplicity, we assume $K = 1$. This does not lose generality, since K is assumed to be a constant, and it does not affect the final error rate. In this case, the true model reduces to $\mathcal{Y}_i = w^*(\boldsymbol{\beta}_{k,m+1}^{*\top} \mathbf{x}_i) \boldsymbol{\beta}_{k,1}^* \circ \cdots \circ \boldsymbol{\beta}_{k,m}^* + \mathcal{E}_i$, for each $i = 1, \ldots, n$. Based on the Step 1 of our algorithm, if the true parameter $\boldsymbol{\beta}_{k,m+1}^*$ is available, we are solving the following sparse tensor decomposition problem,

$$\bar{\mathcal{R}}_k = \mathcal{T} + \bar{\mathcal{E}}, \tag{A1}$$

where the true tensor $\mathcal{T} = w_k^* \boldsymbol{\beta}_{k,1}^* \circ \cdots \circ \boldsymbol{\beta}_{k,m}^*$, the oracle response and the oracle error are, respectively,

$$\bar{\mathcal{R}}_k := \frac{1}{n} \sum_{i=1}^n \mathcal{R}_{ik} = \frac{1}{n} \sum_{i=1}^n \frac{\mathcal{Y}_i}{\boldsymbol{\beta}_{k,m+1}^{*\top} \mathbf{x}_i} \text{ and } \bar{\mathcal{E}} = \frac{1}{n} \sum_{i=1}^n \frac{\mathcal{E}_i}{\boldsymbol{\beta}_{k,m+1}^{*\top} \mathbf{x}_i}.$$

In practice, however, we only have an estimator $\widehat{\boldsymbol{\beta}}_{k,m+1}$. Hence the sparse tensor decomposition method in Step 1 of our algorithm is actually applied to

$$\widehat{\mathcal{R}}_k = \mathcal{T} + \widehat{\mathcal{E}} \tag{A2}$$

with the response tensor

$$\widehat{\mathcal{R}}_k := \frac{1}{n} \sum_{i=1}^n \frac{\mathcal{Y}_i}{\widehat{\boldsymbol{\beta}}_{k,m+1}^\top \mathbf{x}_i}$$

Therefore, according to $(A1)$ and $(A2)$, we have the explicit form of $\widehat{\mathcal{E}}$,

$$\begin{aligned} \widehat{\mathcal{E}} &= \widehat{\mathcal{R}}_k - \bar{\mathcal{R}}_k + \bar{\mathcal{E}} \\ &= \underbrace{\frac{1}{n} \sum_{i=1}^n \frac{(\boldsymbol{\beta}_{k,m+1}^* - \widehat{\boldsymbol{\beta}}_{k,m+1})^\top \mathbf{x}_i}{\widehat{\boldsymbol{\beta}}_{k,m+1}^\top \mathbf{x}_i \boldsymbol{\beta}_{k,m+1}^{*\top} \mathbf{x}_i} \mathcal{Y}_i}_{I_1} + \underbrace{\frac{1}{n} \sum_{i=1}^n \frac{\mathcal{E}_i}{\boldsymbol{\beta}_{k,m+1}^{*\top} \mathbf{x}_i}}_{I_2} \end{aligned} \tag{A3}$$

Before we derive the estimation error of the estimator based on $(A2)$, we introduce a lemma for deriving the error bound of a general sparse tensor decomposition.

Assumption 14 *The decomposition components are incoherent such that*

$$\zeta := \max_{i\neq j}\{|\langle \boldsymbol{\beta}^*_{i,1}, \boldsymbol{\beta}^*_{j,1}\rangle|, |\langle \boldsymbol{\beta}^*_{i,2}, \boldsymbol{\beta}^*_{j,2}\rangle|, |\langle \boldsymbol{\beta}^*_{i,3}, \boldsymbol{\beta}^*_{j,3}\rangle|\} \leq \frac{C_0}{\sqrt{d_0}},$$

with $d_0 = \max\{d_{01}, d_{02}, d_{03}\}$*, and for any* j*,* $\|\sum_{i\neq j} w_i \langle \boldsymbol{\beta}^*_{i,1}, \boldsymbol{\beta}^*_{j,1}\rangle \langle \boldsymbol{\beta}^*_{i,2}, \boldsymbol{\beta}^*_{j,2}\rangle \boldsymbol{\beta}^*_{i,3}\| \leq C_1 w^*_{\max}\sqrt{K}\zeta$*. Moreover, the matrices* $\mathbf{A} := [\boldsymbol{\beta}^*_{i,1}, \cdots, \boldsymbol{\beta}^*_{K,1}]$*,* $\mathbf{B} := [\boldsymbol{\beta}^*_{i,2}, \cdots, \boldsymbol{\beta}^*_{K,2}]$*, and* $\mathbf{C} := [\boldsymbol{\beta}^*_{i,3}, \cdots, \boldsymbol{\beta}^*_{K,3}]$ *satisfy that* $\max\{\|\mathbf{A}\|, \|\mathbf{B}\|, \|\mathbf{C}\|\} \leq 1 + C_2\sqrt{K/d_0}$ *for some positive constants* C_0, C_1, C_2*.*

Define a function $f(\epsilon; K, d_0)$ as

$$f(\epsilon; K, d_0) := \frac{2C_0}{\sqrt{d_0}}\Big(1 + C_2\sqrt{\frac{K}{d_0}}\Big)^2\epsilon + C_1\frac{\sqrt{K}}{d_0} + C_3\epsilon^2,$$

for some constants $C_0, C_1, C_2, C_3 > 0$. When $K = o(d_0^{3/2})$, the first two terms of $f(\epsilon; K, d_0)$ converge to 0 and the last term is the contracting term.

Lemma 15 *(Sun et al., 2017, Lemma S.4.1) Consider the model* $\widehat{\mathcal{T}} = \mathcal{T} + \mathcal{E}$ *where the low-rank and sparse components of* $\mathcal{T}$ *satisfy Assumption 14, and assume* $\|\mathcal{T}\| \leq C_3 w^*_{\max}$ *and* $K = o(d_0^{3/2})$*. In addition, assume the estimators* $\widehat{\boldsymbol{\beta}}_{j,1}$ *and* $\widehat{\boldsymbol{\beta}}_{j,2}$ *satisfy* $D(\widehat{\boldsymbol{\beta}}_{j,1}, \boldsymbol{\beta}^*_{j,1}) \leq \epsilon$ *and* $D(\widehat{\boldsymbol{\beta}}_{j,2}, \boldsymbol{\beta}^*_{j,2}) \leq \epsilon$ *for some* $j \in [K]$*. If the perturbation error* $\eta(\mathcal{E}, d_0 + s)$*, with* $s \geq d_0$*, is small enough such that* $\eta(\mathcal{E}, d_0 + s) < w_j(1-\epsilon^2) - w^*_{\max} f(\epsilon; K, d_0)$*, then the update* $\widehat{\boldsymbol{\beta}}_{j,3}$ *satisfies, with high probability,*

$$D(\widehat{\boldsymbol{\beta}}_{j,3}, \boldsymbol{\beta}^*_{j,3}) \leq \frac{\sqrt{5}w^*_{\max} f(\epsilon; K, d_0) + \sqrt{5}\eta(\mathcal{E}, d_0 + s)}{w_j(1-\epsilon^2) - w^*_{\max} f(\epsilon; K, d_0) - \eta(\mathcal{E}, d_0 + s)}.$$

If we further assume $D(\widehat{\boldsymbol{\beta}}_{j,3}, \boldsymbol{\beta}^*_{j,3}) \leq \epsilon$*, then the update* $\widehat{w} = \widehat{\mathcal{T}} \times_1 \widehat{\boldsymbol{\beta}}_{j,1} \times_2 \widehat{\boldsymbol{\beta}}_{j,2} \times_3 \widehat{\boldsymbol{\beta}}_{j,3}$ *satisfies, with high probability,* $|\widehat{w} - w_j| \leq 2w_j\epsilon^2 + w^*_{\max} f(\epsilon; K, d_0) + \eta(\mathcal{E}, d_0 + s)$*.*

By verifying the conditions in Lemma 15, we are able to compute the estimation error in Step 1 of our algorithm. For simplicity, we consider the case when $m = 3$, while the extension to a more general m is straightforward.

Lemma 16 *Assume* $\|\mathcal{T}\| \leq C_1 w^*_{\max}$*,* $D(\widehat{\boldsymbol{\beta}}_{k,1}, \boldsymbol{\beta}^*_{k,1}) \leq \epsilon$*,* $D(\widehat{\boldsymbol{\beta}}_{k,2}, \boldsymbol{\beta}^*_{k,2}) \leq \epsilon$*, and*

$$\epsilon < \min\left\{\sqrt{\frac{w^*_{\min}}{2(w^*_{\min} + w^*_{\max}C_1)}}, \frac{w^*_{\min}}{4\sqrt{5}w^*_{\max}C_1}\right\}.$$

Assume the error tensor satisfies $\eta(\widehat{\mathcal{E}}, d_0 + s) \leq w^*_{\min}/4$ *with* $s \geq d_0$*, where* $\widehat{\mathcal{E}}$ *is as defined in* $(A3)$*. Then we have*

$$D(\widehat{\boldsymbol{\beta}}_{k,3}, \boldsymbol{\beta}^*_{k,3}) \leq \kappa_1\epsilon + \frac{4\sqrt{5}}{w^*_{\min}}\eta(\widehat{\mathcal{E}}, d_0 + s),$$

where the contraction coefficient

$$\kappa_1 := \frac{4\sqrt{5}w^*_{\max}C_1}{w^*_{\min}}\epsilon < \frac{4\sqrt{5}w^*_{\max}C_1}{w^*_{\min}}\min\left\{\sqrt{\frac{w^*_{\min}}{2(w^*_{\min} + w^*_{\max}C_1)}}, \frac{w^*_{\min}}{4\sqrt{5}w^*_{\max}C_1}\right\} \in (0,1).$$

The proof of Lemma 16 is provided in Section A3.5. Based on Lemma 16, to compute the closed-form error rate in Step 1 of our Algorithm, the remaining step is to compute $\eta(\widehat{\mathcal{E}}, s)$, since $\eta(\widehat{\mathcal{E}}, d_0 + s) \leq 2\eta(\widehat{\mathcal{E}}, s)$ by noting that $s \geq d_0$. Here the explicit form of $\widehat{\mathcal{E}}$ is defined in $(A3)$. Again we only consider $m = 3$ for simplicity, and the proof for a general m follows straightforwardly.

Lemma 17 *Assume the conditions in Lemma 16 hold. Assume that* $\|w^*_k \boldsymbol{\beta}^*_{k,1} \circ \cdots \circ \boldsymbol{\beta}^*_{k,m}\| \leq C_1$*,* $\|\mathbf{x}_i\| \leq C_2$*, and* $|\boldsymbol{\beta}^{*\top}_{k,m+1}\mathbf{x}_i| \geq C_3$ *for each* $i = 1, \ldots, n$*, for some positive constants* C_1, C_2, C_3*. If* $\epsilon \leq C_3/(2C_2)$*, then we have*

$$\eta(\widehat{\mathcal{E}}, s) \leq \underbrace{\frac{2C_2\eta\left(\bar{\mathcal{E}}, s\right)}{C_3^2}}_{\kappa_2}\epsilon + \frac{1}{C_3}\eta\left(\bar{\mathcal{E}}, s\right).$$

where $\bar{\mathcal{E}} := \frac{1}{n}\sum_{i=1}^n \mathcal{E}_i$*.*

The proof of Lemma 17 is provided in Section A3.6. Combining Lemma 16 and Lemma 17, we obtain the final contraction result of Step 1 in Algorithm 1.

Theorem 18 *(Contraction result in Step 1 in Algorithm 1) Assume* $D(\widehat{\boldsymbol{\beta}}_{k,1}, \boldsymbol{\beta}^*_{k,1}) \leq \epsilon$*,* $D(\widehat{\boldsymbol{\beta}}_{k,2}, \boldsymbol{\beta}^*_{k,2}) \leq \epsilon$*, and* $D(\widehat{\boldsymbol{\beta}}_{k,4}, \boldsymbol{\beta}^*_{k,4}) \leq \epsilon$*, with*

$$\epsilon < \min\left\{\sqrt{\frac{w^*_{\min}}{2(w^*_{\min} + w^*_{\max}C_1)}}, \frac{w^*_{\min}}{4\sqrt{5}w^*_{\max}C_1}, \frac{C_3}{2C_2}\right\}.$$

Assume the error tensor satisfies $\eta(n^{-1}\sum_{i=1}^n \mathcal{E}_i, d_0 + s) \leq w^*_{\min}/4$ *with* $s \geq d_0$*. Then we have*

$$D(\widehat{\boldsymbol{\beta}}_{k,3}, \boldsymbol{\beta}^*_{k,3}) \leq (\kappa_1 + \kappa_2)\epsilon + \frac{4\sqrt{5}}{C_3 w^*_{\min}}\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right).$$

A2.2 Estimation Error in Step 2 of Algorithm 1

Next we derive the estimation error in Step 2 of our algorithm. That is, we aim to bound $D(\widehat{\boldsymbol{\beta}}_{k,m+1}, \boldsymbol{\beta}^*_{k,m+1})$ given the estimators $\widehat{w}_k, \widehat{\boldsymbol{\beta}}_{k,1}, \ldots, \widehat{\boldsymbol{\beta}}_{k,m}$.

Denote $\widehat{\mathcal{A}}_k = \widehat{w}_k\widehat{\boldsymbol{\beta}}_{k,1} \circ \cdots \circ \widehat{\boldsymbol{\beta}}_{k,m}$, and $\widehat{\mathcal{T}}_i = \mathcal{Y}_i - \sum_{k'\neq k, k'\in[K]} \widehat{w}_{k'}(\widehat{\boldsymbol{\beta}}^\top_{k',m+1}\mathbf{x}_i)\widehat{\boldsymbol{\beta}}_{k',1} \circ \cdots \circ \widehat{\boldsymbol{\beta}}_{k',m}$, and the closed-form estimator in Step 2 of our algorithm is

$$\widehat{\boldsymbol{\beta}}_{k,m+1} = \left(\frac{1}{n}\sum_{i=1}^n \mathbf{x}_i\mathbf{x}_i^\top\right)^{-1}\frac{n^{-1}\sum_{i=1}^n \langle \widehat{\mathcal{T}}_i, \widehat{\mathcal{A}}_k\rangle \mathbf{x}_i}{\|\widehat{\mathcal{A}}_k\|_F^2}.$$

Theorem 19 *(Contraction result in Step 2 in Algorithm 1) Under Assumption 3, and the assumption that the initialization error satisfies* $\epsilon \le w^*_{\min}/2$, *if* $|\widehat{w}_k - w^*_k| \le \epsilon$, $D(\widehat{\boldsymbol{\beta}}_{k,1}, \boldsymbol{\beta}^*_{k,1}) \le \epsilon, \ldots, D(\widehat{\boldsymbol{\beta}}_{k,m}, \boldsymbol{\beta}^*_{k,m}) \le \epsilon$, *then we have*

$$D(\widehat{\boldsymbol{\beta}}_{k,m+1}, \boldsymbol{\beta}^*_{k,m+1}) \le \kappa_3 \epsilon + \frac{\widetilde{C}}{\sqrt{n}},$$

where $\kappa_3 := 2/w^*_{\min} + 6\sqrt{2}$ *and* $\widetilde{C}$ *is a positive constant as defined in* (A7).

Proof: For simplicity, we only prove for $K = 1$ and $m = 3$. The derivation for a general K and m follows similarly.

Denote $\mathcal{A}^*_k := w^*_k \boldsymbol{\beta}^*_{k,1} \circ \boldsymbol{\beta}^*_{k,2} \circ \boldsymbol{\beta}^*_{k,3}$. The true model reduces to $\mathcal{Y}_i = (\boldsymbol{\beta}^{*\top}_{k,4}\mathbf{x}_i)\mathcal{A}^*_k + \mathcal{E}_i$, for each $i = 1, \ldots, n$. Denote $\Omega := (n^{-1}\sum_{i=1}^n \mathbf{x}_i\mathbf{x}_i^\top)^{-1}$. Given $\widehat{\mathcal{A}}_k = \widehat{w}_k \widehat{\boldsymbol{\beta}}_{k,1} \circ \cdots \circ \widehat{\boldsymbol{\beta}}_{k,3}$, and $\widehat{\mathcal{T}}_i = \mathcal{Y}_i$ when $K = 1$, we have the following simplification of $\widehat{\boldsymbol{\beta}}_{k,4}$,

$$\begin{aligned}
\widehat{\boldsymbol{\beta}}_{k,4} &= \Omega \frac{\sum_{i=1}^n \langle \widehat{\mathcal{T}}_i, \widehat{\mathcal{A}}_k\rangle \mathbf{x}_i}{n\|\widehat{\mathcal{A}}_k\|_F^2} = \Omega \frac{\sum_{i=1}^n \langle (\boldsymbol{\beta}^{*\top}_{k,4}\mathbf{x}_i)\mathcal{A}^*_k + \mathcal{E}_i, \widehat{\mathcal{A}}_k\rangle \mathbf{x}_i}{n\|\widehat{\mathcal{A}}_k\|_F^2} \\
&= \frac{\langle \mathcal{A}^*_k, \widehat{\mathcal{A}}_k\rangle}{\|\widehat{\mathcal{A}}_k\|_F^2}\boldsymbol{\beta}^*_{k,4} + \frac{\Omega\sum_{i=1}^n \langle \mathcal{E}_i, \widehat{\mathcal{A}}_k\rangle \mathbf{x}_i}{n\|\widehat{\mathcal{A}}_k\|_F^2}, \qquad \text{(A4)}
\end{aligned}$$

where the first part in (A4) is due to the fact that $n^{-1}\sum_{i=1}^n (\boldsymbol{\beta}^{*\top}_{k,4}\mathbf{x}_i)\Omega\mathbf{x}_i = n^{-1}\sum_{i=1}^n \Omega\mathbf{x}_i\mathbf{x}_i^\top\boldsymbol{\beta}^*_{k,4} = \boldsymbol{\beta}^*_{k,4}$. Therefore, the error bound of $\widehat{\boldsymbol{\beta}}_{k,4}$ can be simplified as

$$\begin{aligned}
\left\|\widehat{\boldsymbol{\beta}}_{k,4} - \boldsymbol{\beta}^*_{k,4}\right\|_2 &= \left\| \frac{\langle \mathcal{A}^*_k, \widehat{\mathcal{A}}_k\rangle}{\|\widehat{\mathcal{A}}_k\|_F^2}\boldsymbol{\beta}^*_{k,4} - \boldsymbol{\beta}^*_{k,4} + \frac{\Omega\sum_{i=1}^n \langle \mathcal{E}_i, \widehat{\mathcal{A}}_k\rangle \mathbf{x}_i}{n\|\widehat{\mathcal{A}}_k\|_F^2} \right\|_2, \\
&\le \underbrace{\left| \frac{\langle \mathcal{A}^*_k, \widehat{\mathcal{A}}_k\rangle - \|\widehat{\mathcal{A}}_k\|_F^2}{\|\widehat{\mathcal{A}}_k\|_F^2} \right|}_{(I)} + \underbrace{\frac{\|\Omega\sum_{i=1}^n \langle \mathcal{E}_i, \widehat{\mathcal{A}}_k\rangle \mathbf{x}_i\|_2}{n\|\widehat{\mathcal{A}}_k\|_F^2}}_{(II)}. \qquad \text{(A5)}
\end{aligned}$$

In the following lemma, we bound the two terms in (A5) to obtain the final error bound.

Lemma 20 *Under the Conditions in Theorem 19, we have*

$$\begin{aligned}
(I) &\le \left[\frac{2}{w^*_{\min}} + 6\sqrt{2}\right]\epsilon, \qquad \text{(A6)} \\
(II) &\le \underbrace{\frac{\max_i \|\Omega\mathbf{x}_i\|_2 \cdot \mathbb{E}\left[\|\mathcal{G}\|_F\right]}{\|\widehat{\mathcal{A}}_k\|_F}}_{\widetilde{C}} \cdot \frac{1}{\sqrt{n}}. \qquad \text{(A7)}
\end{aligned}$$

Finally, combining the results in (A6) and (A7) leads to the final bound of $\|\widehat{\boldsymbol{\beta}}_{k,4} - \boldsymbol{\beta}^*_{k,4}\|_2$, and hence the bound of $D(\widehat{\boldsymbol{\beta}}_{k,4}, \boldsymbol{\beta}^*_{k,4})$. □

A2.3 Proof of Theorem 6

Now we complete the proof of Theorem 6, by iteratively applying the contraction results in Theorems 18 and 19 for the two steps of Algorithm 1. In iteration $t = 1$, given the initializations $\widehat{\boldsymbol{\beta}}^{(0)}_{k,j}$ and $\widehat{w}^{(0)}$ with initialization error ϵ, Theorem 18 implies that

$$D(\widehat{\boldsymbol{\beta}}^{(1)}_{k,3}, \boldsymbol{\beta}^*_{k,3}) \le (\kappa_1 + \kappa_2)\epsilon + \frac{4\sqrt{5}}{C_3 w^*_{\min}}\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right),$$

where $\kappa_1 + \kappa_2 < 1$ according to Assumptions 4 and 5. The second term converges to zero as sample size increases. Therefore, for a sufficiently large sample size, the above error bound is smaller than ϵ. By a similar derivation, the same error bound holds for $D(\widehat{\boldsymbol{\beta}}^{(1)}_{k,1}, \boldsymbol{\beta}^*_{k,1})$, $D(\widehat{\boldsymbol{\beta}}^{(1)}_{k,2}, \boldsymbol{\beta}^*_{k,2})$, and $|\widehat{w}^{(1)}_k - w^*_k|$. In Step 2 of the algorithm, applying Theorem 19 based on the above estimators in iteration $t = 1$, we obtain that

$$D(\widehat{\boldsymbol{\beta}}^{(1)}_{k,4}, \boldsymbol{\beta}^*_{k,4}) \le \kappa_3(\kappa_1 + \kappa_2)\epsilon + \kappa_3\frac{4\sqrt{5}}{C_3 w^*_{\min}}\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right) + \frac{\widetilde{C}}{\sqrt{n}}.$$

Again, the contraction coefficient $\kappa_3(\kappa_1 + \kappa_2) < 1$ according to Assumptions 4 and 5, and the remaining term converges to zero as sample size increases. For $\kappa = (\kappa_1 + \kappa_2)\kappa_3 \in (0, 1)$, by repeatedly applying these derivations, in the t iteration, we obtain that

$$\begin{aligned}
&\max\left\{\max_k \|\widehat{w}^{(t)}_k - w^*_k\|_2, \max_{k,j}\left\{\|\widehat{\boldsymbol{\beta}}^{(t)}_{k,j} - \boldsymbol{\beta}^*_{k,j}\|_2\right\}\right\} \\
\le\ & \kappa^t\epsilon + \frac{1-\kappa^t}{1-\kappa}\frac{4\sqrt{5}}{C_3 w^*_{\min}}\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right) + \frac{1-\kappa^{t-1}}{1-\kappa}\frac{\widetilde{C}}{\sqrt{n}} \\
\le\ & \kappa^t\epsilon + \frac{1}{1-\kappa}\max\left\{\frac{4\sqrt{5}}{C_3 w^*_{\min}}\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right), \frac{\widetilde{C}}{\sqrt{n}}\right\}.
\end{aligned}$$

This completes the proof of Theorem 6. □

A3 Proofs of Lemmas and Corollaries

This subsection provides all the supporting lemmas and corollaries as well as their proofs.

A3.1 Proof of Lemma 1

To solve (4), we can use the alternating updating method to update one parameter at a time. In particular, for each $j = 1, \ldots, m$, given $\beta^{(j')}_k$ with $j' \ne j$, we solve

$$\widehat{\beta}_{k,j} := \arg \min_{\substack{\beta_{k,j} \\ \|\beta_{k,j}\|_2 = 1, \|\beta_{k,j}\|_0 \le s_j}} \frac{1}{n}\sum_{i=1}^n \alpha_{ik}^2 \left\|\mathcal{R}_i - w_k \beta_{k,1} \circ \cdots \circ \beta_{k,m}\right\|_F^2.$$

According to the matrix representation of tensor operations (Kolda and Bader, 2009; Kim et al., 2014), this optimization problem is equivalent to solve

$$\min_{\substack{\beta_{k,j} \\ \|\beta_{k,j}\|_2 = 1, \|\beta_{k,j}\|_0 \le s_j}} \frac{1}{n}\sum_{i=1}^n \alpha_{ik}^2 \left\|[\mathcal{R}_i]^\top_{(j)} - \mathbf{h}^{(j)}_k \beta^{(j)\top}_k\right\|_F^2, \qquad \text{(A8)}$$

where $[\mathcal{R}_i]_{(j)}$ is the mode-j matricization of the tensor $\mathcal{R}_i$, and

$$\mathbf{h}_k^{(j)} := \beta_{k,m} \odot \cdots \odot \beta_k^{(j+1)} \odot \beta_k^{(j-1)} \odot \cdots \odot \beta_{k,1} \in \mathbb{R}^{\prod_{j' \neq j} d_{j'}}$$

with $\odot$ the Khatri-Rao product. According to Lemma 9, we can conclude that the minimizer of $(A8)$ is also the solution of

$$\min_{\substack{\beta_{k,j} \\ \|\beta_{k,j}\|_2=1, \|\beta_{k,j}\|_0 \leq s_j}} \Big\| [\frac{1}{n} \sum_{i=1}^n \alpha_{ik}^2 \mathcal{R}_i]_{(j)}^\top - \mathbf{h}_k^{(j)} \beta_k^{(j)\top} \Big\|_F^2.$$

This is equivalent to solve

$$\min_{\substack{\beta_{k,j} \\ \|\beta_{k,j}\|_2=1, \|\beta_{k,j}\|_0 \leq s_j}} \Big\| \frac{1}{n} \sum_{i=1}^n \alpha_{ik}^2 \mathcal{R}_i - w_k \beta_{k,1} \circ \cdots \circ \beta_{k,m} \Big\|_F^2.$$

given other parameters $\beta_k^{(j')}$ with $j' \neq j$. Finally, simple algebra leads to the estimator $\widehat{w}_k$. This proves the desirable result in Lemma 1. □

A3.2 Proof of Lemma 2

Denote $[t_i]_{i_1,\ldots,i_m}$ as the $(i_1,\ldots,i_m)$-th entry of the tensor $\mathcal{T}_i$, and denote $a_{i_1,\ldots,i_m}$ as the $(i_1,\ldots,i_m)$-th entry of the tensor $\mathcal{A}_k$. By the definition of the tensor Frobenius norm, we have

$$\frac{\partial \frac{1}{n} \sum_{i=1}^n \Big\| \mathcal{T}_i - \alpha^\top \mathbf{x}_i \mathcal{A}_k \Big\|_F^2}{\partial \alpha} = \frac{1}{n} \sum_{i=1}^n \sum_{i_1,\ldots,i_m} 2([t_i]_{i_1,\ldots,i_m} - \alpha^\top \mathbf{x}_i a_{i_1,\ldots,i_m})(-a_{i_1,\ldots,i_m} \mathbf{x}_i).$$

Setting the above gradient to zero implies that

$$\frac{1}{n} \sum_{i=1}^n \{ \sum_{i_1,\ldots,i_m} [t_i]_{i_1,\ldots,i_m} a_{i_1,\ldots,i_m} \} \mathbf{x}_i = \frac{1}{n} \sum_{i=1}^n \sum_{i_1,\ldots,i_m} \alpha^\top \mathbf{x}_i a_{i_1,\ldots,i_m}^2 \mathbf{x}_i,$$

where the left-hand-side equals $n^{-1} \sum_{i=1}^n \|\mathcal{T}_i * \mathcal{A}_k\|_+ \mathbf{x}_i$, and the right-hand-side equals

$$\{ \sum_{i_1,\ldots,i_m} a_{i_1,\ldots,i_m}^2 \} \frac{1}{n} \sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i^\top \alpha = \|\mathcal{A}_k\|_F^2 \frac{1}{n} \sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i^\top \alpha.$$

This proves the desirable conclusion in Lemma 2. □

A3.3 Proof of Lemma 9

We first derive the solution of

$$\arg\min_\beta \frac{1}{n} \sum_{i=1}^n \gamma_i^2 \Big\| \mathbf{Y}_i - \alpha \beta^\top \Big\|_F^2,$$

and then connect it with the optimization problem on the right-hand-side. Denote $[\mathbf{Y}_i]_{sj} \in \mathbb{R}$ as the (s,j)-th entry of the matrix $\mathbf{Y}_i$, and denote $[\mathbf{Y}_i]_j \in \mathbb{R}^{d_1}$ as the j-th column of the matrix $\mathbf{Y}_i$. Note that, for each $j = 1,\ldots,d_2$, solving

$$\frac{\partial \frac{1}{n} \sum_{i=1}^n \gamma_i^2 \Big\| \mathbf{Y}_i - \alpha \beta^\top \Big\|_F^2}{\partial \beta_j} = \frac{1}{n} \sum_{i=1}^n \sum_{s=1}^{d_1} 2\gamma_i^2 ([\mathbf{Y}_i]_{sj} - \alpha_s \beta_j)(-\alpha_s) = 0$$

leads to the solution

$$\widehat{\beta}_j = \frac{\frac{1}{n} \sum_{i=1}^n \sum_{s=1}^{d_1} \gamma_i^2 [\mathbf{Y}_i]_{sj} \alpha_s}{\frac{1}{n} \sum_{i=1}^n \gamma_i^2 \sum_{s=1}^{d_1} \alpha_s^2} = \frac{\frac{1}{n} \sum_{i=1}^n \gamma_i^2 [\mathbf{Y}_i]_j^\top \alpha}{(\frac{1}{n} \sum_{i=1}^n \gamma_i^2) \alpha^\top \alpha}.$$

The solution $\widehat{\beta} = (\widehat{\beta}_1,\ldots,\widehat{\beta}_{d_2})^\top$ is indeed a minimizer to the original optimization problem by noting that the second order derivative of β_j is positive. By solving a similar equation, we get the minimizer of the optimization problem $\min_{\beta_j} \big\| \frac{1}{n} \sum_{i=1}^n \mathbf{Y}_i - \alpha \beta^\top \big\|_F^2$ as

$$\widetilde{\beta}_j = \frac{\frac{1}{n} \sum_{i=1}^n \gamma_i^2 [\mathbf{Y}_i]_j^\top \alpha}{\alpha^\top \alpha}.$$

Note that $\widehat{\beta}_j$ equals to $\widetilde{\beta}_j$ up to a constant $n^{-1} \sum_{i=1}^n \gamma_i^2$. Therefore, normalizing $\widehat{\beta}_j$ and $\widetilde{\beta}_j$ to unit norm leads to the same solution. This completes the proof of Lemma 9. □

A3.4 Proof of Lemma 13

According to the Cauchy-Schwarz inequality, we have $\|\mathbf{u}\|_1 \leq \sqrt{s}\|\mathbf{u}\|_2 = \sqrt{s}$, and $\|\mathbf{v}\|_1 \leq \sqrt{s}$, $\|\mathbf{w}\|_1 \leq \sqrt{s}$. Therefore, $\|\mathcal{A}\|_1 = \|\mathbf{u} \circ \mathbf{v} \circ \mathbf{w}\|_1 \leq \|\mathbf{u}\|_1 \cdot \|\mathbf{v}\|_1 \cdot \|\mathbf{w}\|_1 \leq s^{3/2}$. □

A3.5 Proof of Lemma 16

The key step is to verify the conditions in Lemma 15. In our example, the incoherence condition, Assumption 14, trivially holds, since the incoherence parameter $\zeta = 0$. Therefore, the function $f(\epsilon; K, d_0) = C_3 \epsilon^2$ in our example. According to Lemma 15, we have

$$D(\widehat{\boldsymbol{\beta}}_{k,3}, \boldsymbol{\beta}_{k,3}^*) \leq \frac{\sqrt{5} w_{\max}^* C_3 \epsilon^2 + \sqrt{5} \eta(\widehat{\mathcal{E}}, d_0 + s)}{w_j(1-\epsilon^2) - w_{\max}^* C_3 \epsilon^2 - \eta(\widehat{\mathcal{E}}, d_0 + s)}.$$

We next simplify the denominator $w_j(1-\epsilon^2) - w_{\max}^* C_3 \epsilon^2 - \eta(\widehat{\mathcal{E}}, d_0+s)$. By the assumption on ϵ, we have

$$w_j(1-\epsilon^2) - w_{\max}^* C_3 \epsilon^2 \geq w_{\min}^*/2,$$

which, together with the condition on the error tensor $\eta(\widehat{\mathcal{E}}, d_0 + s)$, implies that

$$w_j(1-\epsilon^2) - w_{\max}^* C_3 \epsilon^2 - \eta(\widehat{\mathcal{E}}, d_0 + s) \geq w_{\min}^*/4.$$

Therefore, we have

$$D(\widehat{\boldsymbol{\beta}}_{k,3}, \boldsymbol{\beta}_{k,3}^*) \leq \frac{4\sqrt{5} w_{\max}^* C_3}{w_{\min}^*} \epsilon^2 + \frac{4\sqrt{5}}{w_{\min}^*} \eta(\widehat{\mathcal{E}}, d_0 + s),$$

which completes the proof of Lemma 16. □

A3.6 Proof of Lemma 17

According to the explicit form in $(A3)$, we have

$$\eta(\widehat{\mathcal{E}}, s) \leq \eta(I_1, s) + \eta(I_2, s).$$

Next we bound the two terms $\eta(I_1, s)$ and $\eta(I_2, s)$ separately.

Bound $\eta(I_1, s)$: Denote $\mathbb{S}_q^d = \{\mathbf{v} \in \mathbb{R}^d \,|\, \|\mathbf{v}\|_2 = 1, \|\mathbf{v}\|_0 \leq q\}$. According to the definiteness of $\eta(\cdot)$, we have

$$\begin{aligned}\eta(I_1, s) &= \sup_{\mathbf{u}\in\mathbb{S}_s^{d_1},\mathbf{v}\in\mathbb{S}_s^{d_2},\mathbf{w}\in\mathbb{S}_s^{d_3}} |I_1 \times_1 \mathbf{u} \times_2 \mathbf{v} \times_3 \mathbf{w}| \\ &\leq \max_i \left|\frac{(\boldsymbol{\beta}_{k,4}^* - \widehat{\boldsymbol{\beta}}_{k,4})^\top \mathbf{x}_i}{\widehat{\boldsymbol{\beta}}_{k,4}^\top \mathbf{x}_i \boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i}\right| \sup_{\mathbf{u}\in\mathbb{S}_s^{d_1},\mathbf{v}\in\mathbb{S}_s^{d_2},\mathbf{w}\in\mathbb{S}_s^{d_3}} \left|\left(\frac{1}{n}\sum_{i=1}^n \mathcal{Y}_i\right) \times_1 \mathbf{u} \times_2 \mathbf{v} \times_3 \mathbf{w}\right|.\end{aligned}$$

By the Cauchy Schwarz inequality, we have $\|(\boldsymbol{\beta}_{k,4}^* - \widehat{\boldsymbol{\beta}}_{k,4})^\top \mathbf{x}_i\| \leq \|\boldsymbol{\beta}_{k,4}^* - \widehat{\boldsymbol{\beta}}_{k,4}\|\|\mathbf{x}_i\| \leq C_2\|\boldsymbol{\beta}_{k,4}^* - \widehat{\boldsymbol{\beta}}_{k,4}\| \leq C_2\epsilon$. Moreover, note that $|\widehat{\boldsymbol{\beta}}_{k,4}^\top \mathbf{x}_i \boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i| = |\boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i + (\widehat{\boldsymbol{\beta}}_{k,4} - \boldsymbol{\beta}_{k,4}^*)^\top \mathbf{x}_i||\boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i|$. When the element of $\mathbf{x}_i$ is bounded for each $i = 1, \ldots, n$ and the dimension d_{m+1} of $\mathbf{x}_i$ is fixed, we have $\|\mathbf{x}_i\| \leq C_2$. Then by the assumption that $|\boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i| \geq C_3$ and $\|\mathbf{x}_i\| \leq C_2$, we have

$$|\widehat{\boldsymbol{\beta}}_{k,4}^\top \mathbf{x}_i \boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i| \geq (C_3 - C_2\|\widehat{\boldsymbol{\beta}}_{k,4} - \boldsymbol{\beta}_{k,4}^*\|)C_3 \geq (C_3 - C_2\epsilon)C_3 \geq C_3^2/2,$$

where the last inequality is due to the assumption that $\epsilon \leq C_3/(2C_2)$. Then,

$$\max_i \left|\frac{(\boldsymbol{\beta}_{k,4}^* - \widehat{\boldsymbol{\beta}}_{k,4})^\top \mathbf{x}_i}{\widehat{\boldsymbol{\beta}}_{k,4}^\top \mathbf{x}_i \boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i}\right| \leq \frac{2C_2\epsilon}{C_3^2}.$$

Moreover, according to the true model $\mathcal{Y}_i = w^*(\boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i)\boldsymbol{\beta}_{k,1}^* \circ \boldsymbol{\beta}_{k,2}^* \circ \boldsymbol{\beta}_{k,3}^* + \mathcal{E}_i$,

$$\begin{aligned}&\sup_{\mathbf{u}\in\mathbb{S}_s^{d_1},\mathbf{v}\in\mathbb{S}_s^{d_2},\mathbf{w}\in\mathbb{S}_s^{d_3}} \left|\left(\frac{1}{n}\sum_{i=1}^n \mathcal{Y}_i\right) \times_1 \mathbf{u} \times_2 \mathbf{v} \times_3 \mathbf{w}\right| \\ \leq &\sup_{\mathbf{u}\in\mathbb{S}_s^{d_1},\mathbf{v}\in\mathbb{S}_s^{d_2},\mathbf{w}\in\mathbb{S}_s^{d_3}} \left|\left(w^*\left(\boldsymbol{\beta}_{k,4}^{*\top}\frac{1}{n}\sum_{i=1}^n \mathbf{x}_i\right)\boldsymbol{\beta}_{k,1}^* \circ \boldsymbol{\beta}_{k,2}^* \circ \boldsymbol{\beta}_{k,3}^*\right) \times_1 \mathbf{u} \times_2 \mathbf{v} \times_3 \mathbf{w}\right| + \eta\left(\bar{\mathcal{E}}, s\right) \\ = &\eta\left(\bar{\mathcal{E}}, s\right),\end{aligned}$$

where the last equality is due to the fact that the covariate vector $\mathbf{x}_i$ is centered such that $\frac{1}{n}\sum_{i=1}^n \mathbf{x}_i = \mathbf{0}$. Therefore, we have,

$$\eta(I_1, s) \leq \underbrace{\frac{2C_2\eta\left(\bar{\mathcal{E}}, s\right)}{C_3^2}}_{\kappa_2}\epsilon.$$

Bound $\eta(I_2, s)$: By the assumption that, for each i, $|\boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i| \geq C_3$, we have that $\max_i(|\boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i|)^{-1} \leq 1/C_3$, and hence

$$\begin{aligned}\eta(I_2, s) &= \sup_{\mathbf{u}\in\mathbb{S}_s^{d_1},\mathbf{v}\in\mathbb{S}_s^{d_2},\mathbf{w}\in\mathbb{S}_s^{d_3}} \left|\left(\frac{1}{n}\sum_{i=1}^n \frac{\mathcal{E}_i}{\boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i}\right) \times_1 \mathbf{u} \times_2 \mathbf{v} \times_3 \mathbf{w}\right| \\ &\leq \max_i(|\boldsymbol{\beta}_{k,4}^{*\top} \mathbf{x}_i|)^{-1}\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right) \\ &\leq \frac{1}{C_3}\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right).\end{aligned}$$

Combining the above two results, we obtain the desirable upper bound of $\eta(\widehat{\mathcal{E}}, s)$. □

A3.7 Proof of Lemma 20

Bound (I)**:** For any two tensors $\mathcal{A}, \mathcal{B}$ of the same dimension, the Cauchy-Schwarz inequality implies that $\langle \mathcal{A}, \mathcal{B} \rangle \leq \|\mathcal{A}\|_F\|\mathcal{B}\|_F$. Therefore, we have

$$(I) \leq \frac{\|\widehat{\mathcal{A}}_k - \mathcal{A}_k^*\|_F}{\|\widehat{\mathcal{A}}_k\|_F}.$$

We next simplify the above numerator $\|\widehat{\mathcal{A}}_k - \mathcal{A}_k^*\|_F$. By definition,

$$\begin{aligned}&\|\widehat{\mathcal{A}}_k - \mathcal{A}_k^*\|_F = \left\|\widehat{w}_k\widehat{\boldsymbol{\beta}}_{k,1} \circ \widehat{\boldsymbol{\beta}}_{k,2} \circ \widehat{\boldsymbol{\beta}}_{k,3} - w_k^*\boldsymbol{\beta}_{k,1}^* \circ \boldsymbol{\beta}_{k,2}^* \circ \boldsymbol{\beta}_{k,3}^*\right\|_F \\ \leq &\underbrace{\left\|\widehat{w}_k\widehat{\boldsymbol{\beta}}_{k,1} \circ \widehat{\boldsymbol{\beta}}_{k,2} \circ \widehat{\boldsymbol{\beta}}_{k,3} - w_k^*\widehat{\boldsymbol{\beta}}_{k,1} \circ \widehat{\boldsymbol{\beta}}_{k,2} \circ \widehat{\boldsymbol{\beta}}_{k,3}\right\|_F}_{I_1} \\ + &\underbrace{\left\|w_k^*\widehat{\boldsymbol{\beta}}_{k,1} \circ \widehat{\boldsymbol{\beta}}_{k,2} \circ \widehat{\boldsymbol{\beta}}_{k,3} - w_k^*\boldsymbol{\beta}_{k,1}^* \circ \widehat{\boldsymbol{\beta}}_{k,2} \circ \widehat{\boldsymbol{\beta}}_{k,3}\right\|_F}_{I_2} \\ + &\underbrace{\left\|w_k^*\boldsymbol{\beta}_{k,1}^* \circ \widehat{\boldsymbol{\beta}}_{k,2} \circ \widehat{\boldsymbol{\beta}}_{k,3} - w_k^*\boldsymbol{\beta}_{k,1}^* \circ \boldsymbol{\beta}_{k,2}^* \circ \widehat{\boldsymbol{\beta}}_{k,3}\right\|_F}_{I_3} \\ + &\underbrace{\left\|w_k^*\boldsymbol{\beta}_{k,1}^* \circ \boldsymbol{\beta}_{k,2}^* \circ \widehat{\boldsymbol{\beta}}_{k,3} - w_k^*\boldsymbol{\beta}_{k,1}^* \circ \boldsymbol{\beta}_{k,2}^* \circ \boldsymbol{\beta}_{k,3}^*\right\|_F}_{I_4}.\end{aligned}$$

We next bound each term $I_j/\|\widehat{\mathcal{A}}_k\|_F$ for $j = 1, 2, 3, 4$. First, according to the assumptions $|\widehat{w}_k - w_k^*| \leq \epsilon$ and $\epsilon \leq w_{\min}^*/2$, we have $|\widehat{w}_k| \geq w_k^* - \epsilon \geq w_{\min}^*/2$. Therefore, we have

$$\frac{I_1}{\|\widehat{\mathcal{A}}_k\|_F} = \left|\frac{\widehat{w}_k - w_k^*}{\widehat{w}_k}\right| \leq \frac{\epsilon}{|\widehat{w}_k|} \leq \frac{2}{w_{\min}^*}\epsilon.$$

In addition, note that for any vectors $\mathbf{a} \in \mathbb{R}^m, \mathbf{b} \in \mathbb{R}^n$, since the rank of the matrix $\mathbf{a} \circ \mathbf{b}$ is 1, we have $\|\mathbf{a} \circ \mathbf{b}\|_F = \|\mathbf{a} \circ \mathbf{b}\|_2$. This equality and the fact that $\|\boldsymbol{\beta}_{k,j}^*\|_2 = \|\widehat{\boldsymbol{\beta}}_{k,j}\|_2 = 1$ for

any $j = 1, 2, 3$ imply that

$$\frac{I_2}{\|\widehat{\mathcal{A}}_k\|_F} = \frac{\left\|w_k^*(\widehat{\boldsymbol{\beta}}_{k,1} - \boldsymbol{\beta}_{k,1}^*) \circ \widehat{\boldsymbol{\beta}}_{k,2} \circ \widehat{\boldsymbol{\beta}}_{k,3}\right\|_F}{\left\|\widehat{w}_k \widehat{\boldsymbol{\beta}}_{k,1} \circ \widehat{\boldsymbol{\beta}}_{k,2} \circ \widehat{\boldsymbol{\beta}}_{k,3}\right\|_F} \leq \frac{|w_k^*| \|\widehat{\boldsymbol{\beta}}_{k,1} - \boldsymbol{\beta}_{k,1}^*\|_2}{|\widehat{w}_k|} \leq 2\sqrt{2}\epsilon,$$

where the last inequality is due to the inequality $|\widehat{w}_k| \geq w_{\min}^*/2$ as we show above, as well as the fact that $D(\mathbf{u}, \mathbf{v}) \leq \min\{\|\mathbf{u} - \mathbf{v}\|_2, \|\mathbf{u} + \mathbf{v}\|_2\} \leq \sqrt{2} D(\mathbf{u}, \mathbf{v})$ for unit vectors $\mathbf{u}, \mathbf{v}$. By applying similar proof techniques, we also have

$$\frac{I_3}{\|\widehat{\mathcal{A}}_k\|_F} \leq 2\sqrt{2}\epsilon; \quad \frac{I_4}{\|\widehat{\mathcal{A}}_k\|_F} \leq 2\sqrt{2}\epsilon.$$

Combing the above four inequalities, we obtain the desirable bound for (I) in $(A6)$.

Bound (II)**:** It is easy to see that

$$(II) \leq \frac{\frac{1}{n}\sum_{i=1}^n \langle \mathcal{E}_i, \widehat{\mathcal{A}}_k \rangle \|\Omega \mathbf{x}_i\|_2}{\|\widehat{\mathcal{A}}_k\|_F^2}.$$

According to the assumptions that Ω is positive definite with bounded eigenvalues and $\|\mathbf{x}_i\| \leq C_2$ for each i, we have $\max_i \|\Omega \mathbf{x}_i\|_2$ is bounded by some constant $C_1 > 0$. In addition, according to the Gaussian comparison inequality Lemma 10, as well as the large deviation bound, we have that, with high probability

$$\frac{1}{n}\sum_{i=1}^n \langle \mathcal{E}_i, \widehat{\mathcal{A}}_k \rangle \leq \mathbb{E}\left[\frac{1}{\sqrt{n}} \langle \mathcal{G}, \widehat{\mathcal{A}}_k \rangle\right] \leq \frac{1}{\sqrt{n}} \mathbb{E}\left[\|\mathcal{G}\|_F \|\widehat{\mathcal{A}}_k\|_F\right],$$

for some Gaussian tensor $\mathcal{G} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ whose entries are i.i.d. standard normal random variables. Therefore, we have, with high probability, the desirable inequality in $(A7)$ holds, where the whole term $\widetilde{C}$ is bounded by noting that $\max_i \|\Omega \mathbf{x}_i\|_2$ is bounded and all entries of tensors $\mathcal{G}$, and $\widehat{\mathcal{A}}_k$ of the same dimension are bounded. □

A3.8 Proof of Corollary 7

The derivation of $\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right)$ in the Gaussian error tensor scenario consists of three parts. In Stage 1, we apply Lemma 10 to show that

$$\mathbb{P}\left[\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right) > x\right] \leq \mathbb{P}\left[n^{-1/2}\eta(\mathcal{G}, s) > x\right],$$

for some Gaussian tensor $\mathcal{G}$. In Stage 2, we show via the large deviation bound inequality that

$$\mathbb{P}\left(|\eta(\mathcal{G}, s) - \mathbb{E}[\eta(\mathcal{G}, s)]| \geq t\right) \leq 2\exp\left(-\frac{t^2}{2L^2}\right)$$

with some Lipschitz constant L. In Stage 3, by incorporating Lemma 12, and exploring the sparsity constraint, we can compute

$$\mathbb{E}[\eta(\mathcal{G}, s)]| \leq C\sqrt{s^3 \log(d_1 d_2 d_3)},$$

for some constant $C > 0$.

Stage 1: According to the definition of $\eta(\cdot)$ in (8), we have

$$\begin{aligned}\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right) &= \sup_{\substack{\|\mathbf{u}\|=\|\mathbf{v}\|=\|\mathbf{w}\|=1 \\ \|\mathbf{u}\|_0 \leq s, \|\mathbf{v}\|_0 \leq s, \|\mathbf{w}\|_0 \leq s}} \left|\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i \times_1 \mathbf{u} \times_2 \mathbf{v} \times_3 \mathbf{w}\right| \\ &= \sup_{\substack{\|\mathbf{u}\|=\|\mathbf{v}\|=\|\mathbf{w}\|=1 \\ \|\mathbf{u}\|_0 \leq s, \|\mathbf{v}\|_0 \leq s, \|\mathbf{w}\|_0 \leq s}} \left\langle \frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, \mathbf{u} \circ \mathbf{v} \circ \mathbf{w} \right\rangle.\end{aligned}$$

Clearly, for any unit-norm vectors $\mathbf{u}, \mathbf{v}, \mathbf{w}$, when $\mathcal{E}_i, i = 1, \ldots, n$ are i.i.d. Gaussian tensors, we have

$$\mathbb{E}\left[\left\langle \frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, \mathbf{u} \circ \mathbf{v} \circ \mathbf{w} \right\rangle\right] = 0.$$

Since the variance of each entry of $\mathcal{E}_i$ is 1, we also have

$$\begin{aligned}&\mathrm{var}\left[\left\langle \frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, \mathbf{u} \circ \mathbf{v} \circ \mathbf{w} \right\rangle\right] = \mathrm{var}\left[\frac{1}{n}\sum_{i=1}^n \langle \mathcal{E}_i, \mathbf{u} \circ \mathbf{v} \circ \mathbf{w} \rangle\right] \\ = \;& \frac{1}{n^2}\sum_{i=1}^n \sum_{r,s,t} [\mathbf{u} \circ \mathbf{v} \circ \mathbf{w}]_{r,s,t}^2 \mathrm{var}([\mathcal{E}_i]_{r,s,t}) = \frac{\|\mathbf{u} \circ \mathbf{v} \circ \mathbf{w}\|_F^2}{n}.\end{aligned}$$

For some Gaussian tensor $\mathcal{G}$ of the same dimension as $\mathcal{E}_i$, it is easy to show that

$$\begin{aligned}\mathbb{E}\left[\frac{1}{\sqrt{n}} \langle \mathcal{G}, \mathbf{u} \circ \mathbf{v} \circ \mathbf{w} \rangle\right] &= 0 \\ \mathrm{var}\left[\frac{1}{\sqrt{n}} \langle \mathcal{G}, \mathbf{u} \circ \mathbf{v} \circ \mathbf{w} \rangle\right] &= \frac{\|\mathbf{u} \circ \mathbf{v} \circ \mathbf{w}\|_F^2}{n}.\end{aligned}$$

Moreover, for any $\mathcal{A}_1 := \mathbf{u}_1 \circ \mathbf{v}_1 \circ \mathbf{w}_1$ and $\mathcal{A}_2 := \mathbf{u}_2 \circ \mathbf{v}_2 \circ \mathbf{w}_2$, we have

$$\mathrm{var}\left[\left\langle \frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, \mathcal{A}_1 - \mathcal{A}_2 \right\rangle\right] = \frac{\|\mathcal{A}_1 - \mathcal{A}_2\|_F}{n} = \mathrm{var}\left[\frac{1}{\sqrt{n}} \langle \mathcal{G}, \mathcal{A}_1 - \mathcal{A}_2 \rangle\right].$$

Therefore, according to Lemma 10, we have, for each $x > 0$,

$$\mathbb{P}\left[\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right) > x\right] \leq \mathbb{P}\left[\frac{1}{\sqrt{n}}\eta(\mathcal{G}, s) > x\right]. \tag{A9}$$

Stage 2: We show that the function $\eta(\cdot, s)$ is a Lipschitz function in its first argument. For any two tensors $\mathcal{G}_1, \mathcal{G}_2 \in \mathbb{R}^{d_1 \times d_2 \times d_3}$, denote $\mathcal{A}^* = \sup_{\mathcal{A}} \langle \mathcal{G}_1, \mathcal{A} \rangle$. We have

$$\sup_{\mathcal{A}} \langle \mathcal{G}_1, \mathcal{A} \rangle - \sup_{\mathcal{A}} \langle \mathcal{G}_2, \mathcal{A} \rangle \leq \langle \mathcal{G}_1, \mathcal{A}^* \rangle - \sup_{\mathcal{A}} \langle \mathcal{G}_2, \mathcal{A} \rangle \leq \langle \mathcal{G}_1, \mathcal{A}^* \rangle - \langle \mathcal{G}_2, \mathcal{A}^* \rangle \leq \langle \mathcal{G}_1 - \mathcal{G}_2, \mathcal{A}^* \rangle.$$

Therefore, we have

$$\begin{aligned}
& |\eta(\mathcal{G}_1, s) - \eta(\mathcal{G}_2, s)| \\
= & \sup_{\substack{\|\mathbf{u}\|=\|\mathbf{v}\|=\|\mathbf{w}\|=1 \\ \|\mathbf{u}\|_0\le s, \|\mathbf{v}\|_0\le s, \|\mathbf{w}\|_0\le s}} \left|\mathcal{G}_1 \times_1 \mathbf{u} \times_2 \mathbf{v} \times_3 \mathbf{w}\right| - \sup_{\substack{\|\mathbf{u}\|=\|\mathbf{v}\|=\|\mathbf{w}\|=1 \\ \|\mathbf{u}\|_0\le s, \|\mathbf{v}\|_0\le s, \|\mathbf{w}\|_0\le s}} \left|\mathcal{G}_2 \times_1 \mathbf{u} \times_2 \mathbf{v} \times_3 \mathbf{w}\right| \\
\le & \sup_{\substack{\|\mathbf{u}\|=\|\mathbf{v}\|=\|\mathbf{w}\|=1 \\ \|\mathbf{u}\|_0\le s, \|\mathbf{v}\|_0\le s, \|\mathbf{w}\|_0\le s}} \left\langle \mathcal{G}_1 - \mathcal{G}_2, \mathbf{u}\circ\mathbf{v}\circ\mathbf{w} \right\rangle \\
\le & \sup_{\|\mathbf{u}\|=\|\mathbf{v}\|=\|\mathbf{w}\|=1} \|\mathbf{u}\circ\mathbf{v}\circ\mathbf{w}\|_F \cdot \|\mathcal{G}_1 - \mathcal{G}_2\|_F \\
\le & \|\mathcal{G}_1 - \mathcal{G}_2\|_F,
\end{aligned}$$

where the second inequality is due to the fact that $\langle \mathcal{A}, \mathcal{B}\rangle \le \|\mathcal{A}\|_F \|\mathcal{B}\|_F$, and the third inequality is because $\|\mathbf{u}\circ\mathbf{v}\circ\mathbf{w}\|_F = \|\mathbf{u}\circ\mathbf{v}\circ\mathbf{w}\|_2 \le \|\mathbf{u}\|_2\|\mathbf{v}\|_2\|\mathbf{w}\|_2 = 1$ for any unit-norm vectors $\mathbf{u}, \mathbf{v}, \mathbf{w}$.

Applying the concentration result of Lipschitz functions of Gaussian random variables in Lemma 11 with $L = 1$, for the Gaussian tensor $\mathcal{G}$, we have

$$\mathbb{P}\left(|\eta(\mathcal{G}, s) - \mathbb{E}[\eta(\mathcal{G}, s)]| \ge t\right) \le 2\exp\left(-\frac{t^2}{2}\right). \tag{A10}$$

Stage 3: We aim to bound $\mathbb{E}[\eta(\mathcal{G}, s)]|$. For a tensor $\mathcal{T} \in \mathbb{R}^{d_1\times d_2\times d_3}$, denote its L_1-norm regularizer $R(\mathcal{T}) = \sum_{j_1}\sum_{j_2}\sum_{j_3}|\mathcal{T}_{j_1,j_2,j_3}|$. Define the ball of this regularizer as $B_R(\delta) := \{\mathcal{T} \in \mathbb{R}^{d_1\times d_2\times d_3} | R(\mathcal{T}) \le \delta\}$.

For any vectors $\mathbf{u} \in \mathbb{R}^{d_1}, \mathbf{v} \in \mathbb{R}^{d_2}, \mathbf{w} \in \mathbb{R}^{d_3}$ satisfying $\|\mathbf{u}\|_2 = \|\mathbf{v}\|_2 = \|\mathbf{w}\|_2 = 1$, $\|\mathbf{u}\|_0 \le s, \|\mathbf{v}\|_0 \le s$, and $\|\mathbf{w}\|_0 \le s$, denote $\mathcal{A} := \mathbf{u}\circ\mathbf{v}\circ\mathbf{w}$. Lemma 13 implies that $R(\mathcal{A}) \le s^{3/2}$.

Therefore, we have

$$\begin{aligned}
\mathbb{E}[\eta(\mathcal{G}, s)] &= \mathbb{E}\left[\sup_{\substack{\|\mathbf{u}\|=\|\mathbf{v}\|=\|\mathbf{w}\|=1 \\ \|\mathbf{u}\|_0\le s, \|\mathbf{v}\|_0\le s, \|\mathbf{w}\|_0\le s}} \langle \mathcal{G}, \mathbf{u}\circ\mathbf{v}\circ\mathbf{w}\rangle\right] \\
&\le \mathbb{E}\left[\sup_{\mathcal{A}\in B_R(s^{3/2})} \langle \mathcal{G}, \mathcal{A}\rangle\right] = s^{3/2}\mathbb{E}\left[\sup_{\mathcal{A}\in B_R(1)} \langle \mathcal{G}, \mathcal{A}\rangle\right].
\end{aligned}$$

This result, together with Lemma 12, implies that

$$\mathbb{E}[\eta(\mathcal{G}, s)]| \le C\sqrt{s^3\log(d_1d_2d_3)}. \tag{A11}$$

Finally, combing (A10) and (A11), and setting $t = \sqrt{s^3\log(d_1d_2d_3)}$, we have, with probability $1 - 2\exp(-s^3\log(d_1d_2d_3)/2)$,

$$|\eta(\mathcal{G}, s) - \mathbb{E}[\eta(\mathcal{G}, s)]| \le \sqrt{s^3\log(d_1d_2d_3)}.$$

Henceforth

$$\eta(\mathcal{G}, s) \le (C+1)\sqrt{s^3\log(d_1d_2d_3)},$$

which together with (A9), implies that

$$\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right) = O_p\left(\sqrt{\frac{s^3\log(d_1d_2d_3)}{n}}\right).$$

This completes the proof of Corollary 7. □

A3.9 Proof of Corollary 8

The proof follows by incorporating the result in Lemma 7 and the structure assumption in (12). In particular, Lemma 7 implies that, when $\widetilde{\mathcal{E}}_i \in \mathbb{R}^{d\times d}$ is a matrix whose entries are i.i.d. standard Gaussian,

$$\eta\left(\frac{1}{n}\sum_{i=1}^n \widetilde{\mathcal{E}}_i, s\right) = O_p\left(\sqrt{\frac{s^2\log(d^2)}{n}}\right).$$

Moreover, under the structure assumption in (12), we have

$$\eta\left(\frac{1}{n}\sum_{i=1}^n \mathcal{E}_i, s\right) = \eta\left(\frac{1}{n}\sum_{i=1}^n \widetilde{\mathcal{E}}_i, s\right),$$

which completes the proof of Corollary 8. □

Abstract

Reinforcement learning (RL) techniques optimize the accumulated long-term reward of a suitably chosen reward function. However, designing such a reward function often requires a lot of task-specific prior knowledge. The designer needs to consider different objectives that do not only influence the learned behavior but also the learning progress. To alleviate these issues, preference-based reinforcement learning algorithms (PbRL) have been proposed that can directly learn from an expert's preferences instead of a hand-designed numeric reward. PbRL has gained traction in recent years due to its ability to resolve the reward shaping problem, its ability to learn from non numeric rewards and the possibility to reduce the dependence on expert knowledge. We provide a unified framework for PbRL that describes the task formally and points out the different design principles that affect the evaluation task for the human as well as the computational complexity. The design principles include the type of feedback that is assumed, the representation that is learned to capture the preferences, the optimization problem that has to be solved as well as how the exploration/exploitation problem is tackled. Furthermore, we point out shortcomings of current algorithms, propose open research questions and briefly survey practical tasks that have been solved using PbRL.

Keywords: Reinforcement Learning, Preference Learning, Qualitative Feedback, Markov Decision Process, Policy Search, Temporal Difference Learning, Preference-based Reinforcement Learning

1. Introduction

Due to its solid theoretical foundations, *reinforcement learning* (RL) has become a very attractive tool that has seen many successful applications. It achieved a world first success of machine learning, when TD-Gammon learned to play backgammon (Tesauro, 1995), and its applications which used to focus on games and robotics (Mnih et al., 2015; Kober et al., 2013) now extend to diverse problems in the industrial and medical domain (Wang and Usher, 2005; Zhao et al., 2011). However, the success of reinforcement learning applications often crucially depends on the prior knowledge that is put into the definition of the reward function. Although a reward function is a transferable and compact definition of the learning task, the learned policy may be sensitive to small changes of the reward, possibly yielding very different behaviors, depending on the relative values of the rewards. Thus, the choice of the reward function may have a crucial impact on the success of the learner and many tasks, in particular in robotics, require a high amount of reward-engineering. Four problems are mainly responsible for the difficulties in reward engineering.

(1) Reward Hacking: The agent may maximize the given reward, without performing the intended task (Amodei et al., 2016). For example, consider a robotic vacuum cleaner obtaining a positive reward in case all dirt has been removed. As the robot only observes dirt via camera, it may try to cover up the dirt, effectively removing it from its sensor space

(2) Reward Shaping: In many applications, the reward does not only define the goal but also guides the agent to the correct solution, which is also known as reward shaping (Ng et al., 1999). Striking a balance between the goal definition and the guidance task is also often very difficult for the experimenter.

(3) Infinite rewards: Some applications require infinite rewards, for instance, if certain events should be avoided at any cost. For example, in the cancer treatment problem (Zhao et al., 2009), the death of a patient should be avoided at any cost. However, an infinitely negative reward breaks classic reinforcement learning algorithms and arbitrary, finite values have to be selected.

(4) Multi-objective trade-offs: If it is required to aggregate multiple numeric reward signals, a trade-off is required but the trade-off may not be explicitly known. Hence, different parameterizations have to be evaluated for obtaining a policy that correlates with the expected outcome.

The *reward shaping* problem has especially gained attention in recent years, as it is closely related to intrinsic vs. extrinsic motivation problem (Barto, 2013). An optimal reward would define an extrinsic motivation, e.g., for achieving a defined goal, while also motivating the agent to perform useful actions in states where extrinsic motivation is absent. Hence, the intrinsic motivation can be seen as a guidance method. Several methods have been proposed to learn such a reward automatically, but usually only using an extrinsic goal description (Singh et al., 2009, 2004). However, expert's may have an intuition about useful actions or intrinsic motivation that should be used to guide the agent. Defining such a motivation can be challenging, especially in terms of scalar, numeric rewards and several publications show that an agent's performance can be very sensitive to the used values (Singh et al., 2009; Lu et al., 2016).

Preference-based reinforcement learning (PbRL) is a paradigm for learning from non-numerical feedback in sequential domains. Its key idea is that the requirement for a numerical feedback signal is replaced with the assumption of a preference-based feedback signal

that indicates relative instead of absolute utility values. Preferences enable a definition of feedback that is not subject to arbitrary reward choices, reward shaping, reward engineering or predefined objective trade-offs. PbRL aims at rendering reinforcement learning applicable to a wider spectrum of tasks and non-expert users. Several algorithms have been developed for solving this class of problems, however, the field still lacks a coherent framework. Furthermore, most publications do not explicitly state the assumptions that are relevant for the application of the algorithms. In this paper, we will survey and categorize preference-based formulations of reinforcement learning and make these assumptions explicit. We also show the relation to other RL-based settings that deviate from the basic setting, such as inverse reinforcement learning or learning with advice.

This paper is based on a preliminary survey (Wirth and Fürnkranz, 2013c), but has been extended in almost every aspect. In particular, the design principles have been reworked to better capture all relevant aspects, we provide substantially more depth about the differences, advantages and disadvantages of the surveyed methods, and we considerably broadened the scope of the survey. The paper starts with the problem setting and the task description in Sec. 2, including a short discussion of related approaches. We then explain the design principles of the algorithms that fit in this framework in Sec. 3. Experimental domains, including some real-world problems that have been solved with PbRL, are described in Sec. 4. Open research questions are pointed out in Sec. 5 before the paper concludes.

2. Preliminaries

Preference-based reinforcement learning algorithms try to solve the *reinforcement learning* problem (Sutton and Barto, 1998) using preferences between states, actions or trajectories.[1] The goal is to learn a policy that is most consistent with the preferences of the expert. Hence, a PbRL algorithm must determine the intention of the expert and find a policy that is maximally consistent with it. For improving its estimate, the algorithms create trajectories which are evaluated by the expert, thereby, exploring the state-action space. Therefore, many algorithms use the *policy evaluation/policy improvement* cycle (Sutton and Barto, 1998) encountered in classical reinforcement learning. Yet, this cycle differs in the evaluation method from classical RL as we can't obtain and propagate numeric feedback, but can only use pairwise preferences.

2.1 Preference Learning

Preference learning is a recent addition to the suite of learning tasks in machine learning (Fürnkranz and Hüllermeier, 2010). Roughly speaking, preference learning is about inducing predictive preference models from empirical data, thereby establishing a link between machine learning and research fields related to preference modeling and decision making. The key difference to conventional supervised machine learning settings is that the training information is typically not given in the form of scalar target values (like in classification and regression), but instead in the form of pairwise comparisons expressing *preferences* between different objects or labels. Thus, in a way, preference learning is comparable to reinforcement learning in that in both settings, the learner may not receive information about the correct target choice, but instead feedback about a single option (in reinforcement learning) or a comparison between two options (in preference learning).

A preference $\boldsymbol{z}_i \succ \boldsymbol{z}_j$ denotes that $\boldsymbol{z}_i$ is preferred over $\boldsymbol{z}_j$ for two choices $\boldsymbol{z}_i$ and $\boldsymbol{z}_j$ in a set of possible choices $\mathcal{Z}$. Several short-hand notations can be used (Kreps, 1988):

- $\boldsymbol{z}_i \succ \boldsymbol{z}_j$: The first choice is *strictly preferred*.
- $\boldsymbol{z}_i \prec \boldsymbol{z}_j$: The second choice is *strictly preferred*, i.e., $\boldsymbol{z}_j \succ \boldsymbol{z}_i$.
- $\boldsymbol{z}_i \sim \boldsymbol{z}_j$: The choices are *indifferent*, meaning neither $\boldsymbol{z}_i \succ \boldsymbol{z}_j$ nor $\boldsymbol{z}_j \succ \boldsymbol{z}_i$ holds.
- $\boldsymbol{z}_i \succeq \boldsymbol{z}_j$: The first choice is *weakly preferred*, i.e., $\boldsymbol{z}_j \succ \boldsymbol{z}_i$ does not hold.
- $\boldsymbol{z}_i \preceq \boldsymbol{z}_j$: The second choice is *weakly preferred*, i.e., $\boldsymbol{z}_i \succ \boldsymbol{z}_j$ does not hold.

Depending on what constitutes the set of choices $\mathcal{Z}$, Fürnkranz and Hüllermeier (2010) distinguish between *learning from object preferences*, where the training data is given in the form of pairwise comparisons between data objects, and *learning from label preferences*, where the training data is given in the form of pairwise comparisons between labels that are attached to the objects. In the former case, a common performance task is to rank a new set of objects (*object ranking*; Kamishima et al. 2010), whereas in the latter case, the performance task is to rank the set of labels for a new object (*label ranking*; Vembu and Gärtner 2010). For example, in a reinforcement learning context, states may be considered as objects, and actions may be considered as labels, so that the decision problem of ranking the states according to their desirability is an object ranking problem, whereas ranking the available actions in a given state may be considered as a label ranking problem (Fürnkranz et al., 2012).

There are two main approaches to learning representations of preferences, namely *utility functions*, which evaluate individual alternatives, and *preference relations*, which compare pairs of competing alternatives. From a machine learning point of view, the two approaches give rise to two kinds of learning problems, to which we will return in Sec. 3.2.

2.2 Markov Decision Processes with Preferences

In this section, we will introduce *Markov decision processes with preferences (MDPP)*, a formal, mathematical framework for preference-based reinforcement learning. It is based upon Markov decision processes without reward (MDP\R), which have been proposed by Abbeel and Ng (2004), but extends the setting to preference based feedback. An MDPP is defined by a sextuple $(S, A, \mu, \delta, \gamma, \rho)$ with a *state space* S and *action space* A. The states and actions can be discrete or continuous. $A(s)$ defines the set of actions available in state s and $\mu(s)$ is the distribution of possible initial states. The states can also be represented by feature vectors $\boldsymbol{\phi}(s)$ and state action pairs by the feature vector $\boldsymbol{\varphi}(s, a)$. We will denote a trajectory $\boldsymbol{\tau}$ as a sequence of states and actions, i.e.,

$$\boldsymbol{\tau} = \{s_0, a_0, s_1, a_1, \ldots, s_{n-1}, a_{n-1}, s_n\} .$$

Some algorithms (Wirth et al., 2016; Wilson et al., 2012; Akrour et al., 2011, 2012; Jain et al., 2013, 2015; Gritsenko and Berenson, 2014; Zucker et al., 2010; Jain et al., 2013, 2015;

1. State and action preferences can be mapped to trajectory preferences, as we discuss in Sec. 3.1

Gritsenko and Berenson, 2014) also require the definition of a feature-based description of a trajectory, which we denote as $\boldsymbol{\psi}(\boldsymbol{\tau})$.

As in the standard MDP definition, the *state transition model* $\delta(s' \mid s, a)$ is assumed to be stochastic and the parameter $\gamma \in [0, 1)$ is the discount factor. A *policy* $\pi(a \mid s)$ is a conditional distribution that assigns probabilities to action choices based on the current state. The policy is typically given by a parametric distribution $\pi(a \mid s, \boldsymbol{\theta})$, however, non-parametric approaches are also considered (Akrour et al., 2012; Wirth et al., 2016; Busa-Fekete et al., 2013, 2014).

In contrast to conventional MDPs, we do not assume a numeric reward signal $r(s, a)$. Instead, the agent can observe a preference relation over trajectories $\boldsymbol{\tau}_i \succ \boldsymbol{\tau}_j$. Later, in Sec. 3.1, we will also consider preferences between states and actions, and show that they can be reduced to preferences between trajectories. We further assume that a preference for a given pair of trajectories is generated stochastically with a probability distribution ρ because the expert can err and therefore introduce noise. We use $\rho(\boldsymbol{\tau}_i \succ \boldsymbol{\tau}_j)$ for denoting the probability with which $\boldsymbol{\tau}_i \succ \boldsymbol{\tau}_j$ holds for a given pair of trajectories $(\boldsymbol{\tau}_i, \boldsymbol{\tau}_j)$. The distribution ρ is typically not known, yet the agent can observe a set of preferences

$$\zeta = \{\zeta_i\} = \{\boldsymbol{\tau}_{i1} \succ \boldsymbol{\tau}_{i2}\}_{i=1\dots N}\,, \tag{1}$$

which has been sampled using ρ. $\boldsymbol{\Upsilon}$ denotes the set of all trajectories that are part of ζ. A key problem in PbRL is to obtain a representative set of preferences ζ. Two common simplifications are to disregard the stochasticity of the expert and assume strict preferences. The strict preference assumption implies a total order, i.e., for each pair $\boldsymbol{\tau}_i$ and $\boldsymbol{\tau}_j$, exactly one of the two strict preference relations holds. Phrased otherwise, $\rho(\boldsymbol{\tau}_i \succ \boldsymbol{\tau}_j) = 1 - \rho(\boldsymbol{\tau}_j \succ \boldsymbol{\tau}_i)$. As a consequence, there are no incomparable pairs of trajectories. Incomparability can occur when evaluating trajectories based on multiple criteria, where it is impossible to improve one criteria while decreasing another one. If there are incomparable pairs where no preference relation can be defined, the preferences form a partial order.

2.3 Objective

The general objective of the agent is to find a policy π^* that maximally complies with the given set of preferences ζ. A preference $\boldsymbol{\tau}_1 \succ \boldsymbol{\tau}_2 \in \zeta$ is satisfied if

$$\boldsymbol{\tau}_1 \succ \boldsymbol{\tau}_2 \Leftrightarrow \Pr_\pi(\boldsymbol{\tau}_1) > \Pr_\pi(\boldsymbol{\tau}_2),$$

with

$$\Pr_\pi(\boldsymbol{\tau}) = \mu(s_0) \prod_{t=0}^{|\boldsymbol{\tau}|} \pi(a_t \mid s_t) \delta(s_{t+1} \mid s_t, a_t),$$

as the probability of realizing a trajectory $\boldsymbol{\tau}$ with a policy π. However, satisfying this condition is typically not sufficient as the difference can be infinitesimal. Moreover, due to the stochasticity of the expert, the observed preferences can also contradict each other.

We can now reformulate the objective for a single preference as a maximization problem concerning the difference of the probabilities of trajectories $\boldsymbol{\tau}_1$ and $\boldsymbol{\tau}_2$, e.g.,

$$\boldsymbol{\tau}_1 \succ \boldsymbol{\tau}_2 \Leftrightarrow \pi^* = \arg\max_\pi \left(\Pr_\pi(\boldsymbol{\tau}_1) - \Pr_\pi(\boldsymbol{\tau}_2)\right), \tag{2}$$

which is equivalent to creating, if feasible, only dominating trajectories. However, this definition disregards the question of how to deal with multiple preferences.

In general, the goal of all algorithms is to minimize a single preference loss $L(\pi, \zeta_i)$, e.g., $L(\pi, \boldsymbol{\tau}_1 \succ \boldsymbol{\tau}_2) = -\left(\Pr_\pi(\boldsymbol{\tau}_1) - \Pr_\pi(\boldsymbol{\tau}_2)\right)$. The domain of L differs, depending on the approach. Yet, in the multi-preference case, minimizing the loss for one preference might interfere with minimizing the loss for another preference. Hence, without further information, we are not able to define a single loss function but can only specify a multi-objective criterion for the optimal policy where each preference defines a loss function

$$\boldsymbol{L}(\pi, \zeta) = (L(\pi, \zeta_0), L(\pi, \zeta_1), \dots, L(\pi, \zeta_n))$$

Optimizing this multi-objective loss results in several Pareto-optimal solutions. However, we typically want to obtain a single optimal solution. To do so, we can define a scalar objective as the *weighted pairwise disagreement loss* $\mathcal{L}$, as introduced by Duchi et al. (2010),

$$\mathcal{L}(\pi, \zeta) = \sum_{i=1}^{N} \alpha_i L(\pi, \zeta_i), \tag{3}$$

where α_i is the weight or importance assigned to ζ_i. Using such a weighting is a common strategy in preference learning where different evaluation criteria, like the Kendall or the Spearmen distance (Kamishima et al., 2010), are available for different domains. We introduce the weighting α_i to illustrate all preference evaluation criteria in a unified framework.

In PbRL, we want to find a policy that maximizes the realization probability of undominated trajectories while not generating dominated trajectories, if possible. Therefore, preferences concerning the least dominated trajectories should have the highest weight, because the according preferences are most important. Although in other settings, it might be more relevant to realize preferences involving high risk trajectories for preventing major accidents. Hence, different weights α_i can be required. However, all available approaches disregard this problem and use a uniform weight distribution, but focus on requesting preferences over (nearly) undominated trajectories, which has a similar effect as a weighting. In Sec. 3, we explain the different definitions of the single preference loss $L(\pi, \zeta_i)$.

2.4 Preference-Based Reinforcement Learning Algorithms

Learning from preferences is a process that involves two actors: an *agent*, that acts according to a given policy and an *expert* evaluating its behavior. The process is typically composed of several components, as illustrated in Fig. 1. The learning usually starts with a set of trajectories, either predefined or sampled from a given policy. An expert evaluates one or more trajectory pairs $(\boldsymbol{\tau}_{i1}, \boldsymbol{\tau}_{i2})$ and indicates her preference. The method for indicating a preference can differ (cf. Sec. 3.1). For computing a preference-based policy π, three different learning approaches can be found in the literature:

- *learning a policy* computes a policy that tries to maximally comply with the preferences;
- *learning a preference model* learns a model for approximating the expert's preference relation, and

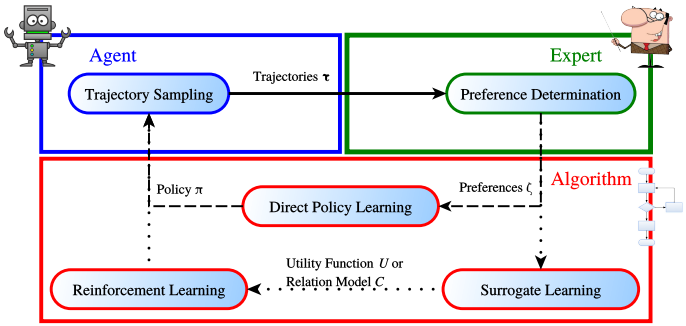

Figure 1: PbRL: Learning policies from preferences via direct (dashed path) and surrogate-based (dotted path) approaches.

- *learning a utility function* estimates a numeric function for the expert's evaluation criterion.

The dashed path in Fig. 1 relates to policy learning. Both other approaches, learning either a preference model or a utility function, are *surrogate-based* in that they learn a surrogate from the obtained preferences, which is in turn used for deriving a maximizing policy (cf. the dotted path in Fig. 1). For this optimization, often conventional reward-based *policy improvement* (PI) algorithms can be used. All three cases are explained in more detail in Sec. 3.2, but the result is always a new policy π_{new}, that can be used to sample new trajectories.

Typically, new trajectories are evaluated repeatedly, and hence, learning from preferences becomes an interactive process between the expert and the algorithm, where the algorithm presents new trajectory pairs to the expert and the expert evaluates them. However, in the interactive setting, a criterion has to be defined for the selection of the preference queries that should be presented to the expert, as described in Sec. 3.4. This criterion must also resolve the exploration/exploitation trade-off as we can only obtain feedback for explicitly requested preferences.

A single pass through the PbRL cycle is often performed in a batch setting, where available trajectories and preference data are used to compute a policy offline.

2.5 Related Problem Settings

Preference-based reinforcement learning is closely related to several other learning settings, which we will briefly discuss in this section.

2.5.1 Learning with Advice

Advice-based algorithms (Torrey and Taylor, 2013; Knox and Stone, 2010, 2012; Griffith et al., 2013) differ from PbRL in that the (possibly preference-based) advice is given in addition to a numeric reward signal. Hence, the main source of feedback is still numeric, not preference-based, and preferences are only used as additional constraints for speeding up the learning process. In addition, not all advice-taking algorithms use preferences. The advice can also be defined via other means, such as rules (Maclin et al., 2005).

Faust et al. (2016) assume that advice is only given in terms of attracting and repulsing states, without an additional reward signal. Such advice is similar to state preferences, but the states are demonstrated by the expert and not evaluated in a pairwise manner.

2.5.2 Ordinal Feedback

PbRL methods can also be used to solve related problem settings. For example, domains with *ordinal feedback signals* can be cast as preference problems by deriving pairwise preferences from the ranking of the ordinal symbols. However, conversely, trying to determine a grading for the ordinal symbols (Weng, 2011) is not feasible if only pairwise preferences are available. Daniel et al. (2014) assume a numeric rating of trajectories. A numeric rating also implicitly defines a ranking which can be again reduced to preferences. While a ranking implicitly contains more information than a binary preference it is not clear whether this additional information can also be transmitted reliably by the expert. Kupcsik et al. (2015) introduced an approach that can use preference as well as numeric feedback. The presented experiments indicate that mixing preference feedback and numeric feedback queries lead to a better performance. However, more experiments with human subjects are needed to shed light on the question of how to combine these feedback types.

2.5.3 Inverse Reinforcement learning

In *inverse reinforcement learning* (IRL; Ng and Russell 2000; Zhifei and Meng Joo 2012), the goal is not to find a policy, but the reward signal that explains the expert's behavior. Stated differently, IRL assumes that the expert maximizes an internal reward function and the goal is to identify this function. However, the expert may use an unknown, true reward which cannot be reconstructed as it may not be subject to the Markov property. Although, it is usually sufficient to find a reward function that produces the same output in each state.

In this setting, the trajectories are supplied by the expert, not by the algorithm. There are also no explicit pairwise preferences, yet they can be derived based on implicit assumptions. In the IRL setting, the demonstrated sequences can be assumed to be preferred over all other trajectories. Hence, the reward-based utility function learning approaches may also be used to solve IRL problems. Many IRL approaches are based on preferences that are defined by implicit assumptions and can be applied to reward-based utility PbRL by adapting them to explicit preferences (see Sec. 3.2.3). Such implicit preferences are also used by Knox and Stone (2009), however, the approach is based on positive (preferred) and negative (dominated) feedback. All positively evaluated sequences are implicitly preferred over all negatively evaluated ones. While most IRL settings assume optimal demonstrations, a few methods (Rothkopf and Dimitrakakis, 2011; Ziebart et al., 2008) relax this assumption and allow sub-optimal demonstrations, based on a parametric optimality prior like a softmax

function. Furthermore, as all trajectories are given by an expert, IRL approaches are not able to obtain new feedback for trajectories and, hence, can not improve upon the expert demonstrations.

2.5.4 Unsupervised Learning

A different line of work (Meunier et al., 2012; Mayeur et al., 2014) uses preferences for learning without a supervised feedback signal. It is assumed that the performance of the policy degrades over time, which is reasonable in some domains. They apply their approach to a robot following task, where a robot needs to follow a second robot based on visual information. Without an optimal policy, the path of the follower will deviate from the leader over time. Therefore, states encountered early in the trajectory are assumed to have higher quality than later states, which again defines an implicit preference. These preferences are used to learn the value function, which induces the policy.

2.5.5 Dueling Bandits

Another related setting is the *dueling bandit* (Yue et al., 2012), which uses preferences in an interactive, but non sequential problem setting. Feedback concerns comparisons of arms of a k-armed bandit. However, PbRL can be phrased as a dueling bandit problem, when using policies as arms. Busa-Fekete et al. (2013, 2014) realized that idea, which we discuss in Sec. 3.2.1. Approaches that learn a preference model from action preferences also share similarities (cf. Sec. 3.2.2). Each state defines a bandit with the actions as arms, but it is required to optimize over sequences of bandits. Furthermore, the mentioned approaches extend the dueling bandit setting by either generalizing over multiple states (bandits) or by deriving (multiple) action preferences from trajectory preferences. Related to dueling bandits is the use of two-point feedback for online convex optimization (Agarwal et al., 2010; Shamir, 2017), which has recently been extended to structured prediction problems (Sokolov et al., 2016).

3. Design Principles for PbRL

Preference-based reinforcement learning algorithms are subject to different design choices, which we will review in this section. First, we consider the different types of preferences, i.e., *trajectory*, *action* or *state* preferences. These types introduce different levels of complexity for the expert and algorithm (Sec. 3.1). The second design choice is how the learning problem is phrased, i.e, *directly learning a policy*, *learning a preference relation model* or a *utility function* as surrogate (Sec. 3.2). The learned representation is connected to the problem of assigning preferences to states and actions, given a delayed feedback signal. We explain this problem and possible approaches in Sec. 3.3. The next design principle is how to collect new feedback, i.e., how new trajectories are generated and selected to obtain new preferences, which we discuss in Sec. 3.4. Having obtained a representation, we need to derive an optimized policy. In Sec. 3.5, we discuss different optimization strategies that can be used to this end. Furthermore, PbRL algorithms may employ different techniques for capturing the transition dynamics, which come with different assumptions, as explained in Sec. 3.6. Sec. 3.7 shows a tabular overview of all algorithms.

3.1 Types of Feedback

There are three different types of preference feedback that can be found in the literature, action, state and trajectory preferences. The most important difference of the preference types is that they impose different challenges for the expert and the algorithm.

3.1.1 Action Preferences

An *action preference* compares two actions for the same state. The action preference $a_{i1} \succ_s a_{i2}$ expresses that in state s, action a_{i1} should be preferred to a_{i2}.

We need to distinguish between short-term optimality (e.g. optimal, immediate reward in terms of reinforcement learning) and long-term optimality (optimal, expected return). Knox and Stone (2012) and Thomaz and Breazeal (2006) analyzed this problem in an advice setting and observed that feedback relating to immediate rewards are difficult to use and feedback concerning the expected, long-term return should be preferred. This observation can be explained by the argument that it is difficult to aggregate short-term action preferences, as they are only valid for a given state. It is unclear how the short-term preferences relate to long-term optimality as we are not able to trade-off preferences for different states. Action preferences are demanding for the expert, she needs to be familiar with the expected long-term outcome. Computationally, this problem is fairly simple as it is sufficient to select the most preferred action in every state, which already implies the best long-term outcome. Hence, only generalization issues remain. The action-preference-based approach of Fürnkranz et al. (2012) also uses long-term action preferences, but not concerning an unknown, optimal policy. They supply a policy for computing the long term expectation. Hence, the expert does not need to be familiar with the expected, optimal policy but can consider samples from the provided policy for its comparison.

3.1.2 State Preferences

A *state preference* $s_{i1} \succ s_{i2}$ determines that state s_{i1} is preferred to state s_{i2}. A state preference is equivalent to saying that there is an action in state s_{i1} that is preferred to all actions available in state s_{i2}.

State preferences are more informative than action preferences as they define relations between parts of the global state space. Yet, they also suffer from the long-term/short-term optimality problem. Long-term state preferences define a clearly defined setting as it is sufficient to discover the most preferred successor state for each state and maximize its selection probability, as analyzed by Wirth and Fürnkranz (2012, 2015). Short-term state preferences do not define a trade-off, because it is unclear whether visiting an undominated state once should be preferred over visiting a rarely dominated state multiple times. Short-term state preferences are used by Zucker et al. (2010) where they try to resolve the trade-off problem using an approximated reward.

State preferences are slightly less demanding for the expert as it is not required to compare actions for a given state. However, the expert still needs to estimate the future outcome of the policy for a given state. State preferences do not directly imply a policy, but it can be easily derived with knowledge of the transition model, as explained in Sec. 3.2.3.

3.1.3 Trajectory Preferences

A *trajectory preference* $\boldsymbol{\tau}_{i1} \succ \boldsymbol{\tau}_{i2}$ specifies that the trajectory $\boldsymbol{\tau}_{i1}$ should be preferred over the dominated trajectory $\boldsymbol{\tau}_{i2}$. Trajectory preferences are the most general form of feedback and the most widely used.

Trajectory preferences are arguably the least demanding preferences type for the expert as she can directly evaluate the outcomes of full trajectories. Trajectories can be evaluated in terms of the resulting behavior (e.g., a jerky vs. a straight movement towards a goal state), or by considering the occurrences of states that are known to be good. Usually, the goal is to keep complexity away from the expert, rendering trajectory preferences the most common approach. Yet, a difficulty with trajectory preferences is that the algorithm needs to determine which states or actions are responsible for the encountered preferences, which is also known as the *temporal credit assignment problem*. This assignment problem is particularly difficult if not all trajectories are starting in the same state. Trajectories with different starting states are solutions to different initial situations. Hence, the preference could be attributed to the initial situation or the applied policy. In practice, no algorithm known to the authors is capable of dealing with preferences between trajectories with different initial states.

Trajectory preferences are the most general form of preference-based feedback because, formally, all preferences can be mapped to trajectory preferences when we admit trajectories with only a single element. An action preference $a_{i1} \succ_s a_{i2}$ is equivalent to the trajectory preference $\boldsymbol{\tau}_{i1} \succ \boldsymbol{\tau}_{i2}, \boldsymbol{\tau}_{i1} = \{s, a_{i1}\}, \boldsymbol{\tau}_{i2} = \{s, a_{i2}\}$. The case of a state preference $s_{i1} \succ s_{i2}$ can be reformulated as indicated above, yielding the set of trajectory preferences $\{\forall a_{i2} \in A(s_{i2}) : (s_{i1}, \pi^*(s_{i1})) \succ (s_{i2}, a_{i2})\}$.

3.2 Defining the Learning Problem

As discussed in Sec. 2.4, preferences can be used to directly learn a policy, or to learn a qualitative preference model or a quantitative utility function, both of which can then be used for deriving a policy. In the following, we will discuss different options for representing a policy, a preference model or a utility function, which have been used in various algorithms in the literature. Unless required otherwise, we only consider the loss for the preferred relation $\succ$, as explained in Sec. 2.2. We use the symbol $L^{\succ}$ for a loss that is only valid for the $\succ$ relation to differentiate from the general, single preference loss L, introduced in Sec. 2.3

3.2.1 Learning a Policy

Direct policy learning assumes a parametric policy space. The learning task is to find a parametrization that maximizes the correspondence of the policies with the observed preferences. Two different approaches have been tried, namely to induce a distribution over a parametric policy space (Wilson et al., 2012), or to compare and rank policies (Busa-Fekete et al., 2013, 2014).

Approximating the Policy Distribution. Wilson et al. (2012) approximate the policy distribution via a *Bayesian likelihood function* subject to the preference-based data probability. A parameterized policy space $\pi(a \mid s, \boldsymbol{\theta})$ is used for defining the policy distribution $\Pr(\pi \mid \zeta)$. Algorithm 1 shows how to collect the preferences. The basic strategy is to sample two policies, described by a parameter vector, from the posterior distribution $\Pr(\pi \mid \zeta)$ induced by the preferences. Each policy pair is used to create one or more trajectories, defining a potential preference query by pairing the resulting trajectories. One of multiple selection criteria, that we discuss in Sec. 3.4.3, is used to select the query to pose to the expert. Variants of the criteria also depend on the policy that created the trajectory or allow to stop the sampling process before m policy pairs are created.

Algorithm 1 Policy Likelihood

Require: prior $\Pr(\pi)$, step limit k, sample limit m, iteration limit n

$\zeta = \emptyset$ ▷ Start with empty preference set
for $i = 0$ **to** n **do**
  $\tilde{\zeta} = \emptyset$ ▷ Clear potential preference queries
  for $j = 0$ **to** m **do**
    $s \sim \mu(s)$ ▷ Draw initial state s
    $\pi_1, \pi_2 \sim \Pr(\pi \mid \zeta)$ ▷ Draw two policies from posterior
    for $j = 0$ **to** n **do**
      $\boldsymbol{\tau}^{\pi_1} = \text{ROLLOUT}(s, \pi_1, k)$ ▷ Create k-step trajectory using policy π_1
      $\boldsymbol{\tau}^{\pi_2} = \text{ROLLOUT}(s, \pi_2, k)$ ▷ Create k-step trajectory using policy π_2
      $\tilde{\zeta} \leftarrow \tilde{\zeta} \cup (\boldsymbol{\tau}^{\pi_1}, \boldsymbol{\tau}^{\pi_2})$ ▷ Add trajectory pair to potential preference queries
    end for
  end for
  $(\boldsymbol{\tau}_1, \boldsymbol{\tau}_2) = \text{SELECTQUERY}(\tilde{\zeta})$ ▷ Select a preference query
  $\zeta \leftarrow \zeta \cup \text{OBTAINTRAJECTORYPREFERENCES}(\boldsymbol{\tau}_1, \boldsymbol{\tau}_2)$ ▷ Query expert
end for
return $\arg\max_\pi \Pr(\pi \mid \zeta)$ ▷ Return maximum-a-posterior

The likelihood $\Pr(\pi \mid \zeta)$ is modeled by comparing trajectories $\boldsymbol{\tau}^\pi$ that are realized by a policy π with the preferred and dominated trajectories in ζ. The likelihood is high if the realized trajectories $\boldsymbol{\tau}^\pi$ of the policy π are closer to preferred trajectory, i.e.,

$$\Pr(\boldsymbol{\tau}_1 \succ \boldsymbol{\tau}_2 \mid \pi) = \Phi\left(\frac{\mathbb{E}[d(\boldsymbol{\tau}_1, \boldsymbol{\tau}^\pi)] - \mathbb{E}[d(\boldsymbol{\tau}_2, \boldsymbol{\tau}^\pi)]}{\sqrt{2}\sigma_p}\right), \tag{4}$$

where the function Φ is the c.d.f of $\mathcal{N}(0, 1)$, which resembles a sigmoidal squashing function. The parameter σ_p accounts for feedback noise to allow the expert to err. The function d is a distance function comparing two trajectories. The policy distribution is then given by applying Bayes theorem, i.e,

$$\Pr(\pi \mid \zeta) \propto \Pr(\pi) \prod_i \Pr(\boldsymbol{\tau}_1 \succ \boldsymbol{\tau}_2 \mid \pi), \tag{5}$$

and the posterior is approximated using *Markov Chain Monte Carlo* simulation (Andrieu et al., 2003). This approach requires the specification of a meaningful distance function, which is hard to define in many domains and requires a large amount of domain knowledge. Wilson et al. (2012) use an Euclidean distance function. Yet, Euclidean distances are hard to use in many domains such as those with high-dimensional continuous state spaces. Furthermore, if the state space is not continuous it may be hard to define a suitable distance

Algorithm 2 Policy Ranking

Require: candidate policies Π_0, step limit k, sample limit m, iteration limit n

for $i = 0$ **to** n **do**
  $\zeta = \emptyset$
  for 0 **to** m **do**
    $\pi_1, \pi_2 = \text{SELECTPOLICIES}(\Pi_i, \zeta)$ ▷ Select policies to compare
    $s \sim \mu(s)$ ▷ Draw initial state s
    $\boldsymbol{\tau}^{\pi_1} = \text{ROLLOUT}(s, \pi_1, k)$ ▷ Create k-step trajectory using policy π_a
    $\boldsymbol{\tau}^{\pi_2} = \text{ROLLOUT}(s, \pi_2, k)$ ▷ Create k-step trajectory using policy π_2
    $\zeta \leftarrow \zeta \cup \text{OBTAINTRAJECTORYPREFERENCES}(\boldsymbol{\tau}^{\pi_1}, \boldsymbol{\tau}^{\pi_2})$ ▷ Query expert
  end for
  $\Pi_{i+1} = \text{EDPS}(\Pi_i, \zeta)$ ▷ Compute candidate policies, based on preferences
end for
return $\arg\max_\pi \sum_{\pi,\pi' \in \Pi_n} \Pr(\pi \succ \pi')$ ▷ Return highest ranked policy

measure d. The definition of a parametric policy also requires domain knowledge, although good parametric policy representations are known for many domains, such as robotics (Kober et al., 2013). Often, such policy representations reduce the dimensionality of the policy and therefore the learning complexity.

Comparing and Ranking Policies. Alternatively, we can directly compare two policies π_1 and π_2 by querying the expert for different trajectory pairs $\boldsymbol{\tau}^{\pi_1}$ and $\boldsymbol{\tau}^{\pi_2}$ that have been realized by the two policies (Busa-Fekete et al., 2013, 2014). The method maintains a set of policies Π_i, described by their parameter vectors. The preference set ζ is used to compute a ranking over policies, as shown in Algorithm 2. A confidence bound method that we discuss in Sec. 3.4.1 determines which policies to select for generating the next trajectory pair for which a preference query is posed.

The outcome of this comparison is then used to compute new policies that are more likely to realize preferred trajectories. A policy π_1 is preferred over a policy π_2 if the generated trajectories $\boldsymbol{\tau}^{\pi_1}$ are on expectation preferred over the trajectories $\boldsymbol{\tau}^{\pi_2}$ realized by the second policy, i.e.,

$$\Pr(\pi_1 \succ \pi_2) \;\Leftrightarrow\; \mathbb{E}_{\boldsymbol{\tau}^{\pi_1}, \boldsymbol{\tau}^{\pi_2}}[\rho(\boldsymbol{\tau}^{\pi_1} \succ \boldsymbol{\tau}^{\pi_2})]. \tag{6}$$

For an observed set of preferences ζ, the expectation in (6) can be approximated as

$$\Pr(\pi_1 \succ \pi_2) \approx \frac{1}{N} \sum_{i=1}^{N} \mathbb{I}(\boldsymbol{\tau}_i^{\pi_1} \succ \boldsymbol{\tau}_i^{\pi_2}). \tag{7}$$

The objective is to find the set of optimal polices $\pi^* = \arg\max_\pi \sum_{\pi,\pi' \in \Pi} \Pr(\pi \succ \pi')$. In contrast to Wilson et al. (2012), no distance function is required. However, preferences can not be reused as we need to obtain new preferences for each policy pair and, hence, a high amount of preferences is required. Busa-Fekete et al. (2013, 2014) deal with incomparabilities and indifference by assuming

$$\boldsymbol{\tau}_{i1} \sim \boldsymbol{\tau}_{i2} \;\Leftrightarrow\; \rho(\boldsymbol{\tau}_{i1} \prec \boldsymbol{\tau}_{i2}) = \rho(\boldsymbol{\tau}_{i1} \succ \boldsymbol{\tau}_{i2}) = 0.5.$$

Algorithm 3 Preference-based Approximate Policy Iteration

Require: initial policy π_0, iteration limit m, state sample limit k, rollout limit n

for $i = 0$ **to** m **do**
  for 0 **to** k **do**
    $s \sim \mu(s)$ ▷ Sample k states per iteration
    $\boldsymbol{\Upsilon} = \emptyset, \zeta = \emptyset$
    for $\forall a \in A(s)$ **do**
      for 0 **to** n **do**
        $\boldsymbol{\Upsilon} \leftarrow \boldsymbol{\Upsilon} \cup \text{ROLLOUT}(s, a, \pi_i)$ ▷ Create trajectory, starting with (s, a)
      end for
    end for
    $\zeta \leftarrow \text{OBTAINACTIONPREFERENCES}(\boldsymbol{\Upsilon})$ ▷ Query expert
  end for
  $C^{\pi_i} = \text{COMPUTEPREFERNCEMODEL}(\zeta)$ ▷ Compute the preference function C
  $\pi_{i+1} = \text{COMPUTEPOLICY}(C^{\pi_i})$ ▷ Compute greedy policy
end for
return improved policy π_m

The optimization itself can be performed with algorithms similar to *evolutionary direct policy search* (EDPS; Heidrich-Meisner and Igel 2009). Policy comparison approaches following the ideas of Busa-Fekete et al. (2013, 2014) can be seen as cases of preference-based multi-armed bandit optimization, where each arm represents one policy. For a survey of such preference-based bandit methods, we refer to Busa-Fekete and Hüllermeier (2014).

3.2.2 Learning a Preference Model

Instead of directly learning a policy, one can also try to learn a model $C(a \succ a' \mid s)$ that predicts the expected preference relation between a and a' for a given state s. The preference relation between actions can be used to obtain a ranking for actions given a state, from which a policy can be derived in turn. The problem of learning $C(a \succ a' \mid s)$ can be phrased as a classification problem trying to correctly predict all observed preferences. As shown in Algorithm 3, *preference-based approximate policy iteration* obtains multiple trajectories for each action in k sampled states (Fürnkranz et al., 2012). This allows to derive multiple action preferences by comparing trajectories, based on the initial actions. Action preferences are directly used as training data $\{s_i, a_{i1}\} \succ \{s_i, a_{i2}\} \Leftrightarrow (a_{i1} \succ a_{i2} \mid s_i)$ for C. From these, a separate classifier $C_{ij}(s)$ is trained, which predicts whether $a_i \succ a_j$ will hold in a state s.

For deriving a ranking over all actions in a given state, the pairwise preference predictions of the trained classifiers C_{ij} may be combined via voting or weighted voting (Hüllermeier et al., 2008), where each prediction issues a vote for its preferred action. The resulting count $k(s, a)$ for each action a in state s

$$k(s, a) = \sum_{\forall a_i \in A(s), a_j \neq a} C(a_i \succ a_j \mid s) = \sum_{\forall a_i \in A(s), a_j \neq a} C_{ij}(s) \tag{8}$$

correlates with $\rho(\,(s,a_i) \succ (s,a_j)\,)$ if the classifiers C approximate ρ well. Hence, we can derive a policy

$$\pi^*(a \mid s) = \begin{cases} 1 & \text{if } a = \arg\max_{a'} k(s,a') \\ 0 & \text{else} \end{cases},$$

that maximizes the realization probability for the most preferred action, satisfying (2).

Wirth and Fürnkranz (2013a,b) also use action preferences in a similar way. However, they treat C as a continuous function, returning a weighted vote for each action instead of a binary vote. Hence, $k(s,a)$ now also contains the uncertainty of the estimated preference, which allows for more efficient exploration. In this case, the function C is defined by a tabular representation with a single value for each state/action/action triplet, and updated using a gradient-based method. Fürnkranz et al. (2012) use a neural network (Bishop, 1995) that is retrained completely in every iteration, allowing for generalization at the cost of potential approximation errors.

3.2.3 Learning a Utility Function

Utility-based approaches estimate a surrogate utility $U(\boldsymbol{\tau})$ for a given trajectory. In many cases, this trajectory utility can be decomposed into state-action utilities $U(s,a)$, i.e, $U(\boldsymbol{\tau}) = \sum_t U(s_t,a_t)$. Note that this surrogate function is not directly comparable to an approximated reward or return function because it may be subject to concept drift if the estimate of the expert's optimality criterion can change over time. As in the IRL case, the expert may derive the preferences from an unknown, true reward which cannot be reconstructed as it may not be subject to the Markov property. However, in the PbRL case it is sufficient to find a reward function that induces the same, optimal policy as the true reward function. Consequently, we call this function a *utility function* to distinguish it from a fixed reward function[2].

Given the surrogate utility, the policy should then maximize the expected trajectory utility

$$\pi^* = \max_{\pi} \mathbb{E}_{\Pr_\pi(\boldsymbol{\tau})}[U(\boldsymbol{\tau})], \tag{9}$$

which is comparable to the expected return in classic *reinforcement learning*. Besides exploring the policy space, as in classic reinforcement learning, we also need to explore the utility space in preference-based RL algorithms. Estimating a utility function has the advantage that we can evaluate new trajectories without asking the expert for explicit feedback. Yet, utility function approaches may suffer from the approximation errors induced by the estimated utility function. A common utility-based approach is to assume a scalar utility for the trajectories, i.e.,

$$\boldsymbol{\tau}_{i1} \succ \boldsymbol{\tau}_{i2} \Leftrightarrow U(\boldsymbol{\tau}_{i1}) > U(\boldsymbol{\tau}_{i2}).$$

A scalar utility function always exists provided that there are no incomparable trajectory pairs (von Neumann and Morgenstern, 1944).

Algorithm 4 summarizes a general process of utility-based PbRL, which forms the basis of a variety of different realizations. Preference queries are generated by sampling one or more trajectories from a policy and derive queries by exhaustive or selective comparison (cf. Sec. 3.4.1 & 3.4.2). The preferences are then used to compute a utility function (Friedman and Savage, 1952) which, in turn, can be used to optimize policies according to the expected utility. Different learning algorithms can be used for modeling the utility function. In the following, we primarily discriminate between linear and non-linear utility models.

2. The definition of a utility function may differ from the functions encountered in utility theory, but is inline with existing PbRL approaches and the preference learning literature.

Algorithm 4 Utility-based PbRL

Require: initial policy π_0, iteration limit m, state sample limit k, rollout limit n

$\zeta = \emptyset$
for $i = 0$ **to** m **do**
  $\boldsymbol{\Upsilon} = \emptyset$
  for 0 **to** k **do**
    $s \sim \mu(s)$ ▷ Sample k states per iteration
    for 0 **to** n **do**
      $\boldsymbol{\Upsilon} \leftarrow \boldsymbol{\Upsilon} \cup \text{ROLLOUT}(s, \pi_i)$ ▷ Create trajectory, starting with state s
    end for
  end for
  $(\boldsymbol{\tau}_1, \boldsymbol{\tau}_2) = \text{createQuery}(\boldsymbol{\Upsilon})$ ▷ Create a preference query
  $\zeta \leftarrow \zeta \cup \text{obtainTrajectoryPreferences}(\boldsymbol{\tau}_1, \boldsymbol{\tau}_2)$ ▷ Query expert
  $U^{\pi_i} = \text{computeUtilityFunction}(\zeta)$ ▷ Compute the utility function
  $\pi_{i+1} = \text{computePolicy}(U^{\pi_i})$ ▷ Compute a policy
end for
return improved policy π_m

Linear utility functions. The most common approach is to use utility functions that are linear in a feature vector. We may use state action features $\boldsymbol{\varphi}(s,a)$ resulting in a utility $U(s,a) = \boldsymbol{\theta}^T \varphi(s,a)$, or trajectory features $\boldsymbol{\psi}(\boldsymbol{\tau})$ yielding $U(\boldsymbol{\tau}) = \boldsymbol{\theta}^T \boldsymbol{\psi}(\boldsymbol{\tau})$. In order to find such a linear utility function, we can define a loss function $\mathcal{L}$ which is given by the (weighted) sum of the pairwise disagreement loss L, i.e.,

$$\mathcal{L}(\boldsymbol{\theta}, \zeta) = \sum_{i=1}^{|\zeta|} \alpha_i L(\boldsymbol{\theta}, \zeta_i), \tag{10}$$

as described in Sec. 2.3. Using the linearity of the utility function, we can define the utility difference

$$d(\boldsymbol{\theta}, \zeta_i) = \boldsymbol{\theta}^T (\boldsymbol{\psi}(\boldsymbol{\tau}_{i1}) - \boldsymbol{\psi}(\boldsymbol{\tau}_{i2})) \tag{11}$$

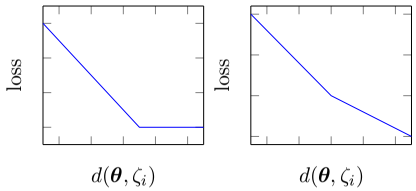
for two trajectories. Different definitions of the pairwise disagreement loss $L(\boldsymbol{\theta}, \zeta_i)$ have been used in the literature and most of them use the utility difference. An intuitive loss directly correlating with the obtained binary feedback is the indicator loss

$$L^{\succ}(\boldsymbol{\theta}, \zeta_i) = \mathbb{I}\left(d(\boldsymbol{\theta}, \zeta_i) \leq \epsilon\right), \tag{12}$$

which states that the utility difference has to be always larger then ϵ, as used by Sugiyama et al. (2012). However, such a binary loss function is typically difficult to optimize and there is no notion of preference violation (or fulfillment) for trading off multiple preferences.

Name	Loss Equation	Reference
ranking SVM	$L^{\succ}(\boldsymbol{\theta}, \zeta_i) = \max(0, 1 - d(\boldsymbol{\theta}, \zeta_i))$	Akrour et al. (2011, 2012) Zucker et al. (2010) Wirth and Fürnkranz (2012, 2015) Runarsson and Lucas (2012, 2014)
IRL	$L^{\succ}(\boldsymbol{\theta}, \zeta_i) = c(d(\boldsymbol{\theta}, \zeta_i))$ $c(x) = \begin{cases} -2x & \textbf{if } x \leq 0 \\ -x & \textbf{otherwise} \end{cases}$	Wirth et al. (2016)
cumulative	$p_{\boldsymbol{\theta}}(\zeta_i) = \Phi\left(\frac{d(\boldsymbol{\theta}, \zeta_i)}{\sqrt{(2)}\sigma_p}\right)$	Kupcsik et al. (2015)
sigmoid	$p_{\text{sig }\boldsymbol{\theta}}(\zeta_i) = \frac{1}{1+\exp(-m \cdot d(\boldsymbol{\theta}, \zeta_i))}$	Christiano et al. (2017)
0/1	$p_{01\ \boldsymbol{\theta}}(\zeta_i) = \mathbb{I}\big(d(\boldsymbol{\theta}, \zeta_i) < 0\big)$	Sugiyama et al. (2012)
combined	$p_{\boldsymbol{\theta}}(\zeta_i) = \frac{\lvert\zeta\rvert - 1}{\lvert\zeta\rvert} p_{01\ \boldsymbol{\theta}}(\zeta_i) + \frac{1}{\lvert\zeta\rvert} p_{\text{sig }\boldsymbol{\theta}}(\zeta_i)$	Wirth et al. (2016)
integrated piecewise	$p_{\boldsymbol{\theta}}(\zeta_i) = \int_0^{\epsilon_{\max}} c(d(\boldsymbol{\theta}, \zeta_i), \epsilon)$ $c(x, \epsilon) = \begin{cases} 0 & \textbf{if } x < -\epsilon \\ 1 & \textbf{if } x > \epsilon \\ \frac{\epsilon + x}{2\epsilon} & \textbf{else}, \end{cases}$	Akrour et al. (2013, 2014)

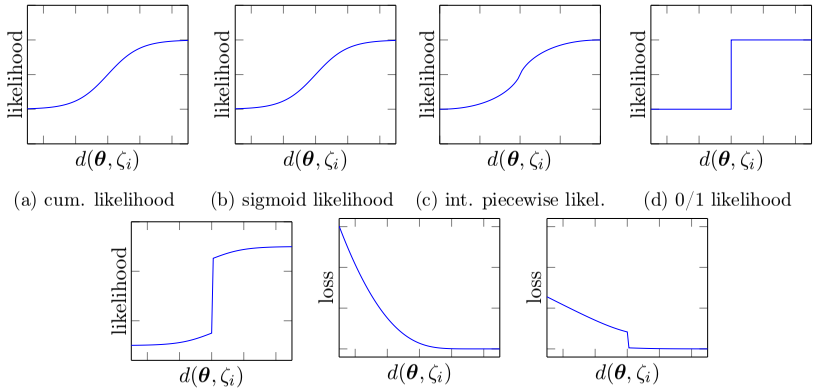
Table 1: Loss functions for linear utility functions



Therefore, continuous loss functions are more often used. A number of continuous loss functions have been proposed in the literature.

Tbl. 1 shows a summary of loss functions and likelihood functions that can be found in the literature. All these approaches try to find a good trade-off between potentially violating preferences and optimizing the utility difference of preferred trajectories. Some algorithms (Akrour et al., 2011, 2012; Zucker et al., 2010; Wirth and Fürnkranz, 2012, 2015; Runarsson and Lucas, 2012, 2014) define the loss function $L^{\succ}(\boldsymbol{\theta}, \zeta_i)$ as hinge loss (Fig. 2a) that can be optimized using SVM ranking algorithms (Joachims, 2002; Herbrich et al., 1999), others (Wirth et al., 2016) as a piecewise linear loss function (Fig. 2b) inspired by inverse reinforcement learning algorithms (Ng and Russell, 2000).

Other algorithms use sigmoidal loss functions to saturate the effect of a high utility differences, in order to overcome the limitations of a linear loss. Such sigmoidal loss functions are often modeled as likelihood functions $p_{\boldsymbol{\theta}}(\zeta_i)$ for the preferences. In this case, we have to optimize the log likelihood, i.e.,



$$\mathcal{L}(\boldsymbol{\theta}, \zeta) = -\log \prod_{i=1}^{|\zeta|} p_{\boldsymbol{\theta}}(\zeta_i) = -\sum_{i=1}^{|\zeta|} \log\left(p_{\boldsymbol{\theta}}(\zeta_i)\right) = \sum_{i=1}^{|\zeta|} \mathcal{L}(\boldsymbol{\theta}, \zeta_i),$$

with $\mathcal{L}(\boldsymbol{\theta}, \zeta) = -\log\left(p_{\boldsymbol{\theta}}(\zeta_i)\right)$. Most algorithms (Akrour et al., 2014; Wirth et al., 2016; Kupcsik et al., 2015) do not directly maximize the likelihood, but obtain the posterior

distribution

$$\Pr(\boldsymbol{\theta} \mid \zeta) \propto \Pr(\boldsymbol{\theta}) \prod_i p_{\boldsymbol{\theta}}(\zeta_i). \tag{13}$$

The expected utility of a new trajectory is then obtained by computing the expectation over the posterior. The posterior is computed using MCMC (Andrieu et al., 2003) by Akrour et al. (2014) and Wirth et al. (2016), whereas the latter uses *elliptic slice sampling* (ELS; Murray et al. 2010). These procedures are sampling based and can only obtain a costly approximation of the posterior. The utility function's posterior is also computed by Kupcsik et al. (2015), but using more efficient *convex optimization*. Wirth et al. (2016) also compare with a direct maximization of the likelihood. The direct maximum likelihood approach is more optimistic in the sense that it disregards the uncertainty.

The only approach that does not use an explicit cost function for obtaining the utility is by Jain et al. (2013, 2015). It uses the preferences to compute a gradient for the parameter vector of the utility function, i.e., $\boldsymbol{\theta}_{k+1} = \boldsymbol{\theta}_k + \alpha\big(\boldsymbol{\psi}(\boldsymbol{\tau}_{k1}) - \boldsymbol{\psi}(\boldsymbol{\tau}_{k2})\big)$, where α is a step-

size. In this case, the parameter vector is updated such that it is correlated with the feature vector of the preferred trajectory. Such a gradient can be mapped to the simple loss function $L(\boldsymbol{\theta}, \zeta_i) = -d(\boldsymbol{\theta}, \zeta_i)$. In general, it is unclear how the aggregated utility loss $\mathcal{L}(\boldsymbol{\theta}, \zeta)$ is related to the policy loss $\mathcal{L}(\pi, \zeta)$ (see Sec. 2.3), as the policy is subject to the system dynamics whereas the utility is not. Nevertheless, it is assumed that maximizing the expected utility (9) yields more preferred trajectories.

Non-Linear Utility Functions. Few approaches allow the use of non-linear utility functions. The utility feature space is usually assumed to be defined in advance, shifting the problem to the user. However, defining such a feature space usually requires expert knowledge. Methods that can use non-linear utilities are easier to apply but may require a higher amount of preferences or trajectory samples, because the learning problem is more complex.

Gritsenko and Berenson (2014) convert the preferences into a ranking and do not operate directly on the preference level. Instead, their algorithm tries to learn a utility distance $d(U, \zeta_i)$, which models the rank difference k_i of a trajectory pair $\boldsymbol{\tau}_{i1}$ and $\boldsymbol{\tau}_{i1}$, i.e.,

$$L^{\succ}(U, \zeta_i) = \|d(U, \zeta_i) - k_i\|_2, \tag{14}$$

This loss function can be minimized by any regression algorithm. For example, Gritsenko and Berenson (2014) use M5' (Wang and Witten, 1997).

The rank values are subject to a somewhat arbitrary scale (e.g., the difference between mispredictions of neighboring ranks is always the same). As an alternative, the rank values can be encoded as classes instead of numeric values (Gritsenko and Berenson, 2014). Such a multi-class problem can be learned by any conventional classification algorithm, Gritsenko and Berenson (2014) use C4.5 (Quinlan, 1993). The classification model is again used as the utility function where the class is used as utility value. The multi-class loss can not be directly mapped to a preference loss $L^{\succ}(\boldsymbol{\theta}, \zeta_i)$ as the classification problem is discrete and disregards the rank or utility difference.

Christiano et al. (2017) use deep neural networks for approximating a non-linear utility function. They directly minimize the negative log likelihood $-\sum_{i=1}^{N} \log\left(p_{\boldsymbol{\theta}}(\zeta_i)\right)$ with a sigmoid likelihood function. The utility function is not linear in the features, but convex. Hence, it is possible to compute a gradient for the parameters $\boldsymbol{\theta}$ and use common backpropagation techniques for minimizing the loss.

Wirth et al. (2016) and Kupcsik et al. (2015) also allow for non-linear utility functions by using kernel-based feature spaces. While the likelihood function is linear in the resulting, infinite feature space, the effective feature space depends non-linearly on the used samples. Wirth et al. (2016) use Gaussian kernel functions whereas Kupcsik et al. (2015) employ Gaussian process preference learning (Chu and Ghahramani, 2005).

In case the utility function should be applicable to states or state/action pairs, the linearity of the MDPs reward has to be considered (Wirth et al., 2016). Hence, the utility must be linear over the state/action pairs within a trajectory and non-linearity has to be achieved by mapping the state/action features itself, as we will discuss in Sec. 3.3.3.

3.3 The Temporal Credit Assignment Problem

As in all sequence learning problems, a key problem is that it is usually not known which states or actions are responsible for the obtained preference. This *temporal credit assignment* problem is comparable to the delayed reward problem in classic reinforcement learning. It is possible to circumvent it by directly estimating a policy's return in order to approximate the policy value. Methods that provide explicit solutions to the credit assignment typically come with the advantage that standard, reward-based RL methods can be employed. Yet, if we try to solve the credit assignment problem explicitly, we also require the expert to comply with the Markov property. This assumption can easily be violated if we do not use a full state representation, i.e., if the expert has more knowledge about the state than the policy. Depending on how the considered algorithm solves the credit assignment problem, different types of utility functions or preferences can be inferred, which we will discuss in the next subsections.

3.3.1 Value-based Utility

Value-based utility functions estimate the expected long-term utility for a given state, similar to a value function in reinforcement learning. Wirth and Fürnkranz (2012, 2015); Runarsson and Lucas (2012, 2014) use state-preferences $s_{i1} \succ s_{i2}$, which are assumed to originate from the expected utility of the long-term behavior, if we are in the current state and follow an optimal policy. The temporal credit assignment problem is in this case left to the human expert and also not solved explicitly by the algorithm, as we can simply select actions, leading to states with maximal (long-term) utility. To compute the utility $U(s) = \boldsymbol{\theta}^T \boldsymbol{\phi}(s)$ from a state preference, we can again make use of the utility difference $d(\boldsymbol{\theta}, \zeta_i) = \boldsymbol{\theta}^T(\boldsymbol{\phi}(s_{i1}) - \boldsymbol{\phi}(s_{i2}))$ using one of the specified loss functions from Tbl. 1. Using the utility function, we can define the policy

$$\pi^*(a \mid s) = \mathbb{I}(a = \arg\max_{a'} \mathbb{E}_{\delta}[U(s') \mid s, a']), \tag{15}$$

as a greedy policy maximizing the expected value of the next state s'. However, this expectation can only be computed exactly if the transition model δ is known and the state space is discrete. Moreover, value-based utilities always depend on a specific, optimal policy. Hence, it is difficult to transfer the learned value-utility function to other domains.

3.3.2 Return-based Utility

Many approaches that use trajectory preferences circumvent the temporal credit assignment problem by disregarding the temporal structure of the solution. They directly optimize the policy return (Akrour et al., 2011, 2012; Jain et al., 2013, 2015; Gritsenko and Berenson, 2014; Kupcsik et al., 2015) as defined by a return-utility function $U(\boldsymbol{\tau})$. The return utility function $U(\boldsymbol{\tau}) = \boldsymbol{\theta}^T \boldsymbol{\psi}(\boldsymbol{\tau})$ is typically defined by a low dimensional trajectory feature space $\boldsymbol{\psi}(\boldsymbol{\tau})$.

This feature space is usually assumed to be domain-specific (Zucker et al., 2010; Jain et al., 2013, 2015; Gritsenko and Berenson, 2014), however, Akrour et al. (2011, 2012) proposed to cluster the state space using ϵ-means clustering (Duda and Hart, 1973) for defining trajectory features. The trajectory features are given by the relative amount of states in a trajectory belonging to a cluster. Such features can not be directly described as state features as they also depend on the length of the trajectory.

Kupcsik et al. (2015) also learn a return-based utility $U(\boldsymbol{\tau})$ but represent a trajectory $\boldsymbol{\tau} = [\boldsymbol{s}, \boldsymbol{\omega}]$ with a context vector $\boldsymbol{s}$ that describes the current task and a parameter vector $\boldsymbol{\omega}$

that specifies the policy. Instead of using a linear feature representation, a Gaussian process is used to model the return utility $U(\boldsymbol{\tau})$, see Sec. 3.2.3.

3.3.3 Reward-based Utility

Many approaches obtain a state-action utility function that resembles a reward function in classical RL methods, i.e., it evaluates the immediate quality of executing action a in state s without considering the long-term behavior. Using reward-based utilities allows us to apply standard RL methods to improve the policy.

Zucker et al. (2010) propose a simple solution by assuming state preferences $s_1 \succ s_2$ that can be directly used for learning a state utility $U(s)$. For learning a reward-based utility from trajectory preferences, Akrour et al. (2013, 2011, 2014) and Wirth et al. (2016) use the *feature average* (Ng and Russell, 2000) along a trajectory

$$\boldsymbol{\psi}(\boldsymbol{\tau}) = \sum_{t=0}^{|\boldsymbol{\tau}|} \gamma^t \boldsymbol{\varphi}(s_t, a_t), \tag{16}$$

to define trajectory features. Hence, the utility return is defined by

$$U(\boldsymbol{\tau}) = \boldsymbol{\theta}^T \boldsymbol{\psi}(\boldsymbol{\tau}) = \sum_{t=0}^{|\boldsymbol{\tau}|} \gamma^t U(s_t, a_t),$$

with $U(s_t, a_t) = \boldsymbol{\theta}^T \boldsymbol{\varphi}(s_t, a_t)$, which coincides with the definition of the return in reinforcement learning. The trajectory utility $U(\boldsymbol{\tau})$ is a linear sum over the state/action utilities but the state/action utilities themselves can be non-linear. As an example, Wirth et al. (2016) use a kernel function to obtain such a non-linear utility by applying the kernel on a state/action level. Sugiyama et al. (2012) proposed an alternative learning method, based on the sum of future utilities

$$\begin{aligned} U(s,a) &= \sum_{s' \in S} \left(\delta(s' \mid s, a) \left(U(s,s') + \max_{a' \in A} \sum_{s'' \in S} \delta(s'', s', a') U(s' \mid s'') \right) \right), \\ U(s,s') &= \boldsymbol{\theta}^T \boldsymbol{\varphi}(s,s'), \end{aligned} \tag{17}$$

with $U(s, s')$ as the utility for the state transition s to s'. However, this idea is only applicable with a known transition function and a discrete action space.

More recently, a method was proposed that does not require the utility to be linear in the state/action features. Christiano et al. (2017) define a learning method for a trajectory utility $U(\boldsymbol{\tau}) = \sum_{t=0}^{|\boldsymbol{\tau}|} U(s_t, a_t)$, that uses a deep neural network for $U(s_t, a_t)$. This method greatly improves on the scalability of the learning process and allows more expressive utility functions, but requires a high amount of preferences.

In contrast to conventional reinforcement learning, a discount factor of $\gamma = 1$ is used for $U(\boldsymbol{\tau})$ in all approaches because the expert should not need to consider the effects of decay. However, using an undiscounted return is not a major problem as all considered trajectories have a finite length. The parameters $\boldsymbol{\theta}$ can now be estimated by using one of the loss functions presented in Sec. 3.2.3, where trajectory preferences are used as constraints for

the utility return $U(\boldsymbol{\tau})$. The underlying assumption of using immediate utility functions is that the expert's evaluation function complies with the Markov property. If this is not the case, the decomposition of the utility return in immediate utilities is error prone. Instead of using state-action utilities $U(s, a)$, some algorithms (Wirth et al., 2016) also disregard action costs and just use a state utility function, i.e., $U(s, a) = U(s)$.

In contrast to value-based utility functions, reward-based utility functions can be easily transferred across domains. Moreover, a reward-based utility is also independent of the system dynamics and, therefore, often has a simpler structure than value based utilities rendering them simpler to learn and generalize.

3.3.4 Intermediate Action Preferences

Wirth and Fürnkranz (2013a) extend the action preference algorithm of Fürnkranz et al. (2012) by deriving additional action preferences for intermediate states in trajectory preferences, defining an approximate solution to the temporal credit assignment problem. As in the original algorithm, preferences are assumed to relate to the long-term expectation. The assignment problem is solved by attributing preferences to an (unknown) subset of action choices made in states occurring in both trajectories, when following a fixed policy in all other states. This enables the computation of the probability that a single state/action pair is responsible for the encountered preference.

This approach may converge faster than the one of Fürnkranz et al. (2012) using a lower amount of preferences. However, the speedup comes at the cost of possible approximation errors due to possibly incorrect, heuristic estimates of the preferences. Wirth and Fürnkranz (2013b) extend this idea further by obtaining more reliable, intermediate preferences based on the assumption that each time step contributed equally to the return of the trajectory. As a result, an even lower amount of preferences is sufficient. However, many domains do not satisfy this uniform reward assumption.

3.4 Trajectory Preference Elicitation

PbRL may be viewed as an interactive process that iteratively queries the expert's preference function to obtain more knowledge about the objectives of the expert while also exploring the system dynamics. In decision making, this process is also known as *preference elicitation*.

Several approaches disregard this problem and only work with an initial set of preferences (Wirth and Fürnkranz, 2012, 2015; Runarsson and Lucas, 2012, 2014; Gritsenko and Berenson, 2014; Zucker et al., 2010; Sugiyama et al., 2012). Fürnkranz et al. (2012) collect new preference feedback, but assume exhaustive samples of the system dynamics and, hence, no additional exploration is needed.

Interactive PbRL algorithms need to decide how to generate new trajectories and how to use these trajectories to query the expert's preference function. Typically, an exploration method is used that reduces the uncertainty of the transition function as well as the expert's preference function. Yet, some approaches apply two distinct methods for exploring the system dynamics and the preference space.

Usually, we want to minimize the amount of expert queries as they require costly, human interaction while generating new trajectories can be a cheaper, mostly autonomous process. Moreover, a trajectory can give us useful information about the system dynamics even if

it is not used for preference generation. Hence, the number of trajectories can be considerably higher than the number of generated preferences. Yet, many algorithms ignore the potentially higher costs of preference generation in comparison to trajectory generation, as we will elaborate in the following discussion.

3.4.1 Trajectory Generation

Interactive PbRL algorithms need to generate diverse trajectories. In order to be informative, the obtained preferences should be different from existing trajectories. Yet, the trajectories should also be close to optimal in order to obtain useful information. Furthermore, the trajectories need to contain sufficient information about the transition function to compute an optimal policy.

Undirected Homogeneous Exploration. *Homogeneous exploration* employs a single exploration to generate diverse solutions, either directed or undirected. Such methods are undirected if they only compute stochastic policies that allow deviations from the optimal strategy while directed methods implement a separate criterion for guiding the exploration in areas of the state space where uncertainty can be reduced. Directed methods usually work better in low-dimensional policy spaces but do not scale well.

Most approaches (Busa-Fekete et al., 2013, 2014; Jain et al., 2013, 2015; Wirth and Fürnkranz, 2013a,b; Kupcsik et al., 2015; Wirth et al., 2016; Christiano et al., 2017) only use undirected exploration for the system dynamics and make the assumption that this will also explore the expert's preference function sufficiently well. Busa-Fekete et al. (2013, 2014) use a *covariance matrix adaptation evolution strategy* (CMA-ES; Hansen and Kern 2004) for optimization and exploration. They implement a criterion for limiting the amount of samples that have to be evaluated to obtain a ranking. The algorithm maintains a collection of candidate policies and discards candidates once they can be considered suboptimal, according to the Hoeffding bound (Hoeffding, 1963). Jain et al. (2013, 2015) use *rapidly-exploring random trees* (LaValle and Kuffner, 1999) whereas Wirth and Fürnkranz (2013a,b) employ approximate policy iteration (Dimitrakakis and Lagoudakis, 2008) with an EXP3-like exploration method (Auer et al., 1995).

Wirth et al. (2016) use *relative entropy policy search* (REPS; Peters et al. 2010) for computing a stochastic policy based on the policy's return, estimated with *least squares temporal difference (LSTD)* learning (Boyan, 1999). Kupcsik et al. (2015) employ *contextual REPS* (Kupcsik et al., 2014), but directly in parameter space instead of state action space. This variant is able to evaluate parametric policies without requiring transition samples due to the black-box character of the algorithm. The result of the policy improvement step is a distribution over parametric policies that is used to sample new trajectories for querying new preferences. In turn, the distribution over possible utility functions is updated for computing an improved estimate of the expected utilities for the next policy update step.

Christiano et al. (2017) use Trust Region Policy Optimization (TRPO; Schulman et al. 2015) and (synchronous) A3C (Mnih et al., 2016), which are policy optimization algorithms for RL with deep neural networks. Both algorithms also ensure exploration by defining stochastic policies, hence they are undirected.

Directed Homogeneous Exploration. In contrast to undirected approaches, Wilson et al. (2012) propose two directed exploration criteria that are derived from the preference learning method explained in Sec. 3.4.3. However, they also only use a single, homogeneous exploration method. The policy improvement is computed by updating the posterior distribution of a parametric policy space, given a preference-based likelihood function. A new preference query is then created by applying two policies to the MDP, selected by the directed exploration criterion. The computation of these criteria requires multiple trajectories, but they are not used for the queries themselves or for the policy improvement step.

Heterogeneous Exploration. *Heterogeneous exploration* methods use two distinct strategies for exploring the system dynamics and the preference function. For example, Akrour et al. (2011, 2012, 2014) employ different criteria that are well suited for the two tasks. A policy search strategy with an intrinsic exploration method is used to optimize a given utility function. In addition, the utility function implements a criterion for directed exploration of the preference function. Therefore, the resulting policy can be used to sample trajectories for preference queries that reduce the uncertainty over the expert's feedback. Such a strategy comes at the cost of sampling new trajectories for multiple policy update steps before each new preference query. Akrour et al. (2014) propose an alternative version using *least squares policy iteration* (Lagoudakis and Parr, 2003), that does not require additional samples for updating the policy in an off-policy manner. Yet, this approach requires a sufficient amount of samples collected in advance which is unrealistic in many scenarios.

User-Guided Exploration. *User-guided exploration* allows the expert to provide additional trajectories to guide the exploration process. The algorithm by Zucker et al. (2010) assumes a set of initial state preferences and optimize the resulting utility function using a randomized planner (*anytime A**; Likhachev et al. 2003). The planning algorithm samples new trajectories and the expert can select any encountered state to provide additional preferences, i.e., the expert is guiding the exploration of its preference space. In case the expert does not provide additional preferences, no further exploration of the preference function is used. The approach of Jain et al. (2013, 2015) extends the used homogeneous strategy with user-guided exploration. Given a trajectory that has been autonomously generated, the expert may correct the trajectory which simultaneously also provides a preference.

3.4.2 Preference Query Generation

Having generated the trajectories, we need to decide which trajectories to use to query the expert's evaluation function. Typically, the newly generated trajectories are compared to so far undominated trajectories (Akrour et al., 2012, 2011; Wirth et al., 2016; Akrour et al., 2014). Yet, this solution is only feasible if all trajectories are directly comparable, e.g., they start in the same initial state, which is a standard assumption for most PbRL algorithms. Alternatively, both trajectories are explicitly generated by the algorithm (Busa-Fekete et al., 2013, 2014; Jain et al., 2013, 2015; Wirth and Fürnkranz, 2013a,b; Kupcsik et al., 2015; Wilson et al., 2012) or the user selects the samples for a preference query (Zucker et al., 2010).

Exhaustive Preference Query Generation. Some approaches require that each trajectory is evaluated by the expert by defining preferences regarding every possible trajectory pair, either for comparing and selecting policies (Busa-Fekete et al., 2013, 2014) or for evaluating and updating a single policy (Jain et al., 2013, 2015; Wirth and Fürnkranz, 2013a,b;

Kupcsik et al., 2015). These approaches ignore that generating preferences can be more costly than generating trajectories and, hence, typically require a large amount of expert queries.

Greedy Preference Query Generation. In greedy approaches (Akrour et al., 2014), we fully optimize a given objective, described in Sec. 3.4.3, which can be either an undirected or directed exploration objective. After the optimization is finished, we use a trajectory generated from the optimized policy to query the expert's evaluation function. While this approach is typically much more efficient in the number of expert queries, it may need many trajectories to be generated in order to optimize the posed objective. Furthermore, many of these trajectories might have been unnecessarily generated as the posed objective is typically quite error-prone in the beginning of the learning process. Hence, the optimization might explore poor trajectories which could have been avoided if new preferences would have been requested earlier before reaching the maximum of the given objective.

Interleaved Preference Query Generation. The above-mentioned problem was recognized by several authors (Akrour et al., 2012, 2011; Wirth et al., 2016; Wilson et al., 2012; Christiano et al., 2017). A simple solution to alleviate it is to prematurely stop the optimization of the given objective and request new preferences. The preferences are subsequently used to update the given optimization objective (see Sec. 3.4.3). This approach is followed by Akrour et al. (2012, 2011) where the search in parameter space is stopped early, after a given number of iterations. Wirth et al. (2016); Christiano et al. (2017) request new preferences after a single iteration of the used policy optimization algorithm. In each iteration, several trajectories are generated by the current policy but only a subset (typically one) is used for an expert query. Wirth et al. (2016) propose to use the trajectory with the highest expected accumulated utility, whereas Christiano et al. (2017) use a variance estimate, based on an ensemble technique. Wilson et al. (2012) apply the same idea to a parametric policy space, using a selection criterion based on expected belief change. An alternative method selects two policies that are used for creating trajectories for a new preference query. In contrast to Wirth et al. (2016), this algorithm completely discards trajectories that are not used for preference queries, as it is only able to use explicitly evaluated trajectories. Hence, not all trajectories are evaluated, but only evaluated trajectories are used to update the policy.

The resulting algorithms allow to choose the trade-off between the cost of trajectory generation and preference generation by controlling the ratio of generated trajectories to generated preferences. Akrour et al. (2012, 2011); Wirth et al. (2016) can also efficiently explore the trajectory space as well as the preference space as they can use trajectories not evaluated by the expert for policy optimization.

3.4.3 Objectives for Exploring the Preference Function Space

A few algorithms formulate an explicit objective in order to efficiently reduce the uncertainty over the expert's preference function. Different versions have been proposed, but no exhaustive comparison of all exploration methods can be found in the literature. A limited, comparative evaluation was conducted by Wilson et al. (2012) who compared two criteria proposed in the paper.

They suggest to sample multiple policies from the posterior distribution of the policy space and use them to compute trajectories for preference queries. The first method only

considers the expected difference of the trajectories generated by two policies

$$\int_{(\boldsymbol{\tau}_i,\boldsymbol{\tau}_j)} \Pr(\boldsymbol{\tau}_i \mid \pi_i) \Pr(\boldsymbol{\tau}_j \mid \pi_j) d(\boldsymbol{\tau}_i, \boldsymbol{\tau}_j), \tag{18}$$

where $d(\boldsymbol{\tau}_i, \boldsymbol{\tau}_j)$ is a trajectory difference function (see (4)). If two policies disagree greatly on what trajectories to create, it is assumed to be beneficial to rule out one. Therefore, samples from π_i and π_j are evaluated and a query is posed in case the value of the criterion exceeds a given threshold.

The second criterion computes the expected belief change over the policy space that results from adding a preference

$$V(\Pr(\pi \mid \zeta) || \Pr(\pi \mid \zeta \cup \{\boldsymbol{\tau}_{i1}, p_i, \boldsymbol{\tau}_{i2}\}), \tag{19}$$

using potential queries by sampling policies from the current distribution. Different measures could be used as V, e.g. the Kullback-Leibler divergence. Wilson et al. (2012) use an approximation of the variational distance. The query maximizing the criterion, based on a finite trajectory sample set, is then posed to the expert.

Akrour et al. (2011, 2012, 2014) define a utility function that includes an exploration term. The simplest form

$$\begin{aligned} \tilde{U}(\pi) &= U(\pi) + \alpha E(\pi), \\ U(\pi) &= \mathbb{E}_{\Pr_\pi(\boldsymbol{\tau})}[U(\boldsymbol{\tau})], \\ E(\pi) &= \min \Delta(\pi, \pi'), \pi' \in \Pi_t, \\ \Delta(\pi, \pi') &= \frac{|S_1| + |S_2| - |S_3|}{\sqrt{|S_1| + |S_3|}\sqrt{|S_2| + |S_3|}}, \end{aligned} \tag{20}$$

used by Akrour et al. (2011), adds a diversity term to the expected utility of a policy, comparing the states in S_1, only visited by π, the states in S_2, only visited by π' and the states in S_3 visited by both policies. Π_t are all policies obtained up to the current iteration. Candidate policies are generated by an evolutionary strategy and $\mathbb{E}_{\Pr_\pi(\boldsymbol{\tau})}[U(\boldsymbol{\tau})]$ is approximated via samples. The diversity function $\Delta(\pi, \pi')$ rewards differences in the states visited and is only applicable to discrete state spaces, however, a discrete description can be obtained using a clustering algorithm (see Sec. 3.3.2). Akrour et al. (2012, 2014) propose a different selection criterion that maximizes the expected utility of selection

$$\tilde{U}(\boldsymbol{\tau}) = \Pr(\boldsymbol{\tau} \succ \boldsymbol{\tau}^* \mid U) \mathbb{E}_{\zeta \cup \{\boldsymbol{\tau} \succ \boldsymbol{\tau}^*\}}[U(\boldsymbol{\tau})] + \Pr(\boldsymbol{\tau} \prec \boldsymbol{\tau}^* \mid U) \mathbb{E}_{\zeta \cup \{\boldsymbol{\tau} \prec \boldsymbol{\tau}^*\}}[U(\boldsymbol{\tau}^*)], \tag{21}$$

with $\boldsymbol{\tau}^*$ as the currently undominated trajectory. It computes the expected utility for the undominated trajectory, differentiating the cases where the new trajectory $\boldsymbol{\tau}$ is preferred over the current best and where it does not improve. $\Pr(\boldsymbol{\tau} \succ \boldsymbol{\tau}^* \mid U)$ is the probability of improvement, given the current distribution over utility functions. The expected utility $\mathbb{E}_{\zeta \cup \{\boldsymbol{\tau} \succ \boldsymbol{\tau}^*\}}[U(\boldsymbol{\tau})]$ is then computed with the assumption that the new preference is added to the preference set ζ. The two publications (Akrour et al., 2012, 2014) differ in the method used to approximate the criterion.

Wirth et al. (2016) also maintains the current, best trajectory for preference queries. The trajectory maximizing the expected utility

$$\boldsymbol{\tau} = \arg\max_{\boldsymbol{\tau} \in \boldsymbol{\tau}^{[i]}} \mathbb{E}\left[U_\zeta(\boldsymbol{\tau})\right], \tag{22}$$

is selected to obtain the second trajectory for the preference query. $\boldsymbol{\tau}^{[i]}$ is a set of trajectories obtained by sampling from the current policy π_i. Trajectories obtained from sampling former policies are not considered.

Christiano et al. (2017) also use trajectories obtained from the current policy, but evaluate pairs based on the variance of the utility. They approximate the variance by obtaining utility samples from an ensemble of utility functions. Each utility function uses a randomly sampled subset of the available preferences, hence, the learned functions may differ.

3.5 Policy Optimization

A major consideration is how the policy is optimized and how the policy optimization method affects the optimality of the learned policy and the sample requirements of the algorithm.

3.5.1 Direct Policy Search

Direct policy search approaches typically directly search in the parameter space of the policy and do not assume the Markov property or use dynamic programming such as standard reinforcement learning approaches. They maximize the objective defined by (2) and (3), however, this is difficult to compute directly due to the dependence on the transition dynamics. Hence, methods like policy likelihood or ranking (cf. Sec. 3.2.1) are used. Alternatively, common return-based optimization can be employed by defining an utility-based return, as introduced in Sec. 3.3.2.

Direct policy search methods are typically not very sample-efficient, as the temporal structure of the problem is ignored, but they can obtain good results because of their simplicity. These methods can be typically used for policies with a moderate number of parameters, typically less than one hundred.

Wilson et al. (2012) employ *Markov Chain Monte Carlo* (MCMC; Andrieu et al. 2003) sampling to obtain the posterior distribution of a parametric policy space. The sampling is computational costly, but does not require new trajectory samples. A sampling approach is also used by Busa-Fekete et al. (2013, 2014), but within an *evolutionary algorithm* where policies are described with a set of parameters. Akrour et al. (2011, 2012, 2014) also use an evolutionary strategy ($1 + \lambda$ ES; Auger 2005) for optimization in a parametric policy space, which requires a high amount of trajectory samples.

The contextual REPS (Kupcsik et al., 2014) algorithm, as employed by Kupcsik et al. (2015), is also a strategy for optimizing parameters of the policy. In the contextual settings, we can learn to adapt the policy parameters to the context of the task. For example, it can learn to adapt the robot's trajectory if we need to throw a ball for a larger distance (Kupcsik et al., 2014).

3.5.2 Value-based Reinforcement Learning

Value-based approaches exploit the temporal structure of the problem by using the Markov property, which, in principle allows for more sample efficient policy optimization. However, these methods might suffer from approximation errors which can lead to instabilities and divergence. Typically, value-based methods use some variant of policy iteration that is again composed of a policy evaluation step and a policy improvement step. In the policy evaluation step, the estimated reward-based utility (Akrour et al. 2014; Wirth et al. 2016; Christiano et al. 2017; cf. Sec. 3.2.3) is used to compute a value function for the policy. This value function can, for example, be estimated by temporal difference methods such as *least squares temporal difference learning* (LSTD; Boyan 1999). Given the value function, a new policy can be obtained in the policy improvement step. For example, Wirth et al. (2016) uses a variant of the *relative entropy policy search* (REPS) algorithm (Peters et al., 2010) to update the policy. The REPS algorithm performs a soft-greedy policy update that stabilizes the policy iteration process and is also applicable in continuous action spaces. The TRPO (Schulman et al., 2015) algorithm employed by Christiano et al. (2017) works comparably, but uses deep neural networks for approximating the value function and the policy. A separate algorithm for computing the value function is not required.

In discrete action spaces, greedy updates using the max-operator have been used (Akrour et al., 2014). However, this approach requires a sufficient amount of transition samples to be obtained beforehand which again stabilizes the policy iteration process.

Other authors (Fürnkranz et al., 2012; Wirth and Fürnkranz, 2012, 2013a,b, 2015; Runarsson and Lucas, 2012, 2014; Sugiyama et al., 2012) assume a utility function directly defining the expected outcome of a state or action. Hence, an optimal policy is derived by directly selecting the action maximizing the utility. In case of state values (Wirth and Fürnkranz, 2012, 2015; Runarsson and Lucas, 2012, 2014), this step requires the transition model to be known.

3.5.3 Planning

Many other approaches (Zucker et al., 2010; Jain et al., 2013, 2015; Gritsenko and Berenson, 2014) use planning algorithms for optimizing policies. Planning-based algorithms use utility-based approaches to derive an evaluation measure for trajectories (or state/actions). Furthermore, a model of the system dynamics is required to determine the effects of actions. It is then possible to plan a sequence of actions that maximizes the given utility. However, a model of the system dynamics is in many cases not available with a sufficient accuracy.

The use of sampling-based *rapidly-exploring random trees* (RRT; LaValle and Kuffner 1999) and their *constrained bi-directional* variant (CBiRRT; Berenson et al. 2009) was explored in (Jain et al., 2013, 2015; Gritsenko and Berenson, 2014). RRTs are guaranteed to find a solution to a planning problem, but provide no guarantees for the optimality of the found solution. Other planning algorithms come with such guarantees, such as *anytime A** (ARA*; Likhachev et al. 2003), as used by Zucker et al. (2010). Planning methods require an accurate model of the system dynamics and inherently suffer from model errors. Small inaccuracies in the model might be exploited by the planning method which may result in solutions that are not feasible on the real system.

3.6 Modelling the Transition Dynamics

The reviewed algorithms also differ with respect to the amount of available model knowledge, which has a big influence on which tasks the approaches are applicable. *Model-based approaches* assume that the system dynamics are known in advance, which allows the use of planning algorithms (Jain et al., 2013, 2015; Gritsenko and Berenson, 2014; Zucker et al., 2010) or to directly derive an optimal policy (Wirth and Fürnkranz, 2012, 2015; Runarsson and Lucas, 2012, 2014; Sugiyama et al., 2012). In addition, some approaches require a model to be able to simulate the system initialized at arbitrary states (Fürnkranz et al., 2012; Wilson et al., 2012).

The transition dynamics of real world problems are usually not known, as they are subject to a wide variate of (unknown) factors. Hence, many model-based approaches try to learn the dynamics based on observed transitions (Grünewälder et al., 2012). However, model learning can be a complicated task in particular for continuous systems and is a research field on its own (Nguyen-Tuong and Peters, 2011). It might require a high amount of samples, we need to choose a suitable model class and the resulting model errors often decrease the quality of the resulting policy.

Alternatively, *model-free approaches* neither assume a model, nor approximate it (Fürnkranz et al., 2012; Wirth and Fürnkranz, 2013a,b; Busa-Fekete et al., 2013, 2014; Wirth et al., 2016; Akrour et al., 2014). For example, Akrour et al. (2014) assume a large database of pre-generated samples which can be subsequently used for model-free, off-policy reinforcement learning algorithms. Most model-free PbRL approaches, with the exception of Wirth et al. (2016), are not able to reuse samples, and therefore require a large amount of samples for comparing or evaluating policies. All algorithms that employ direct policy search strategies are in principle model-free, as the only requirement of such algorithms is that a policy can be executed on the real system. However, as these algorithms often require a lot of policy executions in order to find an optimal policy, it is often assumed that a simulator is available to avoid the costly optimization on the real system. A notable exception is the algorithm by Kupcsik et al. (2015) where the policy optimization is performed without requiring the transition dynamics. Trajectories from the real system are only used to compute an evaluation function for parametric policies.

3.7 Summary of PbRL Algorithms

Tbl. 2 shows a tabular summary of the discussed algorithms, grouped by the different learning problems, introduced in Sec. 3.2. We list the introduced key concepts and the different *requirements*, stated throughout this paper. The *preferences* column is related to the different types of preferences mentioned in Sec. 3.1. The *trajectory generation* and *preference (query) generation* columns are based on the subsections of Sec. 3.4, where we mention how trajectories and preference queries are generated to resolve the exploration problem. The various approaches use different optimization strategies for performing policy optimization and surrogate loss minimization, if applicable. The columns *surrogate optimization* and *policy optimization* show the strategies mentioned in Sec. 3.2 and Sec. 3.5 explicitly.

4. Experiment Domains

Most practical applications for PbRL focus on robot teaching tasks and on board game domains. These domains can be subject to complex reward shaping problems (Ng et al., 1999) as it is required to not only solve the task itself, but also consider constraints like motor limitations or obstacle avoidance. Furthermore, a robot acting in uncontrolled environments needs to cope with changing environments, interact with non expert users and adapt to new tasks. For such tasks, PbRL is a suitable tool as it allows robots to learn without expert knowledge or predefined rewards. In the following, we highlight a few domains where preference-based approaches have been successfully employed in the past.

4.1 Object Handover

Kupcsik et al. (2015) use a preference-based approach to learn a robot handover task where a robot has to pass a bottle to a person sitting, walking or running, as shown in Fig. 4. The handover should be performed as comfortably as possible for the human which approaches at different speed. Hence, the stiffness as well as the trajectory of the robot's end-effector need to be adapted by the learning procedure.

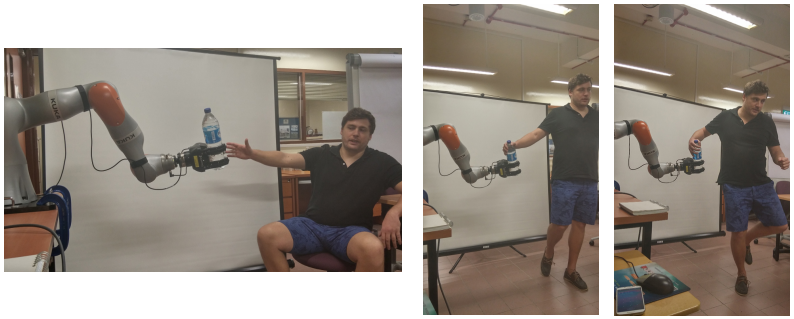

Figure 4: The robot handover task with a sitting, standing and running person

As described in Strabala et al. (2013), this task consists of three stages: approach, signal and transfer. First, the robot needs to approach the human and get ready for the actual handover. In the signaling phase, the robot and the human need to exchange information for determining the intended joint position for the handover. This information exchange is often non-verbal. Lastly, the joint contact needs to be established. This physical transfer should be dynamic and should not require a stationary contact phase. The focus of Kupcsik et al. (2015) is on this last phase. Experiments are performed with a real *7-DoF KUKA LBR arm* and a *Robotiq 3-finger hand* in a laboratory setup, as shown in Fig. 5. The robot performs several handover trials with a human receiving the object. Feedback is obtained in terms of trajectory preferences, but can be enhanced with an ordinal evaluation on a 1–10 scale. The trajectories are considered to be samples of a parametric policy and the related feedback is used to learn an evaluation function for policies, as described in Sec. 3.2.3 and 3.4.1. The evaluation function uses the policy parameters as input, allowing to define a

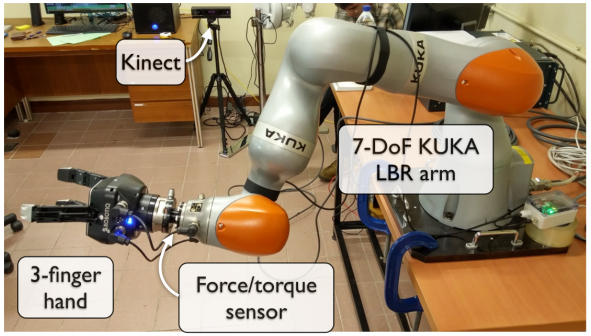

Figure 5: The robot KUKA robot with a 3-finger hand

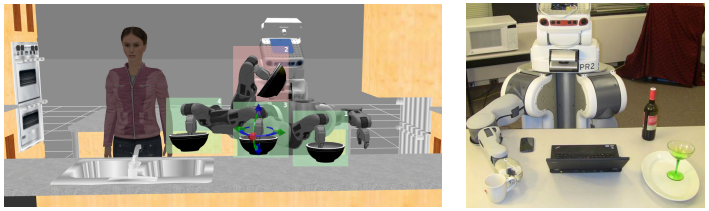
likelihood function for the feedback, given a parametric policy. Using Bayesian inference and a Gaussian process prior, it is possible to infer the policy evaluation function explicitly. Policies can be evaluated without obtaining trajectory samples by directly evaluating the policy parameters. Hence, no costly environment calls are needed for optimizing the policy.



The performed evaluation shows a steady improvement, averaged over 5 trials. Furthermore, the return of the policy approaches a plateau after 80 policy updates. However, the exact amount of used preferences as well as the performance difference to an optimal policy remain unclear.

In general, the approach is very interesting for domains where (low-dimensional) parametric policies are available and trajectory generation is expensive. Only learning the utility function requires trajectory sampling. Furthermore, the process can probably be improved further by considering specific preference function exploration criteria, as introduced in Sec. 3.4.3. However, the approach is most likely not suited for high-dimensional policy spaces because of the Gaussian process. Gaussian process-based methods are computational expensive and require a high number of samples to sufficiently capture complex policies. Hence, a high number of trajectory samples and preferences would be required.

4.2 Path Planning

Jain et al. (2013, 2015) also tries to solve robotic tasks, but use a simulated setup, shown in Fig. 6a. Due to the simulated setup, the authors were able to evaluate their system on a wide range of path planning tasks, namely:

- pick and place, e.g., moving a glass of water without spilling water;
- inserting, e.g., placing or knife inside a holder;
- pouring, e.g., pouring water into a cup;
- heavy-fragile movement, e.g., moving a heavy object with a fragile object close by;
- liquid-electronic movement, e.g., moving a glass of water with a laptop in vicinity;

(a) The simulation environment

(b) The real robot

Figure 6: The experiment setup of Jain et al. (2013, 2015)

- sharp-object movement, e.g., moving a knife with a human in range;
- hot-object movement, e.g., serving a hot drink.

Overall, for evaluating their approach, they defined 35 tasks by changing the objects and/or environment. The robot demonstrates a set of trajectories, which are ranked by the algorithm. The user can then define preferences by re-ranking them or by supplying new trajectories, which are assumed to be an improvement over all trajectories demonstrated by the robot. Hence, they are added to the ranking as the top-ranked element. Preferences are then obtained by computing all pairwise preferences contained in the ranking.

For evaluating the approach, an expert scored 2100 trajectories in total, based on a 1–5 scale. From these scores, the authors derive a ranking and compare it with a ranking based on the learned utility. They achieve an nDCG@1(nDCG@3) ranking error (Manning et al., 2008) of 0.78(0.66) to 0.93(0.92) after obtaining feedback 20 times. The ranking error is averaged over multiple tasks, grouped into three categories. The used feedback is only a re-ranking of 5 obtained trajectories by picking the most preferred one. The exact amount of derived preferences is unclear.

The work of Jain et al. (2013, 2015) is especially interesting because it was demonstrated to be applicable in a wide range of domains. In contrast to Kupcsik et al. (2015), a low-dimensional policy space is not required, but a predefined trajectory feature space. Arguably, this requirement is easier to satisfy and apply. However, the utility function has to be linear in the given feature space but the method could be combined with non-linear utility functions, as introduced by Wirth et al. (2016).

4.3 Chess Agent

An application of PbRL to board games was demonstrated by Wirth and Fürnkranz (2012, 2015). They use already available data from the chess domain to learn an artificial chess agent. Professional chess games are commonly stored in large databases, where many games annotate move and position with a unified symbol set, as shown in Fig. 7. The annotation symbols define the quality of a position or move, e.g., the white/black player has a decisive/moderate/slight advantage over her opponent[3]. In the given example, the annotator

3. http://portablegamenotation.com/Symbols.html

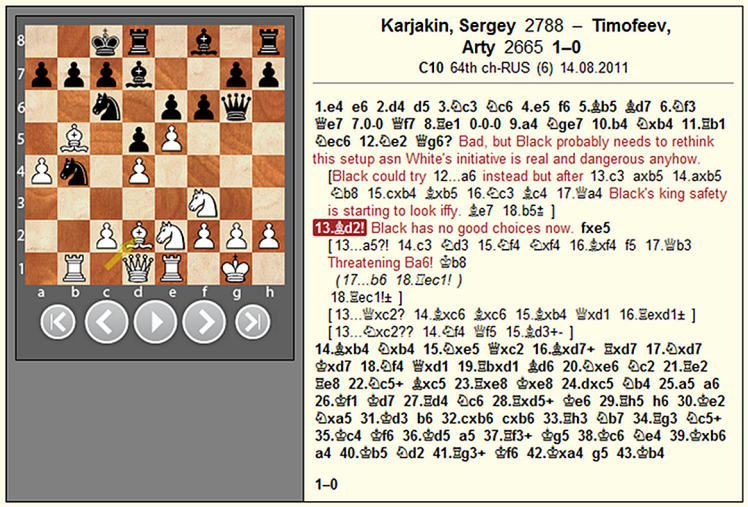


Figure 7: A chess position with move history and annotations.

remarked that White's move 13.♗d2! was a very good move (indicated by the exclamation mark at the end of the move), and provides three alternative replies for the move 13...fxe5 that was played in the game: 13...a5?! is dubious, 13...♕×c2? is a mistake, and 13...♘×c2?? is a losing move. The positions at the end of these variations are also annotated with symbols like ±, indicating a small advantage for White, or +− indicating a decisive advantage for White. It is straight-forward to derive preferences over moves and positions from such annotations. The preferences can then be used to learn a state utility function which estimates the expected outcome of a position. A policy is then derived by maximizing the utility, using the already known chess transition function.

The results in this domain show that it is possible to approach the performance of a near-optimal handcrafted utility function. However, the best results require 2.12M preferences and use a pre-defined utility feature space with only 15 dimensions.

It can be concluded that this approach is interesting for domains where it is easily possible to derive high number of (noisy) preferences. However, if optimal policies are of importance, it should probably only be used for computing an initial solution that can be further refined by applying one of the other PbRL approaches.

4.4 Other Domains

Nearly all other approaches are evaluated on classical reinforcement learning toy domains, where qualitative preferences are derived from the quantitative returns of the trajectories. Commonly used domains are the *mountain car* (Sutton and Barto, 1998), *pendulum swing-up* (Åström and Furuta, 2000), *cart-pole balancing* (Wang et al., 1996), *acrobot* (Spong, 1994),

and the *bicycle balance* (Randløv and Alstrøm, 1998) domains. Two approaches also use a simple grid world defined by Akrour et al. (2014). This *grid world* is easy to solve from a reinforcement learning point of view, but difficult for preference learning as the ground-truth reward values are very similar for some states. Typical state-of-the-art approaches require $5 - 40$ preferences to compute an optimal policy in these domains. Several algorithms are also evaluated on a *cancer treatment* task, derived from a reward based setting by Zhao et al. (2009). More complex toy domains have been used by Christiano et al. (2017), as they employ the ATARI learning environment (Bellemare et al., 2013) and the MuJoCo framework (Todorov et al., 2012) for learning movement and other robotic tasks. Interestingly, they have been able to outperform state-of-the-art RL approaches with numeric rewards in several domains, however they required several hundred preferences.

Runarsson and Lucas (2012, 2014) use the board game Othello, in a setting that is similar to the experiments by Wirth and Fürnkranz (2012, 2015). However, preferences are not derived from human annotations, but by assuming that observed state/action choices are preferable to unseen alternatives. This relates the approach closely to inverse reinforcement learning, although, the system directly learns a value function instead of a reward function. Sugiyama et al. (2012) derive preferences from numeric ratings and also learn a value function, however, in a human dialog setting. They show improvements over classic RL and IRL approaches. A detailed overview of experiment domains and evaluated approaches is given in Tbl. 3. Domain setups are not always identical and may differ in details such as the noise level, used feature space or action limits. Hence, even in the few cases where two papers do publish results of the same evaluation domain, the results are usually not directly comparable.

5. Discussion

While there has been much progress in the recent years in PbRL, many open questions and shortcomings of the approaches remain. For example, none of the utility-based approaches are able to produce a set of Pareto-optimal policies in case of incomparabilities. Only the *direct policy learning* method of Busa-Fekete et al. (2014) can handle incomparabilities by assuming that the incomparable trajectories should be evaluated equally, i.e., that both trajectories receive the same probability. A potential solution to cope with incomparabilities would be to learn a non-scalar utility function, allowing the utility functions to differ in multiple dimensions. A set of Pareto-optimal policies could then be learned using *multi-objective reinforcement learning* (Liu et al., 2015).

The question of preference-space exploration has also not yet been addressed satisfactorily. While a few approaches for preference-space exploration have been proposed (Sec. 3.4.3), a principled integration into the policy-space exploration strategy is still missing. Both tasks should be combined efficiently to reduce the amount of trajectory samples and preferences that are required. In addition, very few utility-based approaches are able to learn non-linear utility functions. Gritsenko and Berenson (2014) learn non-linear utilities but require that the PbRL problem is turned into an ordinal ranking problem first (Sec. 3.2.3). Ordinal rankings are problematic in that arbitrary distances between ranks are introduced when they are treated as regression problems, whereas the classification case suffers from a severe loss of information. Wirth et al. (2016); Kupcsik et al. (2015) employ

Table 3: Overview of evaluation domains

kernels for overcoming this problem, an idea applicable to all linear utility function learning problems. However, this results in a high-dimensional utility space and is computational costly. Hence, the approaches do not scale well to high dimensional spaces. The deep neural network based approach by Christiano et al. (2017) overcomes the scalability issues of kernel-based methods but requires a high amount of preferences. Further research is required to either scale preference-based learning with kernels to larger problems spaces or to improve the results from DNN-based approaches with low amounts of training data.

Another important research question is to find principled ways for combining various types of feedback from the human expert, such as preferences, ordinal or numeric feedback, and demonstrations. In particular, inverse reinforcement learning from demonstrated trajectories could be used to provide good initializations for learning a utility function. This utility could then be refined by preferences of the experts.

Furthermore, PbRL can currently not be used to perform risk-averse optimization (Coraluppi and Marcus, 1999; Geibel, 2001). Risk-adverse optimization guarantees that

the worst case performance of the algorithm is bounded. In many cases, it is required that certain trajectories are not realized, for example, trajectories that would damage the robot or its environment. Such risk-adverse behavior could be realized with weighted preference loss functions such as (3), i.e., by substantially increasing the weights of preferences that concern risky trajectories.

Another important open issue, which would substantially extend the range of possible applications of PbRL, is to develop techniques that are able to use preferences between trajectories starting from different initial states. A potential solution could be to take the expected value of initial states into account and compute the preference based on the advantage function.

As mentioned in Secs. 3.4 and 3.5, most approaches are lacking in terms of sample efficiency. While sample efficiency could already be improved by using reward-based utilities (see Sec. 3.2.3) which allow sample reuse for policy optimization (Wirth et al., 2016), more efficient model-based policy search strategies such as the PILCO algorithm (Deisenroth and Rasmussen, 2011) or guided policy search (Levine and Koltun, 2013) could be employed that learn a system dynamics model from the data and employ it for policy optimization. Moreover, we have seen that the complexity of the tasks that have been used for learning is limited. More complex policies, which, e.g., can directly use sensory feedback as inputs, could be acquired by incorporating recent successes from deep reinforcement learning (Mnih et al., 2015, 2016).

Furthermore, PbRL is still lacking a unified evaluation framework. The different publications use a wide variety of testing domains, usually derived from classic RL problems. However, the specific setups depend on the publication and usually modified the basic configuration by adding noise or removing the terminal conditions. Moreover, many algorithms disregard specific subproblems like policy generalization or utility exploration. Hence, a satisfactory comparison of algorithms is currently not possible.

6. Conclusion

Preference-based reinforcement learning (PbRL) is a suitable tool for learning from qualitative, non-numeric rewards. On the one hand, it can provide solutions in domains where numeric feedback is not readily available, and, on the other hand, it may reduce the demands and prior knowledge that is needed for applying RL to real-world tasks where a numeric feedback signal has to be shaped. This survey provided a first overview over the design choices that have to be considered for PbRL and presented current work in a coherent framework, shedding light on the advantages and limitations of various approaches.

The most substantial problem seems to be the complexity of the learning problem. The presented approaches require a high amount of preferences or well defined feature spaces, either on a policy or trajectory level. The definition of suitable, low-dimensional feature spaces requires expert knowledge, if possible at all. In many domains, high-dimensional feature spaces are required to approximate optimal policies to an acceptable degree. Furthermore, preferences are costly to obtain in an incremental setting with human evaluations. Even in cases where it is possible to obtain preferences from non-expert users, human labor is usually quite expensive. Hence, it is very important to use the available information as efficiently as possible. Utility-based approaches allow to generalize the obtained preference feedback and are an important step towards practical algorithms. Especially reward-based utilities seem to be appropriate for domains without well defined policy spaces, because they allow the application of efficient value-based reinforcement learning methods. Hence, it is possible to use the substantial progress that has already been achieved in this field. However, it is also important to consider the novel problems introduced by using preference-based feedback. Foremost, efficient methods for exploring the preference function space are required.

Recently, interesting real-world applications could be solved by preference-based methods. Yet, several open questions remain. Foremost, sample efficiency and scalibility issues still prevent applications to more complex tasks. DNN-based approaches can tackle the scalibility issues to some degree, but improved solutions to the preference-space exploration problem are required to limited the amount of required preferences. Furthermore, PbRL is still limited by several assumptions like the total order assumption, the uniform preference weighting and the single starting state. Without these assumptions, it would be possible to apply PbRL in multi-objective domains, for risk-adverse problems and in settings that can not be simulated. Methods that can use multiple feedback forms, like preferences, demonstrations or rewards, are also of interested as they are possible able to reduce the cognitive demand even further.

We believe that this line of research could provide the foundation to make reinforcement learning applicable to the non-scientific community because despite many recent successes in reinforcement learning, we believe that the required expertise in machine learning is still a key limitation when it comes to applying RL to real-world tasks.

Abstract

We consider the problem of estimating a low-rank signal matrix from noisy measurements under the assumption that the distribution of the data matrix belongs to an exponential family. In this setting, we derive generalized Stein's unbiased risk estimation (SURE) formulas that hold for any spectral estimators which shrink or threshold the singular values of the data matrix. This leads to new data-driven spectral estimators, whose optimality is discussed using tools from random matrix theory and through numerical experiments. Under the spiked population model and in the asymptotic setting where the dimensions of the data matrix are let going to infinity, some theoretical properties of our approach are compared to recent results on asymptotically optimal shrinking rules for Gaussian noise. It also leads to new procedures for singular values shrinkage in finite-dimensional matrix denoising for Gamma-distributed and Poisson-distributed measurements.

Keywords: Matrix denoising, singular value decomposition, low-rank model, Gaussian spiked population model, spectral estimator, Stein's unbiased risk estimate, random matrix theory, exponential family, optimal shrinkage rule, degrees of freedom.

1. Introduction

1.1 Low rank matrix denoising in an exponential family

In various applications, it is of interest to estimate a signal matrix from noisy data. Typical examples include the case of data that are produced in a matrix form, while others are concerned with observations from multiple samples that can be organized in a matrix form. In such setting, a typical inference problem involves the estimation of an unknown (non-random) signal matrix $\boldsymbol{X} \in \mathbb{R}^{n\times m}$ from a noisy data matrix $\boldsymbol{Y}$ satisfying the model:

$$\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}, \tag{1}$$

where $\boldsymbol{W}$ is an $n \times m$ noise matrix with real entries $\boldsymbol{W}_{ij}$ assumed to be independent random variables with $\mathbb{E}[\boldsymbol{W}_{ij}] = 0$ and $\mathrm{Var}(\boldsymbol{W}_{ij}) = \tau_{ij}^2$ for $1 \le i \le n$ and $1 \le j \le m$. In this paper, we focus on the situation where the signal matrix $\boldsymbol{X}$ is assumed to have a low rank structure, and we consider the general setting where the distribution of $\boldsymbol{Y}$ belongs to a continuous exponential family parametrized by the entries of the matrix $\boldsymbol{X} = \mathbb{E}[\boldsymbol{Y}]$. For discrete observations (count data), we also consider the specific case of Poisson noise.

The low rank assumption on $\boldsymbol{X}$ is often met in practice when there exists a significant correlation between the columns of $\boldsymbol{X}$. This can be the case when the columns of $\boldsymbol{X}$ represent 2D images at different wavelength of hyperspectral data, since images at nearby wavelengths are strongly correlated (Candès et al., 2013). Further applications, where low-rank modeling of $\boldsymbol{X}$ is relevant, can be found in genomics (Wall et al., 2001; Alter et al., 2000), NMR spectroscopy (Nguyen et al., 2011), collaborative filtering (Candès and Recht, 2009) or medical imaging (Bydder and Du, 2006; Lam et al., 2012), among many others.

Low-rank matrix estimation is classically done in the setting where the additive noise is Gaussian with homoscedastic variance. The more general case of observations sampled from an exponential family is less developed, but there exists an increasing research interest in the study of low rank matrix recovery beyond the Gaussian case. Examples of low-rank matrix recovering from Poisson distributed observations can be found in applications with count data such as network traffic analysis (Bazerque et al., 2013) or call center data (Haipeng and Jianhua, 2005). A theory for low-rank matrix recovery and completion in the case of Poisson observations has also been recently proposed in Cao and Xie (2016). Matrix completion under a low rank assumption with additive errors having a sub-exponential distribution and belonging to an exponential family has also been considered in Lafond (2015). The recent work in Udell et al. (2016) proposes a novel framework to approximate, by a low rank matrix, a tabular data set made of numerical, Boolean, categorical or ordinal observations.

1.2 The class of spectral estimators

A standard approach to estimate a low rank matrix relies on the singular value decomposition (SVD) of the data matrix

$$\boldsymbol{Y} = \sum_{k=1}^{\min(n,m)} \tilde{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t, \tag{2}$$

where $\tilde{\sigma}_1 \ge \tilde{\sigma}_2 \ge \ldots \ge \tilde{\sigma}_{\min(n,m)} \ge 0$ denote its singular values, and $\tilde{\boldsymbol{u}}_k, \tilde{\boldsymbol{v}}_k$ denote the associated singular vectors. In this paper, we propose to consider the class of spectral estimators $\hat{\boldsymbol{X}}^f = f(\boldsymbol{Y})$, where $f : \mathbb{R}^{n\times m} \to \mathbb{R}^{n\times m}$ is a (possibly data-dependent) mapping that acts on the singular values of the data matrix $\boldsymbol{Y}$ while leaving its singular vectors unchanged. More precisely, these estimators take the form

$$\hat{\boldsymbol{X}}^f = f(\boldsymbol{Y}) = \sum_{k=1}^{\min(n,m)} f_k(\boldsymbol{Y}) \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t, \tag{3}$$

where, for each $1 \le k \le \min(n,m)$, $f_k(\boldsymbol{Y})$ are real positive values that may depend only on $\tilde{\sigma}_k$ (hence we write $f_k(\tilde{\sigma}_k)$) or on the whole matrix $\boldsymbol{Y}$.

1.3 Investigated spectral estimators

Typical examples of spectral estimators include the classical principal component analysis (PCA) applied to matrix denoising defined, for some $1 \leq r \leq \min(n,m)$, as

$$\hat{\boldsymbol{X}}^r = \sum_{k=1}^{r} \hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t \quad \text{with} \quad \hat{\sigma}_k = f_k(\tilde{\sigma}_k) = \tilde{\sigma}_k \tag{4}$$

for all $1 \leq k \leq r$ and where it is implicitely understood that $f_k(\tilde{\sigma}_k) = 0$ for $k \geq r+1$. Another typical spectral estimator in matrix denoising with Gaussian measurements is the soft-thresholding (Candès et al., 2013) which corresponds to the choice

$$\hat{\boldsymbol{X}}_{\text{soft}} = \sum_{k=1}^{\min(m,n)} \hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t \quad \text{with} \quad \hat{\sigma}_k = f_k(\boldsymbol{Y}) = \left(1 - \frac{\lambda(\boldsymbol{Y})}{\tilde{\sigma}_k}\right)_+ \tilde{\sigma}_k, \tag{5}$$

for all $1 \leq k \leq \min(n,m)$ and where $\lambda(\boldsymbol{Y}) > 0$ is a possibly data-dependent threshold parameter, and $(x)_+ = \max(x,0)$ for any $x \in \mathbb{R}$. Finaly, we will consider a more general class of shrinkage estimators, encompassing the PCA and the soft-thresholding, that perform

$$\hat{\boldsymbol{X}}_w = \sum_{k=1}^{\min(m,n)} \hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t \quad \text{with} \quad \hat{\sigma}_k = f_k(\boldsymbol{Y}) = w_k(\boldsymbol{Y}) \tilde{\sigma}_k, \tag{6}$$

where $w_k(\boldsymbol{Y}) \in [0,1]$ is a possibly data-dependent shrinking weight.

1.4 Main contributions

Under the assumption that the distribution of $\boldsymbol{Y}$ belongs to an exponential family, the goal of this paper is to derive data-driven choices for the weights $w_k(\boldsymbol{Y})$ in (3). We construct estimators via a two-step procedure. First, an active set of non-zero singular values is defined. Then, in a second step, weights $w_k(\boldsymbol{Y})$ associated with non-zero singular values are optimized, and shown to reach desired asymptotical properties in the Gaussian spiked population model. The main contributions of the paper are then the following ones.

1.4.1 An AIC inspired criterion for rank and singular values locations estimation

When no *a priori* is available on the rank of the signal matrix $\boldsymbol{X}$, optimizing for the weights w_k, for all $1 \leq k \leq \min(m,n)$, can lead to estimators with large variance (*i.e.*, overfitting the noise). We propose an automatic rule to prelocalize the subset of non-zero singular values. An active set $s^\star \subseteq \mathcal{I} = \{1,2,\ldots,\min(n,m)\}$ of singular values is defined as the minimizer of a penalized log-likelihood criterion that is inspired by the Akaike information criterion (AIC)

$$s^* \in \arg\min_{s \subseteq \mathcal{I}} \; -2 \log q(\boldsymbol{Y}; \tilde{\boldsymbol{X}}^s) + 2|s| p_{n,m} \quad \text{with} \quad p_{n,m} = \frac{1}{2}\left(\sqrt{m} + \sqrt{n}\right)^2, \tag{7}$$

where $\tilde{\boldsymbol{X}}^s = \sum_{k \in s} \tilde{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t$, $|s|$ is the cardinal of s, and $q(\boldsymbol{Y}; \tilde{\boldsymbol{X}}^s)$ is the likelihood of the data in a given exponential family with estimated parameter $\tilde{\boldsymbol{X}}^s$. For the case of Gaussian measurements with homoscedastic variance τ^2, one has that $q(\boldsymbol{Y}; \tilde{\boldsymbol{X}}^s) = \|\boldsymbol{Y} - \tilde{\boldsymbol{X}}^s\|_F^2 / 2\tau^2$, where $\|\cdot\|_F$ denotes the Frobenius norm of a matrix, and we show that the active set of singular values boils down to

$$s^\star = \{k \; ; \; \tilde{\sigma}_k > c_+^{n,m}\}, \tag{8}$$

where $c_+^{n,m} = \tau(\sqrt{m} + \sqrt{n})$. For Gamma and Poisson measurements, we resort to a greedy optimization procedure described in Section 4.

Once the active set has been determined, the subsequent shrinkage estimator is obtained by optimizing only for the weights within this subset while setting the other ones to zero.

1.4.2 Novel data-driven shrinkage rules minimizing SURE-like formulas

We use the principle of Stein's unbiased risk estimation (SURE) (Stein, 1981) to derive unbiased estimation formulas for the mean squared error (MSE) risk and mean Kullback-Leibler (MKL) risks of spectral estimators. Minimizing such SURE-like formulas over an appropriate class of spectral estimators is shown to lead to novel data-driven shrinkage rules of the singular values of the matrix $\boldsymbol{Y}$. In particular, our approach leads to novel spectral estimators in situations where the variances τ_{ij}^2 of the entries $\boldsymbol{W}_{ij}$ of the noise matrix are not necessarily equal, and may depend on the signal matrix $\boldsymbol{X}$.

As an illustrative example, let us consider spectral estimators of the form

$$\hat{\boldsymbol{X}}_w^1 = f(\boldsymbol{Y}) = w_1(\boldsymbol{Y}) \tilde{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t, \tag{9}$$

which only act on the first singular value $\tilde{\sigma}_1$ of the data while setting all the other ones to zero. In this paper, examples of data-driven choices for the weight $w_1(\boldsymbol{Y})$ are the following ones:

- for Gaussian measurements with $n \leq m$ and known homoscedastic variance τ^2

$$w_1(\boldsymbol{Y}) = \left(1 - \frac{\tau^2}{\tilde{\sigma}_1^2}\left(1 + |m-n| + 2\sum_{\ell=2}^{n} \frac{\tilde{\sigma}_1^2}{\tilde{\sigma}_1^2 - \tilde{\sigma}_\ell^2}\right)\right)_+ \mathbb{1}_{\{\tilde{\sigma}_1 > c_+^{n,m}\}}, \tag{10}$$

- for Gamma measurements with $\tau_{ij}^2 = \boldsymbol{X}_{ij}^2 / L$ and $L > 2$ (see Section 2.1 for a precise definition),

$$w_1(\boldsymbol{Y}) = \min\left[1, \left(\frac{L-1}{Lmn}\sum_{i=1}^{n}\sum_{j=1}^{m} \frac{\hat{\boldsymbol{X}}_{ij}^1}{\boldsymbol{Y}_{ij}} + \frac{1}{Lmn}\left(1 + |m-n| + 2\sum_{\ell=2}^{\min(n,m)} \frac{\tilde{\sigma}_1^2}{\tilde{\sigma}_1^2 - \tilde{\sigma}_\ell^2}\right)\right)^{-1}\right] \mathbb{1}_{\{1 \in s^*\}}, \tag{11}$$

- for Poisson measurements with $\tau_{ij}^2 = \boldsymbol{X}_{ij}$ (see Section 2.1 for a precise definition)

$$w_1(\boldsymbol{Y}) = \min\left[1, \frac{\sum_{i=1}^{n}\sum_{j=1}^{m} \boldsymbol{Y}_{ij}}{\sum_{i=1}^{n}\sum_{j=1}^{m} \hat{\boldsymbol{X}}_{ij}^1}\right] \mathbb{1}_{\{1 \in s^*\}}. \tag{12}$$

Beyond the case of rank one, closed-form solutions for the weights cannot be obtained, except for the case of Gaussian measurements with homoscedastic variance τ^2. In this latter case, the rule for $w_1(\boldsymbol{Y})$ in (10) generalizes to other eigenvalues $w_k(\boldsymbol{Y})$ as

$$w_k(\boldsymbol{Y}) = \left(1 - \frac{\tau^2}{\tilde{\sigma}_k^2}\left(1 + |m-n| + 2\sum_{\ell=1;\ell\neq k}^{\min(n,m)} \frac{\tilde{\sigma}_k^2}{\tilde{\sigma}_k^2 - \tilde{\sigma}_\ell^2}\right)\right)_+ \mathbb{1}_{\{\tilde{\sigma}_k > c_+^{n,m}\}}. \tag{13}$$

For Gamma or Poisson distributed measurements, we propose fast algorithms to get numerical approximations of the weights $w_k(\boldsymbol{Y})$ (see Section 5.2 for more details).

1.4.3 Asymptotic properties in the Gaussian spiked population model

Another contribution of the paper is to discuss the optimality of the shrinking weights (13) for Gaussian noise in the asymptotic setting where the dimensions of the matrix $\boldsymbol{Y}$ are let going to infinity. These theoretical results are obtained for the so-called *spiked population model* that has been introduced in the literature on random matrix theory and high-dimensional covariance matrix estimation (see e.g. Baik and Silverstein (2006); Benaych-Georges and Nadakuditi (2012); Dozier and Silverstein (2007); Shabalin and Nobel (2013)). All the theoretical and asymptotic results of the paper (other than derivation of proposed estimators) assume this model.

Definition 1 *The Gaussian spiked population model corresponds to the following setting:*

- *the $\boldsymbol{W}_{ij}$ in (1) are iid Gaussian random variables with zero mean and variance $\tau^2 = 1/m$,*
- *the $\boldsymbol{X}_{ij}$'s in (1) are the entries of an unknown $n \times m$ matrix $\boldsymbol{X}$ that has a low rank structure, meaning that it admits the SVD $\boldsymbol{X} = \sum_{k=1}^{r^*} \sigma_k \boldsymbol{u}_k \boldsymbol{v}_k^t$, where $\boldsymbol{u}_k$ and $\boldsymbol{v}_k$ are the left and right singular vectors associated to the singular value $\sigma_k > 0$, for each $1 \leq k \leq r^*$, with $\sigma_1 > \sigma_2 > \ldots > \sigma_{r^*}$,*
- *the rank r^* of the matrix $\boldsymbol{X}$ is assumed to be fixed,*
- *the dimensions of the data matrix $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$ are let going to infinity in the asymptotic framework where the sequence $m = m_n \geq n$ is such that $\lim_{n\to+\infty} \frac{n}{m} = c$ with $0 < c \leq 1$.*

In the Gaussian spiked population model, the asymptotic locations of the empirical singular values $\tilde{\sigma}_1 \geq \ldots \geq \tilde{\sigma}_{\min(n,m)}$ are well understood in the random matrix theory (further details are given in Section 3.1). Note that the setting where the rank r^* is not held fixed but allowed to grow with $\min(n,m)$ is very different (see e.g. Ledoit and Wolf (2012) and references therein).

Under the Gaussian spiked population model, our contributions are then as follows:

- we prove the convergence of the SURE formula when the dimensions of $\boldsymbol{Y}$ tend to infinity,
- it is shown that minimizing the asymptotic value of SURE leads to the same estimator as the limiting value of the estimator obtained by minimizing the SURE,

- this model allows to show that the novel data-driven spectral estimators derived in this paper are asymptotically connected to existing optimal shrinkage rules (Shabalin and Nobel, 2013; Gavish and Donoho, 2017; Nadakuditi, 2014) for low-rank matrix denoising,
- in this setting, we are also able to connect the choice of the penalty function $2|s|p_{n,m}$ in (7) with Stein's notion of degrees of freedom (see e.g. Bradley (2004)) for spectral estimators.

1.4.4 Numerical experiments and publicly available source code

As the theoretical properties of our estimators are studied in an asymptotic setting, we report the results of various numerical experiments to analyze the performances of the proposed estimators for finite-dimensional matrices. These experiments allow the comparison with existing shrinkage rules for Gaussian-distributed measurements and they are also used to shed some lights on the finite sample properties of the method for Gamma-distributed or Poisson-distributed measurements. We also exhibit the settings where the signal matrix $\boldsymbol{X}$ is either easy or more difficult to recover. From these experiments, the main findings are the following ones:

- the use of an appropriate active set s of singular values is an essential step for the quality of shrinkage estimators whose weights are data-driven by SURE-like estimators; taking $s = \{1, \ldots, \min(n,m)\}$ leads to poor results while the choice of $s = s^*$ minimizing the AIC criterion (7) appears to yield the best performances,
- for Gaussian noise, the performances of our approach are similar to those obtained by the asymptotically optimal spectral estimator proposed in Gavish and Donoho (2017) when the true rank r^* of the signal matrix $\boldsymbol{X}$ is sufficiently small, but for large to moderate values of the signal-to-noise ratio our approach may perform better than existing methods in the literature,
- for Gamma or Poisson distributed measurements, the spectral estimators proposed in this paper give better results than estimators based on PCA (restricted to the active set s^*) or soft-thresholding of singular values.

Beyond the case of Gaussian noise, the implementation of the estimators is not straightforward, and we thus provide publicly available source code at

`https://www.math.u-bordeaux.fr/~cdeledal/gsure_low_rank`

to reproduce the figures and the numerical experiments of this paper.

1.5 Related results in the literature

Early work on singular value thresholding began with the work in Eckart and Young (1936) on the best approximation of fixed rank to the data matrix $\boldsymbol{Y}$. Spectral estimators with different amounts of shrinkage for each singular value of the data matrix have then been proposed in Efron and Morris (1972, 1976). In the case of Gaussian measurements with

homoscedastic variance, the problem of estimating $\boldsymbol{X}$ under a low-rank assumption has recently received a lot of attention in the literature on high-dimensional statistics (see e.g. Candès et al. (2013); Donoho and Gavish (2014); Josse and Sardy (2015); Shabalin and Nobel (2013)). Recent works (Gavish and Donoho, 2017; Nadakuditi, 2014) also consider the more general setting where the distribution of the additive noise matrix $\boldsymbol{W}$ is orthogonally invariant, and such that its entries are iid random variables with zero mean and finite fourth moment. In all these papers, the authors have focused on spectral estimators which shrink or threshold the singular values of $\boldsymbol{Y}$, while its singular vectors are left unchanged. In this setting, the main issue is to derive optimal shrinkage rules that depends on the class of spectral estimators that is considered, on the loss function used to measure the risk of an estimator of $\boldsymbol{X}$, and on appropriate assumptions for the distribution of the additive noise matrix $\boldsymbol{W}$.

1.6 Organization of the paper

Section 2 is devoted to the analysis of a data matrix whose entries are distributed according to a continuous exponential family. SURE-like formula are first given for the mean squared error risk, and then for the Kullback-Leibler risk. As an example of discrete exponential family, we also derive such risk estimators for Poisson distributed measurements. The computation of data-driven shrinkage rules is then discussed for Gaussian, Gamma and Poisson noises. In Section 3, we restrict our attention to the Gaussian spiked population model in order to derive asymptotic properties of our approach. We study the asymptotic behavior of the SURE formula proposed in Candès et al. (2013); Donoho and Gavish (2014) for spectral estimators using tools from RMT. This result allows to make a connection between data-driven spectral estimators minimizing the SURE for Gaussian noise, and the asymptotically optimal shrinkage rules proposed in Shabalin and Nobel (2013); Nadakuditi (2014) and Gavish and Donoho (2017). In Section 4, we study the penalized log-likelihood criterion (7) used to select an active set of singular values. Its connection to the degrees of freedom of spectral estimators and rank estimation in matrix denoising is discussed. Various numerical experiments are finally proposed in Section 5 to illustrate the usefulness of the approach developed in this paper for low-rank denoising and to compare its performances with existing methods. The proofs of the main results of the paper are gathered in a technical Appendix A, and numerical implementation details are described in Appendix B.

2. SURE-like formulas in exponential families

For an introduction to exponential families, we refer to Brown (1986). The idea of unbiased risk estimation in exponential families dates back to Hudson (1978). More recently, generalized SURE formulas have been proposed for the estimation of the MSE risk, for denoising under various continuous and discrete distributions in Raphan and Simoncelli (2007), and for inverse problems whithin the continuous exponential families in Eldar (2009). In Deledalle (2017), SURE-like formula are derived for the estimation of the Kullback-Leibler risk that applies to both continuous and discrete exponential families. In what follows, we borrow some ideas and results from these works. We first treat the case of continuous exponential families, and then we focus on Poisson data in the discrete case.

2.1 Data sampled from a continuous exponential family

We recall that $\boldsymbol{Y}$ is an $n \times m$ matrix with independent and real entries $\boldsymbol{Y}_{ij}$. For each $1 \leq i \leq n$ and $1 \leq j \leq m$, we assume that the random variable $\boldsymbol{Y}_{ij}$ is sampled from a continuous exponential family, in the sense that each $\boldsymbol{Y}_{ij}$ admits a probability density function (pdf) $q(y; \boldsymbol{X}_{ij})$ with respect to the Lebesgue measure $\mathrm{d}y$ on the real line $\mathcal{Y} = \mathbb{R}$. The pdf $q(y; \boldsymbol{X}_{ij})$ of $\boldsymbol{Y}_{ij}$ can thus be written in the general form:

$$q(y; \boldsymbol{X}_{ij}) = h(y) \exp\left(\eta(\boldsymbol{X}_{ij}) y - A(\eta(\boldsymbol{X}_{ij}))\right), \; y \in \mathcal{Y}, \tag{14}$$

where η (the link function) is a one-to-one and smooth function, A (the log-partition function) is a twice differentiable mapping, h is a known function, and $\boldsymbol{X}_{ij}$ is an unknown parameter of interest belonging to some open subset $\mathcal{X}$ of $\mathbb{R}$. Throughout the paper, we will suppose that the following assumption holds:

Assumption 2 *The link function η and the log-partition function A are such that*

$$A'(\eta(x)) = x \text{ for all } x \in \mathcal{X},$$

where A' denotes the first derivative of A.

Since $\mathbb{E}[\boldsymbol{Y}_{ij}] = A'(\eta(\boldsymbol{X}_{ij}))$ for exponential families in the general form (14), Assumption 2 implies that $\mathbb{E}[\boldsymbol{Y}_{ij}] = \boldsymbol{X}_{ij}$, and thus the data matrix satisfies the relation $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$ where $\boldsymbol{W}$ is a centered noise matrix, which is in agreement with model (1). Now, if we let $\Theta = \eta(\mathcal{X})$, it will be also convenient to consider the expression of the pdf of $\boldsymbol{Y}_{ij}$ in the canonical form:

$$p(y; \boldsymbol{\theta}_{ij}) = h(y) \exp\left(\boldsymbol{\theta}_{ij} y - A(\boldsymbol{\theta}_{ij})\right), \; y \in \mathcal{Y}, \tag{15}$$

where $\boldsymbol{\theta}_{ij} = \eta(\boldsymbol{X}_{ij}) \in \Theta$ is usually called the canonical parameter of the exponential family. Finally, we recall the relation $\mathrm{Var}(\boldsymbol{Y}_{ij}) = A''(\boldsymbol{\theta}_{ij}) = A''(\eta(\boldsymbol{X}_{ij}))$ where A'' denotes the second derivative of A. Then, we denote by $\boldsymbol{\theta}$ the $n \times m$ matrix whose entries are the $\boldsymbol{\theta}_{ij}$'s.

Examples of data satisfying model (14) are the following ones:

Gaussian noise with known variance τ^2:

$$q(y; \boldsymbol{X}_{ij}) = \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{(y - \boldsymbol{X}_{ij})^2}{2\tau^2}\right), \; \mathbb{E}[\boldsymbol{Y}_{ij}] = \boldsymbol{X}_{ij}, \; \mathrm{Var}(\boldsymbol{Y}_{ij}) = \tau^2,$$

$$\mathcal{Y} = \mathbb{R}, \; \mathcal{X} = \mathbb{R}, \; \Theta = \mathbb{R}, \; h(y) = \frac{1}{\sqrt{2\pi\tau}} \exp\left(-\frac{y^2}{2\tau^2}\right), \; \eta(x) = \frac{x}{\tau^2}, \; A(\theta) = \tau^2 \frac{\theta^2}{2}.$$

Gamma-distributed measurements with known shape parameter $L > 0$:

$$q(y; \boldsymbol{X}_{ij}) = \frac{L^L y^{L-1}}{\Gamma(L) \boldsymbol{X}_{ij}^L} \exp\left(-L \frac{y}{\boldsymbol{X}_{ij}}\right) \mathbb{1}_{]0,+\infty[}(y), \; \mathbb{E}[\boldsymbol{Y}_{ij}] = \boldsymbol{X}_{ij}, \; \mathrm{Var}(\boldsymbol{Y}_{ij}) = \frac{\boldsymbol{X}_{ij}^2}{L},$$

$$\mathcal{Y} = \mathbb{R}, \; \mathcal{X} =]0, +\infty[, \; \Theta =]-\infty, 0[, \; h(y) = \frac{L^L y^{L-1}}{\Gamma(L)} \mathbb{1}_{]0,+\infty[}(y), \; \eta(x) = -\frac{L}{x}, \; A(\theta) = -L \log\left(-\frac{\theta}{L}\right).$$

The matrix $\boldsymbol{\theta} = \eta(X)$ can then be estimated via the $n \times m$ matrix $\hat{\boldsymbol{\theta}}^f = \hat{\boldsymbol{\theta}}^f(\boldsymbol{Y})$ whose entries are given by

$$\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}) = \eta\left(\hat{\boldsymbol{X}}^f_{ij}\right), \text{ for all } 1 \leq i \leq n,\ 1 \leq j \leq m, \tag{16}$$

where $\hat{\boldsymbol{X}}^f_{ij}$ is a spectral estimator as defined in eq. (3).

In the rest of this section, we follow the arguments in Eldar (2009) and Deledalle (2017) to derive SURE-like formulas under the exponential family for the estimators $\hat{\boldsymbol{\theta}}^f$ and $\hat{\boldsymbol{X}}^f$, using either the mean-squared error (MSE) risk or the Kullback-Leibler (KL) risk.

2.1.1 Unbiased estimation of the MSE risk

We consider the following MSE risk which provides a measure of discrepancy in the space Θ of natural parameters, and then indirectly in the space of interest $\mathcal{X}$.

Definition 3 *The squared error (SE) risk of* $\hat{\boldsymbol{\theta}}^f$ *is* $\mathrm{SE}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \|\hat{\boldsymbol{\theta}}^f - \boldsymbol{\theta}\|_F^2$*, and the mean-squared error (MSE) risk of* $\hat{\boldsymbol{\theta}}^f$ *is defined as* $\mathrm{MSE}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \mathbb{E}\left[\mathrm{SE}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta})\right] = \mathbb{E}\left[\|\hat{\boldsymbol{\theta}}^f - \boldsymbol{\theta}\|_F^2\right]$.

Using the above MSE risk to compare $\hat{\boldsymbol{\theta}}^f$ and $\boldsymbol{\theta}$ implies that the discrepancy between the estimator $\hat{\boldsymbol{X}}^f$ and the matrix of interest $\boldsymbol{X}$ is measured by the quantity $\mathrm{MSE}_\eta(\hat{\boldsymbol{X}}^f, \boldsymbol{X}) = \mathrm{MSE}(\eta(\hat{\boldsymbol{X}}^f), \eta(\boldsymbol{X}))$ which is different from $\mathrm{MSE}(\hat{\boldsymbol{X}}^f, \boldsymbol{X})$. For Gaussian noise, $\mathrm{MSE}_\eta(\hat{\boldsymbol{X}}^f, \boldsymbol{X}) = \frac{1}{\tau^2}\mathbb{E}\left[\|\hat{\boldsymbol{X}}^f - \boldsymbol{X}\|_F^2\right]$, while for Gamma distributed measurements with known shape parameter $L > 0$, it follows that

$$\mathrm{MSE}_\eta(\hat{\boldsymbol{X}}^f, \boldsymbol{X}) = L^2 \sum_{i=1}^{n}\sum_{j=1}^{m}\left(\frac{\boldsymbol{X}_{ij} - \hat{\boldsymbol{X}}^f_{ij}}{\boldsymbol{X}_{ij}\hat{\boldsymbol{X}}^f_{ij}}\right)^2.$$

The following proposition gives a SURE formula for the MSE risk introduced in Definition 3.

Proposition 4 *Suppose that the data are sampled from a continuous exponential family. Assume that the function* h*, in the definition* (15) *of the exponential family, is twice continuously differentiable on* $\mathcal{Y} = \mathbb{R}$*. If the following condition holds*

$$\mathbb{E}\left[\left|\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})\right|\right] < +\infty, \text{ for all } 1 \leq i \leq n,\ 1 \leq j \leq m, \tag{17}$$

then, the quantity

$$\mathrm{GSURE}(\hat{\boldsymbol{\theta}}^f) = \|\hat{\boldsymbol{\theta}}^f(\boldsymbol{Y})\|^2 + \sum_{i=1}^{n}\sum_{j=1}^{m}\left(2\frac{h'(\boldsymbol{Y}_{ij})}{h(\boldsymbol{Y}_{ij})}\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}) + \frac{h''(\boldsymbol{Y}_{ij})}{h(\boldsymbol{Y}_{ij})}\right) + 2\,\mathrm{div}\,\hat{\boldsymbol{\theta}}^f(\boldsymbol{Y}), \tag{18}$$

where $\mathrm{div}\,\hat{\boldsymbol{\theta}}^f(\boldsymbol{Y}) = \sum_{i=1}^{n}\sum_{j=1}^{m}\frac{\partial\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})}{\partial\boldsymbol{Y}_{ij}}$*, is an unbiased estimator of* $\mathrm{MSE}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta})$

Note that $\mathrm{GSURE}(\hat{\boldsymbol{\theta}}^f)$ is an unbiased estimator of $\mathrm{MSE}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta})$ and not of $\mathrm{MSE}(\hat{\boldsymbol{X}}^f, \boldsymbol{X})$. It is shown in Section 3.3 that the results of Proposition 17 coincide with the approach in Candès et al. (2013) on the derivation of a SURE formula in the case of Gaussian noise for smooth spectral estimators. In the case of Gamma noise, assuming $L > 2$ implies that the conditions on the function h in Proposition 4 is satisfied, hence assuming that conditions (17) holds as well, and using that

$$\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}) = -\frac{L}{f_{ij}(\boldsymbol{Y})} \quad \text{and} \quad \frac{\partial\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})}{\partial\boldsymbol{Y}_{ij}} = \frac{L}{|f_{ij}(\boldsymbol{Y})|^2}\frac{\partial f_{ij}(\boldsymbol{Y})}{\partial\boldsymbol{Y}_{ij}},$$

it follows that

$$\mathrm{GSURE}(\hat{\boldsymbol{\theta}}^f) = \sum_{i=1}^{n}\sum_{j=1}^{m}\frac{L^2}{|f_{ij}(\boldsymbol{Y})|^2} - \frac{2L(L-1)}{\boldsymbol{Y}_{ij}f_{ij}(\boldsymbol{Y})} + \frac{2L}{|f_{ij}(\boldsymbol{Y})|^2}\frac{\partial f_{ij}(\boldsymbol{Y})}{\partial\boldsymbol{Y}_{ij}} - \frac{(L-1)(L-2)}{|\boldsymbol{Y}_{ij}|^2}. \tag{19}$$

2.1.2 Unbiased estimation of KL risks

Following the terminology in Deledalle (2017), let us now introduce two different notions of Kullback-Leibler risk, which arise from the non-symmetry of this discrepancy measure.

Definition 5 *Let* $f : \mathbb{R}^{n\times m} \to \mathbb{R}^{n\times m}$ *be a smooth spectral function. Consider the estimator* $\hat{\boldsymbol{\theta}}^f$ *defined by* (16)*, where* $\boldsymbol{Y}$ *is a matrix whose entries* $\boldsymbol{Y}_{ij}$ *are independent random variables sampled from the exponential family* (15) *in canonical form:*

- *the Kullback-Leibler synthesis (KLS) risk of* $\hat{\boldsymbol{\theta}}^f$ *is defined as*

$$\mathrm{KLS}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \sum_{i=1}^{n}\sum_{j=1}^{m}\int_{\mathbb{R}}\log\left(\frac{p(y;\hat{\boldsymbol{\theta}}^f_{ij})}{p(y;\boldsymbol{\theta}_{ij})}\right)p(y;\hat{\boldsymbol{\theta}}^f_{ij})\,\mathrm{d}y,$$

  and the mean KLS risk of $\hat{\boldsymbol{\theta}}^f$ *is defined as* $\mathrm{MKLS}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \mathbb{E}\left[\mathrm{KLS}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta})\right]$,

- *the Kullback-Leibler analysis (KLA) risk of* $\hat{\boldsymbol{\theta}}^f$ *is defined as*

$$\mathrm{KLA}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \sum_{i=1}^{n}\sum_{j=1}^{m}\int_{\mathbb{R}}\log\left(\frac{p(y;\boldsymbol{\theta}_{ij})}{p(y;\hat{\boldsymbol{\theta}}^f_{ij})}\right)p(y;\boldsymbol{\theta}_{ij})\,\mathrm{d}y,$$

  and the mean KLA risk of $\hat{\boldsymbol{\theta}}^f$ *is defined as* $\mathrm{MKLA}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \mathbb{E}\left[\mathrm{KLA}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta})\right]$.

A key advantage of the Kullback-Leibler risk is that it measures the discrepancy between the unknown distribution $p(y;\boldsymbol{\theta}_{ij})$ and its estimate $p(y;\hat{\boldsymbol{\theta}}^f_{ij})$. It is thus invariant with respect to the reparametrization $\hat{\boldsymbol{\theta}}^f = \eta(\hat{\boldsymbol{X}}^f)$ (unlike the MSE risk), and we may also write $\mathrm{MKLS}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \mathrm{MKLS}(\hat{\boldsymbol{X}}^f, \boldsymbol{X})$ and $\mathrm{MKLA}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \mathrm{MKLA}(\hat{\boldsymbol{X}}^f, \boldsymbol{X})$. As suggested

in Deledalle (2017), the MKLA risk represents how well the distribution $p(y;\hat{\boldsymbol{\theta}}^f_{ij})$ explain a random variable $\boldsymbol{Y}_{ij}$ sampled from the pdf $p(y;\boldsymbol{\theta}_{ij})$. The MKLA risk is a natural loss function in many statistical problems since it takes as a reference measure the true distribution of the data (see e.g. Hall (1987)). The MKLS risk represents how well one may generate an independent copy of $\boldsymbol{Y}_{ij}$ by sampling a random variable from the pdf $p(y;\hat{\boldsymbol{\theta}}^f_{ij})$. The MKLS risk has also been considered in various inference problems in statistics (Hannig and Lee, 2006; Yanagimoto, 1994).

By simple calculation, it follows that

$$\mathrm{MKLS}(\hat{\boldsymbol{\theta}}^f,\boldsymbol{\theta}) = \sum_{i=1}^{n}\sum_{j=1}^{m}\mathbb{E}\left[\left(\hat{\boldsymbol{\theta}}^f_{ij}-\boldsymbol{\theta}_{ij}\right)A'(\hat{\boldsymbol{\theta}}^f_{ij})\right] + A(\boldsymbol{\theta}_{ij}) - \mathbb{E}\left[A(\hat{\boldsymbol{\theta}}^f_{ij})\right], \tag{20}$$

$$\text{and}\quad \mathrm{MKLA}(\hat{\boldsymbol{\theta}}^f,\boldsymbol{\theta}) = \sum_{i=1}^{n}\sum_{j=1}^{m}\mathbb{E}\left[\left(\boldsymbol{\theta}_{ij}-\hat{\boldsymbol{\theta}}^f_{ij}\right)A'(\boldsymbol{\theta}_{ij})\right] + \mathbb{E}\left[A(\hat{\boldsymbol{\theta}}^f_{ij})\right] - A(\boldsymbol{\theta}_{ij}). \tag{21}$$

Hence, in the case of Gaussian measurements with known variance τ^2, we easily retrieve that $\mathrm{MKLS}(\hat{\boldsymbol{\theta}}^f,\boldsymbol{\theta}) = \mathrm{MKLA}(\hat{\boldsymbol{\theta}}^f,\boldsymbol{\theta}) = \frac{\tau^2}{2}\mathrm{MSE}(\hat{\boldsymbol{\theta}}^f,\boldsymbol{\theta}) = \frac{1}{2\tau^2}\mathbb{E}\left[\|\hat{\boldsymbol{X}}^f-\boldsymbol{X}\|_F^2\right]$. In the case of Gamma distributed measurements with known shape parameter $L>0$, it follows that

$$\begin{aligned}
\mathrm{MKLS}(\hat{\boldsymbol{\theta}}^f,\boldsymbol{\theta}) &= L\sum_{i=1}^{n}\sum_{j=1}^{m}\mathbb{E}\left[\frac{\hat{\boldsymbol{X}}^f_{ij}}{\boldsymbol{X}_{ij}} - \log\left(\frac{\hat{\boldsymbol{X}}^f_{ij}}{\boldsymbol{X}_{ij}}\right) - 1\right],\\
\mathrm{MKLA}(\hat{\boldsymbol{\theta}}^f,\boldsymbol{\theta}) &= L\sum_{i=1}^{n}\sum_{j=1}^{m}\mathbb{E}\left[\frac{\boldsymbol{X}_{ij}}{\hat{\boldsymbol{X}}^f_{ij}} - \log\left(\frac{\boldsymbol{X}_{ij}}{\hat{\boldsymbol{X}}^f_{ij}}\right) - 1\right].
\end{aligned}$$

Below, we use some of the results in Deledalle (2017) whose main contributions are the derivation of new unbiased estimators of the MKLS and MKLA risks. For continuous exponential family, the risk estimate derived in Deledalle (2017) is unbiased for the MKLS risk, while it is only asymptotically unbiased for the MKLA risk with respect to the signal-to-noise ratio. For data sampled from a continuous exponential family, this makes simpler the use of the MKLS risk to derive data-driven shinkage in low rank matrix denoising, and we have therefore chosen to concentrate our study on this risk in this setting. The following proposition establishes a SURE formula to estimate the MKLS risk in the continuous case.

Proposition 6 *Suppose that the data are sampled from a continuous exponential family. Assume that the function h, in the definition* (15) *of the exponential family, is continuously differentiable on $\mathcal{Y}=\mathbb{R}$. Suppose that the function A, in the definition* (15) *of the exponential family, is twice continuously differentiable on Θ. If the following condition holds*

$$\mathbb{E}\left[\left|A'(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}))\right|\right] < +\infty, \text{ for all } 1\le i\le n,\ 1\le j\le m, \tag{22}$$

then, the quantity

$$\mathrm{SUKLS}(\hat{\boldsymbol{\theta}}^f) = \sum_{i=1}^{n}\sum_{j=1}^{m}\left(\left(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}) + \frac{h'(\boldsymbol{Y}_{ij})}{h(\boldsymbol{Y}_{ij})}\right)A'(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})) - A(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}))\right) + \operatorname{div} f(\boldsymbol{Y}), \tag{23}$$

where $\operatorname{div} f(\boldsymbol{Y}) = \sum_{i=1}^{m}\sum_{j=1}^{n}\frac{\partial f_{ij}(\boldsymbol{Y})}{\partial \boldsymbol{Y}_{ij}}$, *is an unbiased estimator of* $\mathrm{MKLS}(\hat{\boldsymbol{\theta}}^f,\boldsymbol{\theta}) - \sum_{i=1}^{n}\sum_{j=1}^{m}A(\boldsymbol{\theta}_{ij})$.

A key difference in the formula of unbiased estimates for the MSE and the KL risks is the computation of the divergence term in (18) and (23), when $\hat{\boldsymbol{X}}^f = \sum_{k=1}^{\min(n,m)} f_k(\tilde{\sigma}_k)\tilde{\boldsymbol{u}}_k\tilde{\boldsymbol{v}}_k^t$ is a smooth spectral estimator in the sense where each function $f_k:\mathbb{R}_+\to\mathbb{R}_+$ is assumed to be (almost everywhere) differentiable for $1\le k\le\min(n,m)$. In this setting, the divergence term in the expression of $\mathrm{GSURE}(\hat{\boldsymbol{\theta}}^f)$ depends upon the matrix $\hat{\boldsymbol{\theta}}^f(\boldsymbol{Y}) = \eta(\hat{\boldsymbol{X}}^f)$. Therefore, when η is a nonlinear mapping, it is generally not possible to obtain a simpler expression for $\operatorname{div}\hat{\boldsymbol{\theta}}^f(\boldsymbol{Y})$. To the contrary, for $\mathrm{SUKLS}(\hat{\boldsymbol{\theta}}^f)$, the divergence term is $\operatorname{div} f(\boldsymbol{Y})$ which has the following closed-form expression for any smooth spectral estimators

$$\operatorname{div} f(\boldsymbol{Y}) = |m-n|\sum_{k=1}^{\min(n,m)}\frac{f_k(\tilde{\sigma}_k)}{\tilde{\sigma}_k} + \sum_{k=1}^{\min(n,m)}f'_k(\tilde{\sigma}_k) + 2\sum_{k=1}^{\min(n,m)}f_k(\tilde{\sigma}_k)\sum_{\ell=1;\ell\neq k}^{\min(n,m)}\frac{\tilde{\sigma}_k}{\tilde{\sigma}_k^2-\tilde{\sigma}_\ell^2}, \tag{24}$$

thanks to the results from Theorem IV.3 in Candès et al. (2013).

Note that $\mathrm{SUKLS}(\hat{\boldsymbol{X}}^r_w) = \frac{\tau^2}{2}\,\mathrm{SURE}(\hat{\boldsymbol{X}}^r_w)$ for Gaussian measurements, hence, the GSURE and SUKLS strategies match in this case. In the case of Gamma measurements, assuming that $L>2$ implies that the conditions on the function h in Proposition 6 is satisfied, and by assuming that condition (22) holds as well, it follows that

$$\mathrm{SUKLS}(\hat{\boldsymbol{\theta}}^f) = \sum_{i=1}^{n}\sum_{j=1}^{m}\left((L-1)\frac{f_{ij}(\boldsymbol{Y})}{\boldsymbol{Y}_{ij}} - L\log\left(f_{ij}(\boldsymbol{Y})\right)\right) - Lmn + \operatorname{div} f(\boldsymbol{Y}),$$

where the expression of $\operatorname{div} f(\boldsymbol{Y})$ is given by (24).

Note that it is implicitly understood in the definition of $\operatorname{div} f(\boldsymbol{Y})$ that each mapping $f_{ij}:\mathbb{R}^{n\times m}\to\mathbb{R}$ is differentiable. The differentiability of the spectral function f (and thus of its components f_{ij}) is a consequence of the assumption that the functions $f_1,\dots,f_{\min(n,m)}$ (acting on the singular values) are supposed to be differentiable. For further details, on the differentiability of f and the f_{ij}'s, we refer to Section IV in Candès et al. (2013). From the arguments in Candès et al. (2013), it follows that formula (24) for the divergence of f is also valid under the assumption that each function f_k is differentiable on $\mathbb{R}_+$ except on a set of Lebesgue measure zero.

2.2 The case of Poisson data

For Poisson data, the key result to obtain unbiased estimate of a given risk is the following lemma which dates back to the work in Hudson (1978).

Lemma 7 *Let $f:\mathbb{Z}^{n\times m}\to\mathbb{R}^{n\times m}$ be a measurable mapping. Let $1\le i\le n$ and $1\le j\le m$, and denote by $f_{ij}:\mathbb{Z}^{n\times m}\to\mathbb{R}$ a measurable function. Let $\boldsymbol{Y}\in\mathbb{Z}^{n\times m}$ be a matrix whose entries are independently sampled from a Poisson distribution on $\mathbb{Z}$. Then,*

$$\mathbb{E}\left[\sum_{i=1}^{n}\sum_{j=1}^{m}\boldsymbol{X}_{ij}f_{ij}(\boldsymbol{Y})\right] = \mathbb{E}\left[\sum_{i=1}^{n}\sum_{j=1}^{m}\boldsymbol{Y}_{ij}f_{ij}(\boldsymbol{Y}-\boldsymbol{e}_i\boldsymbol{e}_j^t)\right],$$

where, for each $1 \leq i \leq n$ and $1 \leq j \leq m$, $f_{ij}(\boldsymbol{Y})$ denotes the (i,j)-th entry of the matrix $f(\boldsymbol{Y})$, and $\boldsymbol{e}_i$ (resp. $\boldsymbol{e}_j$) denotes the vector of $\mathbb{Z}^n$ (resp. $\mathbb{Z}^m$) with the i-th entry (resp. j-th entry) equals to one and all others equal to zero.

Hudson's lemma provides a way to estimate (in an unbiased way) the expectation of the Frobenius inner product between the matrix $\boldsymbol{X}$ and the matrix $f(\boldsymbol{Y})$. To see the usefulness of this result, one may consider the following mean-squared error

$$\mathrm{MSE}(\hat{\boldsymbol{X}}^f, \boldsymbol{X}) = \mathbb{E}\left[\left\|\hat{\boldsymbol{X}}^f - \boldsymbol{X}\right\|_F^2\right] = \mathbb{E}\left[\left\|\hat{\boldsymbol{X}}^f\right\|_F^2 - 2\sum_{i=1}^n\sum_{j=1}^m \boldsymbol{X}_{ij}\hat{\boldsymbol{X}}^f_{ij}(\boldsymbol{Y}) + \|\boldsymbol{X}\|_F^2\right].$$

Therefore, by Lemma 7, one immediately obtains that

$$\mathrm{PURE}(\hat{\boldsymbol{\theta}}^f) = \left\|\hat{\boldsymbol{X}}^f\right\|_F^2 - 2\sum_{i=1}^n\sum_{j=1}^m \boldsymbol{Y}_{ij} f_{ij}(\boldsymbol{Y} - \boldsymbol{e}_i\boldsymbol{e}_j^t), \tag{25}$$

is an unbiased estimate for the quantity $\mathrm{MSE}(\hat{\boldsymbol{X}}^f, \boldsymbol{X}) - \|\boldsymbol{X}\|_F^2$.

For Poisson data, one may also define the following KL risks

$$\mathrm{MKLS}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \sum_{i=1}^n\sum_{j=1}^m \mathbb{E}\left[\boldsymbol{X}_{ij} - \hat{\boldsymbol{X}}^f_{ij} - \hat{\boldsymbol{X}}^f_{ij}\log\left(\frac{\boldsymbol{X}_{ij}}{\hat{\boldsymbol{X}}^f_{ij}}\right)\right], \tag{26}$$

$$\mathrm{MKLA}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \sum_{i=1}^n\sum_{j=1}^m \mathbb{E}\left[\hat{\boldsymbol{X}}^f_{ij} - \boldsymbol{X}_{ij} - \boldsymbol{X}_{ij}\log\left(\frac{\hat{\boldsymbol{X}}^f_{ij}}{\boldsymbol{X}_{ij}}\right)\right], \tag{27}$$

which are in agreement with Definition 5 of KL risks for data sampled from a Poisson distribution. From the arguments in Deledalle (2017), there does not currently exist an approach to derive a SURE formula for the MKLS risk in the Poisson case since they are no unbiased formula for $\hat{\boldsymbol{X}}^f_{ij}\log \boldsymbol{X}_{ij}$. Nevertheless, as shown in Deledalle (2017), Hudson's Lemma 7 provides an unbiased estimator for $\boldsymbol{X}_{ij}\log\hat{\boldsymbol{X}}^f_{ij}$, and then it is possible to unbiasedly estimate the MKLA risk as follows.

Proposition 8 *For data sampled from a Poisson distribution, the quantity*

$$\mathrm{PUKLA}(\hat{\boldsymbol{\theta}}^f) = \sum_{i=1}^n\sum_{j=1}^m \hat{\boldsymbol{X}}^f_{ij} - \boldsymbol{Y}_{ij}\log\left(f_{ij}(\boldsymbol{Y} - \boldsymbol{e}_i\boldsymbol{e}_j^t)\right), \tag{28}$$

is an unbiased estimator of $\mathrm{MKLA}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) + \sum_{i=1}^n\sum_{j=1}^m \boldsymbol{X}_{ij} - \boldsymbol{X}_{ij}\log(\boldsymbol{X}_{ij})$.

2.3 Data-driven shrinkage in low-rank matrix denoising

For a matrix $\boldsymbol{X}$ with entries $\boldsymbol{X}_{ij} \in \mathcal{X} = \mathbb{R}$, we consider shrinkage estimators of the form

$$\hat{\boldsymbol{X}}^s_w = f(\boldsymbol{Y}) = \sum_{k\in s} w_k\tilde{\sigma}_k\tilde{\boldsymbol{u}}_k\tilde{\boldsymbol{v}}_k^t, \tag{29}$$

with $s \subseteq \mathcal{I} = \{1, 2, \ldots, \min(n,m)\}$ and $w_k \in [0,1]$, for all $k \in s$.

When the underlying matrix $\boldsymbol{X}$ is constrained to have positive entries, e.g. $\mathcal{X} =]0, +\infty[$ in the Gamma and Poisson cases, we consider instead estimators of the form

$$\hat{\boldsymbol{X}}^s_w = f(\boldsymbol{Y}) = \max\left[\sum_{k\in s} w_k\tilde{\sigma}_k\tilde{\boldsymbol{u}}_k\tilde{\boldsymbol{v}}_k^t, \varepsilon\right], \tag{30}$$

where $\varepsilon > 0$ is an *a priori* lower bound on the smallest value of $\boldsymbol{X}_{ij}$, where for any matrix $\boldsymbol{X}$, $\max[\boldsymbol{X}, \varepsilon]_{ij} = \max[\boldsymbol{X}_{ij}, \varepsilon]$, for all $1 \leq i \leq m$ and $1 \leq j \leq n$.

The construction of the subset s is postponed to Section 4, and we focus here in selecting the weights in a data-driven way for a fixed given s. In the following, we denote by s^c the complementary set of s in $\mathcal{I}$, *i.e.*, $s^c = \mathcal{I} \setminus s$, and we let $\hat{\boldsymbol{\theta}}^s_w = \eta\left(\hat{\boldsymbol{X}}^s_w\right)$. When $\mathcal{X} =]0, +\infty[$, we have found that considering estimators of the form (30) is more appropriate than trying to find shrinking weights $(w_k)_{k\in s}$ such that all the entries of the matrix $\sum_{k\in s} w_k\tilde{\sigma}_k\tilde{\boldsymbol{u}}_k\tilde{\boldsymbol{v}}_k^t$ are positive, for a given subset s.

Gaussian noise with known homoscedastic variance τ^2

By applying the GSURE formula (18) for Gaussian distributed measurements and thanks to the expression (24) for the divergence of smooth spectral estimators, we obtain for $\hat{\boldsymbol{X}}^s_w$, as defined in (29), the SURE expression given by

$$\mathrm{SURE}(\hat{\boldsymbol{X}}^s_w) = -mn\tau^2 + \sum_{k\in s}(w_k - 1)^2\tilde{\sigma}_k^2 + \sum_{k\in s^c}\tilde{\sigma}_k^2 + 2\tau^2\sum_{k=1}^s\left(1 + |m-n| + 2\sum_{\ell=1;\ell\neq k}^{\min(n,m)}\frac{\tilde{\sigma}_k^2}{\tilde{\sigma}_k^2 - \tilde{\sigma}_\ell^2}\right)w_k$$

which unbiasedly estimate $\mathrm{MSE}(\hat{\boldsymbol{X}}^s_w, \boldsymbol{X})$. Hence, for each $k \in s$, by differentiating the above expression with respect to w_k, it follows that a data-driven weight for the k-th empirical singular value is given by

$$w_k(\boldsymbol{Y}) = \left(1 - \frac{\tau^2}{\tilde{\sigma}_k^2}\left(1 + |m-n| + 2\sum_{\ell=1;\ell\neq k}^{\min(n,m)}\frac{\tilde{\sigma}_k^2}{\tilde{\sigma}_k^2 - \tilde{\sigma}_\ell^2}\right)\right)_+, \tag{31}$$

which fullfils the requirement that $w_k(\boldsymbol{Y}) \in [0,1]$. Note that as $\mathrm{SUKLS}(\hat{\boldsymbol{X}}^s_w) = \frac{\tau^2}{2}\mathrm{SURE}(\hat{\boldsymbol{X}}^s_w)$ for Gaussian measurements, the exact same data-driven weight would be obtained by minimizing an estimate of the $\mathrm{MKLS}(\hat{\boldsymbol{X}}^s_w, \boldsymbol{X})$.

The case of estimators with rank one. Consider the case of estimators with rank 1, *i.e.*, let $s = \{1\}$. It follows that $\hat{\boldsymbol{X}}^1_w = \hat{\boldsymbol{X}}^{\{1\}}_w = w_1\hat{\boldsymbol{X}}^1$ where $w_1 \in [0,1]$ is given by

$$w_1(\boldsymbol{Y}) = \left(1 - \frac{\tau^2}{\tilde{\sigma}_1^2}\left(1 + |m-n| + 2\sum_{\ell=1;\ell\neq 1}^{\min(n,m)}\frac{\tilde{\sigma}_1^2}{\tilde{\sigma}_1^2 - \tilde{\sigma}_\ell^2}\right)\right)_+.$$

Gamma and Poisson distributed measurements

In Gamma and Poisson cases, it is not possible to follow the same strategy as in the Gaussian case to derive optimal weights for (30) in a closed-form using the established SURE-like formulas. We shall investigate how data-driven shinkage can be approximated in Section 5 on numerical experiments using fast algorithms. Nevertheless, when the estimator is restricted to rank 1, optimizing KL risk estimators lead to closed-form expressions under the assumption that all the entries of the data matrix $\boldsymbol{Y}$ are strictly positive.

The case of estimators with rank one under Gamma noise. Consider again the case of estimators with rank 1, *i.e.*, let $s = \{1\}$, and let $\hat{\boldsymbol{X}}^1 = \tilde{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t$ denote the PCA approximation of rank 1 of $\boldsymbol{X}$. If all the entries of the matrix $\boldsymbol{Y}$ are strictly positive, by the Perron-Frobenius theorem, all the entries of the first singular vectors $\tilde{\boldsymbol{u}}_1$ and $\tilde{\boldsymbol{v}}_1$ are strictly positive. Therefore, all the entries of $\hat{\boldsymbol{X}}^1$ belong to the set $\mathcal{X} =]0, +\infty[$, and we can consider $\hat{\boldsymbol{X}}_w^1 = \hat{\boldsymbol{X}}_w^{\{1\}} = w_1 \tilde{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t$ as defined in (29) instead of (30). Assuming $L > 2$ for the SUKLS formula to hold, it follows by simple calculations that

$$\mathrm{SUKLS}(\hat{\boldsymbol{\theta}}_w^1) = \sum_{i=1}^{n}\sum_{j=1}^{m}(L-1)w_1\frac{\hat{\boldsymbol{X}}_{ij}^1}{\boldsymbol{Y}_{ij}} - mnL\log(w_1) - L\log\left(\frac{\hat{\boldsymbol{X}}_{ij}^1}{\boldsymbol{Y}_{ij}}\right) - Lmn + (1+|m-n|)w_1 + 2w_1\sum_{\ell=2}^{\min(n,m)}\frac{\tilde{\sigma}_1^2}{\tilde{\sigma}_1^2 - \tilde{\sigma}_\ell^2}.$$

Hence, by differentiating the above expression with respect to w_1 and as it is monotonic on both sides of its unique minimum, the optimal value of $w_1 \in [0,1]$ minimizing $\mathrm{SUKLS}(\hat{\boldsymbol{\theta}}_w^1)$ is given by

$$w_1(\boldsymbol{Y}) = \min\left[1, \left(\frac{L-1}{Lmn}\sum_{i=1}^{n}\sum_{j=1}^{m}\frac{\hat{\boldsymbol{X}}_{ij}^1}{\boldsymbol{Y}_{ij}} + \frac{1}{Lmn}\left(1+|m-n|+2\sum_{\ell=2}^{\min(n,m)}\frac{\tilde{\sigma}_1^2}{\tilde{\sigma}_1^2-\tilde{\sigma}_\ell^2}\right)\right)^{-1}\right],$$

which yields the shrinking rule (11) stated in the introduction of this paper. Note that it is not possible to obtain, in a closed-form, the optimal value of the weight w_1 that minimizes the criterion $\mathrm{GSURE}(\hat{\boldsymbol{\theta}}_w^1)$.

The case of estimators with rank one under Poisson noise. Using again that all the assumption that the entries of $\boldsymbol{Y}$ are positive, we can consider (by the Perron-Frobenius theorem) $\hat{\boldsymbol{X}}_w^1 = \hat{\boldsymbol{X}}_w^{\{1\}} = w_1\tilde{\sigma}_1\tilde{\boldsymbol{u}}_1\tilde{\boldsymbol{v}}_1^t$ as defined in (29) instead of (30). Then, the PURE formula (25) and Proposition 8 apply to the estimator $\hat{\boldsymbol{\theta}}_w^1 = \log\left(\hat{\boldsymbol{X}}_w^1\right)$ which yield to

$$\mathrm{PURE}(\hat{\boldsymbol{\theta}}_w^1) = w_1^2\tilde{\sigma}_1^2 - 2\sum_{i=1}^{n}\sum_{j=1}^{m}\boldsymbol{Y}_{ij}w_1\tilde{\sigma}_1^{(ij)}\tilde{\boldsymbol{u}}_{1,i}^{(ij)}\tilde{\boldsymbol{v}}_{1,j}^{(ij)},$$

$$\text{and}\quad \mathrm{PUKLA}(\hat{\boldsymbol{\theta}}_w^1) = \sum_{i=1}^{n}\sum_{j=1}^{m}w_1\hat{\boldsymbol{X}}_{ij}^1 - \boldsymbol{Y}_{ij}\left(\log(w_1) + \log\left(\tilde{\sigma}_1^{(ij)}\tilde{\boldsymbol{u}}_{1,i}^{(ij)}\tilde{\boldsymbol{v}}_{1,j}^{(ij)}\right)\right),$$

where $\hat{\boldsymbol{X}}_{ij}^1 = \tilde{\sigma}_1\tilde{\boldsymbol{u}}_{1,i}\tilde{\boldsymbol{v}}_{1,j}$, $\tilde{\sigma}_1^{(ij)}$ is the largest singular value of the matrix $\boldsymbol{Y} - \boldsymbol{e}_i\boldsymbol{e}_j^t$, and $\tilde{\boldsymbol{u}}_1^{(ij)}$ (resp. $\tilde{\boldsymbol{v}}_1^{(ij)}$) denotes its left (resp. right) singular vectors. Therefore, by differentiating the above expression with respect to w_1 and as it is monotonic on both sides of its unique minimum, an optimal value for $w_1 \in [0,1]$ which minimizes $\mathrm{PURE}(\hat{\boldsymbol{\theta}}_w^1)$ is given by

$$w_1(\boldsymbol{Y}) = \min\left[1, \frac{1}{\tilde{\sigma}_1^2}\sum_{i=1}^{n}\sum_{j=1}^{m}\boldsymbol{Y}_{ij}\tilde{\sigma}_1^{(ij)}\tilde{\boldsymbol{u}}_{1,i}^{(ij)}\tilde{\boldsymbol{v}}_{1,j}^{(ij)}\right].$$

However, this optimal shrinking rule cannot be used in practice since evaluating the values of $\tilde{\sigma}_1^{(ij)}, \tilde{\boldsymbol{u}}_1^{(ij)}, \tilde{\boldsymbol{v}}_1^{(ij)}$ for all $1 \le i \le n$ and $1 \le j \le m$ is not feasible from a computational point of view for large values of n and m. Nevertheless, a fast algorithm to find a numerical approximation of the optimal value $w_1(\boldsymbol{Y})$ is proposed in Section 5.

To the contrary, using again that all the $\hat{\boldsymbol{X}}_{ij}^1$ are positive by the Perron-Frobenius theorem, the value of $w_1 \in [0,1]$ minimizing $\mathrm{PUKLA}(\hat{\boldsymbol{\theta}}_w^1)$ is

$$w_1(\boldsymbol{Y}) = \min\left[1, \frac{\sum_{i=1}^{n}\sum_{j=1}^{m}\boldsymbol{Y}_{ij}}{\sum_{i=1}^{n}\sum_{j=1}^{m}\hat{\boldsymbol{X}}_{ij}^1}\right],$$

which is straightforward to compute. This corresponds to the shrinkage rule (12) given in the introduction.

3. Gaussian spiked population model

In this section, we restrict our analysis to the Gaussian spiked population model and the asymptotic setting introduced in Definition 1.

3.1 Asymptotic location of empirical singular values

We summarize below the asymptotic behavior of the singular values of the data matrix $\boldsymbol{Y} = \sum_{k=1}^{\min(n,m)}\tilde{\sigma}_k\tilde{\boldsymbol{u}}_k\tilde{\boldsymbol{v}}_k^t$ in the Gaussian spiked population model.

In the case where $\boldsymbol{X} = 0$, it is well known (Anderson et al., 2010; Bai and Silverstein, 2010) that the empirical distribution of the singular values of $\boldsymbol{Y} = \boldsymbol{W}$ (with $\tau = \frac{1}{\sqrt{m}}$) converges, as $n \to +\infty$, to the quarter circle distribution if $c = 1$ and to its generalized version if $c < 1$. This distribution is supported on the compact interval $[c_-, c_+]$ with

$$c_\pm = 1 \pm \sqrt{c}$$

where c_+ is the so-called bulk (right) edge.

When $\boldsymbol{X} \neq 0$ has a low rank structure, the asymptotic behavior of the singular values of $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$ is also well understood (Benaych-Georges and Nadakuditi, 2012; Dozier and Silverstein, 2007; Shabalin and Nobel, 2013), and generalizations to noise matrix $\boldsymbol{W}$ whose distribution is orthogonally invariant have also been recently considered in Benaych-Georges and Nadakuditi (2012). Below, we recall some of these results that will be needed in this paper. To this end, let us introduce the real-valued function ρ defined by

$$\rho(\sigma) = \sqrt{\frac{(1+\sigma^2)(c+\sigma^2)}{\sigma^2}} \text{ for any } \sigma > 0.$$

Then, the following result holds (see e.g. Theorem 2.8 in Benaych-Georges and Nadakuditi (2012) and Proposition 9 in Shabalin and Nobel (2013)).

Proposition 9 *Assume that $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$ is a random matrix sampled from the Gaussian spiked population model with $\tau = \frac{1}{\sqrt{m}}$ and $\boldsymbol{X} = \sum_{k=1}^{r^*} \sigma_k \boldsymbol{u}_k \boldsymbol{v}_k^t$. Then, for any fixed $k \geq 1$, one has that, almost surely,*

$$\lim_{n \to +\infty} \tilde{\sigma}_k = \begin{cases} \rho(\sigma_k) & \text{if } k \leq r^* \text{ and } \sigma_k > c^{1/4}, \\ c_+ & \text{otherwise.} \end{cases}$$

Moreover,

$$\lim_{n \to +\infty} \tilde{\sigma}_{\min(n,m)} = c_-.$$

In what follows, we shall also use the relation

$$\frac{1}{\sigma^2} = \frac{\rho^2(\sigma) - (c+1) - \sqrt{(\rho^2(\sigma) - (c+1))^2 - 4c}}{2c} \text{ that holds for any } \sigma > c^{1/4}, \tag{32}$$

which is a consequence of e.g. the results in Section 3.1 in Benaych-Georges and Nadakuditi (2012).

3.2 Existing asymptotically optimal shrinkage rules

Below, we briefly summarize some results in Gavish and Donoho (2017) and Nadakuditi (2014) on the construction of asymptotically optimal spectral estimators. Let

$$\hat{\boldsymbol{X}}^f = f(\boldsymbol{Y}) = \sum_{k=1}^{\min(n,m)} f_k(\tilde{\sigma}_k) \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t \tag{33}$$

be a given smooth spectral estimator, and consider the standard squared error $\mathrm{SE}(\hat{\boldsymbol{X}}^f, \boldsymbol{X}) = \|\hat{\boldsymbol{X}}^f - \boldsymbol{X}\|_F^2$ as a measure of risk. The set of spectral functions minimizing $\mathrm{SE}(\hat{\boldsymbol{X}}^f, \boldsymbol{X})$ is given by $f_k(\tilde{\sigma}_k) = \tilde{\boldsymbol{u}}_k^t \boldsymbol{X} \tilde{\boldsymbol{v}}_k$, for $1 \leq k \leq \min(n,m)$. However, it cannot be used in practice since $\boldsymbol{X}$ is obviously unknown. A first alternative suggested in Gavish and Donoho (2017) and Nadakuditi (2014) is to rather study the asymptotic risk

$$\mathrm{SE}_\infty(\hat{\boldsymbol{X}}^f) = \lim_{n \to \infty} \mathrm{SE}(\hat{\boldsymbol{X}}^f, \boldsymbol{X}) \text{ (in the almost sure sense)} \tag{34}$$

in the Gaussian spiked population model. Then, it is proposed in Gavish and Donoho (2017) and Nadakuditi (2014) to find an asymptotically optimal choice of f by minimizing $\mathrm{SE}_\infty(\hat{\boldsymbol{X}}^f)$ among a given class of smooth spectral functions. The results in Gavish and Donoho (2017) show that, among spectral estimators of the form $\hat{\boldsymbol{X}}^\eta = \sum_{k=1}^{\min(n,m)} \eta(\tilde{\sigma}_k) \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t$, where $\eta : \mathbb{R}_+ \to \mathbb{R}_+$ is a continuous shrinker such that $\eta(\sigma) = 0$ whenever $\sigma \leq c_+$, an asymptotically optimal shrinkage rule is given by the choice

$$\eta^*(\sigma) = \begin{cases} \frac{1}{\sigma}\sqrt{(\sigma^2 - (c+1))^2 - 4c} & \text{if } \sigma > c_+, \\ 0 & \text{otherwise.} \end{cases} \tag{35}$$

In Nadakuditi (2014), it is proposed to consider spectral estimators of the form $\hat{\boldsymbol{X}}^\delta = \sum_{k=1}^r \delta_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t$ where $\delta_1, \ldots, \delta_r$ are positive weights. By Theorem 2.1 in Nadakuditi (2014), it follows that, if $\sigma_k > c^{1/4}$ for all $1 \leq k \leq r$ with $r \leq r^*$, then the weights which minimize $\mathrm{SE}_\infty(\hat{\boldsymbol{X}}^\delta)$ over $\mathbb{R}_+^r$ are given by

$$\delta_k^* = \delta_k(\sigma_k) = \frac{\sigma_k^4 - c}{\sigma_k \sqrt{(1+\sigma_k^2)(c+\sigma_k^2)}}, \text{ for all } 1 \leq k \leq r. \tag{36}$$

In what follows, the shrinkage rules (35) and (36) are shown to be equivalent, and they will serve as a reference of asymptotic optimality. It should be stressed that the estimators in Gavish and Donoho (2017) and Nadakuditi (2014) are not equivalent. Indeed, the method in Nadakuditi (2014) requires an estimate of the rank, while the approach in Gavish and Donoho (2017) applies the same shrinker to all empirical singular values. Nevertheless, the shrinkage function that is applied to significant singular values (either above the bulk edge in Gavish and Donoho (2017) or up to a given rank in Nadakuditi (2014)) is the same.

3.3 Asymptotic behavior of data-driven estimators based on SURE

Following the principle of SURE, a second alternative to choose a smooth spectral estimator of the form (33) is to study the problem of selecting a set of functions $(f_k)_{1 \leq k \leq \min(n,m)}$ that minimize an unbiased estimate of $\mathrm{MSE}(\hat{\boldsymbol{X}}^f, \boldsymbol{X}) = \mathbb{E}\left[\|\hat{\boldsymbol{X}}^f - \boldsymbol{X}\|_F^2\right]$. For any $1 \leq i \leq m$ and $1 \leq j \leq n$, we recall that $f_{ij}(\boldsymbol{Y})$ denotes the (i,j)-th entry of the matrix $\hat{\boldsymbol{X}}^f = f(\boldsymbol{Y})$. Under the condition that

$$\mathbb{E}\left[|\boldsymbol{Y}_{ij} f_{ij}(\boldsymbol{Y})| + \left|\frac{\partial f_{ij}(\boldsymbol{Y})}{\partial \boldsymbol{Y}_{ij}}\right|\right] < +\infty, \text{ for all } 1 \leq i \leq n,\ 1 \leq j \leq m. \tag{37}$$

it follows from the results in Candès et al. (2013) (or equivalently from Proposition 4 for Gaussian noise with $\tau^2 = 1/m$) that

$$\mathrm{SURE}\left(\hat{\boldsymbol{X}}^f\right) = -n + \|f(\boldsymbol{Y}) - \boldsymbol{Y}\|_F^2 + \frac{2}{m} \operatorname{div} f(\boldsymbol{Y}), \tag{38}$$

is an unbiased estimate of $\mathrm{MSE}(\hat{\boldsymbol{X}}^f, \boldsymbol{X})$, where the divergence $\operatorname{div} f(\boldsymbol{Y})$ admits the closed-form expression (24). The SURE formula (38) has been used in Candès et al. (2013) to find a data-driven value for $\lambda = \lambda(\boldsymbol{Y})$ in the the case of singular values shrinkage by soft-thresholding which corresponds to the choice

$$f_k(\tilde{\sigma}_k) = (\tilde{\sigma}_k - \lambda)_+, \text{ for all } 1 \leq k \leq \min(n,m).$$

We study now the asymptotic behavior of the SURE formula (38). To this end, we shall use Proposition 9, but we will also need the following result (whose proof can be found in the Appendix) to study some of the terms in expression (24) of the divergence of $f(\boldsymbol{Y})$.

Proposition 10 *Assume that $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$ is a random matrix sampled from the Gaussian spiked population model with $\tau = \frac{1}{\sqrt{m}}$ and $\boldsymbol{X} = \sum_{k=1}^{r^*} \sigma_k \boldsymbol{u}_k \boldsymbol{v}_k^t$. Then, for any fixed $1 \leq k \leq r^*$ such that $\sigma_k > c^{1/4}$, one has that, almost surely,*

$$\lim_{n \to +\infty} \frac{1}{n} \sum_{\ell=1; \ell \neq k}^{n} \frac{\tilde{\sigma}_k}{\tilde{\sigma}_k^2 - \tilde{\sigma}_\ell^2} = \frac{1}{\rho\left(\sigma_k\right)} \left(1 + \frac{1}{\sigma_k^2}\right).$$

In what follows, we restrict our analysis to the following class of spectral estimators (the terminology in the definition below is borrowed from Gavish and Donoho (2017)).

Definition 11 *Let $\hat{\boldsymbol{X}}^f = f(\boldsymbol{Y}) = \sum_{k=1}^{\min(n,m)} f_k(\tilde{\sigma}_k) \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t$ be a smooth spectral estimator. For a given $1 \leq r \leq \min(n,m)$, the estimator f is said to be a spectral shrinker of order r that collapses the bulk to 0 if*

$$\left\{ \begin{array}{ll} f_k(\sigma) = 0 & \text{whenever } \sigma \leq c_+ \text{ and } 1 \leq k \leq r, \\ f_k(\sigma) = 0 & \text{for all } \sigma \geq 0 \text{ and } k > r. \end{array} \right.$$

The reason for restricting the study to spectral estimators such that $f_k(\tilde{\sigma}_k) = 0$ whenever $\tilde{\sigma}_k < c_+$ is linked to the choice of the active set s^* (8) of singular values in the Gaussian case, as detailed in Section 4. Now, for a spectral shrinker $\hat{\boldsymbol{X}}^f$ of order r that collapses the bulk to 0, we study the asymptotic behavior of the terms in expression (38) that only depend on f, namely

$$\begin{aligned} \overline{\mathrm{SURE}}\left(\hat{\boldsymbol{X}}^f\right) &= \sum_{k=1}^{r} (f_k(\tilde{\sigma}_k) - \tilde{\sigma}_k)^2 + 2\left(1 - \frac{n}{m}\right) \sum_{k=1}^{r} \frac{f_k(\tilde{\sigma}_k)}{\tilde{\sigma}_k} + \frac{2}{m} \sum_{k=1}^{r} f_k'(\tilde{\sigma}_k) \\ &\quad + 4\frac{n}{m} \sum_{k=1}^{r} f_k(\tilde{\sigma}_k) \left(\frac{1}{n} \sum_{\ell=1; \ell \neq k}^{n} \frac{\tilde{\sigma}_k}{\tilde{\sigma}_k^2 - \tilde{\sigma}_\ell^2} \right) \end{aligned} \tag{39}$$

The reason for studying $\overline{\mathrm{SURE}}\left(\hat{\boldsymbol{X}}^f\right)$ is that finding an optimal shrinkage rule that minimizes $\mathrm{SURE}\left(\hat{\boldsymbol{X}}^f\right)$ is equivalent to minimizing expression (39) over spectral shrinkers of order r that collapses the bulk to 0, since $\mathrm{SURE}\left(\hat{\boldsymbol{X}}^f\right) - \overline{\mathrm{SURE}}\left(\hat{\boldsymbol{X}}^f\right) = -n + \sum_{k=r+1}^{n} \tilde{\sigma}_k^2$ for such $\hat{\boldsymbol{X}}^f$.

Then, using Proposition 9, Proposition 10, and the assumption that the f_k's are continuously differentiable functions on $\mathbb{R}_+$, we immediately obtain the following result.

Lemma 12 *Assume that $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$ is a random matrix sampled from the Gaussian spiked population model with $\tau = \frac{1}{\sqrt{m}}$ and $\boldsymbol{X} = \sum_{k=1}^{r^*} \sigma_k \boldsymbol{u}_k \boldsymbol{v}_k^t$. Let $\hat{\boldsymbol{X}}^f$ be a spectral shrinker of order $r \leq r^*$ that collapses the bulk to 0, such that each function f_k, for $1 \leq k \leq r$, is continuously differentiable on $]c_+, +\infty[$. Moreover, assume that $\sigma_k > c^{1/4}$ for all $1 \leq k \leq r$. Then, one has that, almost surely,*

$$\lim_{n \to +\infty} \overline{\mathrm{SURE}}\left(\hat{\boldsymbol{X}}^f\right) = \sum_{k=1}^{r} (f_k(\rho(\sigma_k)) - \rho(\sigma_k))^2 + 2 f_k(\rho(\sigma_k)) \left(\frac{\sigma_k^2(1+c) + 2c}{\sigma_k^2 \rho(\sigma_k)} \right) \tag{40}$$

Asymptotically optimal shrinkage of singular values. Thanks to Lemma 12, one may determine an asymptotic optimal spectral shrinker as the one minimizing $\lim_{n \to +\infty} \overline{\mathrm{SURE}}\left(\hat{\boldsymbol{X}}^f\right)$. For this purpose, let us define the class of estimators

$$\hat{\boldsymbol{X}}_w^r = \sum_{k=1}^{r} w_k \tilde{\sigma}_k \mathbb{1}_{\{\tilde{\sigma}_k > c_+\}} \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t, \tag{41}$$

where $1 \leq r \leq r^*$ is a given integer, and the w_k's are positive weights. In practice, the estimator $\hat{\boldsymbol{X}}_w^r$ is computed by replacing the bulk edge c_+ by its approximation $c_+^{n,m} = 1 + \sqrt{\frac{n}{m}}$ in eq. (41). For moderate to large values of n and m, the quantities c_+ and $c_+^{n,m}$ are very close, and this replacement does not change the numerical performances of $\hat{\boldsymbol{X}}_w^r$.

Then, provided that $\sigma_k > c^{1/4}$ for all $1 \leq k \leq r$, it follows from Lemma 12 that

$$\lim_{n \to +\infty} \overline{\mathrm{SURE}}\left(\hat{\boldsymbol{X}}_w^r\right) = \sum_{k=1}^{r} \rho^2(\sigma_k)(w_k - 1)^2 + 2 w_k \left(\frac{\sigma_k^2(1+c) + 2c}{\sigma_k^2} \right).$$

Differentiating the above expression with respect to each weight w_k leads to the following choice of asymptotically optimal weights

$$w_k^* = 1 - \frac{\sigma_k^2(1+c) + 2c}{\sigma_k^2 \rho^2(\sigma_k)} \text{ for all } 1 \leq k \leq r. \tag{42}$$

Therefore, if the singular values of the matrix $\boldsymbol{X}$ to be estimated are sufficiently large (namely $\sigma_k > c^{1/4}$ for all $1 \leq k \leq r$), by using Proposition 9 and eq. (42), one has that an asymptotically optimal spectral shrinker of order $r \leq r^*$ is given by the choice of functions

$$f_k^*(\rho(\sigma_k)) = \left\{ \begin{array}{cc} \left(1 - \frac{\sigma_k^2(1+c)+2c}{\sigma_k^2 \rho^2(\sigma_k)}\right) \rho(\sigma_k) & \text{if } \rho(\sigma_k) > c_+, \\ 0 & \text{otherwise,} \end{array} \right. \quad \text{for all } 1 \leq k \leq r. \tag{43}$$

Using, the relation (32) one may also express the asymptotically optimal shrinking rule (43) either as a function of $\rho(\sigma_k)$ only,

$$f_k^*(\rho(\sigma_k)) = \left\{ \begin{array}{cc} \frac{1}{\rho(\sigma_k)} \sqrt{(\rho^2(\sigma_k) - (c+1))^2 - 4c} & \text{if } \rho(\sigma_k) > c_+, \\ 0 & \text{otherwise.} \end{array} \right. \tag{44}$$

or as function of σ_k only (using that $\rho(\sigma_k) > c_+$ is equivalent to $\sigma_k > c^{1/4}$),

$$f_k^*(\rho(\sigma_k)) = \left\{ \begin{array}{cc} \frac{\sigma_k^4 - c}{\sigma_k \sqrt{(1+\sigma_k^2)(c+\sigma_k^2)}} & \text{if } \sigma_k > c^{1/4}, \\ 0 & \text{otherwise.} \end{array} \right. \tag{45}$$

Therefore, for spectral shrinker of order r, we remark that the shrinkage rule (44) coincides with the rule (35) which has been obtained in Gavish and Donoho (2017). Similarly, when the quantity $f_k^*(\rho(\sigma_k))$ is expressed as a function of σ_k only in (45), then we retrieve the shrinking rule (36) derived in Nadakuditi (2014). Therefore, it appears that minimizing either the asymptotic behavior of the SURE, that is $\lim_{n \to +\infty} \overline{\mathrm{SURE}}\left(\hat{\boldsymbol{X}}^f\right)$, or the limit of

SE risk (34) leads to the same choice of an asymptotically optimal spectral estimator.

Data-driven shrinkage of empirical singular values. From the results in Section 2.3, the principle of SURE minimisation leads to the following data-driven choice of spectral shrinker of order r that collapses the bulk to 0

$$\hat{\boldsymbol{X}}_w^r = \sum_{k=1}^{r} f_k(\tilde{\sigma}_k)\tilde{\boldsymbol{u}}_k\tilde{\boldsymbol{v}}_k^t, \tag{46}$$

where $f_k(\tilde{\sigma}_k) = w_k(\boldsymbol{Y})\tilde{\sigma}_k \mathbb{1}_{\{\tilde{\sigma}_k > c_+\}}$, for all $1 \leq k \leq r$, with $w_k(\boldsymbol{Y})$ given by (31). From Proposition 9 and Proposition 10 it follows that, if $\sigma_k > c^{1/4}$, then, almost surely,

$$\lim_{n\to+\infty} f_k(\tilde{\sigma}_k) = \left(1 - \frac{\sigma_k^2(1+c)+2c}{\sigma_k^2\rho^2(\sigma_k)}\right)\rho(\sigma_k), \text{ for all } 1 \leq k \leq r \leq r^*.$$

Therefore, the data-driven spectral estimator $\hat{\boldsymbol{X}}_w^r$ (46) asymptotically leads to the optimal shrinking rule of singular values given by (43) which has been obtained by minimizing the asymptotic behavior of the SURE.

Note that when $\tau \neq 1/\sqrt{m}$, it suffices to replace the condition $\tilde{\sigma}_k > c_+$ by $\tilde{\sigma}_k > \tau(\sqrt{m}+\sqrt{n})$ in the definition of $\hat{\boldsymbol{X}}_w^r$, which yields the shrinking rule (13) stated in the introduction of this paper.

4. Estimating active sets of singular values in exponential families

In this section, we propose to formulate a new Akaike information criterion (AIC) to select an appropriate set of singular values over which a shrinkage procedure might be applied. To this end, we shall consider the estimator $\tilde{\boldsymbol{X}}^s = \sum_{k\in s}\tilde{\sigma}_k\tilde{\boldsymbol{u}}_k\tilde{\boldsymbol{v}}_k^t$ defined for a subset $s \subseteq \mathcal{I} = \{1, 2, \ldots, \min(n,m)\}$, and we address the problem of selecting an optimal subset $s^\star$ from the data $\boldsymbol{Y}$.

In the case of Gaussian measurements, the shrinkage estimators that we use in our numerical experiments are of the form $\hat{\boldsymbol{X}}^f = \sum_{k\in s^\star} f_k(\tilde{\sigma}_k)\tilde{\boldsymbol{u}}_k\tilde{\boldsymbol{v}}_k^t$ where

$$s^\star = \{k \ ; \ \tilde{\sigma}_k > c_+^{n,m}\} \text{ with } c_+^{n,m} = 1 + \sqrt{\frac{n}{m}},$$

for some (possibly data-dependent) shrinkage functions f_k. The set $s^\star$ is based on the knowledge of an approximation $c_+^{n,m}$ of the bulk edge c_+. Thanks to Proposition 9, the bulk edge c_+ is interpreted as the threshold which allows to distinguish the locations of significant singular values in the data from those due to the presence of additive noise. Interestingly, the following result shows that the active set $s^\star$ may be interpreted through the prism of model selection using the minimisation of a penalized log-likelihood criterion.

Proposition 13 *Assume that $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$ where the entries of $\boldsymbol{W}$ are iid Gaussian variables with zero mean and standard deviation $\tau = 1/\sqrt{m}$. Then, we have*

$$s^* = \arg\min_{s\subseteq\mathcal{I}} m\|\boldsymbol{Y} - \tilde{\boldsymbol{X}}^s\|_F^2 + 2|s|p_{n,m} \text{ with } p_{n,m} = \left(\frac{1}{2}\left(\sqrt{m}+\sqrt{n}\right)^2\right), \tag{47}$$

where $\tilde{\boldsymbol{X}}^s = \sum_{k\in s}\tilde{\sigma}_k\tilde{\boldsymbol{u}}_k\tilde{\boldsymbol{v}}_k^t$ for $s \in \mathcal{I} = \{1, 2, \ldots, \min(n,m)\}$, and $|s|$ is the cardinal of s.

Proof We remark that $\boldsymbol{Y} - \tilde{\boldsymbol{X}}^s = \sum_{k\notin s}\tilde{\sigma}_k\tilde{\boldsymbol{u}}_k\tilde{\boldsymbol{v}}_k^t$. It results that

$$m\|\boldsymbol{Y} - \tilde{\boldsymbol{X}}^s\|_F^2 + 2|s|p_{n,m} = m\sum_{k\notin s}\tilde{\sigma}_k^2 + 2|s|p_{n,m} = \sum_{k=1}^{n}\begin{cases} m\tilde{\sigma}_k^2 & \text{if } k \notin s \\ 2p_{n,m} & \text{otherwise} \end{cases}. \tag{48}$$

Using that $\sqrt{2p_{n,m}/m} = c_+^{n,m}$, it follows that the set $s^\star = \{k \ ; \ \tilde{\sigma}_k > c_+^{n,m}\}$ is by definition such that $k \in s^\star$ if and only if $2p_{n,m} < m\tilde{\sigma}_k^2$. Therefore, by (48), the criterion $s \mapsto m\|\boldsymbol{Y} - \tilde{\boldsymbol{X}}^s\|_F^2 + 2|s|p_{n,m}$ is minimum at $s = s^\star$ which concludes the proof. ■

In the model $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$, where the entries of $\boldsymbol{W}$ are iid Gaussian variables with zero mean and variance τ^2, it is well known that the degrees of freedom (DOF) of a given estimator $\hat{\boldsymbol{X}}$ is defined as

$$\mathrm{DOF}(\hat{\boldsymbol{X}}) = \frac{1}{\tau^2}\sum_{i=1}^{n}\sum_{j=1}^{m}\mathrm{Cov}(\hat{\boldsymbol{X}}_{ij}, \boldsymbol{Y}_{ij}) = \frac{1}{\tau^2}\sum_{i=1}^{n}\sum_{j=1}^{m}\mathbb{E}[\hat{\boldsymbol{X}}_{ij}\boldsymbol{W}_{ij}].$$

The DOF is widely used in statistics to define various criteria for model selection among a collection of estimators (see e.g. Bradley (2004)). In low rank matrix denoising, the following proposition shows that it is possible to derive the asymptotic behavior of the DOF of spectral estimators.

Proposition 14 *Assume that $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$ is a random matrix sampled from the Gaussian spiked population model with $\tau = \frac{1}{\sqrt{m}}$ and $\boldsymbol{X} = \sum_{k=1}^{r^*}\sigma_k\boldsymbol{u}_k\boldsymbol{v}_k^t$. Let $\hat{\boldsymbol{X}}^f$ be a spectral shrinker of order $r \leq r^*$ that collapses the bulk to 0, such that each function f_k, for $1 \leq k \leq r$, is continuously differentiable on $]c_+, +\infty[$. Moreover, assume that $\sigma_k > c^{1/4}$ for all $1 \leq k \leq r$. Then, one has that, almost surely,*

$$\lim_{n\to+\infty}\frac{1}{m}\mathrm{DOF}(\hat{\boldsymbol{X}}^f) = \sum_{k=1}^{r}\frac{f_k(\rho(\sigma_k))}{\rho(\sigma_k)}\left(1 + c + \frac{2c}{\sigma_k^2}\right).$$

Proof Thanks to the derivation of the SURE in Stein (1981) and formula (24) on the divergence of spectral estimators, one has that

$$\mathrm{DOF}(\hat{\boldsymbol{X}}^f) = \mathbb{E}\left[\mathrm{div}\,\hat{\boldsymbol{X}}^f\right] = \mathbb{E}\left[|m-n|\sum_{k=1}^{r}\frac{f_k(\tilde{\sigma}_k)}{\tilde{\sigma}_k} + \sum_{k=1}^{r}f_k'(\tilde{\sigma}_k) + 2\sum_{k=1}^{r}f_k(\tilde{\sigma}_k)\sum_{\ell=1;\ell\neq k}^{n}\frac{\tilde{\sigma}_k}{\tilde{\sigma}_k^2 - \tilde{\sigma}_\ell^2}\right].$$

By Proposition 9, Proposition 10, and our assumptions on the f_k's, one has that, almost surely,

$$\lim_{n\to+\infty}\frac{1}{m}\,\mathrm{div}\,\hat{\boldsymbol{X}}^f = \sum_{k=1}^{r}\frac{f_k(\rho(\sigma_k))}{\rho(\sigma_k)}\left(1 + c + \frac{2c}{\sigma_k^2}\right).$$

which completes the proof. ■

Hence, in the Gaussian spiked population model, by Proposition 14 and using that $\sigma_k^2 > \sqrt{c}$ for all $1 \leq k \leq r$, it follows that if $s \subseteq \{1, \dots, r\}$ then

$$\lim_{n \to +\infty} \frac{1}{m} \mathrm{DOF}(\tilde{\boldsymbol{X}}^s) = |s| \left(1 + c + \frac{2c}{\sigma_k^2}\right) \leq |s| \left(1 + \sqrt{c}\right)^2 = |s| c_+^2. \tag{49}$$

Hence, the quantity $2|s| \left(\frac{1}{2}\left(\sqrt{m} + \sqrt{n}\right)^2\right)$ is asymptotically an upper bound of $\mathrm{DOF}(\tilde{\boldsymbol{X}}^s)$ (when normalized by $1/m$) for any given set $s \subseteq \{1, \dots, r\}$.

Let us now consider the more general case where the entries of $\boldsymbol{Y}$ are sampled from an exponential family. To the best of our knowledge, extending the notion of the bulk edge to non-Gaussian data sampled from an exponential family has not been considered so far in the literature on random matrices and low rank perturbation model. Therefore, except in the Gaussian case, it is far from being trivial to find an appropriate threshold value $\bar{c}$ to define an active set in the form $\bar{s} = \{k \,;\, \tilde{\sigma}_k > \bar{c}\}$.

Nevertheless, to select an appropriate active set of singular values, we introduce the following criterion that is inspired by the previous results on the DOF of the estimator $\tilde{\boldsymbol{X}}^s$ in the Gaussian case and the statistical literature on the well known AIC for model selection (Akaike, 1974).

Definition 15 *The AIC associated to* $\tilde{\boldsymbol{X}}^s = \sum_{k \in s} \tilde{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t$ *is*

$$\mathrm{AIC}(\tilde{\boldsymbol{X}}^s) = -2 \log q(\boldsymbol{Y}; \tilde{\boldsymbol{X}}^s) + 2|s| p_{n,m} \quad \textit{with} \quad p_{n,m} = \frac{1}{2}\left(\sqrt{m} + \sqrt{n}\right)^2 . \tag{50}$$

where $|s|$ *is the cardinal of* s*, and* $q(\boldsymbol{Y}; \tilde{\boldsymbol{X}}^s) = \prod_{i=1}^n \prod_{j=1}^m q(\boldsymbol{Y}_{ij}; \tilde{\boldsymbol{X}}^s_{ij})$ *is the likelihood of the data in the general form* (14) *at the estimated parameters* $\boldsymbol{X}_{ij} = \tilde{\boldsymbol{X}}^s_{ij}$*.*

In the above definition of $\mathrm{AIC}(\tilde{\boldsymbol{X}}^s)$, the quantity $2|s|p_{n,m}$ is an approximation of the degree of freedom of $\tilde{\boldsymbol{X}}^s$, i.e., of the numbers of its free parameters as it is justified by Proposition 14 in the case of Gaussian measurements. The AIC allows us to define an optimal subset of active variables as

$$s^* = \operatorname*{arg\,min}_{s \subseteq \mathcal{I}} \mathrm{AIC}(\tilde{\boldsymbol{X}}^s).$$

For Gaussian measurements, Proposition 13 gives the value of the optimal set s^* in a closed-form.

Following the arguments in Section 2.3, for Gamma or Poisson measurements and for a given subset s, we consider the estimator

$$\tilde{\boldsymbol{X}}^s_\epsilon = \max\left[\sum_{k \in s} \tilde{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t, \varepsilon\right], \tag{51}$$

when $\epsilon > 0$ is an *a priori* value to satisfy the positivity constraint on the entries of an estimator in this setting. However, contrary to the case of Gaussian noise, the search of an optimal subset $s^\star \subset \operatorname*{arg\,min}_{s \subseteq \mathcal{I}} \mathrm{AIC}(\tilde{\boldsymbol{X}}^s_\epsilon)$ becomes a combinatorial problem in this context. In

our numerical experiments, we thus choose to construct an approximation $\tilde{s}$ of $s^\star$ with a greedy search strategy that reads as follows

$$\tilde{s} = \mathcal{I} \setminus \left\{k \in \mathcal{I} \,;\, \mathrm{AIC}(\tilde{\boldsymbol{X}}_\epsilon^{\mathcal{I}\setminus\{k\}}) \leq \mathrm{AIC}(\tilde{\boldsymbol{X}}_\epsilon^{\mathcal{I}})\right\}. \tag{52}$$

For Gaussian measurements, $\tilde{s} = s^\star$ since the optimisation problem (52) becomes separable. In our numerical experiments, we have found that $\tilde{s}$ selects a relevant set of active singular values which separates well the structural content of $\boldsymbol{X}$ while removing most of the noise component. Further details are given in Section 5 below.

For Gaussian noise, the computation of the active set s^* of singular values may also be interpreted as a way to estimate the unknown rank r^* of the signal matrix $\boldsymbol{X}$. In this setting, one has that $s^\star = \{k \,;\, \tilde{\sigma}_k > c_+^{n,m}\}$ which suggests the choice

$$\hat{r} = \max\{k \,;\, \tilde{\sigma}_k > c_+^{n,m}\}, \tag{53}$$

as an estimator of r^*.

There exists an abundant literature of the problem of estimating the rank of an empirical covariance matrix for the purpose of selecting the appropriate number of significant components to be kept in PCA or factor analysis. It is much beyond the scope of this paper to give an overview of this topic. We point to the review in Jolliffe (2002) for a summary of existing methods to determine the number of components in PCA that are grouped into three categories: subjective methods, distribution-based test tools, and computational procedures. For recent contributions in the matrix denoising model (1) with Gaussian noise, we refer to the works in Choi et al. (2014); Gavish and Donoho (2014) and references therein. For example for Gaussian data with know variance $\tau^2 = 1/m$, Eq. (11) in Gavish and Donoho (2014) on optimal hard thresholding of singular values suggest to take

$$\hat{r} = \max\{k \,;\, \tilde{\sigma}_k > \lambda(c)\}, \text{ with } \lambda(c) = \sqrt{2(c+1) + \frac{8c}{(c+1) + \sqrt{c^2 + 14c + 1}}}, \tag{54}$$

as a simple method to estimate the rank. It should be remarked that the problem of estimating the true rank r^* of $\boldsymbol{X}$ in model (1) is somewhat ill-posed as, in the Gaussian spiked population model, Proposition 9 implies that one may only expect to estimate the so-called effective rank $r_{\mathrm{eff}} = \max\{k \,;\, \sigma_k > c^{1/4}\}$ (see e.g. Section II.D in Nadakuditi (2014)).

In our numerical experiments, we shall compare different choices for the active set of singular values of the form $\hat{s} = \{1, \dots, \hat{r}\}$ where $\hat{r}$ is either given by (53), (54), or by the "oracle choices" $\hat{r} = r^*$ and $\hat{r} = r_{\mathrm{eff}}$.

Other methods based on hypothesis testing (Choi et al., 2014) could be used for rank estimation in the Gaussian model (1), but it is beyond the purpose of this paper to give a detailed comparison.

For Poisson or Gamma noise, it is more difficult to interpret the computation of s^* as a way to estimate the rank of $\boldsymbol{X}$ since, in our numerical experiments, we have found that the cardinality of s^* is generally not equal to $\max\{k \,; k \in s^*\}$. Moreover, to the best of our knowledge, there is not so much work on the estimation of the true rank of a noisy matrix beyond the Gaussian case. Therefore, we have not included a numerical comparison with other methods for the choice of the active set of singular values in these two cases.

5. Numerical experiments

In this section, we assess of the performance of data-driven srhinkage rules under various numerical experiments involving Gaussian, Gamma and Poisson measurements.

5.1 The case of a signal matrix of rank one

We consider the simple setting where the rank r^* of the matrix $\boldsymbol{X}$ is known and equal to one meaning that

$$\boldsymbol{X} = \sigma_1 \boldsymbol{u}_1 \boldsymbol{v}_1^t,$$

where $\boldsymbol{u}_1 \in \mathbb{R}^n$ and $\boldsymbol{v}_1 \in \mathbb{R}^m$ are vectors with unit norm that are fixed in this numerical experiment, and σ_1 is a positive real that we will let varying. We also choose to fix $n = m = 100$, and so to take $c = \frac{n}{m} = 1$ and $c_+ = 2$. For the purpose of sampling data from Gamma and Poisson distribution, we took singular vectors $\boldsymbol{u}_1$ and $\boldsymbol{v}_1$ with positive entries. The i-th entry (resp. j-th entry) of $\boldsymbol{u}_1$ (resp. $\boldsymbol{v}_1$) is chosen to be proportional to $1 - (i/n - 1/2)^2$ (resp. $1 - (j/m - 1/2)^2$). Let $\boldsymbol{Y} = \sum_{k=1}^{\min(n,m)} \tilde{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t$ be an $n \times m$ matrix whose entries are sampled from model (14) and then satisfying $\mathbb{E}[\boldsymbol{Y}] = \boldsymbol{X}$.

Gaussian measurements

We first consider the case of Gaussian measurements, where $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$ with $\mathbb{E}[\boldsymbol{W}_{ij}] = 0$, $\mathrm{Var}(\boldsymbol{W}_{ij}) = \tau^2$ with $\tau = \frac{1}{\sqrt{m}}$. In this context, we compare the following spectral shrinkage estimators:

- Rank-1 PCA shrinkage

$$\hat{\boldsymbol{X}}^1 = \tilde{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t,$$

- Rank-1 SURE-driven soft-thresholding

$$\hat{\boldsymbol{X}}^1_{\mathrm{soft}} = \hat{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t \quad \text{with} \quad \hat{\sigma}_1 = (\tilde{\sigma}_1 - \lambda(\boldsymbol{Y}))_+,$$

- Rank-1 asymptotically optimal shrinkage proposed in Nadakuditi (2014) and Gavish and Donoho (2017)

$$\hat{\boldsymbol{X}}^1_* = \hat{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t \quad \text{with} \quad \hat{\sigma}_1 = \sqrt{\tilde{\sigma}_1^2 - 4}\, \mathbb{1}_{\{\tilde{\sigma}_1 > 2\}},$$

- Rank-1 SURE-driven weighted estimator that we have derived in Section 2.3

$$\hat{\boldsymbol{X}}^1_w = \hat{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t \quad \text{with} \quad \hat{\sigma}_1 = \left(1 - \frac{1}{\tilde{\sigma}_1^2}\left(\frac{1}{m} + \frac{2}{m}\sum_{\ell=2}^{n} \frac{\tilde{\sigma}_1^2}{\tilde{\sigma}_1^2 - \tilde{\sigma}_\ell^2}\right)\right)_+ \tilde{\sigma}_1 \mathbb{1}_{\{\tilde{\sigma}_1 > 2\}},$$

where the above formula follows from the results in Section 3.3 using that $c = 1$ and $c_+ = 2$ in these numerical experiments, and where, for the soft-thresholding, the value $\lambda(\boldsymbol{Y}) > 0$ is obtained by a numerical solver in order to minimize the SURE. As a benchmark, we will also consider the oracle estimator $\boldsymbol{X}^1_*$ that performs shrinkage by using the knowledge of the true singular-value σ_1 defined as

$$\boldsymbol{X}^1_* = \hat{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t \quad \text{with} \quad \hat{\sigma}_1 = \sqrt{\rho(\sigma_1)^2 - 4}\, \mathbb{1}_{\{\rho(\sigma_1) > 2\}}$$

which corresponds to the asymptotically optimal shrinking rule (44) as a function of $\rho(\sigma_k)$ in the setting $c = 1$ and $c_+ = 2$. Note that form the formula above $\hat{w}_1 = \hat{\sigma}_1/\tilde{\sigma}_1$ is necessary in the range $[0, 1]$ for all considered estimators.

In Figure 1, we compare the estimated singular-values $\hat{\sigma}_1$ and the estimated weights $\hat{w}_1 = \hat{\sigma}_1/\tilde{\sigma}_1$ as functions of σ_1 for the four aforementionned estimators. Because all estimators are subject to noise variance, we display, for all estimators, the median values and the 80% confidence intervals obtained from $M = 100$ noise realizations. It can be seen that the median curves for the eigenvelues and the weights of $\hat{\boldsymbol{X}}^1_w$ and $\hat{\boldsymbol{X}}^1_*$ coincide (up to variations that are slightly larger for the former) which is in agreement with the asymptotic analysis of shrinkage rules that has been carried out in Section 3.3. Spectral estimator obtained by SURE-driven soft-thresholding also leads to an optimal shrinkage rule.

In Figure 2, for each of the four spectral estimators above, we display for $M = 100$ noise realizations, as functions of σ_1, the following normalized MSE

$$\mathrm{NMSE}(\hat{\boldsymbol{X}}) = \frac{\|\hat{\boldsymbol{X}} - \boldsymbol{X}\|_F^2}{\|\boldsymbol{X}\|_F^2}.$$

The normalized MSE of the estimators $\hat{\boldsymbol{X}}^1_{\mathrm{soft}}, \hat{\boldsymbol{X}}^1_*$ and $\hat{\boldsymbol{X}}^1_w$ are the same for values of σ_1 larger than $c^{1/4} = 1$, and they only differ for values of σ_1 close or below the threshold $c^{1/4} = 1$ (corresponding to values of $\rho(\sigma_1)$ below the bulk edge $c_+ = 2$). More remarkably, above $c^{1/4} = 1$, they offer similar NMSE values to the oracle shrinkage estimator $\boldsymbol{X}^1_*$, not only in terms of median but also in terms of variability, as assessed by the confidence intervals. The performances of the estimator $\hat{\boldsymbol{X}}^1$ (standard PCA) are clearly poorer. These numerical experiments also illustrate that, for finite-dimensional low rank matrix denoising with $r^* = 1$, data-driven spectral estimators obtained by minimizing a SURE criterion achieve performances that are similar to asymptotically optimal shrinkage rules.

Gamma and Poisson distributed measurements

Let us now consider the case where the entries of $\boldsymbol{Y}_{ij} \geq 0$ of the data matrix $\boldsymbol{Y}$ are independently sampled from a Gamma or Poisson distribution with mean $\boldsymbol{X}_{ij} > 0$. To satisfy the constraint that the estimators must be matrices with positive entries, we consider estimators of the form (30). In this context, we compare the following spectral shrinkage estimators, set for $\varepsilon = 10^{-6}$, as:

- Rank-1 PCA shrinkage

$$\hat{\boldsymbol{X}}^1 = \max\left[\tilde{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t, \varepsilon\right],$$

- Rank-1 GSURE/SUKLS/PURE/PUKLA-driven soft-thresholding

$$\hat{\boldsymbol{X}}^1_{\mathrm{soft}} = \max\left[\hat{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t, \varepsilon\right] \quad \text{with} \quad \hat{\sigma}_1 = (\tilde{\sigma}_1 - \lambda(\boldsymbol{Y}))_+,$$

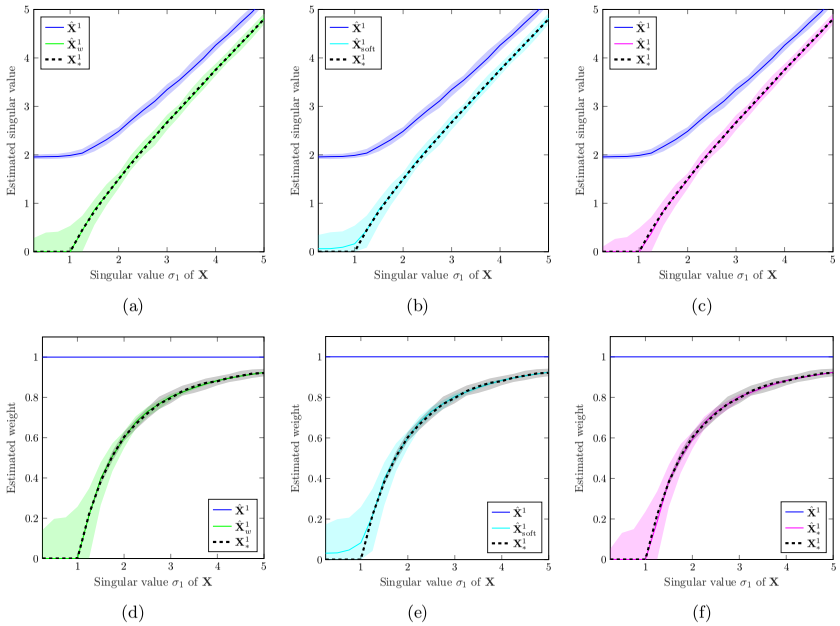

Figure 1: The case of Gaussian measurements with $m = n = 100$. Estimated first singular value $\hat{\sigma}_1$ as a function of the true underlying one σ_1, for (a) our proposed estimator $\hat{\boldsymbol{X}}^1_w$, (b) the soft-thresholding $\hat{\boldsymbol{X}}^1_{\text{soft}}$ and (c) the asymptotical one $\hat{\boldsymbol{X}}^1_*$. All of them are compared to the first singular value $\tilde{\sigma}_1$ of $\boldsymbol{Y}^1$ and the one of the oracle asymptotical estimator $\boldsymbol{X}^1_*$. (c,d,e) Same but for the corresponding weight $\hat{w}_1 = \hat{\sigma}_1/\tilde{\sigma}_1$. Curves have been computed on $M = 100$ noise realizations, only the median and an 80% confidence interval are represented respectively by a stroke and a shadded area of the same color.

- Rank-1 GSURE/SUKLS/PURE/PUKLA-driven weighted estimator

$$\hat{\boldsymbol{X}}^1_w = \max\left[\hat{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t, \varepsilon\right] \quad \text{with} \quad \hat{\sigma}_1 = w_1(\boldsymbol{Y})\tilde{\sigma}_1 \mathbb{1}_{\{1 \in \tilde{s}\}},$$

where $\tilde{s}$ is the approximated active subset as defined in Section 4. For the soft-thresholding, the value $\lambda(\boldsymbol{Y}) > 0$ is obtained by a numerical solver in order to minimize either the GSURE or the SUKLS criterion (in the Gamma case) and either the PURE or the PUKLA criterion (in the Poisson case). The weight $w_1(\boldsymbol{Y}) \in [0, 1]$ is obtained by a numerical solver in order to minimize the GSURE and the PURE, as described in Section B. According to Section 2.3, the weight $w_1(\boldsymbol{Y}) \in [0, 1]$, minimizing the SUKLS criterion, has the following closed-form

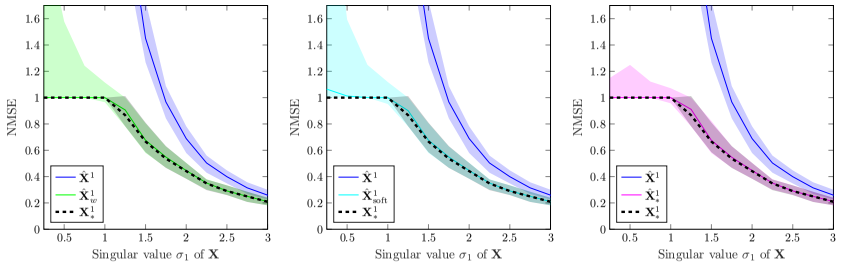

Figure 2: Same as Fig. 1 but for the normalized MSE of the corresponding estimators.

formula

$$w_1(\boldsymbol{Y}) = \min\left[1, \left(\frac{L-1}{Lmn}\sum_{i=1}^{n}\sum_{j=1}^{m}\frac{\hat{\boldsymbol{X}}^1_{ij}}{\boldsymbol{Y}_{ij}} + \frac{1}{Lmn}\left(1 + 2\sum_{\ell=2}^{n}\frac{\tilde{\sigma}_1^2}{\tilde{\sigma}_1^2 - \tilde{\sigma}_\ell^2}\right)\right)^{-1}\right],$$

and for the PUKLA criterion, we have

$$w_1(\boldsymbol{Y}) = \min\left[1, \frac{\sum_{i=1}^{n}\sum_{j=1}^{m}\boldsymbol{Y}_{ij}}{\sum_{i=1}^{n}\sum_{j=1}^{m}\hat{\boldsymbol{X}}^1_{ij}}\right].$$

To evaluate the performances of these estimators, we perform again a study involving $M = 100$ noise realizations.

In the Gamma case with shape parameter $L = 3$, results are reported in Figure 3 where σ_1 ranges from 0.1 to 5. In the Poisson case, results are reported in Figure 4. To generate data from a Poisson distribution with mean value $\boldsymbol{X} = \sigma_1 \boldsymbol{u}_1 \boldsymbol{v}_1^t$, we took σ_1 ranging from 25 to 400. In this context, the entries $\boldsymbol{X}_{i,j}$ are in average ranging from 0.25 to 4. When $\sigma_1 = 25$, about 78% of the entries of $\boldsymbol{Y}$ are 0 and 20% are equals to 1 which correspond to an extreme level of noise, while when $\sigma_1 = 400$, the entries of $\boldsymbol{Y}$ concentrate around 4 with a standard deviation of 2 which correspond to a simpler noisy setting.

In these experiments, it can be seen that all the data-dependent spectral estimators achieve comparable results with really small errors in terms of MSE and MKL risks. Their performances are similar to $\hat{\boldsymbol{X}}^1 = \tilde{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t$ meaning that optimizing either SURE-like criteria leads to a spectral estimator closed to correspond to matrix denoising by ordinary PCA. However, unlike the Gamma case, it might be observed in the Poisson case that when reaching a stronger noise level, *i.e*, for small value of σ_1, the NMSE of all estimator increases as the denoising problem becomes more challenging. Nevertheless, only the weight of $\hat{\boldsymbol{X}}^1_w$ driven by PUKLA does not present a drop wich allows reaching a slightly smaller MKLA. In the Gamma case, the noise level being proportional to the signal level, the NMSE/MKLS remain constant for all σ_1.

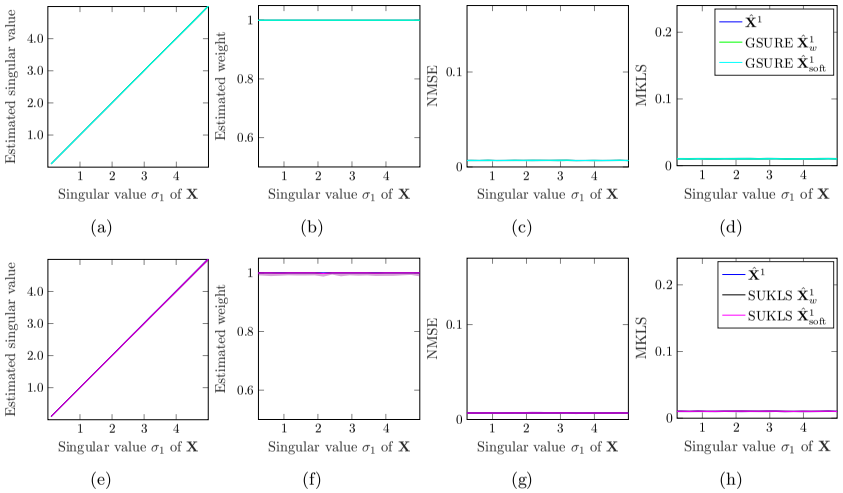

Figure 3: The case of Gamma measurements with $m = n = 100$. (a) Estimated first eigenvalue $\hat{\sigma}_1$ as a function of the true underlying one σ_1 for our proposed estimator $\hat{\boldsymbol{X}}^1_w$ and the soft-thresholding $\hat{\boldsymbol{X}}^1_{\text{soft}}$ when both are guided by the GSURE. Both of them are compared to the first singular value $\tilde{\sigma}_1$ of $\boldsymbol{Y}^1$. Same but for (b) the corresponding weights $\hat{w}_1 = \hat{\sigma}_1/\tilde{\sigma}_1$, (c) the NMSE risk and (d) the MKLS risk. (e-h) Exact same esperiments but when our proposed estimator and the soft-thresholding are both guided by SUKLS. Curves have been computed on $M = 100$ noise realizations, only the median and an 80% confidence interval are represented respectively by a stroke and a shadded area of the same color.

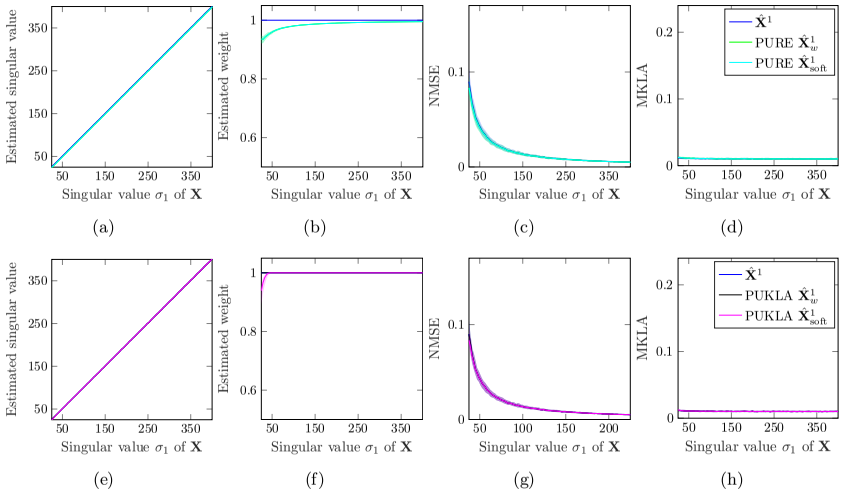

Figure 4: The case of Poisson measurements with $m = n = 100$. (a) Estimated first eigenvalue $\hat{\sigma}_1$ as a function of the true underlying one σ_1 for our proposed estimator $\hat{\boldsymbol{X}}^1_w$ and the soft-thresholding $\hat{\boldsymbol{X}}^1_{\text{soft}}$ when both are guided by the PURE. Both of them are compared to the first singular value $\tilde{\sigma}_1$ of $\boldsymbol{Y}^1$. Same but for (b) the corresponding weights $\hat{w}_1 = \hat{\sigma}_1/\tilde{\sigma}_1$, (c) the NMSE risk and (d) the MKLA risk. (e-h) Exact same esperiments but when our proposed estimator and the soft-thresholding are both guided by PUKLA. Curves have been computed on $M = 100$ noise realizations, only the median and an 80% confidence interval are represented respectively by a stroke and a shadded area of the same color.

Finally, as mentionned by Gavish and Donoho (2017), to use the estimator $\hat{\boldsymbol{X}}^1_*$ in a Gaussian model with homoscedastic variance $\tau^2 \neq \frac{1}{m}$, one may take the estimator $\hat{\boldsymbol{X}}^1_* = \sqrt{m}\tau f^*_1(\tilde{\sigma}_1/(\sqrt{m}\tau))\tilde{\boldsymbol{u}}_1\tilde{\boldsymbol{v}}^t_1$. Hence, provided the variance of the entries of the data matrix $\boldsymbol{Y}$ is known, it is always possible to use a scaled version of the shrinkage rule from Gavish and Donoho (2017) when $\tau^2 \neq \frac{1}{m}$. However, in the setting of Gamma or Poisson noise, the variance of the additive noise varies from one entry to another and depends on the entries of the unknown signal matrix $\boldsymbol{X}$ to recover. For this reason, it is not possible to use a scaled version of the shrinkage rule from Gavish and Donoho (2017) as this would require to use scaling factors depending on the unknown values of the entries of $\boldsymbol{X}$. Therefore, a comparison between our approach and the asymptotically optimal shrinkage proposed in Nadakuditi (2014) and Gavish and Donoho (2017) (for Gaussian noise) is not possible in the case of Gamma or Poisson measurements. Note that for Gamma measurements one has

that $\text{Var}(\boldsymbol{Y}_{ij}) = \boldsymbol{X}^2_{ij}/L$, and, in our numerical experiments, it is assumed that the constant L is known.

A typical example where this assumption is reasonable, is the one of the statistical models of speckle used in coherent imagery, such as, Synthetic Aperture Radar (SAR) and SOund Navigation And Ranging (SONAR) imagery. In such imaging systems, the observed irradiance $\boldsymbol{Y}_{ij}$ of a pixel with indices (i, j) is obtained as the square modulus of a complex signal modeled as being zero-mean circular complex Gaussian distributed (consequence of the Central Limit Theorem), see e.g. Goodman (1976). It follows that $\boldsymbol{Y}_{ij}$ has an exponential distribution[1] with mean $\boldsymbol{X}_{ij}$ corresponding to the underlying irradiance to be estimated. In order to improve the contrast of such images (namely, the signal to noise ratio), an average of L independent and identically distributed images is often performed, and the resulting pixel value becomes Gamma distributed with parameter L (Ulaby and

1. The exponential distribution is a particular instance of the Gamma distribution with parameter $L = 1$

Dobson, 1989). Because the number L of images to be averaged is chosen by the practitioner, the parameter L is absolutely known without uncertainties, and for this reason it does not require to be estimated. Nevertheless the variance $\mathrm{Var}(\boldsymbol{Y}_{ij}) = \boldsymbol{X}_{ij}^2/L$ remains unknown.

While all estimators behave similarly in the rank 1 setting, we will see in the next section that they can significantly differ when the rank is let to be larger than 2.

5.2 The case of a signal matrix of rank larger than two

We now consider the more complex an realistic setting where the rank r^* of the matrix $\boldsymbol{X}$ is unknown and potentially larger than two, i.e.,

$$\boldsymbol{X} = \sum_{k=1}^{r^*} \sigma_k \boldsymbol{u}_k \boldsymbol{v}_k^t,$$

where $\boldsymbol{u}_k \in \mathbb{R}^n$ and $\boldsymbol{v}_k \in \mathbb{R}^m$ are vectors with unit norm that are fixed in this numerical experiment, and σ_k are positive real values also fixed in this experiment. We also choose to fix $n = 100$ and $m = 200$, while the true rank is $r^* = 9$ as shown by the red curve in Figure 5(i). Again, let $\boldsymbol{Y} = \sum_{k=1}^{\min(n,m)} \tilde{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t$ be an $n \times m$ matrix whose entries are sampled from model (14) and then satisfying $\mathbb{E}[\boldsymbol{Y}] = \boldsymbol{X}$.

Gaussian distributed measurements

We first consider the case of Gaussian measurements, where $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$ with $\mathbb{E}[\boldsymbol{W}_{ij}] = 0$, $\mathrm{Var}(\boldsymbol{W}_{ij}) = \tau^2$ with $\tau = 80$. In the following numerical experiments, we study the behavior of the spectral estimator:

- PCA shrinkage

$$\hat{\boldsymbol{X}}^r = \sum_{k=1}^{r} \tilde{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t \, \mathbb{1}_{\{k \le \hat{r}\}},$$

- SURE-driven soft-thresholding

$$\hat{\boldsymbol{X}}_{\mathrm{soft}} = \sum_{k=1}^{\min(m,n)} \hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t \quad \text{with} \quad \hat{\sigma}_k = (\tilde{\sigma}_k - \lambda(\boldsymbol{Y}))_+,$$

- Asymptotically optimal shrinkage proposed in Nadakuditi (2014) and Gavish and Donoho (2017)

$$\hat{\boldsymbol{X}}_*^r = \sum_{k=1}^{r} \hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t \quad \text{with} \quad \hat{\sigma}_k = \frac{1}{\tilde{\sigma}_k} \sqrt{\left(\tilde{\sigma}_k^2 - (c+1)\right)^2 - 4c} \, \mathbb{1}_{\{k \le \hat{r}\}},$$

- SURE-driven weighted estimator that we have derived in Section 2.3

$$\hat{\boldsymbol{X}}_w^r = \sum_{k=1}^{r} \hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t \quad \text{with} \quad \hat{\sigma}_k = \left(1 - \frac{1}{\tilde{\sigma}_k^2}\left(\frac{k}{m} + \frac{2}{m}\sum_{\ell=2}^{n} \frac{\tilde{\sigma}_k^2}{\tilde{\sigma}_k^2 - \tilde{\sigma}_\ell^2}\right)\right)_+ \tilde{\sigma}_k \mathbb{1}_{\{k \le \hat{r}\}},$$

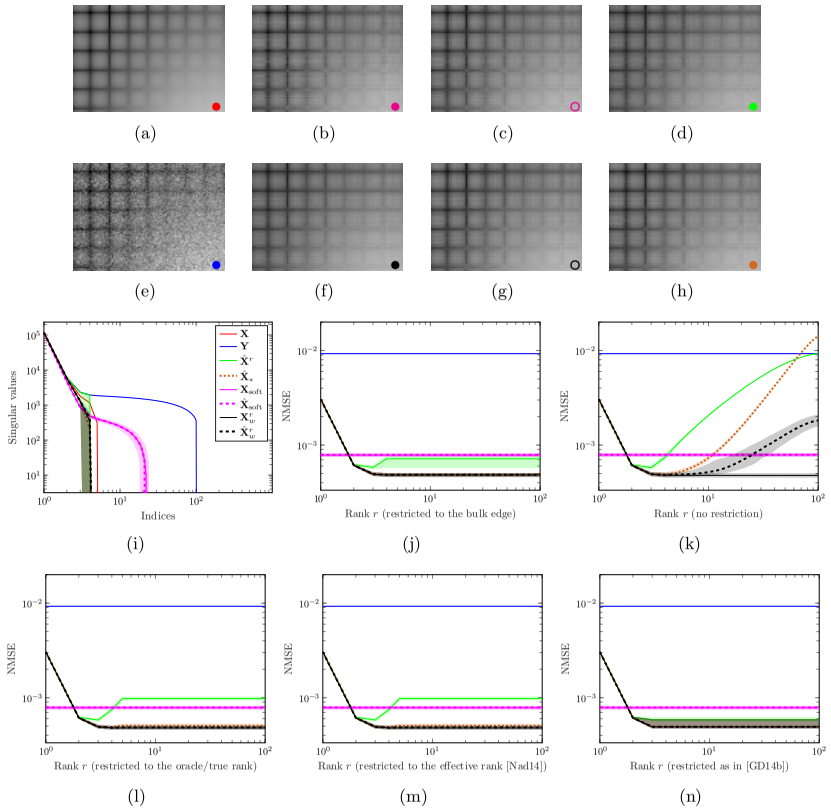

Figure 5: (a) Zoom on a 100×200 noise-free matrix and (e) a single realization of corrupted version by Gaussian noise ($\tau = 80$). (b,c) Oracle soft-thresholding $\boldsymbol{X}_{\mathrm{soft}}$ and data-driven soft-thresholding $\hat{\boldsymbol{X}}_{\mathrm{soft}}$. (d) PCA full rank $\hat{\boldsymbol{X}}^{r_{\max}}$, i.e., $r_{\max} = \min(n, m)$. (f,g,h) Oracle full rank approximation $\boldsymbol{X}_w^{r_{\max}}$, and data-driven full rank estimation $\hat{\boldsymbol{X}}_w^{r_{\max}}$ and $\hat{\boldsymbol{X}}_*^{r_{\max}}$. (i) Their corresponding singular values. (j) NMSE of the various approximations as a function of the rank r. (k) Same but without knowledge the bulk edge, namely $c_+ = 0$. (l,m,n) Same when the active set of singular values is of the form $\hat{s} = \{1, \ldots, \hat{r}\}$ where $\hat{r}$ is either given by $\hat{r} = r^*$ (oracle/true rank), $\hat{r} = r_{\mathrm{eff}}$ (effective rank) or by (54). In all the figures, the solid curves correspond to oracle estimators and the dashed curves correspond to data-driven estimators, obtained over $M = 1,000$ noise realizatrions. The grey areas represent a 80% confidence interval.

where $r \in [1, \min(n,m)]$, and for the soft-thresholding, the value $\lambda(\boldsymbol{Y}) > 0$ is obtained by a numerical solver in order to minimize the SURE. Otherwise specified, we consider $\hat{r} = \max\{k \; ; \; \tilde{\sigma}_k > c_+^{n,m}\}$, *i.e.*, an estimator of the rank using knowledge of the bulk edge $c_+ \approx c_+^{n,m}$, hence, $\mathbb{1}_{\{k \leq \hat{r}\}} = \mathbb{1}_{\{\tilde{\sigma}_k > c_+^{n,m}\}}$. As discussed in Section 4, we compare, in these experiments, the influence of rank estimation by analyzing the performances of the same estimators when either $\hat{r} = r_{\max} = \min(n,m)$ (i.e. without knowledge the bulk edge, namely $c_+ = 0$), $\hat{r} = r^*$ (oracle/true rank), $\hat{r} = r_{\text{eff}}$ (effective rank Nadakuditi (2014)) or by (54) (from hard-thresholding of singular values in Gavish and Donoho (2014)).

In order to assess the quality of SURE as an estimator of the MSE, we also compare the aforementioned approach with their oracle counterparts given by

$$\boldsymbol{X}_{\text{soft}} = \sum_{k=1}^{\min(m,n)} \hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t \quad \text{with} \quad \hat{\sigma}_k = (\tilde{\sigma}_k - \lambda^{\text{oracle}}(\boldsymbol{Y}))_+, \quad \text{and}$$

$$\boldsymbol{X}_w^r = \sum_{k=1}^{r} \hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t \quad \text{with} \quad \hat{\sigma}_k = \tilde{\boldsymbol{v}}_k^t \boldsymbol{X} \tilde{\boldsymbol{u}}_k,$$

where $\lambda^{\text{oracle}}(\boldsymbol{Y})$ minimizes the squared error SE (non-expected risk) over the sets and soft-thresholding approximations respectively. Note that $\boldsymbol{X}_w^r$ and $\boldsymbol{X}_{\text{soft}}$ are ideal approximations of $\boldsymbol{X}$ that cannot be used in practice but serve as benchmarks to evaluate the performances of the data-driven estimators $\hat{\boldsymbol{X}}^r$, $\hat{\boldsymbol{X}}_{\text{soft}}$, $\hat{\boldsymbol{X}}_*^r$ and $\hat{\boldsymbol{X}}_w^r$. In order to shed some light on the variance of these estimators, and indirectly on the variance of the SURE, we perform this experiments over $M = 1000$ independent realizations of $\boldsymbol{Y}$.

The results are reported on Figure 5. For an estimator of the rank given either by $\hat{r} = \max\{k \; ; \; \tilde{\sigma}_k > c_+^{n,m}\}$ (knowledge of the bulk edege), $\hat{r} = r^*$ (oracle/true rank), $\hat{r} = r_{\text{eff}}$ (effective rank) or by (54), it can be observed that $\hat{\boldsymbol{X}}_w^r$, $\hat{\boldsymbol{X}}_*^r$ and $\boldsymbol{X}_w^r$ achieve comparable performances for all $r \in [1, \min(m,n)]$ even though the two first do not rely on the unknown matrix $\boldsymbol{X}$. Similarly $\hat{\boldsymbol{X}}_{\text{soft}}$ and $\boldsymbol{X}_{\text{soft}}$ achieve also comparable performances showing again that the SURE accurately estimates the MSE. In terms of error bands for the NMSE, $\hat{\boldsymbol{X}}_w^r$, $\hat{\boldsymbol{X}}_*^r$ and $\boldsymbol{X}_w^r$ outperform $\hat{\boldsymbol{X}}_{\text{soft}}$ and $\boldsymbol{X}_{\text{soft}}$ provided that r is large enough. Moreover, the performance of $\hat{\boldsymbol{X}}_w^r$ plateaus to its optimum when the rank r becomes large. This allows us to choose $r = \min(n,m)$ when we do not have *a priori* on the true or effective rank.

Interestingly, Fig. 5.(k) shows that when the above estimators are used without the knowledge of the bulk edge (i.e. by taking $c_+^{n,m} = 0$ in their computation instead of $c_+^{n,m} = 1 + \sqrt{\frac{n}{m}}$, which corresponds to the choice $\hat{r} = r_{\max} = \min(n,m)$), the performance of $\hat{\boldsymbol{X}}_w^r$ actually decreases when the rank r becomes too large. Indeed, it is clear from Fig. 5.(k), that the the error band of the NMSE of $\hat{\boldsymbol{X}}_w^r$ becomes much larger as the rank r increases. This illustrates that the SURE suffers from estimation variance in the case of over parametrization when r becomes too large, and thus it cannot be used to estimate jointly a too large number of weights. Therefore, the knowledge of an appropriate estimator $\hat{r}$ of the rank (e.g. using the bulk edge) seems to provide a relevant upper bound on the number of weights that can be jointly and robustly estimated with the SURE.

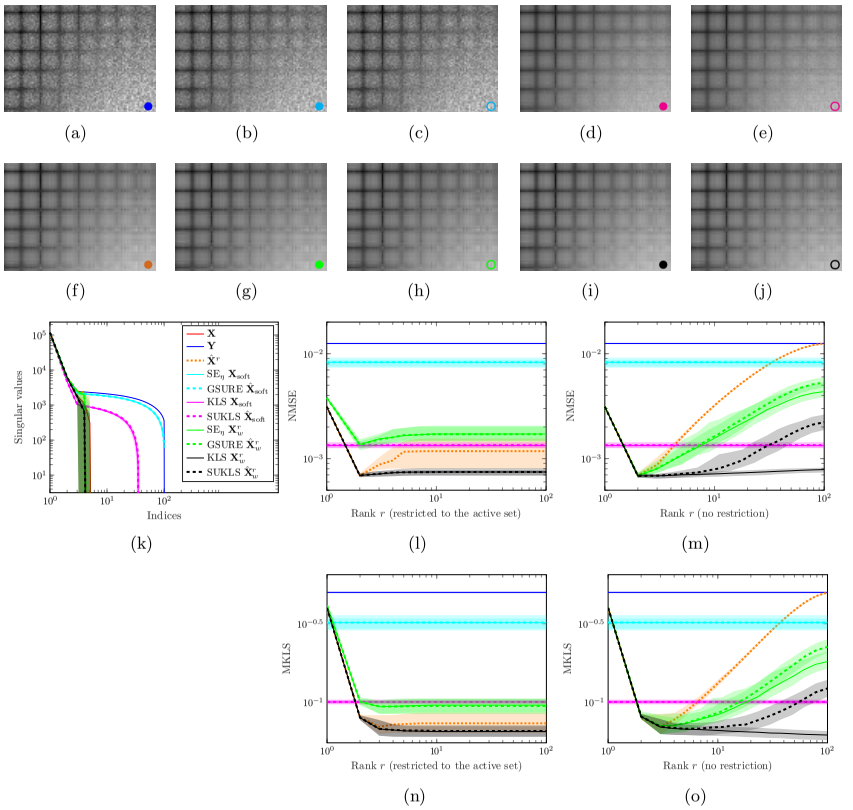

Figure 6: (a) A single realization of corrupted version by Gamma noise ($L = 80$) with zoom on a 100×200 matrix. (b,c,d,e) Oracle soft-thresholding $\boldsymbol{X}_{\text{soft}}$ and data-driven soft-thresholding $\hat{\boldsymbol{X}}_{\text{soft}}$ respectively for SE_η, GSURE, KLS and SUKLS. (f) PCA $\hat{\boldsymbol{X}}^{r_{\max}}$ with full rank approximation i.e. $r_{\max} = \min(n,m)$. (g,h,i,j) Oracle full rank approximation $\boldsymbol{X}_w^{r_{\max}}$, and data-driven full rank estimation $\hat{\boldsymbol{X}}_w^{r_{\max}}$ respectively for SE_η, GSURE, KLS and SUKLS. (k) Their corresponding singular values averaged over $M = 100$ noise realizations. (l,m) NMSE averaged over $M = 100$ noise realizations as a function of the rank r with and without using the active set. (n,o) Same but with respect to MKLS.

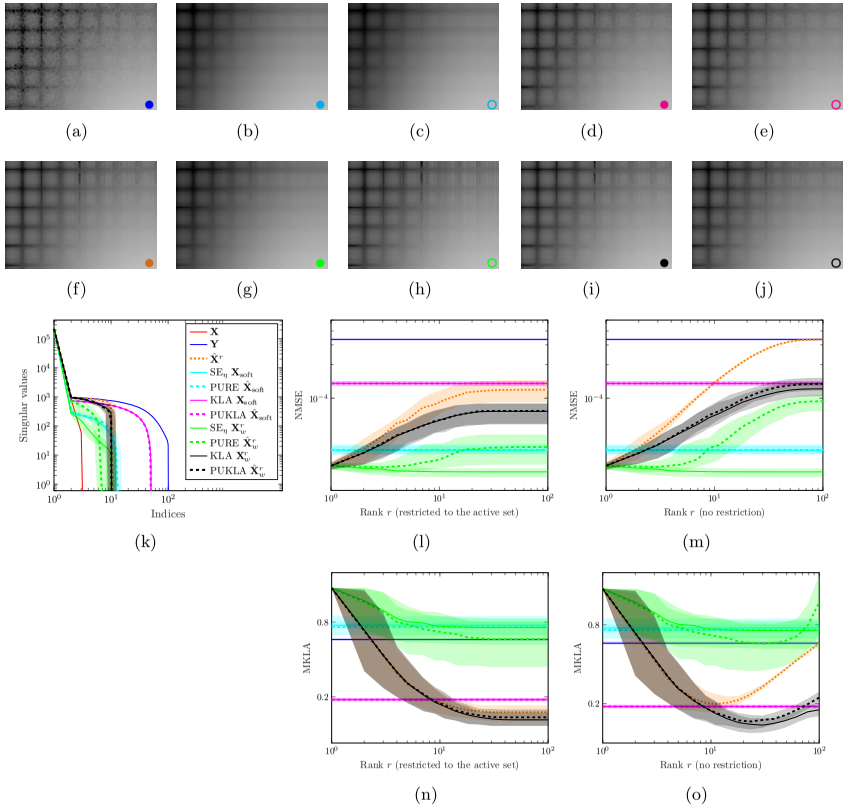

Figure 7: (a) A single realization of corrupted version by Poisson noise with zoom on a 100×200 noise-free matrix (b,c,d,e) Oracle soft-thresholding $\boldsymbol{X}_{\text{soft}}$ and data-driven soft-thresholding $\hat{\boldsymbol{X}}_{\text{soft}}$ respectively for SE, PURE, KLA and PUKLA. (f) PCA $\hat{\boldsymbol{X}}^{r_{\max}}$ with full rank approximation i.e. $r_{\max} = \min(n, m)$. (g,h,i,j) Oracle full rank approximation $\boldsymbol{X}_w^{r_{\max}}$, and data-driven full rank estimation $\hat{\boldsymbol{X}}_w^{r_{\max}}$ respectively for SE, PURE, KLA and PUKLA. (k) Their corresponding singular values averaged over 200 noise realizations. (l,m) NMSE averaged over 200 noise realizations as a function of the rank r with and without using the active set. (n,o) Same but with respect to MKLA. (Matrix entries are displayed in log-scale for better visual assessment.)

Gamma and Poisson measurements

Let us now consider the case where the entries of $\boldsymbol{Y}_{ij} > 0$ of the data matrix $\boldsymbol{Y}$ are independently sampled from a Gamma or Poisson distribution with mean $\boldsymbol{X}_{ij} > 0$. We again consider estimators of the form (30). In this context, we compare the following spectral shrinkage estimators, set for $\varepsilon = 10^{-6}$, as:

- PCA shrinkage

$$\hat{\boldsymbol{X}}^r = \sum_{k=1}^{r} \max\left[\tilde{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t, \varepsilon\right] \quad \text{with} \quad \hat{\sigma}_k = \tilde{\sigma}_k \mathbb{1}_{\{k \in \tilde{s}\}},$$

- GSURE/SUKLS/PURE/SUKLA driven soft-thresholding

$$\hat{\boldsymbol{X}}_{\text{soft}} = \sum_{k=1}^{\min(m,n)} \max\left[\hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t, \varepsilon\right] \quad \text{with} \quad \hat{\sigma}_k = (\tilde{\sigma}_k - \lambda(\boldsymbol{Y}))_+,$$

- GSURE/SUKLS/PURE/SUKLA driven weighted estimator

$$\hat{\boldsymbol{X}}_w^r = \sum_{k=1}^{r} \max\left[\hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t, \varepsilon\right] \quad \text{with} \quad \hat{\sigma}_k = w_k(\boldsymbol{Y}) \tilde{\sigma}_k \mathbb{1}_{\{k \in \tilde{s}\}},$$

where $r \in [1, \min(n, m)]$, and $\tilde{s}$ is the approximated active subset as defined in Section 4. For the soft-thresholding, the value $\lambda(\boldsymbol{Y}) > 0$ is obtained by a numerical solver in order to minimize either the GSURE or the SUKLS criterion (in the Gamma case) and either the PURE or the PUKLA criterion (in the Poisson case). As shown in Section 2.3, in the case of Gamma (resp. Poisson) measurements, the value of $w_k(\boldsymbol{Y})$ for $k \in \tilde{s}$ which minimizes the GSURE (resp. PURE) or the SUKLS (resp. PUKLA), cannot be obtained in closed form. As an alternative, we adopt a greedy one-dimensional optimization strategy starting from the matrix $\tilde{\sigma}_1 \tilde{\boldsymbol{u}}_1 \tilde{\boldsymbol{v}}_1^t$ and next updating the weights w_ℓ sequentially by starting $\ell = 1$ to $\ell = \min(n, m)$, with the constraint that, for all $\ell \notin \tilde{s}$, the weight w_ℓ is set to zero.

To this end, we resort to one-dimensional optimization techniques in the interval $[0, 1]$ using Matlab's command `fminbnd`. This strategy is used for GSURE, SUKLS, PURE and PUKLA by evaluating them as described in Section B. As in the Gaussian setting, we compare this spectral estimators with their oracle counterparts given by

$$\boldsymbol{X}_{\text{soft}} = \sum_{k=1}^{\min(m,n)} \max\left[\hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t, \varepsilon\right] \quad \text{with} \quad \hat{\sigma}_k = (\tilde{\sigma}_k - \lambda^{\text{oracle}}(\boldsymbol{Y}))_+, \quad \text{and}$$

$$\boldsymbol{X}_w^r = \sum_{k=1}^{r} \max\left[\hat{\sigma}_k \tilde{\boldsymbol{u}}_k \tilde{\boldsymbol{v}}_k^t, \varepsilon\right] \quad \text{with} \quad \hat{\sigma}_k = w_k^{\text{oracle}}(\boldsymbol{Y}) \tilde{\sigma}_k \mathbb{1}_{\{k \in \tilde{s}\}}.$$

where $w_k^{\text{oracle}}(\boldsymbol{X})$ and $\lambda^{\text{oracle}}(\boldsymbol{Y})$ minimizes one of the objective SE_η, KLS, SE or KLA (non-expected risks) over the set of matrices sharing with $\boldsymbol{Y}$ the same r first left and right singular vectors, and soft-thresholding approximations respectively. Note again that $\boldsymbol{X}_w^r$ and $\boldsymbol{X}_{\text{soft}}$

are ideal approximations of $\boldsymbol{X}$ that cannot be used in practice but serve as benchmarks to evaluate the performances of the data-driven estimators $\hat{\boldsymbol{X}}_w^r$ and $\hat{\boldsymbol{X}}_{\text{soft}}$.

The results for the Gamma noise are reported on Figure 6. As in the Gaussian setting, it can be observed that $\hat{\boldsymbol{X}}_w^r$ and $\boldsymbol{X}_w^r$ achieve comparable performances, as well as $\hat{\boldsymbol{X}}_{\text{soft}}$ and $\boldsymbol{X}_{\text{soft}}$ showing that the GSURE (resp. SUKLS) accurately estimates the MSE_η (resp. KLS). Visual inspection of the restored matrices tends to show that the estimators driven by MSE_η or GSURE produce less relevant results compared to KLS or SUKLS, as confirmed by the curves of NMSE and MKLS. Performance in terms of NMSE also illustrates that minimizers of SE_η do not coincides with those of SE. As in the Gaussian setting, $\hat{\boldsymbol{X}}_w^r$ and $\boldsymbol{X}^r$ outperform $\hat{\boldsymbol{X}}_{\text{soft}}$, $\boldsymbol{X}_{\text{soft}}$ and standard PCA $\hat{\boldsymbol{X}}^r$ provided that r is large enough. Moreover, the performance of $\hat{\boldsymbol{X}}_w^r$ obtained with KL objectives plateaus to its optimum when the rank r becomes large. Again, this allows us to choose $r = \min(n, m)$ when we do not have *a priori* on the true rank $r^\star$.

The results for the Poisson noise are reported on Figure 7. The conclusions are similar to the Gaussian and Gamma cases. Obviously, the NMSE is smaller for approximations that minimizes SE (or PURE) than for those minimizing KLA (or PUKLA). However, visual inspection of the obtained matrices tends to demonstrate that minimizing such objectives might be less relevant than minimizing KL objectives. In this setting, the performance of $\hat{\boldsymbol{X}}_w^r$ is on a par with the one of $\hat{\boldsymbol{X}}_{\text{soft}}$ based on PUKLA. In fact, for other choices of matrices $\boldsymbol{X}$, $\hat{\boldsymbol{X}}_w^r$ based on PUKLA might improve, in terms of MKLS, much more on $\hat{\boldsymbol{X}}_{\text{soft}}$, and might improve not as much on $\hat{\boldsymbol{X}}_w^r$ based on PURE. Nevertheless, whatever $\boldsymbol{X}$, we observed that $\hat{\boldsymbol{X}}_w^r$ driven by PUKLA always reaches at least as good performance in terms of MKLS as the best of $\hat{\boldsymbol{X}}_w^r$ driven by SE and $\hat{\boldsymbol{X}}_{\text{soft}}$.

Fig. 6.(m), Fig. 6.(o), Fig. 7.(m) and Fig. 7.(o) show that when the above estimators are used without the active set (i.e., by choosing $\tilde{s} = [1, \min(n, m])$, the performance of $\hat{\boldsymbol{X}}_w^r$ actually decreases when the rank r becomes too large. As in the Gaussian setting, this can be explained by the fact that the GSURE, SUKLS, PURE and PUKLA suffer from estimation variance in the case of over parametrization, hence, they cannot be used to estimate jointly a too large number of weights. The active set $\tilde{s}$ (in the same manner as the bulk edge) seems to provide a relevant selection of the weights that can be jointly and robustly estimated in a data driven way.

5.3 Signal matrix with equal singular values and increasing rank

We propose now to highlight potential limitations of our approach in the situation where the rank r^* of the matrix $\boldsymbol{X} = \sum_{k=1}^{r^*} \sigma_k \boldsymbol{u}_k \boldsymbol{v}_k^t$ is let growing and all positive singular values σ_k of $\boldsymbol{X}$ are equal, namely

$$\boldsymbol{Y} = \sum_{k=1}^{r^*} \sigma_k \boldsymbol{u}_k \boldsymbol{v}_k^t + \boldsymbol{W} \quad \text{with} \quad \sigma_k = \gamma c_{n,m}^{1/4} \text{ for all } 1 \leq k \leq r^*, \tag{55}$$

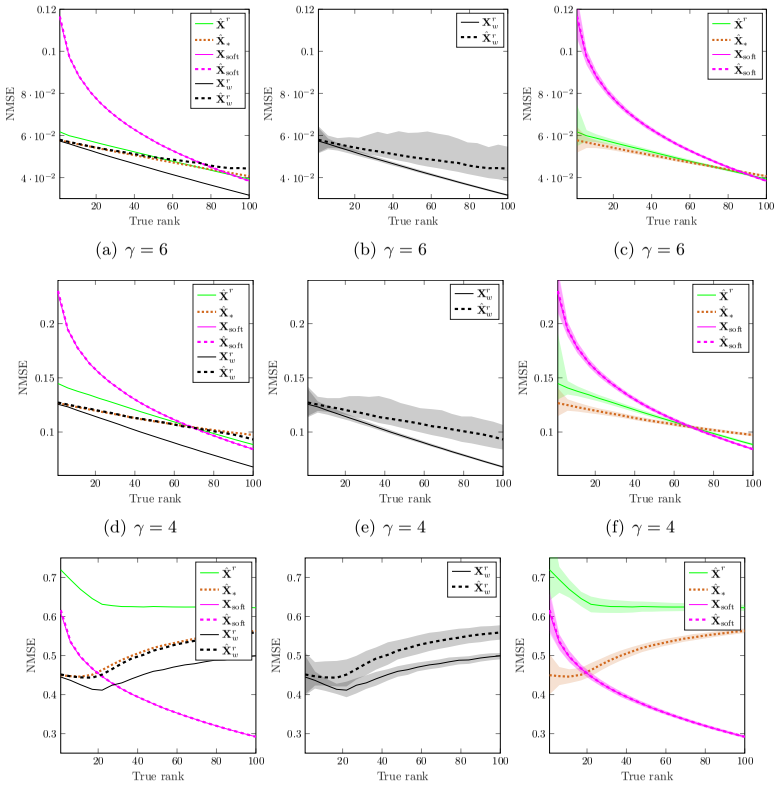
where $\boldsymbol{u}_k \in \mathbb{R}^n$ and $\boldsymbol{v}_k \in \mathbb{R}^m$ are vectors with unit norm that are fixed, $c_{n,m} = \frac{n}{m}$ and $\boldsymbol{W}$ is centered random matrix whose entries are iid Gaussian variables with variance $\tau^2 = 1/m$. We again choose to fix $n = 100$ and $m = 200$, while the true rank is r^* let growing from 1 to $\min(n, m)$ in the following numerical experiments. The constant γ is chosen to be larger than 1. Hence, eq. (55) corresponds to the Gaussian spiked population model in the setting

where all positive singular values are equal and larger than the threshold $c_{n,m}^{1/4}$. The choice $\sigma_k = \gamma c_{n,m}^{1/4}$ with $\gamma > 1$ is motivated by the results from Proposition 9.

For a given value of the true rank r^*, we performed experiments involving $M = 1000$ realizations from model (55) to compare the NMSE of the estimators by oracle soft-thresholding $\boldsymbol{X}_{\text{soft}}$, data-driven soft-thresholding $\hat{\boldsymbol{X}}_{\text{soft}}$, PCA full rank $\hat{\boldsymbol{X}}^{r_{\max}}$ i.e. $r_{\max} = \min(n, m)$, oracle full rank approximation $\boldsymbol{X}_w^{r_{\max}}$, and data-driven full rank estimation $\hat{\boldsymbol{X}}_w^{r_{\max}}$ and $\hat{\boldsymbol{X}}_*^{r_{\max}}$. All these estimators have been introduced in Section 5.2.

In Figure 8, we report the results of numerical experiments by displaying errors bars of the NMSE of these estimators as functions of the true rank r^*. For low values of the true rank ($r^* \leq 20$), the data-driven estimators $\hat{\boldsymbol{X}}_w^{r_{\max}}$ (our approach) and $\hat{\boldsymbol{X}}_*^{r_{\max}}$ (shrinkage rule from Gavish and Donoho (2017)) achieve the best performances that are similar in term of median value of the NMSE. However, our approach has some limitations with respect to the performances of the estimator from Gavish and Donoho (2017) or data-driven soft-thresholding (Candès et al., 2013) in the setting where the signal matrix has equal positive singular values and when its rank is increasing. Moreover, the error bands of the NMSE for our approach becomes significantly larger than those of the other data-driven estimators when the true rank r^* increases. This illustrates that SURE minimization may lead to estimators with a high variance in the case of over parametrization, that is, when there exists a large number of significant and close singular values in the signal matrix.

5.4 Influence of the dimension and the signal-to-noise ratio



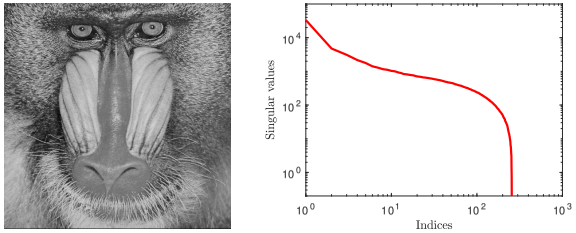
In Section 5.3, we used simulated data consisting of a signal matrix with equal positive singular values and an increasing rank. In such a setting , it is likely that the empirical weights $w_k(\boldsymbol{Y})$, used in our approach, will have a high variance due to the term $\sum_{\ell=1;\ell\neq k}^{\min(n,m)} \frac{\tilde{\sigma}_k^2}{\tilde{\sigma}_k^2 - \tilde{\sigma}_\ell^2}$ in their expression (13). However, the numerical experiments carried out in Section 5.3 correspond to a very specific configuration of the signal matrix (with many equal singular values and a high rank) which is not likely to be encountered with real data.

To conclude these numerical experiments, we finally analyze the influence of the dimension of the data and the signal-to-noise ratio on the performances of our approach and the estimator from Gavish and Donoho (2017) in a more realistic setting (with Gaussian noise). These two estimators are the ones giving the best results, and it is thus of interest to compare them with further experiments.

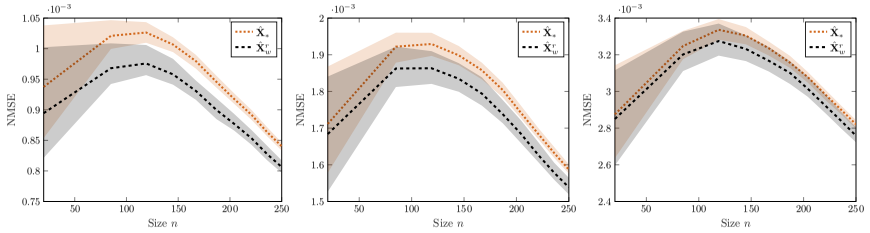
We use real and square signal matrices $\boldsymbol{X} \in \mathbb{R}^{n \times n}$ having a relatively fast decay of their singular values, see Figure 9 and Figure 10. We choose to re-size them to let n varying from 20 to 250, and we define the root of the signal-to-noise ratio (RSNR) as

$$\text{RSNR} = \frac{\sqrt{\frac{1}{n^2}\sum_{i,j=1}^n (\boldsymbol{X}_{ij} - \bar{\boldsymbol{X}})^2}}{\tau} \quad \text{with} \quad \bar{\boldsymbol{X}} = \frac{1}{n^2}\sum_{i,j=1}^n \boldsymbol{X}_{ij}.$$

For each value of n and RSNR (ranging from 5 to 10), we performed experiments involving $M = 400$ realizations from model (55) to compare the NMSE of the estimators by data-driven full rank estimation $\hat{\boldsymbol{X}}_w^{r_{\max}}$ (our approach) and $\hat{\boldsymbol{X}}_*^{r_{\max}}$ (shrinkage rule from Gavish and Donoho (2017)) with $r_{\max} = n$. In Figure 9 and Figure 10, we report the results of these numerical experiments by displaying errors bars of the NMSE of these estimators as



(a) $\gamma = 6$ (b) $\gamma = 6$ (c) $\gamma = 6$



(d) $\gamma = 4$ (e) $\gamma = 4$ (f) $\gamma = 4$

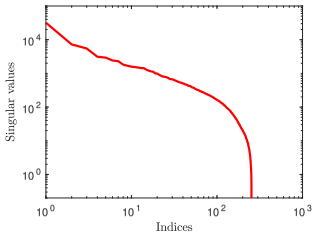
(g) $\gamma = 2$ (h) $\gamma = 2$ (i) $\gamma = 2$

Figure 8: Comparison of NMSE as a function of the true rank r^* in model (55) for different values of γ for the estimator by oracle soft-thresholding $\boldsymbol{X}_{\text{soft}}$, data-driven soft-thresholding $\hat{\boldsymbol{X}}_{\text{soft}}$, PCA full rank $\hat{\boldsymbol{X}}^{r_{\max}}$ i.e. $r_{\max} = \min(n, m)$, oracle full rank approximation $\boldsymbol{X}_w^{r_{\max}}$, and data-driven full rank estimation $\hat{\boldsymbol{X}}_w^{r_{\max}}$ and $\hat{\boldsymbol{X}}_*^{r_{\max}}$. The active set set of singular values is of the form $\hat{s} = \{1, \dots, \hat{r}\}$ where $\hat{r} = \max\{k \ ; \ \tilde{\sigma}_k > c_+^{n,m}\}$ is an estimator of the rank using knowledge of the bulk edge $c_+ \approx c_+^{n,m}$ (a), (d), (g) Median value of the NMSE of the various estimators over $M = 1000$ Gaussian noise realizations in model (55) as a function of the true rank r^*. (b), (c), (e), (f), (h), (i) The grey areas represent error bands of the NMSE of data-driven and oracle estimators.

(a) Signal matrix $\boldsymbol{X}$ (b) Singular values of $\boldsymbol{X}$

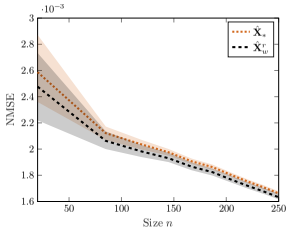
(c) RSNR = 10 (d) RSNR = 7 (e) RSNR = 5

Figure 9: Comparison of NMSE as a function of the dimension n in model (55) with a square matrix $\boldsymbol{X}$ for different values of RSNR for the estimator $\hat{\boldsymbol{X}}_w^{r_{\max}}$ and $\hat{\boldsymbol{X}}_*^{r_{\max}}$ with $r_{\max} = n$. The active set set of singular values is of the form $\hat{s} = \{1, \dots, \hat{r}\}$ where $\hat{r} = \max\{k \ ; \ \tilde{\sigma}_k > c_+^{n,m}\}$ is an estimator of the rank using knowledge of the bulk edge $c_+ \approx c_+^{n,m}$. (a) Signal matrix of size 250×250, (b) Decay of the singular values of $\boldsymbol{X}$ in log-log scale, (c), (d), (e) Median value of the NMSE of $\hat{\boldsymbol{X}}_w^{r_{\max}}$ and $\hat{\boldsymbol{X}}_*^{r_{\max}}$ over $M = 400$ Gaussian noise realizations in model (55) as a function of the dimension n. The orange and grey areas represent error bands of the NMSE of these two estimators.



functions of the dimension n. It can be seen that our approach dominates numerically the estimator from Gavish and Donoho (2017) (for all values of n and RSNR) in settings that are more likely to be encountered in practice than the simulated data used in Section 5.3.

Acknowledgments



We are very much indebted to the referees and the Associate Editor for their constructive criticism, comments and remarks that resulted in a major revision of the original manuscript.

Appendix A. Proof of the main results

A.1 Proof of Proposition 10

Let us first introduce some notation and definitions to be used in the proof. For all $1 \leq \ell \leq n$, let $\tilde{\lambda}_\ell$ be the eigenvalues of $\boldsymbol{Y}\boldsymbol{Y}^t$ namely $\tilde{\lambda}_\ell = \tilde{\sigma}_\ell^2$. For a fixed $1 \leq k \leq r^*$ such that $\sigma_k > c^{1/4}$, let us introduce the complex-valued function g_k defined by

$$g_k(z) = \frac{1}{n} \sum_{\ell=1;\ell\neq k}^{n} \frac{1}{z - \tilde{\lambda}_\ell} \quad \text{for } z \in \mathbb{C} \setminus \mathrm{supp}(\mu_k),$$

where $\mathrm{supp}(\mu_k) = \left\{\tilde{\lambda}_\ell; 1 \leq \ell \leq n,\ \ell \neq k\right\}$ is the support of the random measure $\mu_k = \frac{1}{n}\sum_{\ell=1;\ell\neq k}^{n} \delta_{\tilde{\lambda}_\ell}$ on $\mathbb{R}_+$, where δ_λ denotes the Dirac measure at λ. It is clear that

$$g_k(z) = \int \frac{1}{z-\lambda} d\mu_k(\lambda).$$

The main difficulty in the proof is to show that, almost surely,

$$\lim_{n\to+\infty} g_k(\tilde{\sigma}_k^2) = \frac{1}{\rho^2(\sigma_k)}\left(1 + \frac{1}{\sigma_k^2}\right),$$

which is the purpose of what follows.

For a matrix $A \in \mathbb{R}^{n\times m}$ (with $n \leq m$), we denote its singular values by $\sigma_1(A) \geq \sigma_2(A) \geq \ldots \geq \sigma_n(A) \geq 0$. Hence, one has that $\tilde{\sigma}_\ell = \sigma_\ell(\boldsymbol{Y})$ for all $1 \leq \ell \leq n$. Now, we recall that $\boldsymbol{Y} = \boldsymbol{X} + \boldsymbol{W}$ where $\boldsymbol{X}$ is a fixed matrix of rank r^* and $\boldsymbol{W}$ is a random matrix with iid entries sampled from a Gaussian distribution with zero mean and variance $\frac{1}{m}$. The first step in the proof is to show that the random measure μ_k behaves asymptotically as the almost sure limit of the empirical spectral measure $\mu_{\boldsymbol{W}\boldsymbol{W}^t}$ of the Wishart matrix $\boldsymbol{W}\boldsymbol{W}^t$. By definition, the eigenvalues of $\boldsymbol{W}\boldsymbol{W}^t$ are $\lambda_\ell(\boldsymbol{W}) = \sigma_\ell^2(\boldsymbol{W})$ for all $1 \leq \ell \leq n$ and $\mu_{\boldsymbol{W}\boldsymbol{W}^t}$ is thus defined as

$$\mu_{\boldsymbol{W}\boldsymbol{W}^t} = \frac{1}{n}\sum_{\ell=1}^{n} \delta_{\lambda_\ell(\boldsymbol{W})}.$$

It is well know (see e.g. Theorem 3.6 in Bai and Silverstein (2010)) that, once $m = m_n \geq n$ and $\lim_{n\to+\infty} \frac{n}{m} = c$ with $0 < c \leq 1$, then, almost surely, the empirical spectral measure $\mu_{\boldsymbol{W}\boldsymbol{W}^t}$ converges weakly to the so-called Marchenko-Pastur distribution μ_{MP} which is deterministic and has the following density $\frac{d\mu_{MP}(\lambda)}{d\lambda} = \frac{1}{2\pi c\lambda}\sqrt{(c_+^2 - \lambda)(\lambda - c_-^2)}\ \mathbf{1}_{[c_-^2, c_+^2]}(\lambda)$. We recall that such a convergence can also be characterized through the so-called Cauchy or Stieltjes transform which is defined for any probability measure μ on $\mathbb{R}$ as

$$\forall z \in \mathbb{C} \text{ outside the support of } \mu, \quad g_\mu(z) = \int \frac{1}{z-\lambda} d\mu(\lambda).$$

By eq. (3.3.2) in Bai and Silverstein (2010), one obtains that, almost surely,

$$\lim_{n\to\infty} \int \frac{1}{z-\lambda} d\mu_{\boldsymbol{W}\boldsymbol{W}^t}(\lambda) = g_{MP}(z) \text{ for any } z \in \mathbb{C} \setminus \mathbb{R}, \tag{56}$$

where g_{MP} is the Cauchy transform of μ_{MP} and

$$g_{MP}(z) = \int \frac{1}{z-\lambda} d\mu_{MP}(\lambda) = \frac{z - (1-c) - \sqrt{(z-(c+1))^2 - 4c}}{2cz} \quad \text{for all } z \in \mathbb{C} \setminus [c_-^2, c_+^2].$$

Moreover, by Proposition 6 in Pastur and Lejay (2003), the convergence (56) is uniform over any compact subset of $\mathbb{C} \setminus \mathbb{R}$.

Then, it follows from the so-called Weyl's interlacing inequalities (see e.g. Theorem 3.1.2 in Horn and Johnson (1991)) that for all $1 \leq \ell \leq n$

$$\sigma_{\ell+r^*}(\boldsymbol{W}) \leq \sigma_\ell(\boldsymbol{Y}) \leq \sigma_{\ell-r^*}(\boldsymbol{W}), \tag{57}$$

with the convention that $\sigma_k(\boldsymbol{W}) = -\infty$ if $k > n$ and $\sigma_k(\boldsymbol{W}) = +\infty$ if $k \leq 0$. Thanks to the results that have been recalled above on the asymptotic properties of $\mu_{\boldsymbol{W}\boldsymbol{W}^t}$, one may use inequalities (57) to prove that, almost surely, the random measure μ_k converges weakly to the Marchenko-Pastur distribution μ_{MP}. Under the assumptions of Proposition 10 and using Proposition 9, it can be shown that there exists $\eta_k > 0$ such that, almost surely and for all sufficiently large n

$$\tilde{\lambda}_\ell \notin K_k := [\rho^2(\sigma_k) - \eta_k, \rho^2(\sigma_k) + \eta_k]$$

for any $1 \leq \ell \leq n$ with $\ell \neq k$. Now, recall that the support $\mathrm{supp}(\mu_k)$ of the random measure μ_k is $\left\{\tilde{\lambda}_\ell; 1 \leq \ell \leq n,\ \ell \neq k\right\}$, and that $\mathrm{supp}(\mu_{\mathrm{MP}}) = [\mathrm{c}_-^2, \mathrm{c}_+^2]$. Hence, for all sufficiently large n, one has that

$$\mathrm{supp}(\mu_k) \cap \mathrm{K_k} = \emptyset \quad \text{and} \quad \mathrm{supp}(\mu_{\mathrm{MP}}) \cap \mathrm{K_k} = \emptyset.$$

Therefore, thanks to the weak convergence of μ_k to μ_{MP} and using Ascoli's Theorem, one may prove that

$$\lim_{n\to\infty} \sup_{z\in K_k} |g_k(z) - g_{MP}(z)| = 0 \text{ almost surely.} \tag{58}$$

Thanks to our assumptions, one has that, almost surely, $\lim_{n\to+\infty} \tilde{\sigma}_k^2 = \rho^2(\sigma_k)$ by Proposition 9. Hence, almost surely and for all sufficiently large n, one has that $\tilde{\sigma}_k^2 \in K_k$ and so

$$|g_k(\tilde{\sigma}_k^2) - g_{MP}(\rho^2(\sigma_k))| \leq \sup_{z\in K_k} |g_k(z) - g_{MP}(z)| + |g_{MP}(\tilde{\sigma}_k^2) - g_{MP}(\rho^2(\sigma_k))|.$$

Therefore, using the uniform convergence (58) of g_k to g_{MP} and the continuity of g_{MP} at $z = \rho^2(\sigma_k)$, one obtains that, almost surely,

$$\lim_{n\to+\infty} g_k(\tilde{\sigma}_k^2) = g_{MP}(\rho^2(\sigma_k)) = \frac{1}{\rho^2(\sigma_k)} \times \frac{\rho^2(\sigma_k) - 1 + c - \sqrt{(\rho^2(\sigma_k) - (c+1))^2 - 4c}}{2c}.$$

Since $g_k(\tilde{\sigma}_k^2) = \frac{1}{n}\sum_{\ell=1;\ell\neq k}^n \frac{1}{\tilde{\sigma}_k^2 - \tilde{\sigma}_\ell^2}$, using the above equation and relation (32), it follows immediately that $g_{MP}(\rho^2(\sigma_k)) = \frac{1}{\rho^2(\sigma_k)}\left(1 + \frac{1}{\sigma_k^2}\right)$ so that, almost surely,

$$\lim_{n\to+\infty} \frac{1}{n} \sum_{\ell=1;\ell\neq k}^n \frac{\tilde{\sigma}_k}{\tilde{\sigma}_k^2 - \tilde{\sigma}_\ell^2} = \lim_{n\to+\infty} \tilde{\sigma}_k g_k(\tilde{\sigma}_k^2) = \rho(\sigma_k)\, g_{MP}(\rho^2(\sigma_k)) = \frac{1}{\rho(\sigma_k)}\left(1 + \frac{1}{\sigma_k^2}\right),$$

which completes the proof.

A.2 A technical result to prove SURE-like formulas

We recall the key lemma needed to prove the SURE-like formulas in an exponential family in the continuous case. Similar results have already been formulated in different papers in the literature, see e.g. the review proposed in Deledalle (2017).

Lemma 16 *Let $\boldsymbol{Y} \in \mathbb{R}^{n\times m}$ be a random matrix whose entries $\boldsymbol{Y}_{ij}$ are independently sampled from the continuous exponential family* (15) *in canonical form (that is the distribution of $\boldsymbol{Y}_{ij}$ is absolutely continuous with respect to the Lebesgue measure dy on $\mathbb{R}$). Suppose that the function h is continuously differentiable on $\mathcal{Y} = \mathbb{R}$. Let $1 \leq i \leq n$ and $1 \leq j \leq m$, and denote by $F_{ij} : \mathbb{R}^{n\times m} \to \mathbb{R}$ a continuously differentiable function such that*

$$\mathbb{E}\left[|F_{ij}(\boldsymbol{Y})|\right] < +\infty. \tag{59}$$

Then, the following relation holds

$$\mathbb{E}\left[\boldsymbol{\theta}_{ij} F_{ij}(\boldsymbol{Y})\right] = -\mathbb{E}\left[\frac{h'(\boldsymbol{Y}_{ij})}{h(\boldsymbol{Y}_{ij})} F_{ij}(\boldsymbol{Y}) + \frac{\partial F_{ij}(\boldsymbol{Y})}{\partial \boldsymbol{Y}_{ij}}\right].$$

Proof Using the expression (15) of the pdf of the random varibles $\boldsymbol{Y}_{ij}$, one has that

$$\mathbb{E}\left[\boldsymbol{\theta}_{ij} F_{ij}(\boldsymbol{Y})\right] = \int_{\mathbb{R}^{n\times m}} F_{ij}(Y) h(y_{ij}) \boldsymbol{\theta}_{ij} \exp\left(\boldsymbol{\theta}_{ij} y_{ij} - A(\boldsymbol{\theta}_{ij})\right)\, \mathrm{d}y_{ij} \prod_{\substack{1\leq k\leq n\\ 1\leq \ell\leq m\\ (k,\ell)\neq(i,j)}}^{n} p(y_{k\ell}; \boldsymbol{\theta}_{k\ell})\, \mathrm{d}y_{k\ell}.$$

where $Y = (y_{k\ell})_{1\leq k\leq n, 1\leq \ell\leq m}$. Thanks to condition (59), it follows that

$$\int_{\mathbb{R}^{n\times m}} F_{ij}(Y) h(y_{ij}) \exp\left(\boldsymbol{\theta}_{ij} y_{ij} - A(\boldsymbol{\theta}_{ij})\right)\, \mathrm{d}y_{ij} \prod_{\substack{1\leq k\leq n\\ 1\leq \ell\leq m\\ (k,\ell)\neq(i,j)}}^{n} p(y_{k\ell}; \boldsymbol{\theta}_{k\ell})\, \mathrm{d}y_{k\ell} < +\infty. \tag{60}$$

Therefore, given that $\boldsymbol{\theta}_{ij} \exp\left(\boldsymbol{\theta}_{ij} y_{ij} - A(\boldsymbol{\theta}_{ij})\right) = \frac{\partial \exp(\boldsymbol{\theta}_{ij} y_{ij} - A(\boldsymbol{\theta}_{ij}))}{\partial y_{ij}}$, an integration by part and eq. (60) imply that

$$\mathbb{E}\left[\boldsymbol{\theta}_{ij} F_{ij}(\boldsymbol{Y})\right] = -\int_{\mathbb{R}^{n\times m}} \frac{\partial F_{ij}(Y) h(y_{ij})}{\partial y_{ij}} \exp\left(\boldsymbol{\theta}_{ij} y_{ij} - A(\boldsymbol{\theta}_{ij})\right)\, \mathrm{d}y_{ij} \prod_{\substack{1\leq k\leq n\\ 1\leq \ell\leq m\\ (k,\ell)\neq(i,j)}}^{n} p(y_{k\ell}; \boldsymbol{\theta}_{k\ell})\, \mathrm{d}y_{k\ell}.$$

Now, since $\frac{\partial F_{ij}(Y) h(y_{ij})}{\partial y_{ij}} = h'(y_{ij}) F_{ij}(Y) + \frac{\partial F_{ij}(Y)}{\partial y_{ij}} h(y_{ij})$, we finally obtain that

$$\mathbb{E}\left[\boldsymbol{\theta}_{ij} F_{ij}(\boldsymbol{Y})\right] = -\mathbb{E}\left[\frac{h'(\boldsymbol{Y}_{ij})}{h(\boldsymbol{Y}_{ij})} F_{ij}(\boldsymbol{Y}) + \frac{\partial F_{ij}(\boldsymbol{Y})}{\partial \boldsymbol{Y}_{ij}}\right],$$

which completes the proof. ∎

A.3 Proof of Proposition 4

We remark that

$$\mathrm{MSE}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \sum_{i=1}^n \sum_{j=1}^m \left(\mathbb{E}\left[|\hat{\boldsymbol{\theta}}_{ij}^f(\boldsymbol{Y})|^2 - 2\boldsymbol{\theta}_{ij}\hat{\boldsymbol{\theta}}_{ij}^f(\boldsymbol{Y})\right] + \boldsymbol{\theta}_{ij}^2\right). \tag{61}$$

Using Lemma 16 with $F_{ij}(\boldsymbol{Y}) = \hat{\boldsymbol{\theta}}_{ij}^f(\boldsymbol{Y})$ and condition (17), it follows that

$$\mathbb{E}\left[\boldsymbol{\theta}_{ij}\hat{\boldsymbol{\theta}}_{ij}^f(\boldsymbol{Y})\right] = \mathbb{E}\left[\frac{h'(\boldsymbol{Y}_{ij})}{h(\boldsymbol{Y}_{ij})}\hat{\boldsymbol{\theta}}_{ij}^f(\boldsymbol{Y})\right] + \mathbb{E}\left[\frac{\partial \hat{\boldsymbol{\theta}}_{ij}^f(\boldsymbol{Y})}{\partial \boldsymbol{Y}_{ij}}\right]. \tag{62}$$

Then, by definition (15) of the exponential family, we remark that

$$\mathbb{E}\left[\frac{h''(\boldsymbol{Y}_{ij})}{h(\boldsymbol{Y}_{ij})}\right] = \int_{\mathbb{R}} h''(y_{ij}) \exp\left(\boldsymbol{\theta}_{ij} y_{ij} - A(\boldsymbol{\theta}_{ij})\right)\, \mathrm{d}y_{ij}.$$

Hence, using an integration by parts twice, we arrive at

$$\mathbb{E}\left[\frac{h''(\boldsymbol{Y}_{ij})}{h(\boldsymbol{Y}_{ij})}\right] = \boldsymbol{\theta}_{ij}^2 \int_{\mathbb{R}} h(y_{ij}) \exp\left(\boldsymbol{\theta}_{ij} y_{ij} - A(\boldsymbol{\theta}_{ij})\right)\, \mathrm{d}y_{ij} = \boldsymbol{\theta}_{ij}^2. \tag{63}$$

To complete the proof, it suffices to insert equalities (62) and (63) into (61).

A.4 Proof of Proposition 6

Thanks to eq. (21), one has that

$$\mathrm{MKLS}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) = \sum_{i=1}^{n}\sum_{j=1}^{m} \mathbb{E}\left[\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})A'(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})) - \boldsymbol{\theta}_{ij}A'(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})) - A(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}))\right] + A(\boldsymbol{\theta}_{ij}). \quad (64)$$

Using Lemma 16 with $F_{ij}(\boldsymbol{Y}) = A'(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}))$ and condition (22), it follows that

$$\mathbb{E}\left[\boldsymbol{\theta}_{ij}A'(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}))\right] = -\mathbb{E}\left[\frac{h'(\boldsymbol{Y}_{ij})}{h(\boldsymbol{Y}_{ij})}A'(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}))\right] - \mathbb{E}\left[\frac{\partial\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})}{\partial\boldsymbol{Y}_{ij}}A''(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}))\right]. \quad (65)$$

Thus, inserting equality (65) into (64) implies that

$$\mathrm{SUKLS}(\hat{\boldsymbol{\theta}}^f) = \sum_{i=1}^{n}\sum_{j=1}^{m}\left(\left(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}) + \frac{h'(\boldsymbol{Y}_{ij})}{h(\boldsymbol{Y}_{ij})}\right)A'(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})) - A(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}))\right) + \sum_{i=1}^{n}\sum_{j=1}^{m}A''(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}))\frac{\partial\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})}{\partial\boldsymbol{Y}_{ij}}$$

is an unbiased estimator of $\mathrm{MKLS}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) - \sum_{i=1}^{n}\sum_{j=1}^{m}A(\boldsymbol{\theta}_{ij})$. Now recall that $f_{ij}(\boldsymbol{Y}) = \eta^{-1}\left(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})\right)$ and that $A'(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})) = \eta^{-1}\left(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})\right)$ by Assumption 2. Therefore, $\frac{\partial f_{ij}(\boldsymbol{Y})}{\partial\boldsymbol{Y}_{ij}} = A''(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}))\frac{\partial\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})}{\partial\boldsymbol{Y}_{ij}}$, and thus

$$\mathrm{SUKLS}(\hat{\boldsymbol{\theta}}^f) = \sum_{i=1}^{n}\sum_{j=1}^{m}\left(\left(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}) + \frac{h'(\boldsymbol{Y}_{ij})}{h(\boldsymbol{Y}_{ij})}\right)A'(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y})) - A(\hat{\boldsymbol{\theta}}^f_{ij}(\boldsymbol{Y}))\right) + \sum_{i=1}^{n}\sum_{j=1}^{m}\frac{\partial f_{ij}(\boldsymbol{Y})}{\partial\boldsymbol{Y}_{ij}},$$

which completes the proof.

A.5 Proof of Proposition 8

Thanks to the expression (27) of the MKLA risk for data sampled from a Poisson distribution, it follows that

$$\mathrm{MKLA}(\hat{\boldsymbol{\theta}}^f, \boldsymbol{\theta}) + \sum_{i=1}^{n}\sum_{j=1}^{m}\boldsymbol{X}_{ij} - \boldsymbol{X}_{ij}\log(\boldsymbol{X}_{ij}) = \sum_{i=1}^{n}\sum_{j=1}^{m}\mathbb{E}\left[\hat{\boldsymbol{X}}^f_{ij} - \boldsymbol{X}_{ij}\log\left(\hat{\boldsymbol{X}}^f_{ij}\right)\right]$$

In the case of Poisson data, one has that $\exp(\boldsymbol{\theta}_{ij}) = \boldsymbol{X}_{ij}$ and $\frac{h(\boldsymbol{Y}_{ij}-1)}{h(\boldsymbol{Y}_{ij})} = \boldsymbol{Y}_{ij}$. Therefore, by applying Hudson's Lemma 7 with $F_{ij}(\boldsymbol{Y}) = \log\left(\hat{\boldsymbol{X}}^f_{ij}\right)$, it follows that

$$\mathbb{E}\left[\sum_{i=1}^{n}\sum_{j=1}^{m}\boldsymbol{X}_{ij}\log\left(\hat{\boldsymbol{X}}^f_{ij}\right)\right] = \mathbb{E}\left[\sum_{i=1}^{n}\sum_{j=1}^{m}\boldsymbol{Y}_{ij}\log\left(f_{ij}(\boldsymbol{Y} - \boldsymbol{e}_i\boldsymbol{e}_j^t)\right)\right],$$

which completes the proof.

Appendix B. Implementation details

We discuss below an algorithmic approach to find data-driven spectral estimators.

First, we discuss on how to compute data-driven spectral estimators from the expression of risk estimators. For SUKLS in continuous exponential families, and for SURE in the Gaussian case only, eq. (38) and (23) provide respectively a closed-form solution that can be evaluated in linear time $O(nm)$. On the contrary, the computations of GSURE (beyond the Gaussian case), PURE and PUKLA, given respectively in eq. (19), (25) and (28), cannot be evaluated in reasonable time. They rely respectively on the computation of the divergence $\operatorname{div}\hat{\boldsymbol{\theta}}^f(\boldsymbol{Y})$, $\sum\sum\boldsymbol{Y}_{ij}f_{ij}(\boldsymbol{Y} - \boldsymbol{e}_i\boldsymbol{e}_j^t)$ and $\sum\sum\boldsymbol{Y}_{ij}\log\left(f_{ij}(\boldsymbol{Y} - \boldsymbol{e}_i\boldsymbol{e}_j^t)\right)$. Without further assumptions, such quantities requires $O(n^2m^2)$ operations in general. A standard approach for the computation of the divergence, suggested in Girard (1989); Ramani et al. (2008), is to unbiasedly estimate it with Monte-Carlo simulations by sampling the following relation

$$\operatorname{div}\hat{\boldsymbol{\theta}}^f(\boldsymbol{Y}) = \mathbb{E}_{\boldsymbol{\delta}}\left[\operatorname{tr}\left(\boldsymbol{\delta}^t\frac{\partial\hat{\boldsymbol{\theta}}^f(\boldsymbol{Y})}{\partial\boldsymbol{Y}}\boldsymbol{\delta}\right)\right]$$

at random directions $\boldsymbol{\delta} \in \mathbb{R}^{n\times m}$ satisfying $\mathbb{E}[\boldsymbol{\delta}] = 0$, $\mathbb{E}[\boldsymbol{\delta}_i\boldsymbol{\delta}_i] = 1$ and $\mathbb{E}[\boldsymbol{\delta}_i\boldsymbol{\delta}_j] = 0$. Following Deledalle (2017), a similar first order approximation can be used for the other two quantities as

$$\sum\sum\boldsymbol{Y}_{ij}f_{ij}(\boldsymbol{Y} - \boldsymbol{e}_i\boldsymbol{e}_j^t) \approx \sum\sum\boldsymbol{Y}_{ij}\left[f_{ij}(\boldsymbol{Y}) - \boldsymbol{\delta}_{i,j}\left(\frac{\partial f(\boldsymbol{Y})}{\partial\boldsymbol{Y}}\boldsymbol{\delta}\right)_{i,j}\right], \quad \text{and}$$

$$\sum\sum\boldsymbol{Y}_{ij}\log\left(f_{ij}(\boldsymbol{Y} - \boldsymbol{e}_i\boldsymbol{e}_j^t)\right) \approx \sum\sum\boldsymbol{Y}_{ij}\log\left[f_{ij}(\boldsymbol{Y}) - \boldsymbol{\delta}_{i,j}\left(\frac{\partial f(\boldsymbol{Y})}{\partial\boldsymbol{Y}}\boldsymbol{\delta}\right)_{i,j}\right]$$

where the entries of $\boldsymbol{\delta}$ should be chosen Bernoulli distributed with parameter $p = 0.5$. The advantage of these three approximations is that they can be computed in linear time $O(nm)$ by making use of the results of Lewis and Sendov (2001); Sun and Sun (2003); Edelman (2005); Candès et al. (2013); Deledalle et al. (2012) that provide an expression for the directional derivative given by

$$\frac{\partial f(\boldsymbol{Y})}{\partial\boldsymbol{Y}}\boldsymbol{\delta} = \tilde{\boldsymbol{U}}(\mathbf{D} + \boldsymbol{S} + \boldsymbol{A})\tilde{\boldsymbol{V}}^t \quad (66)$$

where $\tilde{\boldsymbol{U}}$ and $\tilde{\boldsymbol{V}}$ are the matrices whose columns are $\tilde{\boldsymbol{u}}_k$ and $\tilde{\boldsymbol{v}}_k$, and $\mathbf{D}$, $\boldsymbol{S}$ and $\boldsymbol{A}$ are $n\times m$ matrices defined, for all $1 \le i \le n$ and $1 \le j \le m$, as

$$\mathbf{D}_{i,j} = \bar{\boldsymbol{\delta}}_{i,j} \times \begin{cases} f_i'(\tilde{\sigma}_i) & \text{if} \quad i = j \\ 0 & \text{otherwise,} \end{cases}$$

$$\boldsymbol{S}_{i,j} = \frac{\bar{\boldsymbol{\delta}}_{i,j} + \bar{\boldsymbol{\delta}}_{j,i}}{2} \times \begin{cases} 0 & \text{if} \quad i = j \\ \frac{f_i(\tilde{\sigma}_i) - f_j(\tilde{\sigma}_j)}{\tilde{\sigma}_i - \tilde{\sigma}_j} & \text{otherwise,} \end{cases}$$

$$\boldsymbol{A}_{i,j} = \frac{\bar{\boldsymbol{\delta}}_{i,j} - \bar{\boldsymbol{\delta}}_{j,i}}{2} \times \begin{cases} 0 & \text{if} \quad i = j \\ \frac{f_i(\tilde{\sigma}_i) + f_j(\tilde{\sigma}_j)}{\tilde{\sigma}_i + \tilde{\sigma}_j} & \text{otherwise,} \end{cases}$$

where $\tilde{\sigma}_k$ and $f_k(\tilde{\sigma}_k)$ are extended to 0 for $k > \min(n, m)$ and $\bar{\boldsymbol{\delta}} = \tilde{\boldsymbol{U}}^t\boldsymbol{\delta}\tilde{\boldsymbol{V}} \in \mathbb{R}^{n\times m}$.

Abstract

Information about intrinsic dimension is crucial to perform dimensionality reduction, compress information, design efficient algorithms, and do statistical adaptation. In this paper we propose an estimator for the intrinsic dimension of a data set. The estimator is based on binary neighbourhood information about the observations in the form of two adjacency matrices, and does not require any explicit distance information. The underlying graph is modelled according to a subset of a specific random connection model, sometimes referred to as the Poisson blob model. Computationally the estimator scales like $n \log n$, and we specify its asymptotic distribution and rate of convergence. A simulation study on both real and simulated data shows that our approach compares favourably with some competing methods from the literature, including approaches that rely on distance information.

Keywords: adaptation, dimensionality reduction, intrinsic dimension, random connection model, random graph

1. Introduction

In machine learning and computational geometry we often want to discover, or sometimes impose, structure on observations, and dimension plays a crucial role in this task. The dimension of a data set can perhaps be best interpreted as the number of variables needed to describe it. However, there is often a gap between the ambient dimension of a data set – the number of variables *used* to describe it – and its intrinsic dimension – the number of variables *needed* to describe it (eventually up to a certain level of precision). For instance, high-dimensional data sets often live in lower dimensional spaces; infinite-dimensional parameters of non-parametric models can often be accurately estimated using just a few parameters; complex data can potentially be highly compressible. However, this is usually not evident by just looking at the data, so in this paper we propose an algorithm to estimate the intrinsic dimension of a data set, and study its behaviour.

There are plenty of reasons to be interested in intrinsic dimensions. Perhaps the most straightforward one is to perform dimensionality reduction. Dimensionality reduction arises from a need to be able to extract meaningful conclusions from high-dimensional observations. There is an extensive literature on this subject using multidimensional scaling, manifold learning, and projection techniques like principal component analysis and projection pursuit; for a general overview cf. (Fodor, 2002; Burges, 2010; Lee and Verleysen, 2007). For specific techniques see for example (Kohonen, 1990; Cox and Cox, 2000; Tenenbaum et al., 2000; Roweis and Saul, 2000; Donoho and Grimes, 2003; Huo and Chen, 2002; Giné and Koltchinskii, 2006), and the references therein. In order to be used to their full extent, these approaches require a priori knowledge about the intrinsic dimension of the data set. Knowledge about intrinsic dimension is also important in independent component analysis; cf. (Hyviirinen et al., 2001).

From a statistical perspective, the intrinsic dimension provides information about the difficulty of making inference. Non-parametric estimators usually rely on approximation properties of certain function spaces; the dimension of the support of these functions influences these approximation properties. Statistical adaptation often focuses on smoothness, but dimension actually has a more substantial impact on rates of convergence. Knowledge about dimension is also important to avoid (if possible) the curse of dimensionality. Dimension plays an important role in classification problems as well, where performance is greatly compromised in high dimensions; cf. (Bickel and Levina, 2004; Fan and Fan, 2008). There are also connections to search, and to outlier detection; cf. (Amsaleg et al., 2015) and the references therein.

From a computational perspective, the dimension of a data set impacts the amount of space needed to store data (compressibility). The speed of algorithms is also commonly affected by the dimension of input data. Learning the underlying dimension is also important to design algorithms that require less data (meaning, make better use of available data) when data happen to live on a low dimensional space. Because of this, knowledge about dimension is crucial in many fields such as biomedicine, economics, engineering, astronomy, remote sensing, and computer vision, with important applications in mass spectrometry, genetics, networking, image processing, automatic text analysis, among others; for some concrete applications see (Verleysen et al., 1999; Lähdesmäki et al., 2005; Abrahao and Kleinberg, 2008; Carter et al., 2010) and references therein.

Early work on dimension estimation dates back to (Shepard, 1962a,b; Kruskal, 1964a,b; Bennett, 1969) on multidimensional scaling. The idea is that one has measurements of similarities (or dissimilarities) between data points, and would like to find points in a potentially high-dimensional vector space that are consistent with the observed similarities (resp. dissimilarities). Other approaches such as that of (Fukunaga and Olsen, 1971; Fukunaga, 1982) are based on Karhunen–Loève expansions. There, and much in the spirit of principal component analysis, the idea is that minimal representations that capture most of the variation in the data carry information about dimensionality; see also an approach based on testing by (Trunk, 1968). Information criteria such as AIC by (Akaike, 1974) and BIC by (Schwarz, 1978) can also be used to estimate dimensions within a model.

More recent work of (Camastra and Vinciarelli, 2002; Kégl, 2002; Hein and Audibert, 2005; Sricharan et al., 2010) is based on the notion of correlation integral; cf. (Grassberger and Procaccia, 2004). The correlation dimension is a limit associated with this correlation integral. This notion of dimension, which we also use in this paper, is computationally attractive when compared with other notions of dimension such as that of box counting dimension, for example. There are also the techniques of (Costa and Hero, 2004; Farahmand et al., 2007; Leonenko et al., 2008; Kleindessner and von Luxburg, 2015) based on different types of graphs where edges represent some form of proximity, like k-nearest neighbour graphs, and geodesic minimal spanning trees. Their work relies on the fact that certain quantities associated with these graphs scale monotonically with dimension. By exploring this, one can extract information about dimensionality by inverting these relations. A similar idea is used in (Amsaleg et al., 2015) by recurring to notions from extreme value theory. See also (Eriksson and Crovella, 2012) for a clustering-based approach, and the work of (Levina and Bickel, 2004) for an estimator based on an approximation of the likelihood.

There is some room for improvement in the approaches mentioned above. Some of them rely on rather extensive knowledge about distances between all possible pairs of observations, sometimes also of perturbations thereof, or on certain hierarchical constructs like dendrograms; because execution times tend to scale quadratically with the sample size and linearly with dimension, these quickly become computationally costly as the number of observations or the dimension of the measurements is high – exactly the situation where dimension estimation is most important. (In genetics and computer vision applications, for instance, the number of observed dimensions can easily reach hundreds of thousands.) Therefore, either due to the volume or to complexity of the data, we may be computationally limited to work with very crude information, such as knowing only whether each pair of observations is close or not. Because of this, it is of interest to develop methods to estimate dimension that rely on as little information as possible.

Another aspect that is often overlooked in the literature is that the intrinsic dimension of a data set is usually scale-dependent: the dimension of the data set depends on the scale at which we analyse it; cf. (Burges, 2010). Say we sample points uniformly at random on a manifold with noise; if we look at the data set on a fine scale we only pick up on the noise, whereas at a larger scale the features of the manifold will dominate. The manifold itself can have different dimensions depending on which scale we look at it, and the noise may have arbitrary dimension. It is therefore not clear what "the dimension of a data set" is, unless we specify a scale to go with it (or if the support of the distribution of the data is homogeneous or unstructured). However, even then the dimension is very dependent on the specific data (e.g., structure of the manifold, distribution of the noise). Approaches based on regressing the logarithm of the correlation integral on the logarithm of its argument fail to capture this and instead return something akin to an average dimension across scales for the data set. Approaches based on k-nearest-neighbour graphs also have limitations with regards to this; the distance from a datapoint to its k-nearest neighbour scales in a non-trivial way with dimension and is quite dependent on the distribution of the observations. This makes it difficult to estimate dimension by inversion without specific knowledge on the distribution of the data.

In this paper we resolve the limitations identified above. We estimate the intrinsic dimension of a data set at a user-prescribed scale based solely on binary neighbourhood

relations between observations. More specifically, we assume that certain undirected graphs (or their adjacency matrices) can be observed. In this graph, each vertex corresponds to an observation that lives in some high- (possibly infinite-) dimensional space. An edge is present between two vertices if the corresponding observations are *close*. What we consider to be close determines the scale at which we analyse the data. The goal is to estimate the intrinsic dimension of the data set based on the adjacency matrix of the graph only, i.e., without explicit access to distance information. We model such a graph according to a subset of a random connection model, a model from continuum percolation; cf. (Penrose, 1991), and (Meester and Roy, 1996) for an overview on the subject. More specifically, we model it according to a subgraph of a graph sampled from the so called Poisson blob model; cf. (Grimmett, 1999).

We propose an estimator based on the doubling property of the Lebesgue measure and on the notion of correlation integral. The estimator does not rely on distance information about the observations and has computation time that scales like $n \log n$, which is particularly important when dealing with large, high-dimensional data sets. Since only (sparse) adjacency matrices have to be stored, our approach also leads to a reduction of the required storage space. Under an identifiability condition, we show that the estimator is consistent and asymptotically Gaussian, and we compute its rate of convergence. To the best of our knowledge such results are not yet available in the literature. The estimator strongly concentrates around its expectation but in general the constants involved in the rate scale exponentially with the intrinsic dimension; the bias plays an important role as it is the main bottleneck in the procedure leading to a logarithmic rate. We propose a bias corrected estimator that follows the same (optimal) asymptotics, but which performs much better according to our numerical experiments.

Minimax rates are unknown for the type of data that we consider, but in the (easier) case where one has access to the actual observations, these can be found in (Koltchinskii, 2000) and are logarithmic. (For the noiseless case see Kim et al., 2016.) This means that our procedure is essentially optimal and that its computational efficacy is not obtained at the expense of precision. Furthermore, we are capable of producing estimates of the spread of the estimator, without a need for resampling, and these quantify the uncertainty in the estimate fairly well. This is particularly important given the slow convergence rate, and is a major improvement over competing approaches, which tend to overly concentrate around biased estimates. We also run some numerical simulations that show that our estimator compares favourably with competing estimators (particularly when it comes to recuperate an integer dimension), including estimators that rely on distance information.

This paper is structured as follows. In Section 2 we formally define our model. The interpretation of the effect of scale in the model is given in Section 3. Section 4 has a description of our estimator. Section 5 contains consistency results for a relevant probability in the model. Section 6 has our main result about the consistency of our estimator for the intrinsic dimension, and a comparison with related work from the literature. In Section 7 we present some numerical illustrations for our method, and we propose our bias corrected estimator. We close with some conclusions in Section 8. The proofs of our main results are collected in the Appendix.

2. Sampling, Model, Notation, and Problem Formulation

Consider the following model. Sample *design points* $X_1, \ldots, X_n \in \mathbb{R}^D$, independently, from a distribution F, where $D \in \mathbb{N}$ is some *ambient dimension*. Given the design points $\boldsymbol{X} = (X_1, \ldots, X_n)^T$, construct a random undirected graph by placing an edge between two vertices $i < j \in \{1, \ldots, n\}$ if $r(X_i, X_j) \leq \epsilon$, $\epsilon > 0$, where r is a metric[1] on $\mathbb{R}^D$. We denote the adjacency matrix of the resulting random graph as $\boldsymbol{A}_\epsilon$. If we disregard that our design points are typically concentrated (since they are sampled from F), this is a subset of a graph sampled from what is usually called the Poisson blob model, a model from continuum percolation. In this model we allow $\epsilon = \epsilon_n$ to converge to 0 as $n \to \infty$, if need be; we discuss the role of ϵ in more detail in Section 3. Most of the quantities that we define in the following depend on n but this is omitted from the notation except when n plays a role.

We assume that the observations in our data set actually live (potentially in approximate form) in a lower (potentially fractional) dimensional space. For instance, the design points can have the form $X_i = \varphi(\tilde{X}_i) + \sigma \cdot \epsilon_i$, $\sigma \geq 0$, where $\varphi : \mathbb{R}^d \mapsto \mathbb{R}^D$, $d \leq D$, is some embedding. The observations can therefore be highly structured; they can be concentrated around, say, a manifold. The number d is called the *intrinsic dimension* of the data set $\boldsymbol{X}$, and it is our object of interest.

Our statistical problem is the following: for a data set with n observations we have access to a symmetric, binary matrix $\boldsymbol{\mathcal{A}}$ where $\mathcal{A}_{i,j} = \mathcal{A}_{j,i} = 1$ if, and only if, the i-th and j-th observations are "close"; the data points (or distances between data points) are not actually observed. We assume that our notion of "close" is reasonable, in the sense that we can model $\boldsymbol{\mathcal{A}}$ according to a random connection model: $\boldsymbol{\mathcal{A}} = \boldsymbol{A}_\epsilon$ for some ϵ and some metric r (which are not necessarily known to us). Given access to such adjacency matrices[2] we would like to estimate the intrinsic dimension d. The point is that although the support of F may be high-dimensional, most of the mass of F might be concentrated on a (lower) dimensional sub-space or manifold (eventually as $n \to \infty$, or $\sigma \to 0$), such that one can find a parsimonious representation for that data that still preserves its main features.

We denote by $\boldsymbol{B}_\epsilon$ the degrees of the vertices in the graph such that $\boldsymbol{B}_\epsilon = (B_{\epsilon,1}, \ldots, B_{\epsilon,n})$,

$$B_{\epsilon,i} = \sum_{j=1}^{n} A_{\epsilon,i,j}, \quad i = 1, \ldots, n, \tag{1}$$

where the (binary) entries $A_{\epsilon,i,j}$ of the adjacency matrix $\boldsymbol{A}_\epsilon$ satisfy

$$A_{\epsilon,i,j} = A_{\epsilon,j,i} = \mathbf{1}_{\{r(X_i,X_j)\leq\epsilon\}}, \qquad \text{and} \qquad A_{\epsilon,i,i} = 0, \quad i,j = 1, \ldots, n,\ i \neq j. \tag{2}$$

By construction, the distribution of the random matrix $\boldsymbol{A}_\epsilon$ is invariant under any permutation of its rows and columns so that the $B_{\epsilon,i}$ are identically distributed but not independent. Define the two functions

$$p_\epsilon(x) = \mathbb{P}\{r(X, x) \leq \epsilon\}, \qquad \text{and} \qquad p_\epsilon(x, y) = \mathbb{P}\{r(X, x) \leq \epsilon, r(X, y) \leq \epsilon\}, \tag{3}$$

1. All of the assumptions on the metric will be implicit.
2. In fact we consider two adjacency matrices as it will become clear from the definition of our estimator in (7). We argue in Section 4, that this is inevitable since ϵ trades off with the standard deviation of F.

where the probability is taken with respect to $X \sim F$. This is the (local) connection probability for a design point at site x, and the probability of two design points at sites x and y sharing a neighbour. With this notation,

$$B_{\epsilon,i}|X_i \sim \text{Bin}\{n-1,\, p_\epsilon(X_i)\}. \tag{4}$$

From this we see that if p were constant, then the model would reduce to the Erdős–Rényi model of (Erdős and Rényi, 1959). If p_ϵ (which depends exclusively on F and ϵ) is not constant, then this leads to some inhomogeneity for the resulting random graph.

In what follows we denote, for i, j, k mutually different,

$$p_{\epsilon,1} = \mathbb{E}A_{\epsilon,i,j}, \qquad \text{and} \qquad p_{\epsilon,2} = \mathbb{E}A_{\epsilon,i,k}A_{\epsilon,k,j}. \tag{5}$$

These two numbers (or sequences, if $\epsilon \to 0$) are the probability that two vertices connect and the probability that two vertices have a common neighbour, respectively. Note that if X, Y, Z are independent and distributed according to F, then

$$p_{\epsilon,1} = \mathbb{P}\{r(X, Y) \leq \epsilon\} = \mathbb{E}\mathbb{P}\{r(X, Y) \leq \epsilon|X\} = \mathbb{E}p_\epsilon(X),$$

and in the same way,

$$p_{\epsilon,2} = \mathbb{E}\mathbb{P}\{r(X, Z) \leq \epsilon, r(Z, Y) \leq \epsilon|X, Y\} = \mathbb{E}p_\epsilon(X, Y).$$

By definition, $p_\epsilon(X, X) = p_\epsilon(X)$. Also, by independence and Jensen's inequality,

$$p_{\epsilon,2} = \mathbb{E}\mathbb{P}\{r(X, Z) \leq \epsilon, r(Z, Y) \leq \epsilon|Z\} = \mathbb{E}\{p_\epsilon(Z)^2\} \geq \mathbb{E}\{p_\epsilon(Z)\}^2 = p_{\epsilon,1}^2.$$

In fact, the (non-negative) difference $p_{\epsilon,2} - p_{\epsilon,1}^2$ is the variance of the connection probability function $p_\epsilon(x)$ which will play an important role later in the paper.

Both $p_{\epsilon,1}$ and $p_{\epsilon,2}$ depend on ϵ (and F), but also on the dimensionality of the data. For example, it is clear that $p_{\epsilon,1}$ and $p_{\epsilon,2}$ decrease as ϵ decreases. In fact, most of what follows is based on this dependence. Before we give the intuition behind our estimator, we discuss the role of ϵ in our approach.

3. Role of ϵ in the Model

The parameter $1/\epsilon$ can be seen as a resolution level that determines at which distance we distinguish between design points. This parameter plays a crucial role in our approach as is explained in this section. In Figure 1 we exemplify the effect of the size of ϵ. We sampled points uniformly at random on a manifold, then added some (3-dimensional) Gaussian noise; these points are the design points $\boldsymbol{X}$ and are embedded on a 3-dimensional space. We then took one of the design points, and coloured red all points that fall within a given Euclidean distance ϵ of the selected design point; the three plots correspond to different choices of ϵ.

If ϵ is so small that no red dots would be present, then the detected dimension is 0. If ϵ is large enough to capture just a few nearest neighbours (leftmost plot), then we capture only the effect of the noise – 3-dimensional in our case – but arbitrary in general. Increasing ϵ (central plot), the intersection is now a 2-dimensional section of the surface of the manifold. Further increasing ϵ (rightmost plot) changes the shape of the intersection which is now the

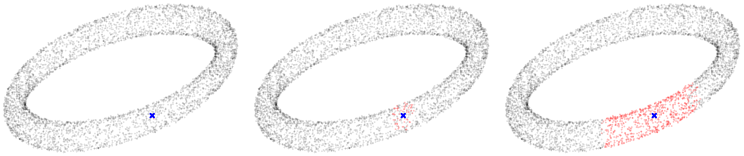

Figure 1: Design points sampled uniformly on a torus, with noise. Design points within an ϵ distance (increasing from left to right) of a fixed design point are coloured red.

(1-dimensional) surface of a tube. In either case, with much larger choices for ϵ we would capture all design points and the volume of the intersection would vanish with respect to ϵ; this would again lead the trivial case where dimension 0 is detected.

Of course the dimension can also be fractal, and we could also be interested in the dimension of just a region of the manifold in which case the choice of ϵ (and the design point that defines the neighbourhood) plays an important role again. The bottom line is that ϵ should be considered a parameter of the model (as opposed to a parameter of the estimator) in that the target intrinsic dimension should be seen as a function of ϵ; cf. (Burges, 2010) for a similar discussion. In other words, the resolution level should be chosen in line with the goals of the analysis; to learn the structure of the noise one would pick relatively small values of ϵ, while to learn the dimension of the manifold we would have to pick larger values. This is related to the scale of the observations, and it should be taken into consideration when choosing ϵ. Another issue is that one should also account for the sample size in the form of a finite sample correction. We return to this point in Section 7 where we use some numerical experiments to illustrate this point.

Next we define and give the intuition for our estimator of the intrinsic dimension d.

4. Estimation of the Intrinsic Dimension

We start by providing some heuristic motivation for our estimator of d. Consider, for $x \in \mathbb{R}^m$, $m \in \mathbb{N}$ the balls $V_\epsilon(x,m) = \{y \in \mathbb{R}^m : r(x,y) \leq \epsilon\}$ for a homogeneous, translation-invariant metric r, and denote $V_\epsilon(m) = V_\epsilon(0,m)$. Assume, without loss of generality, that $0 \in \mathcal{X} \subseteq \mathbb{R}^D$, where $\mathcal{X}$ is an appropriate high probability set in the support of F. If ϵ is small (or if $\epsilon \to 0$) and if F admits a continuous density f with respect to the Lebesgue measure μ, then we expect

$$p_\epsilon(x) \approx \int_{\mathcal{X}} \mathbf{1}_{V_\epsilon(x,D)}(y)\, f(y)\, d\mu(y) \approx f(x) \cdot \int_{\mathcal{X}} \mathbf{1}_{V_\epsilon(D)}(y)\, d\mu(y) \triangleq f(x) \cdot v_\epsilon.$$

The assumption that the intrinsic dimension of the data set is d, corresponds to assuming, with mild abuse of the notation, that (for all appropriately small ϵ)

$$v_\epsilon \triangleq \mu\{V_\epsilon(D) \cap \mathcal{X}\} \approx \mu\{V_\epsilon(d)\}.$$

(In fact, this relation can be seen as a definition of the ϵ-scale intrinsic dimension.) This has the interpretation that at the ϵ-scale the data looks d-dimensional. The point is that $p_\epsilon(x)$

should not be sensitive to the dimension D of the data points, but instead to the intrinsic dimension d of the data set and an ϵ-scale.

Since $p_{\epsilon,1} = \mathbb{E}\{p_\epsilon(X)\}$, we can approximate

$$p_{\epsilon,1} \approx \mathbb{E}f(X) \cdot \mu\{V_\epsilon(d)\}.$$

One can estimate d by replacing $p_{\epsilon,1}$ by an estimator and inverting the relation above. However, this would only be feasible with knowledge of the distribution F via the constant $\mathbb{E}f(X)$ and of the parameter ϵ, which in general we do not have access to.

Arguably, the most reasonable way to get rid of the dependence on F and ϵ is to examine the data at two different scales simultaneously. For appropriately small ϵ,

$$\frac{p_{2\epsilon,1}}{p_{\epsilon,1}} \approx \frac{\mu\{V_{2\epsilon}(d)\}}{\mu\{V_\epsilon(d)\}}. \tag{6}$$

This is a natural idea. Looking back at Figure 1, the (hyper-)volume of the intersections (which can be inferred from the number of points in the intersection) does not give us any information about dimension; it is how this quantity *scales* with ϵ that is informative.

With this approximation in mind, we define an estimator for d: for an arbitrary function $g_\epsilon(d)$ – ideally $p_{2\epsilon,1}/p_{\epsilon,1}$, but in general any reasonable approximation of $\mu\{V_{2\epsilon}(d)\}/\mu\{V_\epsilon(d)\}$ – the estimator is defined as (any) implicit solution $\hat{d}_n$ to the equality

$$\frac{\hat{p}_{n,2\epsilon,1}}{\hat{p}_{n,\epsilon,1}} = g_\epsilon\big(\hat{d}_n\,\big), \tag{7}$$

where $\hat{p}_{n,\epsilon,1}$ is any estimator for $p_{\epsilon,1}$, $\epsilon > 0$. If d is an integer, then we can consider an estimator $[\hat{d}_n\,]$, where $[\,\cdot\,]$ represents the argument rounded to the closest integer. Note that the function g_ϵ is allowed to depend on n.

The need to look at the data at two different scales simultaneously should not be a surprise. The probability $p_{\epsilon,1}$ itself does not carry any information about dimension if F is unknown; it is instead how $p_{\epsilon,1}$ scales as a function of ϵ that provides information about dimension. This notion of scaling is in fact connected with the notion of expansion dimension of (Karger and Ruhl, 2002).

For a given metric r one can numerically approximate the function $\mu\{V_{2\epsilon}(d)\}/\mu\{V_\epsilon(d)\}$, but in analogy to the doubling property of the Lebesgue measure this function should be constant over ϵ, at least if ϵ is appropriately small. So a canonical choice (independent of ϵ) would be $g_\epsilon(d) = 2^d$, in which case one has an explicit estimator for d:

$$\hat{d}_n = \frac{\log \hat{p}_{n,2\epsilon,1} - \log \hat{p}_{n,\epsilon,1}}{\log 2}. \tag{8}$$

This is just an example of a possible form that the estimator can take. However, it does suggest that at least for certain models one can expect to have explicit estimators for d that do not require knowledge of ϵ, F, or r and are therefore completely parameter-free.

Although ϵ should be known (or indeed picked, as pointed out in the discussion in Section 3), one can define reasonable estimators for d in the case where ϵ is unknown. In fact, it is is not possible to estimate ϵ consistently from adjacency matrices $\boldsymbol{A}_\epsilon$ without

knowledge of the distribution F. This follows from the trade-off between the standard deviation of the distribution F and the radius ϵ. Let $\sigma > 0$, and say $\boldsymbol{A}_{\epsilon/\sigma}$ is associated with design points $X \sim F$ and $\boldsymbol{A}'_\epsilon$ is associated with design points $X' \sim F(\cdot/\sigma)$; then

$$A_{\epsilon/\sigma,i,j} = \mathbf{1}_{\{r(X_i,X_j)\le\epsilon/\sigma\}} = \mathbf{1}_{\{r(\sigma X_i,\sigma X_j)\le\epsilon\}} \sim A'_{\epsilon,i,j},$$

so that information about ϵ cannot be retrieved from the adjacency matrix without knowledge of the distribution F. However, if ϵ is known, one may try to flesh out lower order terms in the approximation above to reduce the bias of the estimates.

We can more precisely approximate the local connection probability as

$$p_\epsilon(x) \approx f(x)\cdot v_\epsilon + \int_{\mathcal{X}} \mathbf{1}_{V_\epsilon(x,D)}(y)\,(y-x)^T\nabla f(x)\,d\mu(y),$$

where ∇f denotes the gradient of the density f, so that by taking expectation,

$$p_{\epsilon,1} \approx \mathbb{E}f(X)\cdot v_\epsilon\cdot\big(1+\Delta_\epsilon\big), \qquad \Delta_\epsilon = \frac{\mathbb{E}\int_{\mathcal{X}}\mathbf{1}_{V_\epsilon(X,D)}(y)\,(y-X)^T\nabla f(X)\,d\mu(y),}{\mathbb{E}f(X)\cdot v_\epsilon}.$$

For our canonical choice $g_\epsilon(d) = 2^d$ we thus obtain the approximation

$$\frac{\log p_{2\epsilon,1} - \log p_{\epsilon,1}}{\log 2} \approx \frac{\log v_{2\epsilon} - \log v_\epsilon + \log\big(1+\Delta_{2\epsilon}\big) - \log\big(1+\Delta_\epsilon\big)}{\log 2} \approx d + \frac{\Delta_{2\epsilon}-\Delta_\epsilon}{\log 2}.$$

By the Cauchy-Schwarz inequality to the inner product $(y-x)^T\nabla f(x)$, we conclude that

$$\frac{|\Delta_{2\epsilon}-\Delta_\epsilon|}{\log 2} \le \frac{3}{\log 2}\cdot\frac{\mathbb{E}\|\nabla f(X)\|}{\mathbb{E}f(X)}\cdot\epsilon.$$

Although the multiplier above is unknown, it depends only on F and is therefore fixed. Furthermore, it is reasonable to expect the multiplier to be of order d, since the gradient of the density should only be non-trivial along d independent directions. This means that certain choices for the function $g_\epsilon(d)$, like for example choices that are independent of the scale ϵ, should result in a bias of order $O(d\cdot\epsilon)$. We return to this discussion in Section 6 after we have specified the asymptotics of $\hat{d}_n$ for arbitrary g_ϵ.

Remark 1 *A similar reasoning to the one that was applied to $p_{\epsilon,1}$ above can be applied to other probabilities associated with the model, like for example $p_{\epsilon,2}$, to motivate alternative estimators for the intrinsic dimension. Although not reported here, we did not find any noticeable difference between the $\hat{d}_n$ estimator defined in* (7) *and a $p_{\epsilon,2}$ based estimator.*

From the discussion above, it is clear that the consistency of the estimators defined in (7) depends on three factors: the consistency of the estimates of $p_{\epsilon,1}$ that are used, the quality of the approximation in (6), and the slope of $g_\epsilon(d)$ around the underlying intrinsic dimension d. First we address the estimation of $p_{\epsilon,1}$.

5. Estimates of the Connection Probability and their Asymptotics

An estimator for $p_{\epsilon,1}$ is obtained by averaging off-diagonal entries of the matrix $\boldsymbol{A}_\epsilon$. For any $m_n \le n$ (m_n is for now left unspecified, and is a parameter of the estimator),

$$\hat{p}_{n,\epsilon,1} = \frac{1}{m_n}\sum_{i=1}^{m_n}\frac{B_{\epsilon,i}}{n-1} = \frac{2}{m_n(n-1)}\sum_{i=1}^{m_n}\sum_{j=i+1}^{n} A_{\epsilon,i,j}, \tag{9}$$

using the symmetry of $\boldsymbol{A}_\epsilon$. Since $\mathbb{E}B_{\epsilon,i}/(n-1) = p_{\epsilon,1}$, the estimator $\hat{p}_{n,\epsilon,1}$ is unbiased. This estimator can be evaluated in $O(n\,m_n)$ instructions. If we set $m_n = n$ then the execution time may be prohibitive if n is large so the parameter m_n offers some flexibility. However, as we will see below and in Sections 6 and 7, the role of the sequence m_n goes beyond just controlling the computational complexity of the estimator. In Section 7.2, in particular, we discuss what constitutes a "good" choice for m_n.

The following theorem provides the asymptotics for the estimator in (9).

Theorem 2 *Let $m_n \le n$ and $m_n \to \infty$ as $n \to \infty$. If $m_n = o(n)$, and $p_{\epsilon,2} > p_{\epsilon,1}^2$, then*

$$S_{n,\epsilon,1}^{-1/2}\cdot\left\{\frac{\hat{p}_{n,\epsilon,1}}{p_{\epsilon,1}} - 1\right\} \xrightarrow{d} N(0,1), \qquad \textit{where} \qquad S_{n,\epsilon,1} = \frac{p_{\epsilon,2}-p_{\epsilon,1}^2}{m_n\,p_{\epsilon,1}^2}. \tag{10}$$

If $m_n = n$ then the previous display also holds if we further assume that $n(p_{\epsilon,2}-p_{\epsilon,1}^2)^2 \to \infty$. (This assumption always holds if ϵ is fixed.)

■

The proof of this theorem can be found in the Appendix. This result is valid irrespectively of the distribution F, and holds even if $\epsilon \to 0$, as $n \to \infty$, so that $p_{\epsilon,1}, p_{\epsilon,2} \to 0$. The difference $p_{\epsilon,2} - p_{\epsilon,1}^2 = \mathbb{E}\{p_\epsilon(X)^2\} - \{\mathbb{E}p_\epsilon(X)\}^2$ is the variance of the function p_ϵ. From this we see that p_ϵ being more variable has a negative impact on the estimation of $p_{\epsilon,1}$, which is not surprising. If ϵ is fixed, then $p_{\epsilon,1}$ can be estimated with rate $m_n^{-1/2}$. However, if $\epsilon \to 0$ the rates may be different depending on how the probabilities involved scale with ϵ, which in turn depends on the specific distribution F and the metric r at hand.

Next we give conditions under which the estimators (7) are consistent for d.

6. Consistency of Estimates for the Intrinsic Dimension

Based on the asymptotics of $\hat{p}_{n,\epsilon,1}$ from the previous section, whether the procedure outlined in Section 4 delivers consistent estimates for d or not, now depends on the specific model in question and on $g_\epsilon(d)$.

Theorem 3 *Consider the implicit estimators* (7). *Assume that the conditions of Theorem 2 required for the convergence of $\hat{p}_{n,\epsilon,1}$ and $\hat{p}_{n,2\epsilon,1}$ with rate $m_n^{-1/2}$ hold. For that ϵ, d, and m_n, assume that, as $n \to \infty$,*

$$p_{2\epsilon,1} = p_{\epsilon,1}\cdot g_\epsilon\Big\{d + o(m_n^{-1/2})\Big\}. \tag{B}$$

Assume also that the derivative (with respect to d) of $g_\epsilon(d)$ exists, is continuous and non-zero at d. If $p_{\epsilon,1}\cdot(1-p_{2\epsilon,1}) = o\big[n\{p_{\epsilon,2\epsilon,2} - p_{\epsilon,1}\cdot p_{2\epsilon,1}\}\big]$ and $m_n = o(n)$, then as $n\to\infty$,

$$S_{n,\epsilon}^{-1/2}\cdot\Big\{\hat{d}_n - d\Big\} \xrightarrow{d} N(0,1), \qquad \text{where} \qquad S_{n,\epsilon} = \left\{\frac{\partial \log g_\epsilon(d)}{\partial d}\right\}^2\cdot\frac{\mathcal{V}_\epsilon}{m_n}$$

where for $p_{\epsilon_1,\epsilon_2,2} = \mathbb{P}\{r(X,Z)\le\epsilon_1, r(Y,Z)\le\epsilon_2\}$,

$$\mathcal{V}_\epsilon = \frac{p_{\epsilon,1}^2\cdot p_{2\epsilon,2} - 2\cdot p_{\epsilon,2\epsilon,2}\cdot p_{\epsilon,1}\cdot p_{2\epsilon,1} + p_{2\epsilon,1}^2\cdot p_{\epsilon,2}}{p_{\epsilon,1}^2\cdot p_{2\epsilon,1}^2}$$

■

Remark 4 *In Theorem 3 we consider the case $m_n = o(n)$, which is the most relevant case in practice. The general expression for $\mathcal{V}_\epsilon$ (meaning for any sequence $m_n \le n$) can be found in* (16)*, in the Appendix.*

Remark 5 *Condition* (B) *controls the asymptotic bias of the estimator for d. Note that this condition should be interpreted as a condition on g_ϵ and on the sequence m_n, and not a condition on ϵ, since ϵ is a modelling parameter set by the user. If condition* (B) *does not hold, then the statement of the previous theorem is still valid if we centre $\hat{d}_n$ with $\mathbb{E}(\hat{d}_n)$ instead of d, but in that case the estimator might be asymptotically biased. Alternatively, if* (B) *holds with $r_n = o(m_n)$, instead of m_n, then we conclude that $r_n^{-1/2}\big(\hat{d}_n - d\big) = o_P(1)$. (Note that the condition becomes more restrictive for faster rates.)*

For the explicit estimator in (8) the $g_\epsilon(d)$-dependent scaling in the variance is $\log(2)^{-2}$. In this case, the bias condition (B) reduces to

$$p_{2\epsilon,1} = p_{\epsilon,1}\cdot 2^{d+o\left(m_n^{-1/2}\right)}.$$

This requires the connection probability $p_{\epsilon,1}$ to approximately have a doubling property: if the distance at which vertices connect doubles, then the probability of connection goes up by a factor 2^d, approximately. (Note that also ϵ should in general depend on n, but we return to this point in Section 7.1.) How much leverage we have in terms of the approximation depends mostly on the sequence m_n and is, in a sense, the price to pay for the computational speed-up. However, the choice of m_n goes well beyond this.

Remark 6 *Since our estimator for d only requires access to m_n rows of $\boldsymbol{A}_\epsilon$ and $\boldsymbol{A}_{2\epsilon}$, one can obtain several (correlated) estimates $\hat{d}_n^{(1)}$, $\hat{d}_n^{(2)}$, ..., of d based on disjoint sets of rows if $m_n = o(n)$. From these one can estimate the variance of $\hat{d}_n$.*

Say that we consider the following estimator for the variance

$$\hat{\sigma}_n^2 = \widehat{\mathbb{V}\hat{d}_n} = \frac{1}{t_n - 1}\sum_{i=1}^{t_n-1}\Big\{\hat{d}_n^{(i)} - \bar{d}_n\Big\}^2, \qquad \text{with} \qquad \bar{d}_n = \frac{1}{t_n}\sum_{i=1}^{t_n}\hat{d}_n^{(i)},$$

where $t_n\in\mathbb{N}$ is at most n/m_n. It is straightforward to check that

$$\mathbb{E}\hat{\sigma}_n^2 = \sigma^2\Big[1 - \rho\big\{\hat{d}_n^{(1)}, \hat{d}_n^{(2)}\big\}\Big],$$

where $\rho(X,Y)$ represents the correlation between X and Y. Making use of the fact that $\hat{p}_{n,\epsilon,1}^{(i)}$ and $\hat{p}_{n,2\epsilon,1}^{(i)}$ are independent for $i\in\mathbb{N}$, we have

$$\mathbb{V}\big\{\hat{d}_n^{(1)}, \hat{d}_n^{(2)}\big\} = \frac{1}{\big\{\log(2)^2\big\}}\Big[\mathbb{V}\big\{\log\hat{p}_{n,\epsilon,1}^{(1)}, \log\hat{p}_{n,\epsilon,1}^{(2)}\big\} + \mathbb{V}\big\{\log\hat{p}_{n,2\epsilon,1}^{(1)}, \log\hat{p}_{n,2\epsilon,1}^{(2)}\big\}\Big].$$

Using the approximation[3] $\mathbb{V}(\log X, \log Y)\approx\mathbb{V}(X,Y)/(\mathbb{E}X\cdot\mathbb{E}Y)$*, it is enough to look at $\mathbb{V}\big\{\hat{p}_{n,\epsilon,1}^{(1)}, \hat{p}_{n,\epsilon,1}^{(2)}\big\}$. If we denote the range of rows associated with these two estimators as respectively I_1 and I_2, then writing the covariance as a four-fold sum, we get*

$$\begin{aligned}\mathbb{V}\big\{\hat{p}_{n,\epsilon,1}^{(1)}, \hat{p}_{n,\epsilon,1}^{(2)}\big\} &= \left\{\frac{2}{m_n(n-1)}\right\}^2\sum_{i_1\in I_1}\sum_{i_2\in I_2}\sum_{j_1=i_1+1}^{n}\sum_{j_2=i_2+1}^{n}\mathbb{V}\big(A_{\epsilon,i_1,j_1}, A_{\epsilon,i_2,j_2}\big)\\ &\le \frac{4}{n-1}\big(p_{\epsilon,2} - p_{\epsilon,1}^2\big),\end{aligned}$$

where we use the fact that since $I_1\cap I_2 = \emptyset$, then $\mathbb{V}\big(A_{\epsilon,i_1,j_1}, A_{\epsilon,i_2,j_2}\big) = p_{\epsilon,2} - p_{\epsilon,1}^2$ if $j_1 = j_2$, and $\mathbb{V}\big(A_{\epsilon,i_1,j_1}, A_{\epsilon,i_2,j_2}\big) = 0$, if $j_1\neq j_2$. Finally, under the conditions of Theorems 2 and 3, we can put everything together to bound

$$\big|\mathbb{E}\hat{\sigma}_n^2 - \sigma^2\big| \lesssim \frac{m_n}{n}\cdot\frac{S_{n,\epsilon,1}}{S_{n,\epsilon}};$$

this upper bound converges to zero for appropriate ϵ, if $m_n = o(n)$.

Note that when the metric r is induced by the Euclidean norm $\|\cdot\|_2$, and $m_n = n$, the estimator $\hat{p}_{n,\epsilon,1}$ (as a function of ϵ) coincides with a realisation of the so-called correlation integral; cf. (Camastra and Vinciarelli, 2002). This is defined in the following way. With $x_1,\ldots,x_n$ denoting points on a manifold whose dimension we would like to measure, let

$$C_n(\epsilon) = \frac{2}{n(n-1)}\sum_{i=1}^{n-1}\sum_{j=i+1}^{n}\mathbf{1}_{\{\|x_i - x_j\|_2\le\epsilon\}}; \tag{11}$$

the correlation integral $C(\epsilon)$ is the limit, when $n\to\infty$, of $C_n(\epsilon)$. The underlying idea behind the intrinsic dimension being d is that $C(\epsilon)$ should scale like ϵ^d so that the limit as $\epsilon\to 0$ of $\log\{C(\epsilon)\}/\log(\epsilon)$ is d; this is then called the correlation dimension, which is a type of fractal dimension. Following up on Remark 1, basing our estimator on $p_{\epsilon,2}$ would lead to a variation on the correlation integral above. We found no advantage in using the $p_{\epsilon,2}$ based estimator over the $p_{\epsilon,1}$ based one.

Some estimators for intrinsic dimension like that of (Grassberger and Procaccia, 1983) are based on the idea of regressing $\log\{C_n(\epsilon)\}$ on $\log(\epsilon)$, and estimating the (correlation) dimension from the slope of the fit. However, based on the discussion from Section 3, this slope actually corresponds to some average dimension over different scales, which is not what we are interested in; cf. Fig. 3.3 of Lee and Verleysen, 2007, for an example of the scale dependence of the correlation integral. Further, this also makes extensive use of

3. Here we use the fact that $\mathbb{V}(\log X, \log Y) = \mathbb{V}\{\log(X/\mathbb{E}X), \log(Y/\mathbb{E}Y)\}\approx\mathbb{V}(X/\mathbb{E}X - 1, Y/\mathbb{E}Y - 1) = \mathbb{V}(X,Y)/(\mathbb{E}X\cdot\mathbb{E}Y)$, since $\log(1+x)\approx x$, for all appropriately small x.

distances between the observations, while we rely only on the neighbourhood information provided by adjacency matrices.

As we argue in the previous section, one has to examine the data at (at least) two different scales to derive meaningful information about dimension, and this has been noted in the literature before. (Kégl, 2002) proposed a scale dependent notion of correlation dimension based on

$$D_n(\epsilon_1, \epsilon_2) = \frac{\log\{C_n(\epsilon_2)\} - \log\{C_n(\epsilon_1)\}}{\log(\epsilon_2) - \log(\epsilon_1)} \tag{12}$$

This improves upon the idea of regressing the logarithms of the empirical version of the correlation integral (cf. Grassberger and Procaccia, 1983; Pettis et al., 1979) on the logarithm of ϵ by allowing one to focus on a specific range of scales. Indeed, this is closely reflected in our estimator $\hat{d}_n$, although we distinguish ourselves from other approaches by deriving the asymptotic distribution of our estimator within a flexible framework; to the best of our knowledge the central limit theorem that we derive is new to the literature.

Other approaches to intrinsic dimension estimation follow similar ideas but make use of other notions of dimension like for example Hausdorff dimension, information dimension, box counting dimension, (generalised) expansion dimension, packing dimension, and also local versions of these concepts. The success of such approaches depends mostly on how computationally tractable computing the estimate of the dimension is, and how adequate the particular notion of dimension at hand is for the model under consideration.

Another approach corresponds to the maximum likelihood estimator of (Bickel and Levina, 2004). This estimator is based on maximising the likelihood obtained by assuming that the observations come from a homogeneous Poisson process. The estimator is then based on distances to the k-the nearest neighbour of each point, with k interpreted as a "bandwidth" parameter of the estimator. Another estimator based on k-nearest-neighbours is that of (Kleindessner and von Luxburg, 2015). In both cases the connection between k and the scale at which we estimate dimension has not yet been explored in detail, however. The disadvantage of k-nearest-neighbour approaches seems to be that the way in which the distance of an observation to its k nearest neighbour scales with dimensions may heavily depend on the underlying distribution of the data. Although this does open the door to sharper estimates of the intrinsic dimension, this is done at the expense of needing more information about the distribution of the data. Besides this, relating k to the scale at which the intrinsic dimensions is being estimated also seems to be difficult.

The approaches mentioned above, as well as our approach, are examples of so called geometric methods. A different class of methods are eigenvalue (or projection) methods. These stem from the work of (Fukunaga and Olsen, 1971); see also (Bruske and Sommer, 1998). These methods are typically based on principal component analysis (PCA) and estimate the dimension based on how many eigenvalues are above certain (small) threshold. They seem to be less useful for estimating intrinsic dimension because of the difficulty of determining what constitutes an appropriate threshold; cf. (Verveer and Duin, 1995).

In the next section we present some numerical results to illustrate our approach. These results guide us in our choice of the sequence m_n.

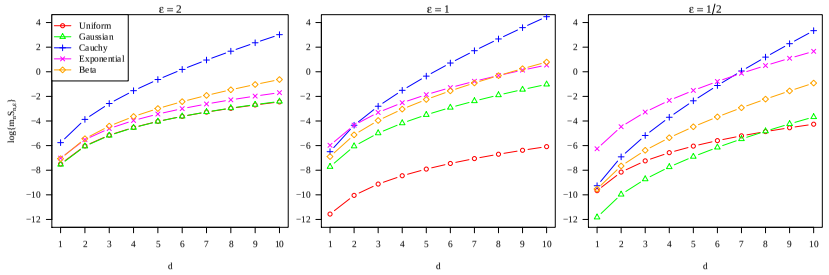

Figure 2: Effect of the distribution of the design points, d, and ϵ on the logarithm of the asymptotic variance of our estimator for d. The three plots correspond to $\epsilon \in \{2, 1, 1/2\}$, left to right. In each plot, each line corresponds to a different distribution for the design points.

7. Numerical Results

In this section we present some numerical results. We start by exemplifying in Section 7.1 how the probabilities $p_{\epsilon,1}$ and $p_{\epsilon,2}$ determine the bias and variance of our estimator for different distributions for the observations $\boldsymbol{X}$. Section 7.2 is about the consequences of the choice of the sequence m_n in our estimator. In Section 7.3 the performance of our estimator is evaluated for different combinations of dimension d and resolution $1/\epsilon$. The main goal of these first three subsections is to understand what constitutes a good choice for the sequence m_n that features in the definition (9). Section 7.4 concerns a non-trivial choice for the function g_ϵ (meaning a choice other than 2^d), as well as other types of bias correction. In Section 7.5 we illustrate the effect of noise on our estimator. Finally, in Section 7.6, we apply our estimator to a batch of data sets of both simulated, and real data. To simplify the exposition, in all cases the metric r is the Euclidean distance.

7.1 Scaling of $p_{\epsilon,1}$ and $p_{\epsilon,2}$, and their Influence on the Bias and Variance of $\hat{d}_n$

The probabilities $p_{\epsilon,1}$ and $p_{\epsilon,2}$ play an important role in our approach. The quantity $\{p_{\epsilon,2} - p_{\epsilon,1}^2\}/p_{\epsilon,1}^2$ is the variance of the function $p_\epsilon(x)/p_{\epsilon,1}$, which is the relative connection probability at each site x. We see, for example, that if $m_n = o(n)$, then the scaling $m_n \cdot S_{n,\epsilon}$ that features in the asymptotics for our estimator for d is up to a constant factor the variance of $p_\epsilon(X)/p_{\epsilon,1} - p_{2\epsilon}(X)/p_{2\epsilon,1}$. However, this quantity still depends on ϵ and d, so it is interesting to see how it behaves for different distributions for the design points.

In Figure 2 we plot the logarithm of $m_n \cdot S_{n,\epsilon}$, as a function of the intrinsic dimension d for several different choices for the distribution of the design points, for three choices of ϵ. If ϵ is fixed, then $m_n S_{n,\epsilon}$ is just the constant that features in the rate of convergence of the estimator of $\hat{d}_n$. (The curves were computed by numerical integration, but are otherwise exact.) The coordinates of the design points X_i were sampled independently from the indicated distributions (uniform, Gaussian, exponential, and beta$\{2, 5\}$, all scaled standard deviation 1; Cauchy with scale parameter 1). The main message is that for appropriately

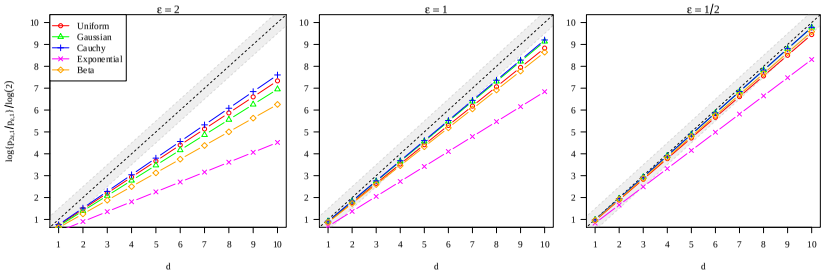

Figure 3: Effect of the distribution of the design points, d, and ϵ on $\{\log p_{2\epsilon,1} - \log p_{\epsilon,1}\}/\log(2)$. Left to right, the plots correspond to $\epsilon \in \{2, 1, 1/2\}$. The shaded area corresponds to $d \pm 1/2$.

large d (about $d \geq 5$) the lines increase roughly linearly, which would mean that the constants in the asymptotic statement in Theorem 3 increase exponentially with d. In general, d is fixed, but these plots give an indication that if the intrinsic dimension is large, then in order to attain a given level of precision, one should need a fairly large number of observations. This should give a notion of when the asymptotics described in Section 6 *kick in*. The effect of ϵ, on the other hand, does not seem too pronounced and affects mostly how the lines behave when the intrinsic dimension d is relatively small.

While the variance of the estimator is, up to the scaling $\{\partial \log g_\epsilon(d)/\partial d\}^2$, only model dependent, the bias depends greatly on the function g_ϵ used in the definition of the estimator. In particular it depends on how well $g_\epsilon(d)$ approximates $p_{2\epsilon,1}/p_{\epsilon,1}$ as prescribed by the bias condition (B). As discussed in Section 4, for appropriately small ϵ, it should hold that $p_{2\epsilon,1}/p_{\epsilon,1} \approx 2^d$, making $g_\epsilon(d) = 2^d$ our canonical choice for g_ϵ. For this choice of g and for the same distributions as before, in Figure 3 we plot $d \mapsto \{\log p_{2\epsilon,1} - \log p_{\epsilon,1}\}/\log(2)$, for different ϵ; we compare it with the identity $d \mapsto d$.

In the plots above, the black dotted line along the diagonal is the identity, and the grey shaded area encompasses $d \pm 1/2$ (for reference). As before, the remaining lines correspond to different distributions for the design points. As expected from the discussion in Section 4, as ϵ gets smaller, these lines mimic the doubling property of the Lebesgue measure more closely so that $d \mapsto p_{2\epsilon,1}/p_{\epsilon,1}$ indeed gets closer to $d \mapsto 2^d$. The plots also suggest that considering $g_\epsilon(d) = 2^d$ should lead to the dimension being systematically underestimated, and that one may want to consider a multiplicative correction based on ϵ. In a sense, this is the price to be paid for having a parameter-free estimator.

Part of the bias is a consequence of the fact that, in general, we do not have access to a good (model dependent) function g. For example, if g is constant over ϵ, as discussed in Section 4, the bias should, in fact, be of order ϵ. One should therefore consider to take ϵ small to reduce the bias of the estimates. However, this is somewhat at odds with the notion put forward in Section 3, where we explain that ϵ determines the scale at which we examine the data and is therefore a (fixed) modelling parameter.

As it turns out, there is a justification for taking $\epsilon = \epsilon_n$ converging to zero. The rationale is the following. Typically, there will be noise in our data so that the support of F is an enlarged version of the manifold whose dimension we would like to estimate. If the design points are relatively concentrated, in the sense that $\mathbb{P}\{r(0, X) > x\} \lesssim \exp(-x^2)$, $x > 0$, say, then, by the union bound,

$$\mathbb{P}\Big\{ \max_{i=1,\ldots,n} r(0, X_i) > \sqrt{\delta \log n} \Big\} \leq \sum_{i=1}^{n} \mathbb{P}\Big\{ r(0, X_i) > \sqrt{\delta \log n} \Big\} \lesssim n^{1-\delta}, \qquad \delta > 1.$$

In other words, if ϵ_1 is to express the distance at which we would like to analyse the data, then if we observe only n points and take $\epsilon \equiv \epsilon_1$, we are overestimating the typical distances between points by roughly a factor $\sqrt{\log n}$. In a sense, this growing spread can be thought of as arising from noise, so that we should therefore establish connections at a slightly smaller distance, say for instance $\epsilon_n = \epsilon_1/\sqrt{\log(1+n)}$, $\epsilon_1 > 0$. This can also be seen as a finite sample correction for the estimator; cf. (Grassberger, 1988). Another reason to consider ϵ of this kind would be to ensure that the adjacency matrices that we work with remain relatively sparse. This means that we avoid storage problems even when the sample size n is large. This can also be motivated from the point of view of discriminability; cf. (Beyer et al., 1999; Weber et al., 1998; Houle, 2013). If the dimensionality of the data is high, then distance values are less discriminative, in the sense that they tend to concentrate more around the mean of their distribution. Because of this, it makes sense to increase the strictness with which new connections are accepted as the sample size grows.

This has three important consequences. The first is that for the parameter-free estimator (8), with the finite sample correction described above should have squared bias $O(1/\log n)$. This means that the sequence m_n should be set to $O(\log n)$ to balance variance and squared bias. The proverbial *less is more* comes to mind: picking m_n large and averaging over many vertices leads to deceptive results, since the variance of the estimate is reduced, while the bias remains unchanged. This is an inherent feature of estimators obtained via inversion, but it is something that is invariably missed in the literature – estimates are strongly concentrated around biased estimates. This is undesirable from the point of view of uncertainty quantification; see also the next section. By doing this our estimator attains the minimax rate for this problem which is known to be logarithmic; cf. (Koltchinskii, 2000).

The second consequence follows from the first: setting $m_n = O(\log n)$ leads to an algorithm with complexity $O(n \log n)$. This is a great advantage over competing algorithms whose execution time typically scales like $O(n^2)$, sometimes like $O(D\, n^2)$; cf. Table 1 in (Eriksson and Crovella, 2012). Finally, since m_n is rather small compared with n, this means that we are estimating d based on the degrees of only a few vertices. By repeating the estimation for disjoint sets of vertices we can estimate the standard deviation of the estimator without a need for resampling. The conclusion is that picking small m_n is better, both from a theoretical and practical perspective.

In the next subsection we perform some numerical experiments to investigate more closely the consequences of different choices for m_n.

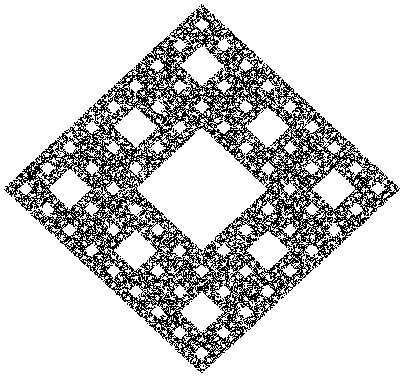

Figure 4: Example of $5 \cdot 10^4$ points sampled uniformly at random on a Sierpinski carpet. Points like these are used as design points in the simulations in this section.

7.2 Different Choices of m_n

In this section we look more closely at the choice of m_n by exemplifying the effect that the choice of this sequences has on: a) the bias, b) the variance, and c) the execution time. To have a nontrivial dimension we consider design points sampled uniformly at random on a Sierpinski carpet. This can be done in the following way. Consider

$$P_0 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \qquad \text{and} \qquad \boldsymbol{C} = \begin{bmatrix} 0 & 1/2 & 1 & 1/2 & 0 & -1/2 & -1 & -1/2 \\ 1 & 1/2 & 0 & -1/2 & -1 & -1/2 & 0 & 1/2 \end{bmatrix}.$$

Let $e_i = [0 \cdots 0\, 1\, 0 \cdots 0]^T$, $i = 1, \ldots, 8$, be unit vectors that have a 1 in the i-th position, and let $i_j \sim U\{1, \ldots, 8\}$, $j = 1, 2, \ldots$, be a sequences of independent, discrete uniform random variables taking values on $\{1, \ldots, 8\}$. A point can be drawn uniformly at random on a Sierpinski carpet as

$$P = P_0 + \boldsymbol{C} \sum_{j=1}^{\infty} 3^{-j} \cdot e_{i_j}.$$

Figure 4 depicts $5 \cdot 10^4$ points drawn according to this procedure. In practice we truncate the sum at 100 terms. (Note that this is accurate enough to get the neighbourhood matrices $\boldsymbol{A}_\epsilon$ exactly.) The correlation dimension of the Sierpinski carpet is, to the best of our knowledge, unknown, but its Hausdorff dimension is $\log 8 / \log 3 \approx 1.89$, which should provide a good indication to what the intrinsic dimension should be.

In this section we ran our algorithm for all combinations of $n = 10 \cdot 2^\gamma$, $\gamma \in \{0, 1, \ldots, 8\}$, and m_n either $\log(n)$ or n^γ, $\gamma \in \{1/4, 1/2, 3/4, 1\}$. The parameter ϵ was set to $\epsilon_n = \text{sd}\{\text{vect}(\boldsymbol{X})\}/\sqrt{\log(n+1)}$, where vect($\boldsymbol{X}$) represents the entries for $\boldsymbol{X}$ written as a vector; the standard deviation of the coordinates of the design points, although in practice unknown,

		m_n

Table 1: Results for the estimation of the intrinsic dimension d for random Sierpinski carpet design points, for different combinations of n and m_n. For each combination, $\hat{d}_n$ was estimated 10^5 times; we display the mean estimate, and in parenthesis the standard deviation among the estimates.

was used here to ensure that ϵ is on the right scale. These simulations were repeated 10^5 times and the results are averaged.

Table 1 summarises the average and standard deviation of the estimates that were obtained for each combination of n and m_n. Irrespectively of the sequence m_n, it is clear that as n grows the estimates stabilise. This is in tune with our consistency result, also in that the reduction of the bias is rather slow. It is also clear from the results that the sequence m_n does not seem to have much influence on the quality of the estimate, particularly as n grows. This is also in tune with our results: larger m_n does increase the precision of the estimates of the probabilities $p_{\epsilon,1}$; what mainly determines the precision of the estimate of d is the bias introduced by the function g_ϵ, though. The effect of m_n on the standard deviation is also as expected: increasing either n or m_n generally leads to a decreased of the variability of the estimate. From this it might seem reasonable to set m_n to a large value (after all, it does reduce the variance of the estimator without reducing precision). There are however two good reasons to keep the growth of m_n slow.

The first reason is execution time. Figure 5 shows the evolution of the average execution time of the algorithm as a function of n, when $m_n = \log(n)$. For comparison, Table 2 shows the average execution time as a multiplier of the execution time for $m_n = \log(n)$, for the same value of n. In words: the numbers on the table indicate how much slower it is to set m_n to each choice, compared to just setting it to $\log(n)$.

The conclusion from Figure 5 is that the execution time for $m_n = \log(n)$ grows roughly linearly with n. On the other hand, from Table 2, for other choices of m_n the execution time quickly becomes prohibitive, particularly for faster-growing sequences m_n.

There is a second reason to set $m_n = O\{\log(n)\}$. Table 3 shows the percentage of runs in which d falls within 2 standard deviations from $\hat{d}_n$. The effect of m_n is clear. The confidence interval contains the true value of d, only when m_n grows appropriately slowly.

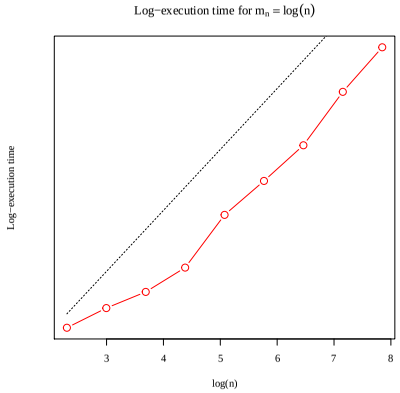

Figure 5: The evolution of the average execution time of our algorithm as a function of n when $m_n = \log(n)$. The plot is on a log-log scale. For reference, the dashed line represents $\log(n)$ plotted against $\log(n) - 10$. The execution time grows roughly linearly with n.

		m_n			
		$n^{1/4}$	$n^{1/2}$	$n^{3/4}$	n
n	10	1.13	1.65	2.14	3.20
	20	1.29	1.63	2.94	5.98
	40	1.34	2.63	5.59	12.72
	80	1.31	3.51	9.75	28.43
	160	1.20	3.57	12.10	42.46
	320	1.52	5.24	21.72	90.87
	640	1.91	8.05	39.19	194.22
	1280	1.53	9.03	53.86	325.12
	2560	1.99	12.68	89.80	638.54

Table 2: Average execution times for the algorithm. For each combination of n and sequence m_n, the respective entry in the table specifies how many times larger the execution time of the algorithm is compared to using $m_n = \log(n)$. For example, if we set $m_n = n$, then, when n is 2560, we have to wait more than 638 times longer for the algorithm to terminate than if we had used $m_n = \log(n)$.

Since the estimates are biased, if the sequence m_n grows too quickly, then the variance of the estimates is too small. The estimate $\hat{d}_n$ becomes overly concentrated around its

		m_n				
		$\log(n)$	$n^{1/4}$	$n^{1/2}$	$n^{3/4}$	n

	2560	84.95	71.52	4.52	0.00	0.00

Table 3: Percentage of the 10^5 runs where the true value of d is within 2 standard deviations of $\hat{d}_n$.

biased mean. In effect, because the bias and the variance are out of balance, the standard deviation fails to properly quantify the uncertainty in the estimate. Also remember that if m_n is small, then we can produce several estimates of d, from which we can estimate the standard deviation without a need for resampling.

To conclude, the sequence m_n affects the variance of the estimator $\hat{d}_n$, but it does not affect the bias of the estimate, which comes mostly from the function g_ϵ. Faster growing m_n therefore leads to estimates that are overly concentrated around their (biased) mean, so that their variability gives misleading information about the uncertainty in the estimate. Such choices of m_n also lead to a large computations cost. Therefore, setting $m_n = O\{\log(n)\}$ is arguably the correct choice to make.

7.3 Different Combinations of d and n

In this section we show how the estimator $\hat{d}_n$ behaves for different combinations of d and n. We set the distribution of the design points $X \sim N_d(0, \boldsymbol{I})$, for $d \in \{1, 2, 3, 4, 5, 10\}$, and chose $n \in \{10^3, 10^4, 10^5, 10^6, 10^7\}$; irrespectively of the dimension we always set $\epsilon = \epsilon_n = 4/(\log n)^{1/2}$. Based on the discussion from the previous section, the parameter m_n was set to $\max(1, \log n)$.

Table 4 below contains the results of estimating the intrinsic dimension d 10 times: for each combination of n and d we sampled an adjacency matrix, estimated d 10 times from 10 disjoint subsets of m_n vertices (chosen at random, without replacement); the average and (in brackets) the standard deviation of the 10 estimates make up the entries of the table. Note that since we only average over a relatively small number of vertices in the graph, producing Table 4 does not actually require any resampling; the same data set can be used (for each combination of n and d). Note also that for the choice of m_n above, the execution time of the algorithm is $O(n \log n)$, meaning that it is considerable faster than any alternative approach.

		n				
		10^3	10^4	10^5	10^6	10^7
d	1	0.49 (0.15)	0.58 (0.11)	0.54 (0.12)	0.63 (0.07)	0.71 (0.15)
	2	0.91 (0.18)	1.18 (0.19)	1.31 (0.26)	1.41 (0.25)	1.53 (0.17)
	3	1.76 (0.24)	1.99 (0.29)	2.23 (0.36)	2.28 (0.34)	2.51 (0.20)
	4	2.55 (0.50)	2.94 (0.30)	3.23 (0.42)	3.05 (0.44)	3.42 (0.32)
	5	3.24 (0.37)	3.61 (0.38)	3.96 (0.43)	4.31 (0.18)	4.39 (0.44)
	10	5.95 (0.61)	7.46 (0.53)	8.59 (0.70)	8.81 (0.70)	8.97 (0.75)

Table 4: Results for the estimation of d for Gaussian design points for different combinations of d and n. For each combination $\hat{d}_n$ was estimated 10 times; we display the mean estimate, and in parentheses the standard deviation among the estimates.

A few things are clear from the results in Table 4. As hinted in Section 7.1, the estimator tends to underestimate the true intrinsic dimension, especially if the dimension is large. However, as far as recuperating the integer dimension, the estimator performs well, especially considering that the data is entirely comprised of random fluctuations. The standard deviation also does a good job at quantifying the precision of the estimate.

We emphasise that the estimates are parameter free – one can improve the results with extra knowledge about the distribution of the data. We do this in the following subsection.

7.4 Non-canonical Choice of $g_\epsilon(d)$, and Bias Corrections

In this section we propose some modifications of our estimator aimed at removing (or at least mitigating) its bias. Since we know that the estimator $\hat{d}_n$ systematically underestimates d, a simple way of obtaining a "bias corrected" estimator is by scaling $\hat{d}_n$ up. We consider three different ways of doing this.

Following the discussion at the end of Section 4, where we justified that the bias should be of order $O(d \cdot \epsilon)$, we consider

$$\tilde{d}_n = \hat{d}_n \cdot \left\{1 + \frac{2}{\log(2)} \cdot \epsilon\right\}. \tag{13}$$

The motivation for considering this form is indeed the heuristic upper bound on the bias from Section 4. We replaced the factor $3/\log(2)$ with a $2/\log(2)$ to be conservative, since we do not expect the upper bound on the bias to be tight. We also use the fact that the ratio of expectations in the bound can reasonably be expected to be of order d since, on average, the gradient of the density should only be non-trivial along d independent directions. A multiplicative correction of this form seems to be appropriate not just for the Gaussian case, where the expectations that feature in the bound on the bias can be computed. Indeed, this form of the estimator performs quite well without any adjustments on subsequent experiments; see Table 8. With more knowledge about F one can certainly make more informed choices about the specific constants in (13). Table 5 shows the values that the bias corrected estimates (13) take.

		n				
		10^3	10^4	10^5	10^6	10^7
d	1	0.55 (0.17)	0.64 (0.12)	0.59 (0.13)	0.69 (0.08)	0.78 (0.16)
	2	1.03 (0.20)	1.32 (0.21)	1.44 (0.29)	1.54 (0.28)	1.66 (0.18)
	3	2.00 (0.27)	2.22 (0.32)	2.46 (0.40)	2.49 (0.37)	2.72 (0.22)
	4	2.89 (0.57)	3.28 (0.34)	3.55 (0.46)	3.34 (0.48)	3.71 (0.35)
	5	3.67 (0.42)	4.02 (0.43)	4.37 (0.48)	4.71 (0.19)	4.77 (0.48)
	10	6.74 (0.69)	8.31 (0.59)	9.47 (0.77)	9.63 (0.77)	9.74 (0.81)

Table 5: This table contains the results of repeating the experiment from the previous section, but we compensate for the bias by considering a multiplicative correction.

Comparing these results with those of Table 4, we see that indeed this correction seems to substantially improve the estimates.

One can also consider other choices for the function g_ϵ to reduce the bias. The idea is to use knowledge of the distribution of the design points to select a better suited candidate for this function. This also leads to more precise estimates of the intrinsic dimension. If $X \sim N_d(0, \boldsymbol{I})$, independent of $Y \sim N_d(0, \boldsymbol{I})$ then $Z = X - Y \sim N_d(0, 2\boldsymbol{I})$, so that, if we abbreviate $\mathcal{Z}_\epsilon = \{z \in \mathbb{R}^d : \|z\| \leq \epsilon\}$, then

$$p_{\epsilon,1} = \mathbb{P}(\|X - Y\| \leq \epsilon) = \mathbb{P}(\|Z\| \leq \epsilon) = \frac{1}{(4\pi)^{d/2}} \int_{\mathcal{Z}_\epsilon} e^{-\frac{1}{4}\|z\|^2}\, dz = \frac{v_\epsilon}{(4\pi)^{d/2}} \int_0^1 e^{-\frac{1}{4}u^2\epsilon^2}\, du,$$

where v_ϵ represents the volume of a d-dimensional Euclidean ball of radius ϵ. The integral above can be expressed in terms of the Gauss error function erf, so that

$$p_{\epsilon,1} = (4\pi)^{-d/2} \cdot v_\epsilon \cdot \frac{\sqrt{\pi}}{\epsilon} \cdot \mathrm{erf}(\epsilon/2), \qquad \text{whence} \qquad \frac{p_{2\epsilon,1}}{p_{\epsilon,1}} = 2^d \cdot \frac{\mathrm{erf}(\epsilon)/2}{\mathrm{erf}(\epsilon/2)}.$$

What is arguably the ideal choice for the function g_ϵ is then

$$g_\epsilon(d) = 2^d \cdot \frac{\mathrm{erf}(\epsilon)/2}{\mathrm{erf}(\epsilon/2)}, \qquad \text{leading to} \qquad \bar{d}_n = \hat{d}_n + \frac{\log\{\mathrm{erf}(\epsilon/2)\} - \log\{\mathrm{erf}(\epsilon)/2\}}{\log 2},$$

where $\hat{d}_n$ is the canonical estimator from (8). Note that using the exact function $g_\epsilon(d)$ does not entirely remove the bias of the estimate since $g_\epsilon(d)$ is not linear in d, and since $\hat{p}_{n,2\epsilon,1}/\hat{p}_{n,\epsilon,1}$ is not an unbiased estimator for $p_{2\epsilon,1}/p_{\epsilon,1}$. Note also that the correction factor depends only on ϵ, but not on d. To understand the effect of this new estimator based on the more precise choice of $g_\epsilon(d)$, we repeat the numerical experiment of the previous section now for the estimator $\bar{d}_n$ from the previous display; Table 6 summarises these results. Comparing Tables 4 and 6, it is clear that, as one would expect, a more informed choice for mapping g_ϵ considerably improves the estimates. The improvement provided by this additive correction typically performs somewhat worse than the multiplicative correction, but the difference

		n				
		10^3	10^4	10^5	10^6	10^7

Table 7: This table contains the results of repeating the experiment from the previous section, but we compensate for the bias by adding two standard deviations to the estimate.

seems to be small. This is most likely due to the fact that the multiplicative correction is better at compensating for the bias induced by the bias of our moment estimator of $p_{2\epsilon,1}/p_{\epsilon,1}$.

As a third and final alternative, one can also shift the estimates up by a factor depending on the standard deviations of the estimates. This is motivated by the fact that our choice of $m_n = O\{\log(n)\}$ balances squared bias and variance. (Again, the standard deviation is estimated using the same data as $\hat{d}_n$ without any need from resampling.) Table 7 presents the results of adding (since we otherwise under-estimate) two standard deviations to the corresponding estimate $\hat{d}_n$.

This correction performs well, particularly considering that it requires no extra information about the distribution of the data. Overall this seems to present the best correction for exactly this reason.

Although asymptotically any of the three corrections performs equally well, for finite samples, and with extra knowledge of the distribution of the design points, the multiplicative correction provides the best results. Without extra knowledge though, the variance based

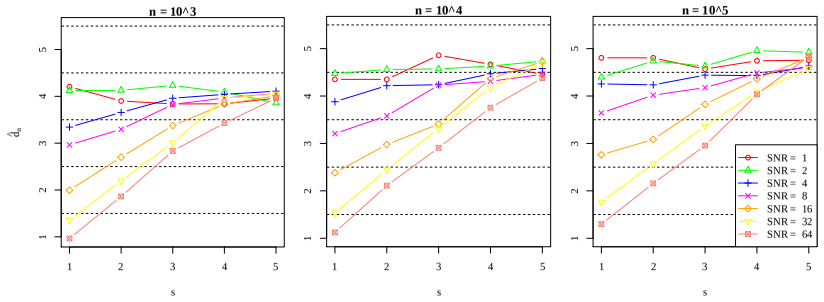

Figure 6: The estimator's sensitivity to noise. Each plot corresponds to a different sample size, from left to right: $n \in \{10^3, 10^4, 10^5\}$. The lines correspond to different estimates of the intrinsic dimension for different values of s, and the different colours correspond to different SNR.

correction still improves the canonical estimate $\hat{d}_n$ considerably. However, this does not change the fact that one will always need a large sample size n when the intrinsic dimension d is large.

7.5 Effect of the Noise

An important aspect to be taken into consideration is the robustness of the estimation procedure to the presence of noise. Irrespectively of the nature of the observations, if they are corrupted with enough noise, the estimation procedure will only detect the noise. In this respect we would like to see how sensitive the estimator is to the presence of noise. To see if this, we sampled design points $\boldsymbol{X}^{(s)}$ in $\mathbb{R}^5$ according to

$$X_i^{(s)} \overset{i.i.d.}{\sim} N_5\Big\{0,\ \mathrm{diag}\big(\overbrace{\sigma^2_{\text{signal}},\ldots,\sigma^2_{\text{signal}}}^{s},\overbrace{\sigma^2_{\text{noise}},\ldots,\sigma^2_{\text{noise}}}^{5-s}\big)\Big\},\quad i=1,\ldots,n,\ s=1,\ldots,5.$$

We set $\epsilon = \epsilon_n = \sigma_{\text{signal}}(2\log n)^{-1/2}$, and ran our estimation procedure on the adjacency matrix obtained from $\boldsymbol{X}^{(s)}$ for $s = 1,\ldots,5$. Each plot in Figure 6 corresponds to a different sample size $n \in \{10^3, 10^4, 10^5\}$. The coloured lines in each plot correspond to the 5 estimates $\hat{d}_n$, averaged over 10 disjoint sets of vertices. Different colours correspond to different signal to noise ratio (SNR); namely, we fixed $\sigma_{\text{signal}} = 1$ and chose σ_{noise} such that SNR $= \sigma^2_{\text{signal}}/\sigma^2_{\text{noise}} \in \{1, 2, 4, 8, 16, 32, 64\}$.

The estimator performs as intended. Consider first the rightmost plot in Figure 6, where n is the largest. When the SNR is 1, the intrinsic dimension is 5; in this case, we detect intrinsic dimension 5 for $s = 1,\ldots,5$, and the corresponding line is roughly the constant function $s \mapsto 5$. When the SNR is high, the mass of the design points is mostly concentrated on an s-dimensional subspace so that the intrinsic dimension is s; the resulting estimates are then close to the identity $s \mapsto s$. Between these extreme cases it is not clear exactly what the intrinsic dimension is. However, the lines corresponding to the estimates behave roughly monotonically. This means that the estimator is correctly picking up on the fact

	n	d	D	Data set	$\tilde{d}_n$

Table 8: Numerical experiments from Section 4.2 of (Kleindessner and von Luxburg, 2015) for different simulated and real data sets. For each data set we indicate the sample size, intrinsic dimension d, and ambient dimension D. The first seven data sets are simulated, while the last five are real. The intrinsic dimension of the real data sets is unknown.

that the mass of the distribution is concentrating on a lower dimensional subspace, and gradually changing to reflect this. For smaller sample sizes, as per the discussion from Section 7.1, the rightmost points in the plot are not reliable estimates.

7.6 Comparison with Other Estimators

We compare our estimator with competing approaches from the literature. To do this we repeat the numerical simulations of Section 4.2 of (Kleindessner and von Luxburg, 2015), which is conceptually close to our estimator. Our results can then be compared directly with the results from their Table 1. Note that we base our estimates on two (symmetric) adjacency matrices $\boldsymbol{A}_\epsilon$ and $\boldsymbol{A}_{2\epsilon}$, while the estimators from (Kleindessner and von Luxburg, 2015) are based on a (directed) k-nearest neighbour graph, so that both approaches require the same number of measurements. We consider twelve data sets; seven consist of simulated data, and five of real data. Table 8 contains the results.

The simulated data sets are self explanatory. The *Isomap faces* data set[4] contains 698 images ($D = 64 \times 64$ pixels) of a rendered face of a sculpture taken from different angles, under different lighting conditions. The *Hands* data set[5] contains 481 frames ($D = 512 \times 480$ pixels) from a video of a hand holding a rice bowl and revolving it while moving from right

4. http://isomap.stanford.edu/datasets.html
5. http://vasc.ri.cmu.edu//idb/html/motion/hand/index.html

to left. The *MNIST* data sets[6] contain 7141, 6824, and 6313 images ($D = 28 \times 28$ pixels) of handwritten digits "3", "4", and "5", respectively.

About the choice of ϵ for the experiments. For every synthetic data set we set $\epsilon = 4/(\log n)^{1/2}$ as before. For the real data sets this turned out to be inappropriate since the observations are on completely different scales. We scaled ϵ up so that the resulting adjacency matrices $\boldsymbol{A}_\epsilon$ and $\boldsymbol{A}_{2\epsilon}$ were neither complete graphs nor empty graphs, since this would lead to trivial estimates. This turn out to give us ϵ equal to 14, 17, 1600, 1600, and 1600, for data sets 8–12, respectively. In practice this can be achieved based on some notion of the scale of the observations, or based on a preliminary analysis, simulated data sets, or subsamples. In all experiments we set $m_n = 2 \log n$.

Our estimator compares quite well with the competing approaches, particularly as far as recuperating the integer dimension is concerned; the results are perhaps closer to the ones obtained by the estimator of (Levina and Bickel, 2004), but contrary to their estimator we do not require any knowledge about how the distance from a given point to its k-nearest-neighbour scales, or any distance data, or for any parameters to be set in the estimator. Also, the computational complexity of our estimator scales like $O(n \log n)$, considerably smaller than the typical $O(n^2)$. Furthermore, the results in each row of Table 8 were obtained from a single data set, without repeated sampling. Because of this we can provide standard deviations for our estimates without a need to resample the data, including for the real data sets. These standard deviations are much more realistic than the ones associated with competing approaches. We suspect that this is because for those it is difficult to properly balance the variance and the squared bias of the estimator, resulting in estimates that are overly concentrated around their biased means.

For the simulated data sets the true dimension is recuperated with good accuracy, with the exception of the sixth and seventh data set where the intrinsic dimension is relatively high. Indeed, as discussed in Section 7.1, in order to recuperate the intrinsic dimension consistently, the sample size should be quite large compared to the intrinsic dimension, since the minimax rates for the problem are logarithmic in n. This also comes from the fact that the support of the data set is rather unstructured, unlike for example data set 2, 4, and 5, or even 10, 11, and 12.

Less can be said about the results for the real data sets since the true intrinsic dimension is unknown. However, our results are comparable to the ones obtained by competing approaches. In particular, in all cases the intrinsic dimension is substantially smaller than the ambient dimension. For the *Isomap faces* data set we estimate the intrinsic dimension as 4; although the statue is 3-dimensional, the different lighting conditions may explain the fact that we detect an extra dimension in the data set. For the *Hands* data set we estimate the dimension as 2.14. One would probably expect the dimension to be 3, but given the symmetries in the hand and bowl, and that the images actually make up a smooth animation may explain the lower estimate. As for the *MNIST* data set, it seems reasonable that the estimates are not too different for the three digits. Also, if one were to parametrise the digits in terms of lengths, relative angles, and curvatures of the line segments, the estimate seems rather natural.

8. Discussion

In this paper we propose a method to estimate the intrinsic dimension of high-dimensional data sets. The approach combines the notion of correlation dimension with the doubling property of the Lebesgue measure to provide a computationally tractable estimator for data sets with (potentially) scale-dependent dimension. The approach does not require any parameters to be chosen, other than the scale at which one would like to estimate the dimension. This is particularly useful for data that live on manifolds whose dimension may be different at different scales, data sets corrupted with noise, or whenever not much is known about the distribution of the data. We compute the estimator's asymptotic distribution and rate of convergence. The rate that we obtain matches the logarithmic minimax rate for the (easier) problem where one has access to the observations – not just whether each pair of observations is close or not – and is therefore optimal. The estimator can be quickly evaluated in $O(n \log n)$ steps which is also an advantage over competing approaches, whose execution time typically scales like $O(n^2)$. Also in terms of storage there are advantages because the adjacency matrix that we base our estimator on will typically be sparse (since the underlying graph is embedded in a Euclidean space). Our results provide important information for algorithms commonly used to perform dimensionality reduction, learn manifolds, compress information, do statistical adaptation, and design efficient algorithms.

Distance-based estimators usually require rather (distribution specific) knowledge since one needs to know quite precisely how distances between perturbed observations scale. These also usually require certain bandwidth parameters to be defined without an automatic, or data driven way of picking them. Rather than assuming that we have access to the observations (or distances between them), we simply assume that we observe a graph encoding whether observations are close or not at the scale we are interested in. This is particularly relevant when dealing with large data sets. Modelling the resulting graph as a random connection model allows us to provide bounds on the probability of recuperating the correct intrinsic dimension of the data set, under a mild identifiability condition.

Our numerical experiments show that the intrinsic dimension can be well recuperated even without access to any distance information between the observations. Furthermore, our estimator properly picks up on the uncertainty of the estimate (the standard deviation of the estimator can be estimated without need for resampling), which can be used to avoid the estimator to be overly concentrated around its biased mean. Distance-based estimators tend to be much more costly, computationally. The estimator is parameter-free, but it can easily be improved by using any knowledge one may have about the distribution of the data. This is done by incorporating this knowledge into the choice of the function g_ϵ that features in the definition of the estimator.

Similar distance-free estimators such as those based on k-nearest-neighbours, seem to somewhat underperform in comparison. Although based on a similar idea, it seems like the number of k-nearest-neighbours to a fixed observations does not scale in a simple way with the dimension, making it more difficult to recuperate the dimension accurately from such kind of information alone. It is also not clear how to control exactly at which scale the dimension is being recuperated by choice of k. This suggests that in data sets with different dimensions at different scales, or data sets corrupted with noise, those estimators may return some form of "average dimension" across scales.

Another point to make is that one can also use our work for estimation of local dimension; cf. (Amsaleg et al., 2015). These are cases where the dimension of the underlying manifold of interest is not equal everywhere, and the space is instead some heterogeneous manifold. Our estimator is based on looking at just m_n vertices in the underlying neighbourhood graph. If we focus on vertices corresponding to the region of the manifold where we would like to estimate the local dimension (rather than picking these m_n vertices arbitrarily), then our estimator promptly delivers an estimate of this local dimension.

Acknowledgments

We would like to thank the Action Editor and the two anonymous Referees for pointing out inconsistencies in the notation of our initial submission, for suggesting references to other closely related work, and for their useful comments and suggestions.

Appendix

In this appendix we collect the proofs to our results.

Proof of Theorem 2: By the symmetry of $\boldsymbol{A}_\epsilon$ it suffices to control the sum

$$\sum_{i=1}^{m_n}\sum_{j=i+1}^{n}\{A_{\epsilon,i,j}-p_{\epsilon,1}\}=\sum_{i=1}^{m_n}\sum_{j=i+1}^{m_n}\{A_{\epsilon,i,j}-p_{\epsilon,1}\}+\sum_{i=1}^{m_n}\sum_{j=m_n+1}^{n}\{A_{\epsilon,i,j}-p_{\epsilon,1}\}=(A)+(B).$$

The proof now proceeds in two different ways: if $m_n = n$ then $(B) = 0$ and use the martingale central limit theorem to show that a properly rescaled version of (A) is asymptotically standard Gaussian[7]; if $m_n = o(n)$ then (B) dominates (A), so we show instead that (B) is asymptotically Gaussian.

Let $m_n = n$. By the symmetry of $\boldsymbol{A}_\epsilon$, and since $A_{\epsilon,i,i} = 0$, (A) can be rewritten as

$$\sum_{i=2}^{n}\left[\sum_{j=1}^{i-1}\{A_{\epsilon,i,j}-p_\epsilon(X_j)\}+(n-i)\{p_\epsilon(X_i)-p_{\epsilon,1}\}\right]+(n-1)\{p_\epsilon(X_1)-p_{\epsilon,1}\}.$$

(Note that we are just adding and subtracting $p_\epsilon(X_j)$ inside the double sum and reordering terms.) Denote the term in square brackets as $\eta_{n,i}$. The two terms in the previous display are uncorrelated; the variance of the second term is $(n-1)^2(p_{\epsilon,2}-p_{\epsilon,1}^2)$. Further, $\eta_{n,i}$ has expectation 0, and is measurable with respect to $\mathcal{F}_{n,i} = \mathcal{F}_i = \sigma(X_1,\ldots,X_i)$. Since $j < i$,

$$\mathbb{E}[\eta_{n,i}\mid\mathcal{F}_{i-1}]=\sum_{j=1}^{i-1}\{\mathbb{E}[A_{\epsilon,i,j}\mid X_j]-p_\epsilon(X_j)\}+(n-i)\{\mathbb{E}p_\epsilon(X_i)-p_{\epsilon,1}\}=0,\quad i=2,\ldots,n,$$

so that $\eta_{n,i}$ is a martingale increment. This means that if we define $S_{n,k}=\sum_{i=2}^{k}\eta_{n,i}$, then $\{S_{n,k},\mathcal{F}_{n,k},2\le k\le n,n\ge 2\}$ is a martingale array.

7. The case where $O(n) \le m_n < n$ is controlled in the same way.

We show that a scaled version of $S_{n,n}$ is asymptotically standard Gaussian, as $n \to \infty$. With the convention that $p_\epsilon(X_i, X_i) = p_\epsilon(X_i)$, by expanding the square and taking conditional expectations term-wise it holds that

$$\begin{aligned}\mathbb{E}\big[\eta_{n,i}^2 \mid \mathcal{F}_{i-1}\big] = &\sum_{j_1=1}^{i-1}\sum_{j_2=1}^{i-1}\big\{p_\epsilon(X_{j_1}, X_{j_2}) - p_\epsilon(X_{j_1})p_\epsilon(X_{j_2})\big\} + \\ &+ 2(n-i)\sum_{j=1}^{i-1}\big\{\mathbb{E}\big[A_{\epsilon,i,j}\, p_\epsilon(X_i) \mid X_j\big] - p_{\epsilon,1}\, p_\epsilon(X_j)\big\} + (n-i)^2(p_{\epsilon,2} - p_{\epsilon,1}^2),\end{aligned} \tag{14}$$

where we use the definitions of $p_\epsilon(X)$ and $p_\epsilon(X, Y)$, the fact that $p_\epsilon(X_j) \in \mathcal{F}_{n,i-1}$, for $j \le i-1$, and that X_i – or indeed $p_\epsilon(X_i)$ – is independent of $\mathcal{F}_{n,i-1}$, $i = 2, \dots, n$.

The expectation of $\eta_{n,i}^2$ is obtained by taking expectation of the previous display and noting that for any $j_1, j_2, j \ne i$,

$$\begin{aligned}\mathbb{E}\big\{p_\epsilon(X_{j_1}, X_{j_2}) - p_\epsilon(X_{j_1})p_\epsilon(X_{j_2})\big\} &= \{p_{\epsilon,1} - \mathbb{V}P_\epsilon(X)\}\, 1_{\{j_1=j_2\}} + p_{\epsilon,2} 1_{\{j_1\ne j_2\}} - p_{\epsilon,1}^2, \\ \mathbb{E}\big\{\mathbb{E}\big[A_{\epsilon,i,j}\, p_\epsilon(X_i) \mid X_j\big] - p_{\epsilon,1}\, p_\epsilon(X_j)\big\} &= p_{\epsilon,2} - p_{\epsilon,1}^2.\end{aligned}$$

Note that $\sum_{i=2}^n (i-1)$ is $n^2\{1/2 + o(1)\}$, and the sums $\sum_{i=2}^n (n-i)^2$, $2\sum_{i=2}^n (n-i)(i-1)$, and $\sum_{i=2}^n (i-1)(i-2)$ are all $n^3\{1/3 + o(1)\}$. We assume[8] that $p_{\epsilon,1} - p_{\epsilon,2} = o\{n(p_{\epsilon,2} - p_{\epsilon,1}^2)\}$, as $n \to \infty$ so that the variance of $S_{n,n}$ becomes

$$\mathbb{V}S_{n,n} = \sum_{i=2}^n \mathbb{E}\eta_{n,i}^2 = \left\{\frac{n^2}{2}(p_{\epsilon,1} - p_{\epsilon,1}^2) + n^3(p_{\epsilon,2} - p_{\epsilon,1}^2)\right\}\{1 + o(1)\} = n^3(p_{\epsilon,2} - p_{\epsilon,1}^2)\{1 + o(1)\}.$$

We therefore define $Z_{n,i} = S_{n,i}/\{\mathbb{V}S_{n,n}\}^{1/2}$, with increments $\xi_{n,i} = \eta_{n,i}/\{\mathbb{V}S_{n,n}\}^{1/2}$.

Based on the preceding, $\{Z_{n,i}, \mathcal{F}_{n,i}, 2 \le i \le n, n \ge 2\}$ is a (zero-mean, unit variance) martingale array. Since $\mathcal{F}_{n,i} = \mathcal{F}_i$, the σ-fields satisfy $\mathcal{F}_{n,i} \subseteq \mathcal{F}_{n+1,i}$, $2 \le i \le n$, $n \ge 2$, so that they are nested. We check the conditions of Corollary 3.1 of (Hall and Heyde, 2014):

$$\sum_{i=2}^n \mathbb{E}\big[\xi_{n,i}^2 \mathbf{1}_{\{|\xi_{n,i}| > \delta\}} \mid \mathcal{F}_{i-1}\big] \xrightarrow{P} 0, \quad \delta > 0, \qquad \text{and} \qquad \sum_{i=2}^n \mathbb{E}\big[\xi_{n,i}^2 \mid \mathcal{F}_{i-1}\big] \xrightarrow{P} 1. \tag{15}$$

To check the first condition we use $\mathbb{E}\big[|Z|^2 \mathbf{1}_{\{|Z|>\delta\}}\big] \le \mathbb{E}Z^4/\delta^2$ (by the Cauchy-Schwarz inequality, and Markov's inequality), and $(a+b)^4 \le 2^3(a^4 + b^4)$, $a, b \in \mathbb{R}$ (by Young's inequality). Therefore, checking (15) reduces to showing that as $n \to \infty$,

$$\sum_{i=2}^n \frac{\mathbb{E}\big[\big(\sum_{j=1}^{i-1}\{A_{\epsilon,i,j} - p_\epsilon(X_j)\}\big)^4 \mid \mathcal{F}_{i-1}\big]}{n^6(p_{\epsilon,2} - p_{\epsilon,1}^2)^2} \xrightarrow{P} 0, \qquad \sum_{i=2}^n \frac{(n-i)^4 \mathbb{E}\big[\big(p_\epsilon(X_i) - p_{\epsilon,1}\big)^4\big]}{n^6(p_{\epsilon,2} - p_{\epsilon,1}^2)^2} \longrightarrow 0.$$

If ϵ is fixed, then $p_{\epsilon,1}$ and $p_{\epsilon,2}$ are fixed, the numerators are of order n^5 and the conditions are met. Assume therefore that $\epsilon \to 0$ so that $p_\epsilon(x) \to 0$. Since the summands are positive, both conditions follow if we assume that $n(p_{\epsilon,2} - p_{\epsilon,1}^2)^2 \to \infty$.

8. This assumption is weaker than the assumption $n(p_{\epsilon,2} - p_{\epsilon,1}^2)^2 \to \infty$ which will be imposed later.

To show the second condition in (15) holds, it suffices to show that the sum over $i = 2, \dots, n$ of each of the three terms in (14) divided by $n^3(p_{\epsilon,2} - p_{\epsilon,1}^2)$ converges to 1/3, in probability; this is obvious for the third term, for the second term it follows easily from Chebyshev's inequality (since the terms in the sum are independent), so that only the convergence of the first term requires justification.

By Chebyshev's inequality and symmetry, it suffices to show that

$$\frac{\mathbb{E}\left(\sum_{i=2}^n \sum_{j_1=1}^{i-1}\sum_{j_2=1}^{i-1}\{p_\epsilon(X_{j_1}, X_{j_2}) - p_\epsilon(X_{j_1})p_\epsilon(X_{j_2}) - (p_{\epsilon,2} - p_{\epsilon,1}^2)\}\right)^2}{n^6(p_{\epsilon,2} - p_{\epsilon,1}^2)^2}$$

converges to zero. By Jensen's inequality, we can upper bound the previous display by

$$(n-1)\sum_{i=2}^n \frac{\mathbb{E}\left(\sum_{j_1=1}^{i-1}\sum_{j_2=1}^{i-1}\{p_\epsilon(X_{j_1}, X_{j_2}) - p_\epsilon(X_{j_1})p_\epsilon(X_{j_2}) - (p_{\epsilon,2} - p_{\epsilon,1}^2)\}\right)^2}{n^6(p_{\epsilon,2} - p_{\epsilon,1}^2)^2} \lesssim \frac{1}{n(p_{\epsilon,2} - p_{\epsilon,1}^2)^2}.$$

The last equality follows from the fact that of the $(i-1)^4$ involved in the square above, $(i-1)^2(i-3)^2$ of them have zero mean; the remaining terms are $O(i^3)$. The previous display is $o(1)$ since we assume $n(p_{\epsilon,2} - p_{\epsilon,1}^2)^2 \to \infty$.

To complete the proof, we consider the case $m_n = o(n)$. Adding and subtracting $p_\epsilon(X_i)$ inside the double sum, and then interchanging the two summations we can rewrite (B) as

$$\sum_{j=m_n+1}^n \left[\sum_{i=1}^{m_n}\big\{A_{\epsilon,i,j} - p_\epsilon(X_i)\big\}\right] + (n - m_n)\sum_{i=1}^{m_n}\big\{p_\epsilon(X_i) - p_{\epsilon,1}\big\} = (C) + (D).$$

Since the terms in (D) are independent, it is easy to see that the variance of (D) is $m_n(n - m_n)^2(p_{\epsilon,2} - p_{\epsilon,1}^2)$, so that it dominates the terms in (A), and is asymptotically Gaussian. It remains to show that the variance of (C) is dominated by that of (D).

Define the sum in square brackets in the previous display as ζ_j. These terms are uncorrelated: for indices $j_1 \ne j_2$, with $j_1, j_2 > i_1, i_2$,

$$\begin{aligned}\mathbb{E}\zeta_{j_1}\zeta_{j_2} = &\sum_{i=1}^{m_n}\mathbb{E}\big\{A_{\epsilon,i,j_1} - p(X_i)\big\}\big\{A_{\epsilon,i,j_2} - p(X_i)\big\} \\ &+ \sum_{i_1=1}^{m_n}\sum_{\substack{i_2=1 \\ i_2\ne i_1}}^{m_n}\mathbb{E}\big\{A_{\epsilon,i_1,j_1} - p_\epsilon(X_{i_1})\big\}\big\{A_{\epsilon,i_2,j_2} - p_\epsilon(X_{i_2})\big\},\end{aligned}$$

which is zero. From this we conclude that the variance of (C) is $O\{nm_n^2(p_{\epsilon,2} - p_{\epsilon,1}^2)\}$, and is therefore dominated by that of (D). This concludes the proof.

Proof of Theorem 3: We apply the delta method. For this we need to know the joint distribution of $\{\hat{p}_{n,\epsilon,1}, \hat{p}_{n,2\epsilon,1}\}$. This is established using the Cramér-Wold device by showing that for each $\alpha, \beta \in \mathbb{R}$, $\alpha\,\hat{p}_{n,\epsilon,1} + \beta\,\hat{p}_{n,2\epsilon,1}$ is asymptotically Gaussian. As in the proof of Theorem 2 we control

$$\sum_{i=1}^{m_n}\sum_{j=i+1}^n \big\{\alpha A_{\epsilon,i,j} + \beta A_{2\epsilon,i,j} - \alpha p_{\epsilon,1} - \beta p_{2\epsilon,1}\big\} = \sum_{i=1}^{m_n}\sum_{j=i+1}^n \big\{A_{\epsilon,i,j}^* - p_{\epsilon,1}^*\big\}.$$

Since $A^*_{\epsilon,i,j}$ is measurable with respect to X_i and X_j, and bounded, and since the previous display has mean zero, we can follow exactly the same steps as in Theorem 2 to show that the previous display is asymptotically Gaussian.

To fully specify the asymptotic distribution of $\{\hat{p}_{n,\epsilon,1}, \hat{p}_{n,2\epsilon,1}\}$ it remains to compute the covariance of the estimates $\hat{p}_{n,\epsilon,1}$ and $\hat{p}_{n,2\epsilon,1}$. Define $p_{\epsilon_1,\epsilon_2,2} = \mathbb{P}\{r(X,Z) \leq \epsilon_1, r(Z,Y) \leq \epsilon_2\}$, and assume that $p_{\epsilon,1} - p_{\epsilon,1} \cdot p_{2\epsilon,1} = o\big[n\{p_{\epsilon,2\epsilon,2} - p_{\epsilon,1} \cdot p_{2\epsilon,1}\}\big]$. Simple computations then give

$$\mathbb{V}\big\{\hat{p}_{n,\epsilon,1},\, \hat{p}_{n,2\epsilon,1}\big\} = \frac{(n+3m_n)\{p_{\epsilon,2\epsilon,2} - p_{\epsilon,1}p_{2\epsilon,1}\}}{n \cdot m_n}\{1 + o(1)\}.$$

Write $A_\epsilon = p_{\epsilon,2} - p_{\epsilon,1}^2$, $B_\epsilon = p_{2\epsilon,2} - p_{2\epsilon,1}^2$, and $C_\epsilon = (n+3m_n)\{p_{\epsilon,2\epsilon,2} - p_{\epsilon,1} \cdot p_{2\epsilon,1}\}/n$. Conclude that under the assumptions of Theorem 2 (verified also with ϵ replaced with 2ϵ),w

$$m_n^{1/2}\left\{\begin{bmatrix}\hat{p}_{n,\epsilon,1}\\ \hat{p}_{n,2\epsilon,1}\end{bmatrix} - \begin{bmatrix}p_{\epsilon,1}\\ p_{2\epsilon,1}\end{bmatrix}\right\} \xrightarrow{d} N\left\{\begin{bmatrix}0\\0\end{bmatrix}, \begin{bmatrix}A_\epsilon & C_\epsilon\\ C_\epsilon & B_\epsilon\end{bmatrix}\right\}.$$

In the general case of the implicit estimates in (7), consider $d \mapsto g_\epsilon(d)$; let g_ϵ^{-1} represent the inverse of g_ϵ (which exists, at least in a neighbourhood of d). The asymptotic distribution of the estimator $\hat{d}_n$ is obtained by applying the delta method to the previous display using the function $(\alpha,\beta) \mapsto g_\epsilon^{-1}(\beta/\alpha)$, whose gradient is $\{\partial \log g_\epsilon(d)/\partial d\}^{-1}[-1/\alpha, 1/\beta]^T$. This delivers the asymptotic distribution of

$$g_\epsilon^{-1}(\hat{p}_{n,\epsilon,1}/\hat{p}_{n,2\epsilon,1}) - g_\epsilon^{-1}(p_{\epsilon,1}/p_{2\epsilon,1}) = \hat{d}_n - d + d - g_\epsilon^{-1}(p_{\epsilon,1}/p_{2\epsilon,1}) = \hat{d}_n - d + o(m_n^{-1/2}),$$

where the last equality follows from the bias condition (B). We conclude that

$$m_n^{1/2}\left\{\hat{d}_n - d\right\} \xrightarrow{d} N\left\{0,\, \left\{\frac{\partial \log g_\epsilon(d)}{\partial d}\right\}^{-2}\left[\frac{A_\epsilon}{p_{\epsilon,1}^2} + \frac{B_\epsilon}{p_{2\epsilon,1}^2} - \frac{2C_\epsilon}{p_{\epsilon,1}\, p_{2\epsilon,1}}\right]\right\}.$$

Replacing A_ϵ, B_ϵ, and C_ϵ, the component of the variance in square brackets is

$$6\frac{m_n}{n} + \frac{p_{\epsilon,1}^2 p_{2\epsilon,2} + p_{2\epsilon,1}^2 p_{\epsilon,2}}{p_{\epsilon,1}^2 p_{2\epsilon,1}^2} - 2\left(1 + 3\frac{m_n}{n}\right)\frac{p_{\epsilon,2\epsilon,2}}{p_{\epsilon,1}p_{2\epsilon,1}}. \tag{16}$$

For the explicit estimator from (8), the delta method is used with the function $(\alpha,\beta) \mapsto \log(\beta/\alpha)/\log(2) = g_\epsilon^{-1}(\beta/\alpha)$, such that the scaling in the variance becomes $\log(2)^{-2}$.

Abstract

In this work, we address the problem of solving a series of underdetermined linear inverse problemblems subject to a sparsity constraint. We generalize the spike-and-slab prior distribution to encode a priori correlation of the support of the solution in both space and time by imposing a transformed Gaussian process on the spike-and-slab probabilities. An expectation propagation (EP) algorithm for posterior inference under the proposed model is derived. For large scale problems, the standard EP algorithm can be prohibitively slow. We therefore introduce three different approximation schemes to reduce the computational complexity. Finally, we demonstrate the proposed model using numerical experiments based on both synthetic and real data sets.

Keywords: Linear inverse problems, bayesian inference, expectation propagation, sparsity-promoting priors, spike-and-slab priors

1. Introduction

Many problems of practical interest in machine learning involve a high dimensional feature space and a relatively small number of observations. Inference is in general difficult for such underdetermined problems due to high variance and therefore regularization is often the key to extracting meaningful information from such problems (Tibshirani, 1994). The classical approach is Tikhonov regularization (also known as ℓ_2 regularization), but during the last few decades sparsity has been an increasingly popular choice of regularization for many problems, giving rise to methods such as the LASSO (Tibshirani, 1994), Sparse Bayesian Learning (Tipping, 2001) and sparsity promoting priors (Mitchell and Beauchamp, 1988).

In this work, we address the problem of finding sparse solutions to linear inverse problems of the form

$$\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x} + \boldsymbol{e}, \tag{1}$$

where $\boldsymbol{x} \in \mathbb{R}^D$ is the desired solution, $\boldsymbol{y} \in \mathbb{R}^N$ is an observed measurement vector, $\boldsymbol{A} \in \mathbb{R}^{N\times D}$ is a known forward model and $\boldsymbol{e} \in \mathbb{R}^N$ is additive measurement noise. We are mainly interested in the underdetermined regime, where the number of observations is smaller than the number of unknowns, that is $N < D$. In the sparse recovery literature, it has been shown that the sparsity constraint is crucial for recovering $\boldsymbol{x}$ from a small set of linear measurements (Candès et al., 2006). Furthermore, the ratio between the number non-zero coefficients $K = \|\boldsymbol{x}\|_0$ and the dimension D dictates the required number of measurements N for robust reconstruction of $\boldsymbol{x}$ and this relationship has given rise to so-called *phase transition curves* (Donoho and Tanner, 2010). A large body of research has been dedicated to improve these phase transition curves and these endeavors have lead to the concepts of *multiple measurement vectors* (Cotter et al., 2005) and *structured sparsity* (Huang et al., 2009).

The multiple measurement vector problem (MMV) is a natural extension of eq. (1), where multiple measurements $\boldsymbol{y}_1, \boldsymbol{y}_2, \ldots, \boldsymbol{y}_T$ are observed and assumed to be generated from a series of signals $\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_T$, which share a common sparsity pattern. In matrix notation, we can write the problem as

$$\boldsymbol{Y} = \boldsymbol{A}\boldsymbol{X} + \boldsymbol{E}, \tag{2}$$

where the desired solution is now a matrix $\boldsymbol{X} = \begin{bmatrix}\boldsymbol{x}_1 & \boldsymbol{x}_2 & \ldots & \boldsymbol{x}_T\end{bmatrix} \in \mathbb{R}^{D\times T}$ and similarly for the measurement matrix $\boldsymbol{Y} \in \mathbb{R}^{N\times T}$ and the noise term $\boldsymbol{E} \in \mathbb{R}^{N\times T}$. The assumption of *joint sparsity* allows one to recover $\boldsymbol{X}$ with significantly fewer observations compared to solving each of the T inverse problems in eq. (1) separately (Cotter et al., 2005). The MMV approach has also been generalized to problems, where the sparsity pattern is evolving slowly in time (Ziniel and Schniter, 2013a). Structured sparsity, on the other hand, is a generalization of simple sparsity and seeks to exploit the fact that the sparsity patterns of many natural signals contain a richer structure than simple sparsity, for example, *group sparsity* (Jacob et al., 2009b) or *cluster structured sparsity* (Yu et al., 2012).

In this paper, we combine these two approaches and focus on problems, where the sparsity pattern of $\boldsymbol{X}$ exhibits a spatio-temporal structure. In particular, we assume that the row and column indices of $\boldsymbol{X}$ can be associated with a set of spatial and temporal coordinates, respectively. This can equivalently be interpreted as a sparse linear regression problem, where the support of the regressors is correlated in both space and time. Applications of such a model include dynamic compressed sensing (Ziniel and Schniter, 2013a), background subtraction in computer vision (Cevher et al., 2009) and EEG source localization problem (Baillet et al., 2001).

We take a Bayesian approach to modeling this structure since it provides a natural way of incorporating such prior knowledge in a model. In particular, we propose a hierarchical probabilistic model for $\boldsymbol{X}$ based on the so-called spike-and-slab prior (Mitchell and Beauchamp,

1988). We introduce a smooth latent variable controlling the spatio-temporal structure of the support of $\boldsymbol{X}$ by extending the work by Andersen et al. (2014). We aim for full Bayesian inference under the proposed probabilistic model, but inference w.r.t. the exact posterior distribution of interest is intractable. Instead we resort to approximate inference using Expectation Propagation (Minka, 2001; Opper and Winther, 2000), which has been shown to provide accurate inference for spike-and-slab priors (Hernández-Lobato et al., 2013; Hernandez-Lobato et al., 2010; Jylänki et al., 2014; Peltola et al., 2014). Our model formulation is generic and generalizes easily to other types of observations. In particular, we also combine the proposed prior with a probit observation model to model binary observations in a sparse linear classification setting.

The contribution of this paper is three-fold. First we extend the structured spike-and-slab prior and the associated EP inference scheme to incorporate both spatial and temporal smoothness of the support. However, the computational complexity of the resulting EP algorithm is prohibitively slow for problems of even moderate sizes of signal dimension D and length T. To alleviate the computational bottleneck of the EP algorithm we propose three different approximation schemes. Finally, we discuss several approaches for learning the hyperparameters and evaluate them based on synthetic and real data sets.

1.1 Related Work

In this section, we briefly review some of the most common approaches to simple sparsity and their generalization to structured sparsity. The classical approach to sparsity is the LASSO (Tibshirani, 1994), which operates by optimizing a least squares cost function augmented with an ℓ_1 penalty on the regression weights. Several extensions have been proposed in the literature to generalize the LASSO to the structured sparsity setting, examples include group and graph LASSO (Jacob et al., 2009b). From a probabilistic perspective sparsity can be encouraged through the use of *sparsity-promoting priors*. A non-exhaustive list of sparsity-promoting priors includes the Laplace prior (Park and Casella, 2008), Automatic Relevance Determination prior (Neal, 1996), the horseshoe prior (Carvalho et al., 2009) and the spike-and-slab prior (Mitchell and Beauchamp, 1988). All of these were originally designed to enforce simply sparsity, but they have all been generalized to the structured sparsity setting. The general strategy is to extend univariate densities to correlated multivariate densities by augmenting the models with a latent multivariate variable, where the correlation structure can be controlled explicitly, for example, using Markov Random Fields (Cevher et al., 2009; Hernandez-Lobato et al., 2011) or multivariate Gaussian distributions (Engelhardt and Adams, 2014). Here we limit ourselves to consider the latter.

From a probabilistic perspective, optimizing with an ℓ_1 regularization term can be interpreted as maximum a posteriori (MAP) inference under an i.i.d. Laplace prior distribution on the regression weights (Park and Casella, 2008). The univariate Laplace prior has been generalized to the multivariate Laplace (MVL) distribution, which couples the prior variance of the regression weights through a scale mixture formulation (Gerven et al., 2009).

Another approach is Automatic Relevance Determination (ARD) (Neal, 1996), which works

by imposing independent zero mean Gaussian priors with individual precision parameters on the regression weights. These precision parameters are then optimized using a maximum likelihood type II and the idea is then that the precision parameters of irrelevant features will approach infinity and thereby forcing the weights of the irrelevant features to zero. Wu et al. (2014b) extend the ARD framework to promote spatial sparsity by introducing a latent multivariate Gaussian distribution to impose spatial structure onto the precision parameters of ARD giving rise to *dependent relevance determination priors*.

The horseshoe prior is defined as a scale mixture of Gaussians, where a half-Cauchy distribution is used as prior for the standard deviation of the Gaussian density (Carvalho et al., 2009). The resulting density has two very appealing properties for promoting sparsity, namely heavy tails and an infinitely large spike at zero. A generalization to the multivariate case has been proposed by Hernández-Lobato and Hernández-Lobato (2013).

The spike-and-slab prior is an increasingly popular choice of sparsity promoting prior and is given by a binary mixture of two components: a Dirac delta distribution (spike) at zero and Gaussian distribution (slab) (Mitchell and Beauchamp, 1988; Carbonetto and Stephens, 2012). The spike-and-slab prior has been generalized to the group setting by Hernández-Lobato et al. (2013), to clustered sparsity setting by Yu et al. (2012) and spatial structures by Andersen et al. (2014), Nathoo et al. (2014), and Engelhardt and Adams (2014). Nathoo et al. (2014) induce the spatial structure using basis functions and Andersen et al. (2014) impose the structure using a multivariate Gaussian density. The latter is the starting point of this work.

Our work is closely related to the work on the multivariate Laplace prior (MVL) (Gerven et al., 2009) as mentioned above and the work on the network-based sparse Bayesian classification algorithm (NBSBC) (Hernandez-Lobato et al., 2011). The former also uses EP for approximating the posterior distribution of a Gaussian linear model with the MVL prior, where the structure of the support is encoded into the model using a sparse precision matrix. The NBSBC method also uses EP to approximate the posterior distribution of linear model with coupled spike-and-slab priors, but the structure of the support is encoded in a network using a Markov Random Field (MRF) prior. In contrast, we can inject a priori knowledge of the structure into the model using generic covariance functions rather than clique potentials as in the MRF-based models, which makes it easier to interpret interesting quantities like the characteristic lengthscale etc.

1.2 Structure of Paper

This paper is organized as follows. In Section 2 we review the structured spike-and-slab prior and in Section 3 we discuss different ways of extending the model to include the temporal structure as well. After introducing the models we propose an algorithm for approximate inference based on the expectation propagation (EP) framework. We review the basics of EP and describe the proposed algorithm in Section 4. In Section 5 we introduce three simple approximation schemes to speed of the inference process and discuss their properties.

Finally, in Section 7 we demonstrate the proposed method using synthetic and real data sets.

1.3 Notation

We use bold uppercase letters to denote matrices and bold lowercase letters to denote vectors. Unless stated otherwise, all vectors are column vectors. Furthermore, we use the notation $\boldsymbol{a}_{n,\cdot} \in \mathbb{R}^{1\times D}$ and $\boldsymbol{a}_{\cdot,i} \in \mathbb{R}^{N\times 1}$ for the n'th row and i'th column in the matrix $\boldsymbol{A} \in \mathbb{R}^{N\times D}$, respectively. $[K]$ denotes the set of integers from 1 to K, that is $[K] = \{1, 2, .., K\}$. We use the notation $\boldsymbol{a} \circ \boldsymbol{b}$ to denote the element-wise Hadamard product of $\boldsymbol{a}$ and $\boldsymbol{b}$ and $\boldsymbol{A} \otimes \boldsymbol{B} \in \mathbb{R}^{MN\times MN}$ for the Kronecker product of matrices $\boldsymbol{A} \in \mathbf{R}^{M\times M}$ and $\boldsymbol{B} \in \mathbf{R}^{N\times N}$. We use $\mathcal{N}(\boldsymbol{x}|\boldsymbol{m}, \boldsymbol{V})$ to denote a multivariate Gaussian density over $\boldsymbol{x}$ with mean vector $\boldsymbol{m}$ and covariance matrix $\boldsymbol{V}$ and $\mathrm{Ber}(z|p)$ denotes a Bernoulli distribution on z with probability of $p(z = 1) = p$.

2. The Structured Spike-and-Slab Prior

The purpose of this section is to describe the *structured spike-and-slab prior* (Andersen et al., 2014), but first we briefly review the conventional spike-and-slab prior (Mitchell and Beauchamp, 1988). For $\boldsymbol{x} \in \mathbb{R}^D$, the spike-and-slab prior distribution is given by

$$p(\boldsymbol{x}|p_0, \rho_0, \tau_0) = \prod_{i=1}^{D} \left[(1 - p_0)\delta(x_i) + p_0\mathcal{N}(x_i|\rho_0, \tau_0)\right], \tag{3}$$

where $\delta(x)$ is the Dirac delta function and p_0, ρ_0 and τ_0 are hyperparameters. In particular, p_0 is the prior probability of a given variable being active, that is $p(x_i \neq 0) = p_0$, and ρ_0, τ_0 are the prior mean and variance, respectively, of the active variables. The spike-and-slab prior in eq. (3) is also known as the Bernoulli-Gaussian prior since the prior can decomposed as

$$p(\boldsymbol{x}|p_0, \rho_0, \tau_0) = \sum_{\boldsymbol{z}} \prod_{i=1}^{D} \left[(1 - z_i)\delta(x_i) + z_i\mathcal{N}(x_i|\rho_0, \tau_0)\right] \prod_{i=1}^{D} \mathrm{Ber}(z_i|p_0), \tag{4}$$

where the sum is over all the binary variables z_i for $i \in [D]$. Thus, the latent binary variable $z_i \in \{0, 1\}$ can interpreted as an indicator variable for the event $x_i \neq 0$. We will refer to $\boldsymbol{z}$ as the *sparsity pattern* or the *support* of $\boldsymbol{x}$. In eq. (3) and (4) we condition explicitly on the hyperparameters p_0, ρ_0, τ_0, but to ease the notation we will omit this in the remainder of this paper.

The variables x_i and x_j are assumed to be independent for $i \neq j$ as seen in eq. (3) and (4). This implies that the number of active variables follows a binomial distribution and hence, the marginal probability of x_i and x_j being jointly active, is given by $p(x_i \neq 0, x_j \neq 0) = p_0^2$ for all $i \neq j$. However, in many applications the variables $\{x_k\}_{k=1}^D$ might a priori have an underlying topographic relationship such as a spatial or temporal structure. Without loss of generality we will assume a spatial relationship, where $\boldsymbol{d}_i$ denotes the spatial coordinates of x_i. For such models, it is often a reasonable assumption that $p(x_i \neq 0, x_j \neq 0)$ should

depend on $\|\boldsymbol{d}_i - \boldsymbol{d}_j\|$. For instance, neighboring voxels in functional magnetic resonance imaging (fMRI) analysis (Penny et al., 2005) are often more likely to be active simultaneously compared to two voxels far apart. Such a priori knowledge is neglected by the conventional spike-and-slab prior in eq. (3).

The structured spike-and-slab model is capable of modeling such structure and is given in terms of a hierarchical model

$$p(\boldsymbol{x}|\boldsymbol{z}) = \prod_{i=1}^{D} \left[(1 - z_i)\,\delta(x_i) + z_i\mathcal{N}\left(x_i\middle|\rho_0, \tau_0\right)\right], \tag{5}$$

$$p(\boldsymbol{z}|\boldsymbol{\gamma}) = \prod_{i=1}^{D} \mathrm{Ber}\left(z_i\middle|\phi(\gamma_i)\right), \qquad \phi : \mathbb{R} \to (0, 1), \tag{6}$$

$$p(\boldsymbol{\gamma}) = \mathcal{N}\left(\boldsymbol{\gamma}\middle|\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_0\right), \tag{7}$$

where $\boldsymbol{\gamma}$ is a latent variable controlling the structure of the sparsity pattern. Using this model prior knowledge of the structure of the sparsity pattern can be encoded using $\boldsymbol{\mu}_0$ and $\boldsymbol{\Sigma}_0$. The mean value $\boldsymbol{\mu}_0$ controls the expected degree of sparsity and the covariance matrix $\boldsymbol{\Sigma}_0$ determines the prior correlation of the support. The map $\phi : \mathbb{R} \to (0, 1)$ serves the purpose of squeezing γ_i into the unit interval and thereby $\phi(\gamma_i)$ represents the probability of $z_i = 1$. Here we choose ϕ to be the standard normal cumulative distribution function (CDF), but other choices, such as the logistic function, are also possible.

Using this formulation, the marginal prior probability of the i'th variable being active is given by

$$p(z_i = 1) = \int p(z_i = 1|\gamma_i)p(\gamma_i)\mathrm{d}\gamma_i = \int \phi(\gamma_i)\mathcal{N}\left(\gamma_i\middle|\mu_i, \Sigma_{0,ii}\right)\mathrm{d}\gamma_i = \phi\left(\frac{\mu_i}{\sqrt{1 + \Sigma_{0,ii}}}\right). \tag{8}$$

From this expression it is seen that when $\mu_i = 0$, the prior belief of z_i is unbiased and $p(z_i = 1) = 0.5$, but when $\mu_i < 0$ the variable z_i is biased toward zero and vice versa. If a subset of features $\{x_j|j \in \mathcal{J} \subset [D]\}$ is a priori more likely to explain the observed data $\boldsymbol{y}$, then this information can be encoded in the prior distribution by assigning the prior mean of $\boldsymbol{\gamma}$ such that $\mu_j > \mu_i$ for all $j \in \mathcal{J}$ and for all $i \notin \mathcal{J}$. However, in the remainder of this paper we will assume that the prior mean is constant, that is $\mu_i = \nu_0$ for some $\nu_0 \in \mathbb{R}$. For more details on the prior distribution, see Appendix D.

The prior probability of two variables, x_i and x_j, being jointly active is

$$p(z_i = 1, z_j = 1) = \int \phi(\gamma_i)\phi(\gamma_j)\,\mathcal{N}\left(\boldsymbol{\gamma}\middle|\boldsymbol{\mu}, \boldsymbol{\Sigma}_0\right)\mathrm{d}\boldsymbol{\gamma}. \tag{9}$$

If $\boldsymbol{\Sigma}_0$ is a diagonal matrix, γ_i and γ_j become independent and we recover the conventional spike-and-slab prior. On the other hand, if we choose $\boldsymbol{\Sigma}_0$ to be a covariance matrix of the form $\Sigma_{0,ij} = g(\|\boldsymbol{d}_i - \boldsymbol{d}_j\|)$, we see that the joint activation probabilities indeed depend on the spatial distance as desired. Finally, we emphasize that this parametrization it not limited to nearest neighbors-type structures. In fact, this parametrization supports general structures that can be modeled using generic covariance functions.

3. The Spatio-temporal Spike-and-Slab Prior

In the following we will extend the structured spike-and-slab prior distribution to model temporal smoothness of the sparsity pattern as well. Let $t \in [T]$ be the time index, then $\boldsymbol{x}_t$, $\boldsymbol{z}_t$ and $\boldsymbol{\gamma}_t$ are the signal coefficients, the sparsity patterns and the latent structure variable at time t. Furthermore, we define the corresponding matrix quantities $\boldsymbol{X} = \begin{bmatrix}\boldsymbol{x}_1 & \boldsymbol{x}_2 & \boldsymbol{x}_T\end{bmatrix}$, $\boldsymbol{Z} = \begin{bmatrix}\boldsymbol{z}_1 & \boldsymbol{z}_2 & \boldsymbol{z}_T\end{bmatrix}$ and $\boldsymbol{\Gamma} = \begin{bmatrix}\boldsymbol{\gamma}_1 & \boldsymbol{\gamma}_2 & \dots & \boldsymbol{\gamma}_T\end{bmatrix}$.

There are several natural temporal extensions of the model. The simplest extension is to assume that $\{\boldsymbol{\gamma}_t\}_{t=1}^T$ is independent in time, so that $p(\boldsymbol{Z}, \boldsymbol{\Gamma}) = \prod_{t=1}^T p(\boldsymbol{z}_t|\boldsymbol{\gamma}_t) \prod_{t=1}^T p(\boldsymbol{\gamma}_t)$, which is equivalent to solving each of the T regressions problems in eq. (1) independently. Another simple extension is to use the so-called *joint sparsity* assumption (Cotter et al., 2005; Zhang and Rao, 2011; Ziniel and Schniter, 2013b) and assume that the sparsity pattern is static across time, and thus all $\{\boldsymbol{x}_t\}_{t=1}^T$ vectors share a common binary support vector $\boldsymbol{z}$, and $p(\boldsymbol{X}|\boldsymbol{z}) = \prod_{t=1}^T \prod_{i=1}^D \left[(1-z_i)\,\delta\left(x_{i,t}\right) + z_i \mathcal{N}\left(x_{i,t}|\rho_0, \tau_0\right)\right]$. A more interesting and flexible model is to assume that the support is slowly changing in time, by modelling the temporal evolution of $\boldsymbol{\gamma}_t$ using a first order Gauss-Markov process of the form $p\left(\boldsymbol{\gamma}_t|\boldsymbol{\gamma}_{t-1}\right) = \mathcal{N}\left(\boldsymbol{\gamma}_t|\,(1-\alpha)\,\boldsymbol{\mu}_0 + \alpha\boldsymbol{\gamma}_{t-1}, \beta\boldsymbol{\Sigma}_0\right)$, where the hyperparameters $\alpha \in [0,1]$ and $\beta > 0$ control the temporal correlation and the "innovation" of the process, respectively.

The first order model has the advantage that it factorizes across time, which makes the resulting inference problem much easier. On the other hand, first order Markovian dynamics is often not sufficient for capturing long range correlations. Imposing a Gaussian process distribution on $\boldsymbol{\Gamma}$ with arbitrary covariance structure would facilitate modeling of long range correlations in both time and space. Therefore, the hierarchical prior distribution for $\boldsymbol{X}$ becomes

$$p(\boldsymbol{X}|\boldsymbol{Z}) = \prod_{t=1}^T \prod_{i=1}^D \left[(1-z_{i,t})\,\delta\left(x_{i,t}\right) + z_{i,t}\mathcal{N}\left(x_{i,t}|\rho_0, \tau_0\right)\right], \tag{10}$$

$$p(\boldsymbol{Z}|\boldsymbol{\Gamma}) = \prod_{t=1}^T \mathrm{Ber}\left(\boldsymbol{z}_t|\phi\left(\boldsymbol{\gamma}_t\right)\right), \tag{11}$$

$$p(\boldsymbol{\Gamma}) = \mathcal{N}\left(\boldsymbol{\Gamma}|\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_0\right), \tag{12}$$

where the mean $\boldsymbol{\mu}_0 \in \mathbb{R}^{TD\times 1}$ and covariance matrix $\boldsymbol{\Sigma}_0 \in \mathbb{R}^{TD\times TD}$ are now defined for the full $\boldsymbol{\Gamma}$-space. This model is more expressive, but the resulting inference problem becomes infeasible for even moderate sizes of D and T. But if we assume that the underlying spatio-temporal grid can be written in Cartesian product form, then covariance matrix simplifies to a Kronecker product

$$p(\boldsymbol{\Gamma}) = \mathcal{N}\left(\boldsymbol{\Gamma}|\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_{\text{temporal}} \otimes \boldsymbol{\Sigma}_{\text{spatial}}\right), \tag{13}$$

where $\boldsymbol{\Sigma}_{\text{temporal}} \in \mathbb{R}^{T\times T}$ and $\boldsymbol{\Sigma}_{\text{spatial}} \in \mathbb{R}^{D\times D}$. This decomposition leads to more efficient inference schemes as we will discuss in Section 5. In the remainder of the paper, we will focus on the model with Kronecker structure, but we refer to (Andersen et al., 2015) for more details on the first order model and joint sparsity model.

The coefficients $\{x_{i,t}\}$ are conditionally independent given the support $\{z_{i,t}\}$. For some applications it could be desirable to impose either spatial smoothness, temporal smoothness or both on the non-zero coefficients themselves (Wu et al., 2014a; Ziniel and Schniter, 2013a), but in this work we only assume a priori knowledge of the structure of the support. Although temporal smoothness of $x_{i,t}$ could easily be incorporated into the models described above.

4. Inference Using Spatio-temporal Priors

In the previous sections we have described the structured spike-and-slab prior and how to extend it to model temporal smoothness as well. We now turn our attention on how to perform inference using these models. We focus our discussion on the most general formulation using as given in eq. (10)-(12). Let $\boldsymbol{Y} = \begin{bmatrix}\boldsymbol{y}_1 & \boldsymbol{y}_2 & \dots & \boldsymbol{y}_T\end{bmatrix}$ be an observation matrix, where $\boldsymbol{y}_t \in \mathbb{R}^N$ is an observation vector for time t. We assume that the distribution on $\boldsymbol{Y}$ factors over time and is given by

$$p(\boldsymbol{Y}|\boldsymbol{X}) = \prod_{t=1}^T p(\boldsymbol{y}_t|\boldsymbol{x}_t). \tag{14}$$

We consider two different noise models: an isotropic Gaussian noise model and a probit noise model. The Gaussian noise model $p(\boldsymbol{y}_t|\boldsymbol{x}_t) = \mathcal{N}\left(\boldsymbol{y}_t|\boldsymbol{A}\boldsymbol{x}_t, \sigma_2\boldsymbol{I}\right)$ is suitable for linear inverse problems with forward model $\boldsymbol{A} \in \mathbb{R}^{N\times D}$ or equivalently sparse linear regression problems with design matrix $\boldsymbol{A} \in \mathbb{R}^{N\times D}$. On the other hand, the probit model is suitable for modeling binary observations, with $y_{t,n} \in \{-1, 1\}$, and is given by $p(\boldsymbol{y}_t|\boldsymbol{x}_t) = \prod_{n=1}^N \phi\left(y_{t,n}\boldsymbol{a}_{n,\cdot}\boldsymbol{x}_t\right)$, where $\boldsymbol{a}_{n,\cdot}$ is the n'th row of $\boldsymbol{A}$. For both models we further assume that the matrix $\boldsymbol{A}$ is constant across time. However, this assumption can be easily relaxed to have $\boldsymbol{A}$ depend on t.

For both noise models the resulting joint distribution becomes

$$\begin{aligned} p\left(\boldsymbol{Y}, \boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Gamma}\right) &= p(\boldsymbol{Y}|\boldsymbol{X})p(\boldsymbol{X}|\boldsymbol{Z})p(\boldsymbol{Z}|\boldsymbol{\Gamma})p(\boldsymbol{\Gamma}) &(15)\\ &= \prod_{t=1}^T p(\boldsymbol{y}_t|\boldsymbol{x}_t) \prod_{t=1}^T \left[(1-\boldsymbol{z}_t)\circ\delta\left(\boldsymbol{x}_t\right) + \boldsymbol{z}_t \circ \mathcal{N}\left(\boldsymbol{x}_t|0, \tau\boldsymbol{I}\right)\right] \\ &\quad \prod_{t=1}^T \mathrm{Ber}\left(\boldsymbol{z}_t|\phi\left(\boldsymbol{\gamma}_t\right)\right)\mathcal{N}\left(\boldsymbol{\Gamma}|\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_0\right). &(16)\end{aligned}$$

We seek the posterior distribution of the parameters $\boldsymbol{X}, \boldsymbol{Z}$ and $\boldsymbol{\Gamma}$ conditioned on the observations $\boldsymbol{Y}$, which is obtained by applying Bayes's Theorem to the joint distribution in eq. (15)

$$\begin{aligned} p\left(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Gamma}|\boldsymbol{Y}\right) &= \frac{1}{Z}\prod_{t=1}^T p(\boldsymbol{y}_t|\boldsymbol{x}_t) \prod_{t=1}^T \left[(1-\boldsymbol{z}_t)\circ\delta\left(\boldsymbol{x}_t\right) + \boldsymbol{z}_t \circ \mathcal{N}\left(\boldsymbol{x}_t|0, \tau\boldsymbol{I}\right)\right] \\ &\quad \prod_{t=1}^T \mathrm{Ber}\left(\boldsymbol{z}_t|\phi\left(\boldsymbol{\gamma}_t\right)\right)\mathcal{N}\left(\boldsymbol{\Gamma}|\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_0\right), &(17)\end{aligned}$$

where $Z = p(\boldsymbol{Y})$ is the marginal likelihood of $\boldsymbol{Y}$. Due to the product of mixtures in the distribution $p(\boldsymbol{X}|\boldsymbol{Z})$, the expression for the marginal likelihood Z involves a sum over 2^{DT} terms. This renders the computation of the normalization constant Z intractable for even small D and T. Hence, the desired posterior distribution is also intractable and we have to resort to approximate inference.

In the literature researchers have applied a whole spectrum of approximate inference methods for spike-and-slab priors, for example, Monte Carlo-methods (Mitchell and Beauchamp, 1988), mean-field variational inference (Titsias and Lazaro-Gredilla, 2011), approximate message passing (Vila and Schniter, 2013) and expectation propagation (Hernández-Lobato et al., 2013; Andersen et al., 2014). We use the latter since expectation propagation has been shown to have good performance for linear models with spike-and-slab priors (Hernández-Lobato et al., 2015) and it has been shown to provide a much better approximation of the first and second moment posterior moment for spike-and-slab models (Peltola et al., 2014).

4.1 The Expectation Propagation Framework

In this section, we briefly review expectation propagation for completeness. Expectation propagation (EP) (Minka, 2001; Opper and Winther, 2000) is a deterministic framework for approximating probability distributions. Consider a probability distribution over the variable $\boldsymbol{x} \in \mathbb{R}^D$ that factorizes into N components

$$f(\boldsymbol{x}) = \prod_{i=1}^{N} f_i(\boldsymbol{x}_i), \tag{18}$$

where $\boldsymbol{x}_i$ is taken to be a subvector of $\boldsymbol{x}$. EP takes advantage of this factorization and approximates f with a distribution Q that shares the same factorization

$$Q(\boldsymbol{x}) = \prod_{i=1}^{N} \tilde{f}_i(\boldsymbol{x}_i). \tag{19}$$

EP approximates each *site term* f_i with a (scaled) distribution $\tilde{f}_i$ from the exponential family. Since the exponential family is closed under products, the *global approximation* Q will also be in the exponential family. Consider the product of all $\tilde{f}_i$ terms except the j'th term

$$Q^{\backslash j}(\boldsymbol{x}) = \prod_{i \neq j} \tilde{f}_i(\boldsymbol{x}_i) = \frac{Q(\boldsymbol{x})}{\tilde{f}_j(\boldsymbol{x}_j)}. \tag{20}$$

The core of the EP framework is to choose $\tilde{f}_j$ such that $\tilde{f}_j(\boldsymbol{x}_j)Q^{\backslash j}(\boldsymbol{x}_j) \approx f_j(\boldsymbol{x}_j)\, Q^{\backslash j}(\boldsymbol{x}_j)$. By approximating f_j with $\tilde{f}_j$ in the context of $Q^{\backslash j}$, we ensure that the approximation is most accurate in the region of high density according to the *cavity distribution* $Q^{\backslash j}$. This scheme is implemented by iteratively minimizing the Kullbach-Leibler divergence $\mathrm{KL}\left(f_j(\boldsymbol{x}_j)\, Q^{\backslash j}(\boldsymbol{x}) \middle|\middle| \tilde{f}_j(\boldsymbol{x}_j)\, Q^{\backslash j}(\boldsymbol{x})\right)$. Since $\tilde{f}_j(\boldsymbol{x}_j)\, Q^{\backslash j}(\boldsymbol{x})$ belongs to the exponential family, the unique solution is obtained by matching the expected sufficient statistics (Bishop, 2006).

Once the solution,

$$Q^* = \underset{q}{\operatorname{argmin}}\ \mathrm{KL}\Big(f_j(\boldsymbol{x}_j)\, Q^{\backslash j}(\boldsymbol{x}) \Big|\Big| q\Big), \tag{21}$$

is obtained, the j'th site approximation is updated as

$$\tilde{f}_j^*(\boldsymbol{x}_j) \propto \frac{Q^*(\boldsymbol{x})}{Q^{\backslash j}(\boldsymbol{x})}. \tag{22}$$

The steps in eq. (20), (21) and (22) are repeated sequentially for all $j \in [D]$ until convergence is achieved.

4.2 The Expectation Propagation Approximation

The EP framework provides flexibility in the choice of the approximating factors. This choice is a trade-off between analytical tractability and sufficient flexibility for capturing the important characteristics of the true density. Consider the desired posterior density of interest

$$\begin{aligned} p(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Gamma}|\boldsymbol{Y}) \propto & \underbrace{\prod_{t=1}^{T} p(\boldsymbol{y}_t|\boldsymbol{x}_t)}_{f_1(\boldsymbol{X})} \underbrace{\prod_{t=1}^{T} \left[(1 - \boldsymbol{z}_t) \circ \delta(\boldsymbol{x}_t) + \boldsymbol{z}_t \circ \mathcal{N}\left(\boldsymbol{x}_t|0, \tau \boldsymbol{I}\right)\right]}_{f_2(\boldsymbol{X}, \boldsymbol{Z})} \\ & \underbrace{\prod_{t=1}^{T} \mathrm{Ber}\left(\boldsymbol{z}_t|\phi(\boldsymbol{\gamma}_t)\right)}_{f_3(\boldsymbol{Z}, \boldsymbol{\Gamma})} \underbrace{\mathcal{N}\left(\boldsymbol{\Gamma}|\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_0\right)}_{f_4(\boldsymbol{\Gamma})}. \end{aligned} \tag{23}$$

This posterior density is decomposed into four terms f_i for $i = 1, .., 4$, where the first three terms can be further decomposed. The term $f_1(\boldsymbol{X})$ is decomposed into T terms of the form $f_{1,t}(\boldsymbol{x}_t) = p(\boldsymbol{y}_t|\boldsymbol{x}_t)$, whereas the terms f_2 and f_3 are further decomposed as follows

$$f_1(\boldsymbol{X}) = \prod_{t=1}^{T} \tilde{f}_{1,}(\boldsymbol{x}_t) = \prod_{t=1}^{T} p(\boldsymbol{y}_t|\boldsymbol{x}_t), \tag{24}$$

$$f_2(\boldsymbol{X}, \boldsymbol{Z}) = \prod_{t=1}^{T} \prod_{i=1}^{D} f_{2,i,t}(x_{i,t}, z_{i,t}) = \prod_{t=1}^{T} \prod_{i=1}^{D} \left[(1 - z_{i,t}) \circ \delta(x_{i,t}) + z_{i,t} \circ \mathcal{N}\left(x_{i,t}|\rho, \tau\right)\right], \tag{25}$$

$$f_3(\boldsymbol{Z}, \boldsymbol{\Gamma}) = \prod_{t=1}^{T} \prod_{i=1}^{D} f_{3,i,t}(z_{i,t}, \gamma_{i,t}) = \prod_{t=1}^{T} \prod_{i=1}^{D} \mathrm{Ber}\left(z_{i,t}|\phi(\gamma_{i,t})\right). \tag{26}$$

Each $f_{1,t}$ term only depends on $\boldsymbol{x}_t$, $f_{2,i,t}$ only depends on $x_{i,t}$ and $z_{i,t}$ and $f_{3,j,t}$ only depends on $z_{i,t}$ and $\gamma_{i,t}$. Furthermore, the terms $f_{2,i,t}$ couple the variables $x_{i,t}$ and $z_{i,t}$, while $f_{3,i,t}$ couple the variables $z_{i,t}$ and $\gamma_{i,t}$. Based on these observations, we choose $\tilde{f_{1,t}}$, $\tilde{f}_{2,i,t}$ and $\tilde{f}_{3,j,t}$ to have the following forms

$$\tilde{f}_{1,t}(\boldsymbol{x}_t) = \mathcal{N}\left(\boldsymbol{x}_t|\hat{\boldsymbol{m}}_{1,t}, \hat{\boldsymbol{V}}_{1,t}\right), \tag{27}$$

$$\tilde{f}_{2,i,t}(x_{i,t}, z_{i,t}) = \mathcal{N}\left(x_{i,t}|\hat{m}_{2,i,t}, \hat{v}_{2,i,t}\right) \mathrm{Ber}\left(z_{i,t}|\phi(\hat{\gamma}_{2,i,t})\right), \tag{28}$$

$$\tilde{f}_{3,i,t}(z_{i,t}, \gamma_{i,t}) = \mathcal{N}\left(\gamma_{i,t}|\hat{\mu}_{3,j,t}, \hat{\sigma}_{3,i,t}\right) \mathrm{Ber}\left(z_{i,t}|\phi(\hat{\gamma}_{3,j,t})\right). \tag{29}$$

The exact term f_1 is a distribution wrt. $\boldsymbol{y}$ conditioned on $\boldsymbol{x}$, whereas the approximate term $\tilde{f}_1$ is a function of $\boldsymbol{x}$ that depends on the data $\boldsymbol{y}$ through $\hat{\boldsymbol{m}}_1$ and $\hat{\boldsymbol{V}}_1$ etc. Finally, f_4 already belongs to the exponential family and does therefore not have to be approximated by EP. That is, $\tilde{f}_4(\boldsymbol{\Gamma}) = f_4(\boldsymbol{\Gamma}) = \mathcal{N}(\boldsymbol{\Gamma}|\mu_0, \boldsymbol{\Sigma}_0)$.

Define $\hat{\boldsymbol{m}}_{2,t} = \begin{bmatrix}\hat{m}_{2,t,1} & \hat{m}_{2,t,2} & \dots & \hat{m}_{2,t,D}\end{bmatrix}^T$, $\hat{\boldsymbol{V}}_{2,t} = \operatorname{diag}\begin{pmatrix}\hat{v}_{2,t,1} & \hat{v}_{2,t,2} & \dots & \hat{v}_{2,t,D}\end{pmatrix}^T$ and $\hat{\boldsymbol{\gamma}}_{2,t} = \begin{bmatrix}\hat{\gamma}_{2,t,1} & \hat{\gamma}_{2,t,2} & \dots & \hat{\gamma}_{2,t,D}\end{bmatrix}$ and similarly for $\hat{\boldsymbol{\mu}}_{3,t}$, $\hat{\boldsymbol{\Sigma}}_{3,t}$ and $\hat{\gamma}_{3,t}$, then the resulting global approximation becomes

$$
\begin{aligned}
Q(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Gamma}) &\propto \prod_{t=1}^{T} \underbrace{\mathcal{N}\left(\boldsymbol{x}_t|\hat{\boldsymbol{m}}_{1,t}, \hat{\boldsymbol{V}}_{1,t}\right)}_{\tilde{f}_{1,t}} \prod_{t=1}^{T} \underbrace{\mathcal{N}\left(\boldsymbol{x}_t|\hat{\boldsymbol{m}}_{2,t}, \hat{\boldsymbol{V}}_{2,t}\right) \operatorname{Ber}\left(\boldsymbol{z}_t|\phi\left(\hat{\boldsymbol{\gamma}}_{2,t}\right)\right)}_{\tilde{f}_{2,t}} \\
&\quad \prod_{t=1}^{T} \underbrace{\mathcal{N}\left(\boldsymbol{\gamma}_t|\hat{\boldsymbol{\mu}}_{3,t}, \hat{\boldsymbol{\Sigma}}_{3,t}\right) \operatorname{Ber}\left(\boldsymbol{z}_t|\phi\left(\hat{\boldsymbol{\gamma}}_{3,t}\right)\right)}_{\tilde{f}_{3,t}} \underbrace{\mathcal{N}\left(\boldsymbol{\Gamma}|\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_0\right)}_{\tilde{f}_4} \\
&\propto \prod_{t=1}^{T} \mathcal{N}\left(\boldsymbol{x}_t|\hat{\boldsymbol{m}}_t, \hat{\boldsymbol{V}}_t\right) \prod_{t=1}^{T} \operatorname{Ber}\left(\boldsymbol{z}_t|\phi\left(\hat{\boldsymbol{\gamma}}_t\right)\right) \mathcal{N}\left(\boldsymbol{\Gamma}|\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\Sigma}}\right), \qquad (30)
\end{aligned}
$$

where the parameters of the global approximation are obtained by summing the natural parameters. In terms of mean and variance, we get

$$
\hat{\boldsymbol{V}}_t = \left[\hat{\boldsymbol{V}}_{1,t}^{-1} + \hat{\boldsymbol{V}}_{2,t}^{-1}\right]^{-1}, \qquad (31)
$$

$$
\hat{\boldsymbol{m}}_t = \hat{\boldsymbol{V}}_t\left[\hat{\boldsymbol{V}}_{1,t}^{-1}\hat{\boldsymbol{m}}_{1,t} + \hat{\boldsymbol{V}}_{2,t}^{-1}\hat{\boldsymbol{m}}_{2,t}\right], \qquad (32)
$$

$$
\hat{\boldsymbol{\Sigma}} = \left[\boldsymbol{\Sigma}_0^{-1} + \hat{\boldsymbol{\Sigma}}_3^{-1}\right]^{-1}, \qquad (33)
$$

$$
\hat{\boldsymbol{\mu}} = \hat{\boldsymbol{\Sigma}}\left[\boldsymbol{\Sigma}_0^{-1}\boldsymbol{\mu}_0 + \hat{\boldsymbol{\Sigma}}_3^{-1}\hat{\boldsymbol{\mu}}_3\right], \qquad (34)
$$

$$
\phi\left(\hat{\gamma}_{i,t}\right) = \frac{\phi\left(\hat{\gamma}_{2,i,t}\right)\phi\left(\hat{\gamma}_{3,i,t}\right)}{\left(1-\phi\left(\hat{\gamma}_{2,i,t}\right)\right)\left(1-\phi\left(\hat{\gamma}_{3,j,t}\right)\right) + \phi\left(\hat{\gamma}_{2,i,t}\right)\phi\left(\hat{\gamma}_{3,i,t}\right)}, \qquad (35)
$$

where $\hat{\boldsymbol{\Sigma}}_3 \in \mathbb{R}^{TD\times TD}$ is a diagonal matrix, whose the diagonal is obtained by stacking the site variances $\hat{\boldsymbol{\Sigma}}_{3,t}$ for each time point and $\hat{\boldsymbol{\mu}}_3 \in \mathbb{R}^{TD}$ is a vector obtained by stacking the site means $\hat{\boldsymbol{\mu}}_{3,t}$ for each time point. To compute the global approximation, we need to estimate the parameters $\hat{\boldsymbol{m}}_{1,t}$, $\hat{\boldsymbol{V}}_{1,t}$, $\hat{\boldsymbol{m}}_{2,t}$, $\hat{\boldsymbol{V}}_{2,t}$, $\hat{\boldsymbol{\mu}}_{3,t}$, $\hat{\boldsymbol{\Sigma}}_{3,t}$, $\hat{\boldsymbol{\gamma}}_{2,t}$ and $\hat{\boldsymbol{\gamma}}_{3,t}$ for all $t \in [T]$ using EP. The estimation procedure of $\hat{\boldsymbol{m}}_{1,t}$ and $\hat{\boldsymbol{V}}_{1,t}$ depends on the observation model being used, whereas the estimation procedure of the remaining parameters are independent on the choice of observation model.

In principle, we could choose the approximate posterior distribution of $\boldsymbol{\Gamma}$ in eq. (30) from a family of distributions that factorizes across space, time or both to reduce the computational complexity. This choice would indeed reduce the computational burden, but in contrast to classical variational inference schemes, the correlation structure of the prior would be ignored in the EP scheme and thus, the resulting posterior approximation would

be meaningless for this specific model.

In the conventional EP algorithm, the site approximations are updated in a sequential manner meaning that the global approximation is updated every time a single site approximation (Minka, 2001) is refined. In this work, we use the parallel update scheme to reduce the computational complexity of the algorithm. That is, we first update all the site approximations of the form $\tilde{f}_{2,i,t}$ for $i \in [D]$, $t \in [T]$, and then we update the global approximation w.r.t. $\boldsymbol{x}_t$ and similarly for the $\tilde{f}_{3,i,t}$ and the global approximation w.r.t. $\boldsymbol{\gamma}_t$. From a message passing perspective this can be interpreted as a particular scheduling of messages (Minka, 2005). The proposed algorithm is summarized in Algorithm 1.

- Initialize approximation terms $\tilde{f}_a$ for $a = 1, 2, 3, 4$ and Q
- Repeat until stopping criteria
  - For each $\tilde{f}_{1,n,t}$ (*For non-Gaussian likelihoods only*):
    - Compute cavity distribution: $Q^{\setminus 1,n,t} \propto \frac{Q}{\tilde{f}_{1,n,t}}$
    - Minimize: $\mathrm{KL}(f_{1,n,t}Q^{\setminus 1,n,t}||Q^{1,t,\mathrm{new}})$ w.r.t. Q^{new}
    - Compute: $\tilde{f}_{1,n,t} \propto \frac{Q^{1,t,\mathrm{new}}}{Q^{\setminus 1,n,t}}$ to update parameters $\hat{m}_{1,n,t}, \hat{v}_{1,n,t}$ and $\hat{\gamma}_{1,n,t}$.
  - For each $\tilde{f}_{2,i,t}$:
    - Compute cavity distribution: $Q^{\setminus 2,i,t} \propto \frac{Q}{\tilde{f}_{2,i,t}}$
    - Minimize: $\mathrm{KL}(f_{2,i,t}Q^{\setminus 2,i,t}||Q^{2,t,\mathrm{new}})$ w.r.t. Q^{new}
    - Compute: $\tilde{f}_{2,i,t} \propto \frac{Q^{2,t,\mathrm{new}}}{Q^{\setminus 2,i,t}}$ to update parameters $\hat{m}_{2,i,t}, \hat{v}_{2,i,t}$ and $\hat{\gamma}_{2,i,t}$.
  - Update joint approximation parameters: $\hat{\boldsymbol{m}}, \hat{\boldsymbol{V}}$ and $\hat{\boldsymbol{\gamma}}$
  - For each $\tilde{f}_{3,i,t}$:
    - Compute cavity distribution: $Q^{\setminus 3,i,t} \propto \frac{Q}{\tilde{f}_{3,i,t}}$
    - Minimize: $\mathrm{KL}(f_{3,i,t}Q^{\setminus 3,i,t}||Q^{3,t,\mathrm{new}})$ w.r.t. $Q^{3,t,\mathrm{new}}$
    - Compute: $\tilde{f}_{3,i,t} \propto \frac{Q^{3,t,\mathrm{new}}}{Q^{\setminus 3,i,t}}$ to update parameters $\hat{\mu}_{3,i,t}, \hat{\sigma}_{3,i,t}$ and $\hat{\gamma}_{3,i,t}$
  - Update joint approximation parameters: $\hat{\boldsymbol{\mu}}, \hat{\boldsymbol{\Sigma}}$ and $\hat{\boldsymbol{\gamma}}$
- Compute marginal likelihood approximation

Algorithm 1: Proposed algorithm for approximating the joint posterior distribution over $\boldsymbol{X}$, $\boldsymbol{Z}$ and $\boldsymbol{\Gamma}$ conditioned on $\boldsymbol{Y}$ using parallel EP.

4.3 Estimating Parameters for $\tilde{f}_{1,t}$

The estimation procedure for $\tilde{f}_{1,t}$ depends on the choice of observation model. Here we consider two different observation models, namely the isotropic Gaussian and the probit models. Both of these models lead to closed form update rules, but this is not true for all choices of $p(\boldsymbol{y}_t|\boldsymbol{x}_t)$. In general if $p(\boldsymbol{y}_t|\boldsymbol{x}_t)$ factorizes over n and each term only depends on $\boldsymbol{x}_t$ through $\boldsymbol{A}\boldsymbol{x}_t$, then the resulting moment integrals are 1-dimensional and can be solved relatively fast using numerical integration procedures (Jylänki et al., 2011) if no closed form

solution exists.

Under the Gaussian noise model, we have

$$f_{1,t}\left(\boldsymbol{x}_t\right) = p(\boldsymbol{y}_t|\boldsymbol{x}_t) = \mathcal{N}\left(\boldsymbol{y}_t|\boldsymbol{A}\boldsymbol{x}_t, \sigma^2\boldsymbol{I}\right). \tag{36}$$

Thus, $f_{1,t}$ is already in the exponential family for all $t \in [T]$ and does therefore not have to be approximated using EP. In particular, the parameters for $\tilde{f}_{1,t}$ are determined by the relations $\hat{\boldsymbol{V}}_{1,t}^{-1} = \frac{1}{\sigma^2}\boldsymbol{A}^T\boldsymbol{A}$ and $\hat{\boldsymbol{V}}_{1,t}^{-1}\hat{\boldsymbol{m}}_{1,t} = \frac{1}{\sigma^2}\boldsymbol{A}^T\boldsymbol{y}_t$. For simplicity we also assume that the noise variance is constant for all t.

Under the probit likelihood the term $f_{1,t}$ decompose to $f_{1,t} = \prod_{n=1}^{N} f_{1,t,n}$. In this case, the update of each site approximation $\tilde{f}_{1,t,n}$ resembles the updates for Gaussian process classification using EP, see appendix C for details.

4.4 Estimating Parameters for $\tilde{f}_{2,t}$

The terms $\tilde{f}_{2,t} = \prod_{i=1}^{D} \tilde{f}_{2,i,t}\left(x_{i,t}, z_{i,t}\right)$ factor over i, which implies that we only need the marginal cavity distributions of each pair of $x_{i,t}$ and $z_{i,t}$. Consider the update of the j'th term at time t, that is $\tilde{f}_{2,j,t}\left(x_{j,t}, z_{j,t}\right)$. The first step is to compute the marginal cavity distributions by removing the contribution of $\tilde{f}_{2,j,t}\left(x_{j,t}, z_{j,t}\right)$ from the marginal of the global approximation Q using eq. (20)

$$Q^{\setminus 2,j,t}\left(x_{j,t}, z_{j,t}\right) = \frac{Q^{\setminus 2,j,t}\left(x_{j,t}, z_{j,t}\right)}{\tilde{f}_{2,j,t}\left(x_{j,t}, z_{j,t}\right)} \propto \mathcal{N}\left(x_{j,t}|\mu^{\setminus 2,j,t}, \Sigma^{\setminus 2,j,t}\right) \mathrm{Ber}\left(z_{j,t}|\phi\left(\gamma^{\setminus 2,j,t}\right)\right). \tag{37}$$

When the approximate distribution belongs to the exponential family, the cavity distribution is simply obtained by computing the differences in natural parameters. Expressed in terms of mean and variance, we get

$$\hat{v}^{\setminus 2,j,t} = \left[\hat{V}_{t,jj}^{-1} - \hat{v}_{2,j,t}^{-1}\right]^{-1}, \tag{38}$$

$$\hat{m}^{\setminus 2,j,t} = \hat{v}^{\setminus 2,j,t}\left[\hat{V}_{t,jj}^{-1}\hat{m}_{j,t} - \hat{v}_{2,j,t}^{-1}\hat{m}_{2,j,t}\right], \tag{39}$$

$$\hat{\gamma}^{\setminus 2,j,t} = \hat{\gamma}_{3,j,t}. \tag{40}$$

The cavity parameter for $\gamma_{j,t}$ in $f_{2,j,t}$ is simply equal to $\hat{\gamma}_{3,j,t}$ (and vice versa) since $\hat{\gamma}_{2,j,t}$ and $\hat{\gamma}_{3,j,t}$ are the only two terms contributing to the distribution over $\boldsymbol{z}_{j,t}$. Next, we form the *tilted* distribution $f_{2,j,t}Q^{\setminus 2,j,t}$ and compute the solution to the KL minimization problem in eq. (21) by matching the expected sufficient statistics. This amounts to computing the zeroth, first and second moments w.r.t. $x_{j,t}$

$$X_m = \sum_{z_{j,t}} \int x_{j,t}^m \cdot f_{2,j,t}\left(x_{j,t}, z_{j,t}\right) Q^{\setminus 2,j,t}\left(x_{j,t}, z_{j,t}\right) \mathrm{d}x_{j,t} \quad \text{for} \quad m = 0, 1, 2, \tag{41}$$

and the first moment of $z_{j,t}$

$$Z_1 = \sum_{z_{j,t}} \int z_{j,t} \cdot f_{2,j,t}\left(x_{j,t}, z_{j,t}\right) Q^{\setminus 2,j,t}\left(x_{j,t}, z_{j,t}\right) \mathrm{d}x_{j,t}. \tag{42}$$

For notational convenience we have dropped the dependencies of X_m and Z_1 on the indices t and j. Alternatively, the moments could be obtained by computing the partial derivatives of the log normalizer of the tilted distribution.

The central moments of Q^* in eq.(21) are given by

$$E\left[x_{j,t}\right] = \frac{X_1}{X_0}, \qquad V\left[x_{j,t}\right] = \frac{X_2}{X_0} - \frac{X_1^2}{X_0^2}, \qquad E\left[z_{j,t}\right] = \frac{Z_1}{X_0}. \tag{43}$$

Refer to Appendix A for analytical expressions for these moments. Once Q^* has been obtained, we can compute the new update site approximation for $\tilde{f}_{2,j,t}$ using eq. (22) as follows

$$\tilde{f}_{2,j,t}^*\left(x_{j,t}, z_{j,t}\right) = \frac{Q^*\left(x_{j,t}, z_{j,t}\right)}{Q^{\setminus 2,j,t}\left(x_{j,t}, z_{j,t}\right)} \propto \mathcal{N}\left(x_{j,t}|\hat{m}_{2,j,t}^*, \hat{v}_{2,j,t}^*\right) \mathrm{Ber}\left(z_{j,t}|\phi\left(\hat{\gamma}_{2,j,t}^*\right)\right), \tag{44}$$

where the new site parameters $\hat{m}_{2,j,t}^*$ and $\hat{v}_{2,j,t}^*$, are obtained by computing differences in natural parameters in the same manner as for the cavity parameters in eq. (38) - (40)

$$\hat{v}_{2,j,t}^* = \left[V\left[x_{j,t}\right]^{-1} - \left(\hat{v}^{\setminus 2,j,t}\right)^{-1}\right]^{-1}, \tag{45}$$

$$\hat{m}_{2,j,t}^* = \hat{v}_{2,j,t}^*\left[V\left[x_{j,t}\right]^{-1} E\left[x_{j,t}\right] - \left(\hat{v}^{\setminus 2,j,t}\right)^{-1}\hat{m}^{\setminus 2,j,t}\right]. \tag{46}$$

The new site parameters for $z_{j,t}$ are obtained as (see Appendix A for details)

$$\phi\left(\hat{\gamma}_{2,j,t}^*\right) \overset{(a)}{=} \frac{\frac{E[z_{j,t}]}{\phi\left(\hat{\gamma}^{\setminus 2,j,t}\right)}}{\frac{1-E[z_{j,t}]}{1-\phi\left(\hat{\gamma}^{\setminus 2,j,t}\right)} + \frac{E[z_{j,t}]}{\phi\left(\hat{\gamma}^{\setminus 2,j,t}\right)}} \overset{(b)}{=} \frac{\mathcal{N}\left(0|\hat{m}^{\setminus 2,i} - \rho_0, \hat{V}^{\setminus 2,j,t} + \tau_0\right)}{\mathcal{N}\left(0|\hat{m}^{\setminus 2,i}, \hat{V}^{\setminus 2,i}\right) + \mathcal{N}\left(0|\hat{m}^{\setminus 2,i} - \rho_0, \hat{V}^{\setminus 2,j,t} + \tau_0\right)}, \tag{47}$$

where (a) follows from forming the quotient of the two Bernoulli distributions and (b) follows from straightforward algebraic reduction after substituting in the expression for the expectation of $z_{j,t}$.

4.5 Estimating Parameters for $\tilde{f}_{3,t}$

The procedure for updating $\tilde{f}_{3,t} = \prod_{i=1}^{D} \tilde{f}_{3,j,t}$ is completely analogously to the procedure for $\tilde{f}_{2,t}$. Consider the update for the j'th term at time t, that is $\tilde{f}_{3,j,t}$. After computing the cavity distribution in the same manner as in eq. (38)-(40), we now compute the moments w.r.t. $\gamma_{j,t}$ and $z_{j,t}$ of the (unnormalized) tilted distribution

$$G_m = \sum_{z_{j,t}} \int \gamma_{j,t}^m \cdot f_{3,j,t}\left(z_{j,t}, \gamma_{j,t}\right) Q^{\setminus 3,j,t}\left(z_{j,t}, \gamma_{j,t}\right) \mathrm{d}\gamma_{j,t} \quad \text{for} \quad m = 0, 1, 2, \tag{48}$$

$$Z_1 = \sum_{z_{j,t}} \int z_{j,t} \cdot f_{3,j,t}\left(z_{j,t}, \gamma_{j,t}\right) Q^{\setminus 3,j,t}\left(z_{j,t}, \gamma_{j,t}\right) \mathrm{d}\gamma_{j,t}. \tag{49}$$

Given these moments, we can obtain the central moments for Q^* in eq. (21)

$$E\left[\gamma_{j,t}\right] = \frac{G_1}{G_0}, \qquad V\left[\gamma_{j,t}\right] = \frac{G_2}{G_0} - \frac{G_1^2}{G_0^2}, \qquad E\left[z_{j,t}\right] = \frac{Z_1}{G_0}. \tag{50}$$

Refer to Appendix B for analytical expression of the moments. These moments completely determine Q^* and the j'th site update at the t is computed analogous to $\tilde{f}_{2,j,t}$ in eq. (44) using eq. (45), (46) and (47).

4.6 The Computational Details

In the previous sections, we have described how to use EP for approximate inference for the proposed model, and in this section, we discuss some of the computational details of the resulting EP algorithm.

4.6.1 Updating the Global Covariance Matrices

Given a set of updated site approximations, $\tilde{f}_{2,t} = \prod_j \tilde{f}_{2,j,t}$, we can compute the parameters for the global approximate distribution of $\boldsymbol{x}_t$ using eq. (31) and (32). Direct evaluation of eq. (31) results in a computational complexity of $\mathcal{O}\left(D^3\right)$. Recall, that N is assumed to be smaller than D. This implies that $\hat{\boldsymbol{V}}_{1,t}^{-1} = \frac{1}{\sigma_0^2}\boldsymbol{A}^T\boldsymbol{A}$ has low rank. Furthermore, the matrix $\hat{\boldsymbol{V}_{2,t}}$ is diagonal, and therefore we can apply the matrix inversion lemma as follows

$$\hat{\boldsymbol{V}}_t = \hat{\boldsymbol{V}}_{2,t} - \hat{\boldsymbol{V}}_{2,t}\boldsymbol{A}^T\left(\sigma_0^2\boldsymbol{I} + \boldsymbol{A}\hat{\boldsymbol{V}}_{2,t}\boldsymbol{A}^T\right)^{-1}\boldsymbol{A}\hat{\boldsymbol{V}}_{2,t}. \tag{51}$$

The inverse of $\sigma_0^2\boldsymbol{I} + \boldsymbol{A}\hat{\boldsymbol{V}}_{2,t}\boldsymbol{A}^T = \boldsymbol{L}_t\boldsymbol{L}_t^T$ can be computed in $\mathcal{O}\left(N^3\right)$ using a Cholesky decomposition. Thus, for $N < D$ eq. (51) scales as $\mathcal{O}\left(ND^2\right)$. Moreover, eq. (38) shows that we only require the diagonal elements of $\tilde{\boldsymbol{V}}_t$ in order to update the site approximation parameters for $\tilde{f}_{2,t}$. Hence, we can further reduce the computational complexity by only computing the diagonal of $\hat{\boldsymbol{V}}_t$ as follows

$$\begin{aligned}\operatorname{diag}\left[\hat{\boldsymbol{V}}_t\right] &= \operatorname{diag}\left[\hat{\boldsymbol{V}}_{2,t}\right] - \operatorname{diag}\left[\hat{\boldsymbol{V}}_{2,t}\boldsymbol{A}^T\boldsymbol{L}_t^{-T}\boldsymbol{L}_t^{-1}\boldsymbol{A}\hat{\boldsymbol{V}}_{2,t}\right] \\ &= \operatorname{diag}\left[\hat{\boldsymbol{V}}_{2,t}\right] - \operatorname{diag}\left[\hat{\boldsymbol{V}}_{2,t}^2\right] \circ \left(\boldsymbol{1}^T\left(\boldsymbol{R}_t \circ \boldsymbol{R}_t\right)\right),\end{aligned} \tag{52}$$

where $\boldsymbol{R}_t \in \mathbb{R}^{N\times D}$ is defined as $\boldsymbol{R}_t = \boldsymbol{L}_t^{-1}\boldsymbol{A}$ and $\boldsymbol{1}$ is a column vector of ones. The resulting computational cost is $\mathcal{O}\left(N^2D\right)$. Similarly, the mean of the global approximate distribution of $\boldsymbol{x}_t$, can be efficiently evaluated as

$$\hat{\boldsymbol{m}}_t = \hat{\boldsymbol{V}}_{2,t}\boldsymbol{\eta}_t - \hat{\boldsymbol{V}}_{2,t}\boldsymbol{R}_t^T\boldsymbol{R}_t\hat{\boldsymbol{V}}_{2,t}\boldsymbol{\eta}_t, \tag{53}$$

where $\boldsymbol{\eta}_t = \hat{\boldsymbol{V}}_{1,t}^{-1}\hat{\boldsymbol{m}}_{1,t} + \hat{\boldsymbol{V}}_{2,t}^{-1}\hat{\boldsymbol{m}}_{2,t}$. The total cost of updating the posterior distribution for $\boldsymbol{x}_t$ for all $t \in [T]$ is therefore $\mathcal{O}\left(TN^2D\right)$.

Unfortunately, we cannot get the same speed up for the refinement of the global approximation of $\boldsymbol{\Gamma}$ since the prior covariance matrix $\boldsymbol{\Sigma}_0$ in general is full rank. However,

we still only require the diagonal elements of the approximate covariance matrix $\hat{\boldsymbol{\Sigma}}$. We implement the update as advocated by Rasmussen and Williams (2006), that is,

$$\begin{aligned}\hat{\boldsymbol{\Sigma}} &= \left[\boldsymbol{\Sigma}_0^{-1} + \hat{\boldsymbol{\Sigma}}_3^{-1}\right]^{-1} \\ &= \boldsymbol{\Sigma}_0 - \boldsymbol{\Sigma}_0\hat{\boldsymbol{\Sigma}}_3^{-\frac{1}{2}}\left(\hat{\boldsymbol{\Sigma}}_3^{-\frac{1}{2}}\boldsymbol{\Sigma}_0\hat{\boldsymbol{\Sigma}}_3^{-\frac{1}{2}} + \boldsymbol{I}\right)^{-1}\hat{\boldsymbol{\Sigma}}_3^{-\frac{1}{2}}\boldsymbol{\Sigma}_0,\end{aligned} \tag{54}$$

where the second equality follows from the matrix inverse lemma. Again, we compute the required inverse matrix using the Cholesky decomposition, so that the total cost is $\mathcal{O}\left(D^3T^3\right)$.

4.6.2 Initialization, Convergence and Negative Variances

We initialize all the site terms to be rather uninformative, that is $\hat{m}_{2,i,t} = 0$, $\hat{v}_{2,i,t} = 10^4$, $\hat{\gamma}_{2,i,t} = 0$, $\hat{\mu}_{3,i,t} = 0$, $\hat{\sigma}_{3,i,t} = 10^4$, $\hat{\gamma}_{3,i,t} = 0$ for all $i \in [D]$ and $t \in [T]$ assuming standard scaling of the forward model $\boldsymbol{A}$.

There are in general no convergence guarantees for EP and the parallel version in particular can suffer from convergence problems (Seeger, 2005). The standard procedure to overcome this problem is to use "damping" when updating the site parameters

$$\tilde{f}^* = \tilde{f}_{\text{old}}^{1-\alpha}\,\tilde{f}_{\text{new}}^{\alpha}, \tag{55}$$

where $\alpha \in [0, 1]$ is the damping parameter and $\tilde{f}_{\text{old}}$ is the site approximation at the previous iteration. Since both $\tilde{f}_{\text{old}}$ and $\tilde{f}_{\text{new}}$ belongs to the exponential family, the update in eq. (55) corresponds to taking a convex combination of the previous and the new natural parameters of the site approximation.

Negative variances occur "naturally" in EP (Bishop, 2006) when updating the site approximations. However, this can lead to instabilities of the algorithm, non-positive semi-definitiveness of the posterior covariance matrices and convergence problems. We therefore take measures to prevent negative site variances. One way to circumvent this is to change a negative variance to $+\infty$, which corresponds to minimizing the KL divergence in eq. (21) with the site variance constrained to be positive (Hernández-Lobato et al., 2013). In practice, when encountering a negative variance after updating a given site we use $v_\infty = 10^2$ and $\sigma_\infty = 10^6$ for $\tilde{f}_{2,i,t}$ and $\tilde{f}_{3,i,t}$, respectively.

5. Further Approximations

As mentioned earlier, the updates of the global parameters for $\boldsymbol{x}_t$ and $\boldsymbol{\Gamma}$ are the dominating operations scaling as $\mathcal{O}\left(TN^2D\right)$ and $\mathcal{O}\left(D^3T^3\right)$, respectively. The latter term becomes prohibitive for moderate sizes of D and T and calls for further approximations. In this section, we introduce three simple approximations to reduce the computational complexity of the refinement of the posterior distribution for $\boldsymbol{\Gamma}$. The approximations and their computational complexities are summarized in table 1.

Approximation		Complexity	Storage
Full EP	(EP)	$\mathcal{O}\left(T^3D^3\right)$	$\mathcal{O}\left(T^2D^2\right)$
Low rank	(LR)	$\mathcal{O}\left(K^2TD\right)$	$\mathcal{O}\left(KTD\right)$
Common precision	(CP)	$\mathcal{O}\left(TD^2 + DT^2\right)$	$\mathcal{O}\left(D^2 + T^2\right)$
Group	(G)	$\mathcal{O}\left(T_g^3 D_g^3\right)$	$\mathcal{O}\left(T_g^2 D_g^2\right)$

Table 1: Summary of approximation schemes for updating the global parameters for $\boldsymbol{\Gamma}$.

5.1 The Low Rank Approximation

The eigenvalue spectrum of many prior covariance structures of interest, for example simple neighborhoods, decay relatively fast. Therefore, we can approximate $\boldsymbol{\Sigma}_0$ with a low rank approximation plus a diagonal matrix $\boldsymbol{\Sigma}_0 \approx \boldsymbol{U}\boldsymbol{S}\boldsymbol{U}^T + \boldsymbol{\Lambda}$, where $\boldsymbol{S} \in \mathbb{R}^{K\times K}$ is a diagonal matrix containing K largest eigenvalues, and $\boldsymbol{U} \in \mathbb{R}^{DT\times K}$ is a matrix containing the corresponding eigenvectors (Riihimäki et al., 2014). The diagonal matrix $\boldsymbol{\Lambda}$ is chosen such that the diagonal in the exact prior covariance matrix $\boldsymbol{\Sigma}_0$ is preserved. This allows us to apply the matrix inversion lemma to compute the update of the posterior covariance matrix for $\boldsymbol{\Gamma}$ (see Section 4.6.1).

Computing the eigendecomposition of $\boldsymbol{\Sigma}_0 \in \mathbb{R}^{DT\times DT}$ scales in general as $\mathcal{O}\left(D^3T^3\right)$. However, when the prior covariance has Kronecker structure, the eigendecompositions of $\boldsymbol{\Sigma}_0 = \boldsymbol{\Sigma}_t \otimes \boldsymbol{\Sigma}_s$ can be efficiently obtained from the eigendecompositions of $\boldsymbol{\Sigma}_t \in \mathbb{R}^{T\times T}$ and $\boldsymbol{\Sigma}_s \in \mathbb{R}^{D\times D}$. In this case, the eigendecomposition of $\boldsymbol{\Sigma}_0$ can be obtained in $\mathcal{O}\left(D^3 + T^3\right)$.

Using a K-rank approximation, the computational cost of refining the covariance matrix for $\boldsymbol{\Gamma}$ becomes $\mathcal{O}\left(K^2DT\right)$ and the memory footprint is $\mathcal{O}\left(TDK\right)$. For a fixed value of K this scales linearly in both D and T. However, to maintain a sufficiently good approximation K can scale with both D and T.

5.2 The Common Precision Approximation

Rather than approximating the prior covariance matrix as done in the low rank approximation, we now approximate the EP approximation scheme itself. If the prior covariance matrix for $\boldsymbol{\Gamma}$ can be written in terms of Kronecker products, we can significantly speed up the computation of the posterior covariance matrix of $\boldsymbol{\Gamma}$ by approximating the site precisions with a single common parameter. Let $\tilde{\boldsymbol{\theta}}_3 \in \mathbb{R}^{DT\times 1}$ be a vector containing the site precisions (inverse variances) for the site approximations $\{f_{3,i,t}\}$ for all $i \in [D]$ and for all $t \in [T]$, then we make the following approximation

$$\tilde{\boldsymbol{\Sigma}}_3 \approx \bar{\theta}^{-1}\boldsymbol{I}, \tag{56}$$

where $\bar{\theta}$ is the mean of value of $\tilde{\boldsymbol{\theta}}_3$. Assume the prior covariance matrix for $\boldsymbol{\Gamma}$ can be decomposed into a temporal part and a spatial part as follows $\boldsymbol{\Sigma}_0 = \boldsymbol{\Sigma}_t \otimes \boldsymbol{\Sigma}_s$. Let $\boldsymbol{U}_t$, $\boldsymbol{U}_s$ and $\boldsymbol{S}_t$, $\boldsymbol{S}_s$ be eigenvectors and eigenvalues for $\boldsymbol{\Sigma}_t \in \mathbb{R}^{T\times T}$ and $\boldsymbol{\Sigma}_s \in \mathbb{R}^{D\times D}$, respectively. The global covariance matrix is updated as $\tilde{\boldsymbol{\Sigma}} = \boldsymbol{\Sigma}_0\left(\boldsymbol{\Sigma}_0 + \tilde{\boldsymbol{\Sigma}}_3\right)^{-1}\tilde{\boldsymbol{\Sigma}}_3$. We now use the

properties of eigendecompositions for Kronecker products to compute the inverse matrix

$$\begin{aligned}\left(\boldsymbol{\Sigma}_t \otimes \boldsymbol{\Sigma}_s + \tilde{\boldsymbol{\Sigma}}_3\right)^{-1} &\approx \left(\boldsymbol{\Sigma}_t \otimes \boldsymbol{\Sigma}_s + \bar{\Sigma}_3\boldsymbol{I}\right)^{-1} \\ &= \left[\left(\boldsymbol{U}_t \otimes \boldsymbol{U}_s\right)\left(\boldsymbol{S}_t \otimes \boldsymbol{S}_s\right)\left(\boldsymbol{U}_t^T \otimes \boldsymbol{U}_s^T\right) + \bar{\Sigma}_3\boldsymbol{I}\right]^{-1} \\ &= \left(\boldsymbol{U}_t \otimes \boldsymbol{U}_s\right)\left(\boldsymbol{S}_t \otimes \boldsymbol{S}_s + \bar{\Sigma}_3\boldsymbol{I}\right)^{-1}\left(\boldsymbol{U}_t^T \otimes \boldsymbol{U}_s^T\right), \end{aligned} \tag{57}$$

where $\left(\boldsymbol{S}_t \otimes \boldsymbol{S}_s + \bar{\Sigma}_3\boldsymbol{I}\right)$ is diagonal and therefore fast to invert. The *common precision* approximation $\hat{\boldsymbol{\Sigma}}_{CP}$ is then obtained as

$$\begin{aligned}\hat{\boldsymbol{\Sigma}}_{CP} &= \left(\boldsymbol{\Sigma}_t \otimes \boldsymbol{\Sigma}_s\right)\left(\boldsymbol{\Sigma}_t \otimes \boldsymbol{\Sigma}_s + \bar{\Sigma}_3\boldsymbol{I}\right)^{-1}\bar{\Sigma}_3\boldsymbol{I} \\ &= \left(\boldsymbol{U}_t \otimes \boldsymbol{U}_s\right)\left(\boldsymbol{S}_t \otimes \boldsymbol{S}_s\right)\left(\boldsymbol{S}_t \otimes \boldsymbol{S}_s + \bar{\Sigma}_3\boldsymbol{I}\right)^{-1}\left(\boldsymbol{U}_t^T \otimes \boldsymbol{U}_s^T\right)\bar{\Sigma}_3. \end{aligned} \tag{58}$$

Let $\boldsymbol{M} \in \mathbb{R}^{TD\times 1}$ denote the diagonal of $\left(\boldsymbol{S}_t \otimes \boldsymbol{S}_s\right)\left(\boldsymbol{S}_t \otimes \boldsymbol{S}_s + \bar{\Sigma}_3\boldsymbol{I}\right)^{-1}$, then we can compute the diagonal of $\hat{\boldsymbol{\Sigma}}_{CP}$ as follows

$$\begin{aligned}\operatorname{diag}\left[\hat{\boldsymbol{\Sigma}}_{CP}\right]_i &= \bar{\Sigma}_3\sum_k \left(\boldsymbol{U}_t \otimes \boldsymbol{U}_s\right)_{ik} M_k \left(\boldsymbol{U}_t^T \otimes \boldsymbol{U}_s^T\right)_{ki} \\ &= \bar{\Sigma}_3\sum_k \left(\boldsymbol{U}_t \otimes \boldsymbol{U}_s\right)_{ik}^2 M_k \\ \Rightarrow \quad \operatorname{diag}\left[\hat{\boldsymbol{\Sigma}}_{CP}\right] &= \bar{\Sigma}_3\left(\boldsymbol{U}_t \circ \boldsymbol{U}_t \otimes \boldsymbol{U}_s \circ \boldsymbol{U}_s\right)\boldsymbol{M}, \end{aligned} \tag{59}$$

where $\circ$ is the Hadamard-product. We now see that the desired diagonal can be obtained by multiplying a Kronecker product with a vector and this can be computed efficiently using the identity

$$\operatorname{vec}\left[\boldsymbol{A}\boldsymbol{B}\boldsymbol{C}\right] = \left(\boldsymbol{C}^T \otimes \boldsymbol{A}\right)\operatorname{vec}\left[\boldsymbol{B}\right]. \tag{60}$$

Therefore,

$$\operatorname{diag}\left[\hat{\Sigma}_{CP}\right] = \bar{\Sigma}_3 \cdot \operatorname{vec}\left[\left(\boldsymbol{U}_s \circ \boldsymbol{U}_s\right)\operatorname{vec}^{-1}\left[\boldsymbol{M}\right]\left(\boldsymbol{U}_t \circ \boldsymbol{U}_t\right)^T\right]. \tag{61}$$

Since the Hadamard products can be precomputed, this scales as $\mathcal{O}\left(D^2T + T^2D\right)$. During the EP iterations we only need to store $\boldsymbol{U}_s \in \mathbb{R}^{D\times D}$ and $\boldsymbol{U}_t \in \mathbb{R}^{T\times T}$, so the resulting memory footprint is $\mathcal{O}\left(D^2 + T^2\right)$. The posterior mean vector can also be computed efficiently by iteratively applying the result from eq. (60)

$$\hat{\boldsymbol{\Sigma}}_{CP}\boldsymbol{\eta} = \left(\boldsymbol{U}_t \otimes \boldsymbol{U}_s\right)\operatorname{diag}\left[M\right]\left(\boldsymbol{U}_t^T \otimes \boldsymbol{U}_s^T\right)\boldsymbol{\eta}, \tag{62}$$

where $\boldsymbol{\eta} = \hat{\boldsymbol{\Sigma}}_3^{-1}\hat{\boldsymbol{\mu}}_3 + \hat{\boldsymbol{\Sigma}}_0^{-1}\hat{\boldsymbol{\mu}}_0$.

The proposed approximation reduces the cost from $\mathcal{O}\left(D^3T^3\right)$ to $\mathcal{O}\left(D^2T + T^2D\right)$. If the spatial covariance matrix is a Kronecker product itself, for example, $\boldsymbol{\Sigma}_s = \boldsymbol{\Sigma}_x \otimes \boldsymbol{\Sigma}_{\boldsymbol{y}}$ or $\boldsymbol{\Sigma}_s = \boldsymbol{\Sigma}_x \otimes \boldsymbol{\Sigma}_y \otimes \boldsymbol{\Sigma}_z$, the computational complexity can be further reduced. Such covariance structures could occur in image application or in analysis of fMRI data.

This common precision approximation is closely related to the recently proposed *Stochastic Expectation Propagation* (SEP) (Li et al., 2015), where both the means and variances of the site approximation terms have been tied together. Tying both means and variances is reasonable when the site terms are approximating likelihood terms and $N \gg D$. In case of the present model, we expect positive values of $\Gamma_{i,t}$ for $z_{i,t} = 1$ and negative values of $\Gamma_{i,t}$ for $z_{i,t} = 0$, and thus enforcing a common mean for the site approximation terms $\tilde{f}_{3,i,t}$ would not make sense.

From experiments we have observed that this common precision approach significantly increases the number of iterations until convergence. However, this problem can be mitigated by repeating the updates for the site approximations $\tilde{f}_{3,i,t}$ and the global approximation for $\boldsymbol{\Gamma}$ a few times before moving on to update the site approximations for $\tilde{f}_{2,i,t}$. Specifically, within each EP iteration we repeat the updates for posterior distribution of $\boldsymbol{\Gamma}$ 5 times. The added computational workload is still negligible compared to full EP. Furthermore, for some problem instances CP-EP can oscillate. The oscillation can be alleviated heuristically by decreasing the damping parameter α by 10% if the approximate log likelihood decreases from one iteration to another after the first 100 iterations.

5.3 Grouping the Latent Structure Variables

Consider a problem, where the spatial coordinates $\boldsymbol{d}_i$ for each $x_{i,\cdot}$ form a uniformly spaced grid. Assume the characteristic length-scale of the sparsity pattern is large relative to the grid size, then support variables $\{z_i\}$ in a neighborhood could "share" the same γ-variable with a little loss of accuracy (Jacob et al., 2009a; Hernández-Lobato et al., 2013). This *grouping* of the latent variables could either be in the spatial, temporal or both dimensions. Let G be the number of groups and $g : [D] \times [T] \to [G]$ be a grouping function that maps from a spatial and temporal index to a group index, then the grouped version of the prior is given by

$$p(\boldsymbol{Z}|\boldsymbol{\gamma}) = \prod_{t=1}^{T}\prod_{i=1}^{D} \mathrm{Ber}\left(z_{t,i}|\phi\left(\gamma_{g(i,t)}\right)\right), \tag{63}$$

$$p(\boldsymbol{\gamma}) = \mathcal{N}\left(\boldsymbol{\gamma}|\boldsymbol{\mu}_0, \boldsymbol{\Sigma}_0\right), \tag{64}$$

where $\boldsymbol{\mu}_0 \in \mathbb{R}^G$ and $\boldsymbol{\Sigma}_0 \in \mathbb{R}^{G\times G}$ are the prior mean and covariance for the new grouped model. The resulting computational complexity is indeed determined by the size of the groups. For example, assume that the support variable for a given problem have been grouped in groups of 2 in both the spatial dimension and temporal dimension, then the total number of groups becomes $G = \frac{1}{2}D\frac{1}{2}T = \frac{1}{4}DT$ and the resulting computational cost is reduced to a fraction of $\left(\frac{1}{4}\right)^3$ of the cost of the full EP scheme. Furthermore, if necessary both the low rank and the common precision approximation can be applied on top of this approximation.

6. The Marginal Likelihood Approximation and Model Selection

The model contains several hyperparameters $\boldsymbol{\Omega} \in \mathbb{R}^L$, which include, for example, the hyperparameters of the kernel for $\boldsymbol{\Gamma}$. In a fully Bayesian setting, the natural approach to handle hyperparameters is to impose prior distributions and marginalize over the hyperparameters. The exact, but generally intractable marginalization integral is given by

$$p(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Gamma}|\boldsymbol{Y}) = \int p(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Gamma}|\boldsymbol{Y}, \boldsymbol{\Omega}) p\left(\boldsymbol{\Omega}\middle|\boldsymbol{Y}\right) \mathrm{d}\boldsymbol{\Omega}, \tag{65}$$

where $p\left(\boldsymbol{\Omega}\middle|\boldsymbol{Y}\right) \propto p(\boldsymbol{Y}|\boldsymbol{\Omega})p(\boldsymbol{\Omega})$ for some prior distribution $p(\boldsymbol{\Omega})$. The true marginal likelihood $p(\boldsymbol{Y}|\boldsymbol{\Omega})$ is given by the following marginalization

$$p(\boldsymbol{Y}|\boldsymbol{\Omega}) = \int f_1\left(\boldsymbol{X}|\boldsymbol{\Omega}\right) \sum_{\boldsymbol{Z}} f_2\left(\boldsymbol{X}, \boldsymbol{Z}|\boldsymbol{\Omega}\right) \mathrm{d}\boldsymbol{X} \int f_3\left(\boldsymbol{Z}, \boldsymbol{\Gamma}|\boldsymbol{\Omega}\right) f_4\left(\boldsymbol{\Gamma}|\boldsymbol{\Omega}\right) \mathrm{d}\boldsymbol{\Gamma}. \tag{66}$$

The exact quantity is intractable, but the EP framework provides an approximation to the marginal likelihood conditioned on the hyperparameters, $p(\boldsymbol{Y}|\boldsymbol{\Omega}) \approx Q(\boldsymbol{Y}|\boldsymbol{\Omega})$. The approximation $Q(\boldsymbol{Y}|\boldsymbol{\Omega})$ is obtained by substituting the exact site terms, for example, $f_{2,i,t}$, with a scaled version of the corresponding site approximation, for example, $s_{2,i,t}\tilde{f}_{2,i,t}$, and then carrying out the marginalization analytically. The scaling constants, for example, $s_{2,i,t}$, are chosen such that

$$\mathbb{E}_{Q^{\setminus 2,i,t}}\left[f_{2,i,t}\left(x_{i,t}, z_{i,t}\right)\right] = s_{2,i,t}\mathbb{E}_{Q^{\setminus 2,i,t}}\left[\tilde{f}_{2,i,t}\left(x_{i,t}, z_{i,t}\right)\right] \tag{67}$$

and similarly for all the site terms $f_{a,i,t}$ for $a \in [4]$, $i \in [D]$, $t \in [T]$. In the following, we will describe three different approximation strategies based on the marginal likelihood approximation.

6.1 Maximum Likelihood and MAP Estimation

This simplest and most crude approximation is to use a point estimate of $\boldsymbol{\Omega}$ instead of integrating over the uncertainty. Specifically, we aim to locate the maximum a posteriori (MAP) value by maximizing $\ln Q\left(\boldsymbol{\Omega}|\boldsymbol{Y}\right) = \ln Q\left(\boldsymbol{Y}\middle|\boldsymbol{\Omega}\right) + \ln p\left(\boldsymbol{\Omega}\right) + \text{constant}$ using gradient-based methods. A maximum likelihood type II estimate is obtained by choosing an (improper) flat prior $p\left(\boldsymbol{\Omega}\right) \propto 1$. For severely ill-posed problems, the marginal likelihood approximation can be completely non-informative with regard to one or more hyperparameters and thus, the maximum likelihood estimate can lead to suboptimal and unstable results for some problems. For some problem instances, it can also happen that the marginal likelihood solution with regard to the prior mean and variance of $\boldsymbol{\Gamma}$ is not in the interior of $\mathbb{R}^2$ and thus, gradient-based optimization with regard to these parameters will diverge. However, this problem is easily solved by imposing a weakly informative prior on the prior variance of $\boldsymbol{\Gamma}$ with little influence on the result (see Appendix D for more details).

The marginal likelihood approximation, $Q\left(\boldsymbol{Y}\middle|\boldsymbol{\Omega}\right)$, depends on the hyperparameters $\boldsymbol{\Omega}$ directly as well as through the site parameters, but the latter dependency can be ignored in gradients computations when the EP fixed point conditions hold (Seeger, 2005). The hyperparameter optimization procedure proceeds in an iterative two-stage fashion, where we first run EP until convergence and then we take a gradient step with regard to the hyperparameters and then repeat.

6.2 Approximate Marginalization using Numerical Integration

As a better approximation of eq. (65), we propose to approximate the marginalization integral using numerical integration with a finite sum using a central composite design (CCD) grid (Rue et al., 2009). This method has previously been successfully applied for marginalizing over hyperparameters in Gaussian process based models and the accuracy is reported to be between empirical Bayes and full marginalization using a dense grid (Vanhatalo et al., 2010). We approximate the marginal posterior distribution as follows

$$p(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Gamma}|\boldsymbol{Y}) \approx \int Q(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Gamma}|\boldsymbol{Y}, \boldsymbol{\Omega}) Q\left(\boldsymbol{\Omega}\middle|\boldsymbol{Y}\right) \mathrm{d}\boldsymbol{\Omega} \tag{68}$$

$$\approx \sum_{m=1}^{M} Q(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Gamma}|\boldsymbol{Y}, \boldsymbol{\Omega}_m) Q\left(\boldsymbol{\Omega}_m\middle|\boldsymbol{Y}\right) w_m, \tag{69}$$

for a set of points $\{\boldsymbol{\Omega}_m\}_{m=1}^M$, a set of integration weights $\{w_m\}_{m=1}^M$. Thus, the resulting approximate marginal posterior distribution becomes a Gaussian mixture model with mixing weights $\pi_m = Q\left(\boldsymbol{\Omega}_m\middle|\boldsymbol{Y}\right) w_m$ and components $Q(\boldsymbol{X}, \boldsymbol{Z}, \boldsymbol{\Gamma}|\boldsymbol{Y}, \boldsymbol{\Omega}_m)$.

To keep the computational burden to a minimum, we use a so-called Central Composite Design (CCD) to choose the points and weights. Most of the hyperparameters are variance or scale parameters and hence constrained to be positive. Therefore, we first transform these parameters into an unconstrained space using a log transformation, $\lambda_i = \ln \Omega_i$. Next, we locate the mode in the transformed parameter space, $\hat{\boldsymbol{\lambda}}_{\mathrm{MAP}}$, by optimizing $Q\left(\boldsymbol{Y}\middle|\boldsymbol{\lambda}\right)$ with regard to $\boldsymbol{\lambda}$ using gradient-based optimization methods and numerically estimate the inverse Hessian, $\hat{\boldsymbol{S}} = \boldsymbol{H}^{-1}$, at the mode $\hat{\boldsymbol{\lambda}}_{\mathrm{MAP}}$.

The CCD integration points are then obtained as $\boldsymbol{\lambda}_m = \hat{\boldsymbol{S}}^{\frac{1}{2}} \boldsymbol{p}_m + \hat{\boldsymbol{\lambda}_{\mathrm{MAP}}}$, where $\{\boldsymbol{p}_m\}_{m=1}^M$ is a CCD design grid (Rue et al., 2009) in L-dimensions. The points on the CCD grid consist of a fractional factorial design as well as $2K$ star points and a center point. All points, except for the center point, lives on the surface of a L-dimensional ball with radius $\sqrt{L}$. This specific design choice requires a much smaller number of points compared to a dense grid. For example, for $L = 2, 3, 4, 5$ parameters, the number of CCD points are $M = 9, 15, 25, 43$, respectively. The integration weights $\{w_m\}_{m=1}^M$ are chosen such that the integral match for the first three moments of a L-dimensional standardized Gaussian random variable, $\boldsymbol{z} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_L)$, and $\mathbb{E}\left[1\right] = 1$, $\mathbb{E}\left[\boldsymbol{z}\right] = 0$, $\mathbb{E}\left[\boldsymbol{z}^T\boldsymbol{z}\right] = L$.

6.3 Bayesian Optimization

There can be some challenges with gradient-based optimization of the marginal likelihood approximation. Firstly, the optimization problem is in general non-convex and thus, the results can suffer from poor local optima. Secondly, for some problem instances the marginal likelihood approximate can exhibit discontinuities (as discussed in experiment 7.1).

To counter these issues, we consider Bayesian optimization (Shahriari et al., 2016; Snoek et al., 2012) as a third strategy to model selection as it does not depend on gradient information. As indicated by the name, Bayesian optimization is a probabilistic approach to

optimization, where the objective function is modelled as a random function. Thus, the approach allows us to model the potential discontinuities. Specifically, we use a Gaussian process to model log posterior density as follows

$$\ln Q(\boldsymbol{\Omega}|Y) \sim \mathcal{GP}\left(\mu\left(\boldsymbol{\Omega}\right), k\left(\boldsymbol{\Omega}, \boldsymbol{\Omega}'\right)\right), \tag{70}$$

where $\mu : \mathbb{R}^K \to \mathbb{R}$ is a mean function and $k : \mathbb{R}^L \times \mathbb{R}^L \to \mathbb{R}$ is the kernel function. Rather than following the direction of the gradient, Bayesian optimization works by exploring values of $\boldsymbol{\Omega}$, that are likely to improve the value of the objective function as measured by a so-called acquisition function. For more details on Bayesian optimization, we refer to (Shahriari et al., 2016; Snoek et al., 2012; Brochu et al., 2010) .

7. Numerical Experiments

In this section, we conduct a series of experiments designed to investigate the properties of the proposed model and the associated EP inference scheme.

We describe seven experiments with a Gaussian observation model and one experiment with a probit observation model. In the first five experiments, we focus on problem instances with a single measurement vector. Experiment 1 investigates the effect of the prior by analyzing a synthetic data set with a range of different values for the hyperparameters. In the second experiment, we compare the three different approximation schemes (low rank, common precision, group) to standard EP. Specifically, we analyze a synthetic data set with all four methods and compare the results. Experiment 3 is designed to investigate how the EP algorithms perform as a function of the undersampling ratio N/D giving rise to the so-called *phase transition curves* (Donoho and Tanner, 2010). In experiment 4, we apply the proposed model to a compressed sensing problem and in experiment 5, we apply our model to a binary classification task, where the goal is to discriminate between utterances of two different vowels using log-periodograms as features.

In Experiment 6-8, we turn our attention to problems with multiple measurement vectors. In the sixth experiment, we qualitatively study the properties of the proposed methods in the multiple measurement vector setting. We demonstrate the benefits of modeling both the spatial and temporal structure of the support and discuss the marginal likelihood approximation for hyperparameter tuning. Experiment 7 studies the performance of the EP algorithms as a function of the undersampling ratio when multiple measurement vectors are available and compare the results to competing methods. Finally, in Experiment 8 we apply the proposed method to an EEG source localization problem (Baillet et al., 2001).

For the subset of experiments, where the ground truth solutions are available, we use the *Normalized Mean Square Error (NMSE)* and the *F-measure* (Rijsbergen, 1979) to quantify the performance of the algorithms. In particular, we compute the NMSE between the posterior mean $\hat{\boldsymbol{X}} = \mathbb{E}_{Q(\boldsymbol{X}|\boldsymbol{Y})}\left[\boldsymbol{X}\right]$ and the true solution $\boldsymbol{X}_0$ to quantify the algorithms abilities to reconstruct the true signal $\boldsymbol{X}_0$

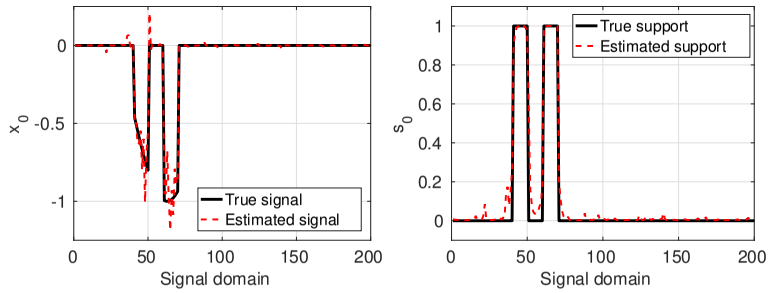
$$\mathrm{NMSE} = \frac{\|\hat{\boldsymbol{X}} - \boldsymbol{X}_0\|_{\mathrm{F}}^2}{\|\boldsymbol{X}_0\|_{\mathrm{F}}^2}, \tag{71}$$

where $\|\cdot\|_{\mathrm{F}}$ is the Frobenius norm. We use the F-measure to quantify the algorithms' abilities to recover the true support set

$$F = \frac{2 \cdot \text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}}, \tag{72}$$

where *precision* (positive predictive value) is the fraction of non-zero weights found by the algorithm that are also non-zero in the true model, while recall *sensitivity* is the fraction of non-zeros in the true model that have been identified by the algorithm. Here a given weight $x_{i,t}$ is identified as being non-zero if the posterior mean of $z_{i,t}$ is above 0.5.

The code is available at `https://github.com/MichaelRiis/SSAS`.



7.1 Experiment 1: The Effect of the Prior

In this experiment, we investigate the effect of the structured spike-and-slab prior on the reconstructed support set. For simplicity we only consider spatial structure, $T = 1$, and we further assume that the spatial coordinates are on a regular 1D grid. We construct a sparse 1D test signal $\boldsymbol{x}_0 \in \mathbb{R}^{200}$, where the active coefficients are sampled from a cosine function, see Figure 1(a)–(b). Based on this signal we generate a synthetic data set using the linear model $\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}_0 + \boldsymbol{e}$, where $A_{ij} \sim \mathcal{N}(0,1)$, $\boldsymbol{e} \sim \mathcal{N}(0, 5\boldsymbol{I})$ is isotropic Gaussian noise (SNR $\approx$ 5dB) and the number of samples is $N = 0.5D$. The prior on $\boldsymbol{\gamma}$ is of the form $p(\boldsymbol{\gamma}) = \mathcal{N}(\boldsymbol{\gamma}|\boldsymbol{\mu}, \boldsymbol{\Sigma})$, where

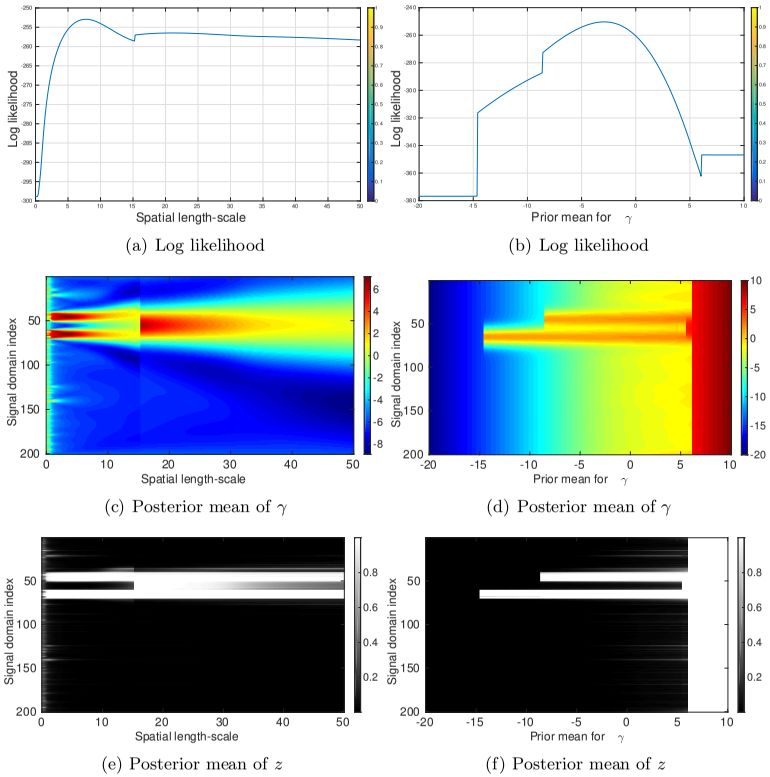
$$\boldsymbol{\mu} = \nu \cdot \mathbf{1} \quad \text{and} \quad \boldsymbol{\Sigma}_{ij} = \kappa_1^2 \exp\left(-\frac{D_{ij}^2}{2\kappa_2^2}\right).$$

We sample the length-scale κ_2 equidistantly 100 times in $\left[10^{-3}, 50\right]$ and run the algorithm on the synthetic data set for each value of κ_2. For this experiment we use the standard EP scheme with no further approximations. The noise variance is fixed to the true value and the remaining hyperparameters are fixed $\nu = 0$, $\tau = 1, \kappa_1^2 = 5$. The posterior results are shown in the panels in leftmost column in Figure 2. The topmost panel shows the marginal likelihood approximation as a function of the spatial length scale κ_2. The panel in the middle shows the posterior mean $\mathbb{E}_{Q(z_i|\boldsymbol{y})}[\gamma_i]$, as a function of the scale κ_2. That is, each column in the image corresponds to the posterior mean of $\boldsymbol{\gamma}$ for a specific value of κ_2. The panel in the bottom shows a similar plot for the posterior support probabilities $\mathbb{E}_{Q(z_i|\boldsymbol{y})}[z_i]$.

When κ_2 is close to zero the posterior mean vectors for both $\boldsymbol{\gamma}$ and $\boldsymbol{z}$ are very irregular and resemble the solution of an independent spike-and-slab prior. As the length-scale increases the posterior mean vector $\boldsymbol{\gamma}$ becomes more and more smooth and eventually give rise to well-defined clusters in the support. The algorithm recovers the correct support for $\kappa_2 \in [3, 15]$. However, at $\kappa_2 \approx 15$ a discontinuity is seen. Since the prior distribution on $\boldsymbol{z}$ does not exhibit any phase transitions with regard to κ_2, this is likely to be an effect of a unimodal approximation to a highly multimodal distribution. The discontinuity is also present in the marginal likelihood approximation as seen in the top panel and therefore one should be cautious when optimizing the marginal likelihood using line search based methods. We repeated this experiment for multiple realizations of the noise and the discontinuity was

(a) Signal (b) Support

Figure 1: (a) Synthetic test signal $\boldsymbol{x}_0$ superimposed with the posterior mean of the test signal. The active coefficients are sampled from a cosine function (b) The support of the test signal superimposed with the posterior support probabilities.



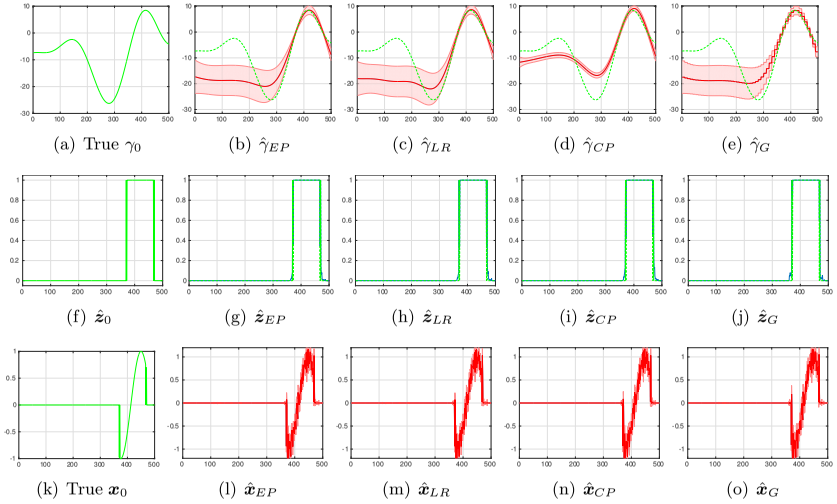
only present occasionally.

The rightmost column in Figure 2 shows equivalent figures for a sweep over ν, which is the prior mean of γ_i, where it is seen that the algorithm recovers the correct support for $\nu \in [-15, 0]$. It is seen that when ν is below some threshold ν_{lower}, the posterior mean of z_i is close to zero for all $i \in [D]$. The total number of active variables increases with ν, until ν surpasses an upper threshold ν_{upper}, where all variables are included in the support set. It is also seen that variables are included cluster-wise rather than individually, which gives rise to discontinuities in the marginal likelihood in the topmost panel.

Figure 1 shows the estimated signal and the estimated support probabilities for the optimal hyperparameter values in the top row of Figure 2, that is the prior mean $\nu = -2.93$ and lengthscale $\kappa_2 = 7.72$, where it is seen that both the estimated coefficients $\hat{\boldsymbol{x}}$ and the estimated support $\hat{\boldsymbol{s}}$ are high-quality approximations of the true quantities. We will make these relationships more quantitative in experiment 3.

7.2 Experiment 2: Comparison of Approximation Schemes

In this experiment, we investigate the properties of the proposed algorithm and the three approximation schemes: standard EP (EP), the low rank approximation (LR-EP), the common precision approximation (CP-EP) and the group approximation (G-EP). Using a similar setup as in Experiment 1, we generated a sample of $\boldsymbol{\gamma}_0$, $\boldsymbol{z}_0$ and $\boldsymbol{x}_0$ from the prior distribution specified in eq. (5)-(7) with $\rho_0 = 0, \tau_0 = 1$ and a squared exponential kernel with variance $\kappa_1^2 = 100$ and lengthscale $\kappa_2 = 75$. The generated sample is shown in the leftmost panels in Figure 3. We generated observations from a linear measurement model $\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}_0 + \boldsymbol{e}$, where $A_{ij} \sim \mathcal{N}(0,1)$ and the noise variance σ^2 is chosen such that the signal-to-noise is 20dB. Next, we computed the posterior distributions of $\boldsymbol{x}_0$, $\boldsymbol{z}_0$ and $\boldsymbol{\gamma}_0$ from



(a) Log likelihood (b) Log likelihood

(c) Posterior mean of γ (d) Posterior mean of γ

(e) Posterior mean of z (f) Posterior mean of z

Figure 2: The effect of the spatial prior distribution. The left-most column shows the approximate marginal log likelihood, posterior mean of $\boldsymbol{\gamma}$ and posterior mean of z as a function of the prior length-scale of $\boldsymbol{\gamma}$. The right-most column shows similar plots as a function of the prior mean ν_0 of $\boldsymbol{\gamma}$.

the observed measurements $\boldsymbol{y}$ using standard EP and the three approximation schemes. For the low rank approximation we included 7 eigenvectors corresponding to 99% percent of the variance and for G-EP we used a group size of 10 variables. Columns 2-5 in Figure 3 show the posterior mean values for $\boldsymbol{x}, \boldsymbol{z}$, and $\boldsymbol{\gamma}$ for EP, LR-EP, CP-EP and G-EP, respectively. Consider the posterior mean and standard deviation for $\boldsymbol{\gamma}$ for standard EP (topmost row, second column). In the region where $\boldsymbol{\gamma}_0$ is positive the posterior mean accurately recovers $\boldsymbol{\gamma}_0$ with high precision, whereas both the accuracy and the precision is lower in regions where $\boldsymbol{\gamma}_0$ is negative. The reason for the additional uncertainty is that negative values of γ_i are in

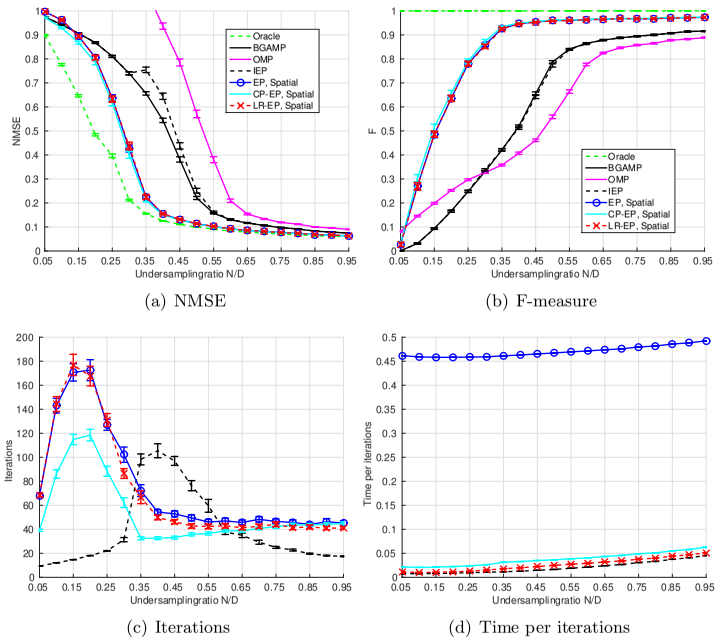
(a) True $\boldsymbol{\gamma}_0$ (b) $\hat{\boldsymbol{\gamma}}_{EP}$ (c) $\hat{\boldsymbol{\gamma}}_{LR}$ (d) $\hat{\boldsymbol{\gamma}}_{CP}$ (e) $\hat{\boldsymbol{\gamma}}_{G}$

(f) $\hat{\boldsymbol{z}}_0$ (g) $\hat{\boldsymbol{z}}_{EP}$ (h) $\hat{\boldsymbol{z}}_{LR}$ (i) $\hat{\boldsymbol{z}}_{CP}$ (j) $\hat{\boldsymbol{z}}_{G}$

(k) True $\boldsymbol{x}_0$ (l) $\hat{\boldsymbol{x}}_{EP}$ (m) $\hat{\boldsymbol{x}}_{LR}$ (n) $\hat{\boldsymbol{x}}_{CP}$ (o) $\hat{\boldsymbol{x}}_{G}$

Figure 3: Comparison of approximation schemes. The panels in the first column shows a realization $\boldsymbol{x}, \boldsymbol{z}$, and $\boldsymbol{\gamma}$ from the prior distribution in eq. (5)-(7). The columns 2-5 show the posterior mean quantities for EP, the low rank approximation (LR-EP), the common precision approximation (CP-EP) and the group approximation (G-EP), respectively. The pink shaded areas depict $\pm$ standard deviation.

general associated with a small value of $|x_i|$, but $|x_i|$ can be small for two reason. Recall that each x_i can be considered as a product $x_i = z_i \cdot c_i$, where $z_i \in \{0, 1\}$ and $c_i \in \mathbb{R}$. If $z_i = 0$, then clearly $x_i = 0$, but we can still have that $x_i \approx 0$ even if $z_i = 1$ and $c_i \approx 0$ and thus the increased uncertainty.



We can now compare the posterior distribution of $\boldsymbol{\gamma}_i$ for standard EP with the three approximations. Based on visual inspection one cannot tell the difference between the standard EP and EP with the low rank approximation, but the results for CP-EP and G-EP are quite different. For CP-EP it is seen that the posterior mean in the positive region is accurate, but the CP-EP approximation underestimates the uncertainty in general. The grouping effect for G-EP is clearly seen in the topmost panel in the last column, but despite the staircase pattern the posterior mean and variance are accurately recovered. The second and the third row in Figure 3 show the reconstructions of $\boldsymbol{x}$ and $\boldsymbol{z}$. We see that all of the four approaches accurately reconstruct the true quantities despite the approximation of the posterior distribution of $\boldsymbol{\gamma}$.

7.3 Experiment 3: Phase Transitions for a Single Measurement Vector

The purpose of this experiment is two-fold. The experiment serves to validate the inference algorithm, but it also serves to quantify the relationship between the recovery performance of the algorithm as a function of the undersampling ratio. It is well-known that the quality of the inferred solutions strongly depend on both the undersampling ratio $\delta = N/D$ and the number of non-zeros $K = ||\boldsymbol{x}||_0$ and that linear inverse problems exhibit a phase transition from almost perfect recovery to no recovery of solution $\boldsymbol{x}$ in the (δ, K)-space (Donoho and Tanner, 2010; Donoho et al., 2011). We hypothesize that the phase transition curves for signals with structured support can be improved, so that we can recover structured sparse signals using fewer measurements for a given number of non-zero coefficients K by taking advantage of the structure. We investigate this hypothesis by measuring the recovery performance of the EP algorithms as a function of the undersampling ratio N/D and compare with state-of-the-art probabilistic methods that ignore the structure of the support.

Using a squared exponential kernel for $\boldsymbol{\gamma}$ with variance $\kappa_1^2 = 50$ and lengthscale $\kappa_2 = 10$, we generated 100 realizations of $\boldsymbol{x}_0$ from the prior for $D = 500$. We fixed the expected sparsity to $K = \frac{1}{4}D = 125$ by choosing the prior mean of $\boldsymbol{\gamma}$ to $\nu = \phi^{-1}\left(\frac{1}{4}\right)(1 + \kappa_1^2)$. As the recovery performance is very sensitive to the number of non-zero coefficients, we conditioned each sample of $\boldsymbol{x}$ on $||\boldsymbol{x}||_0 = K$ by discarding samples where $||\boldsymbol{x}||_0 \neq K$ to reduce the variance of the resulting curves for NMSE and F-measure. For each of the samples, we generated measurements $\boldsymbol{y} \in \mathbb{R}^N$ through the linear observation $\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}_0 + \boldsymbol{e}$ for a range of values for N. The forward model $\boldsymbol{A}$ is a Gaussian i.i.d. ensemble, where the column have been scaled to unit ℓ_2-norm. The noise $e \sim \mathcal{N}\left(0, \sigma^2\right)$ is zero-mean Gaussian noise, where the noise variance σ^2 is chosen such that the signal-to-noise (SNR) ratio is fixed to 20dB. We choose values of N such that $\frac{N}{D} \in [0.05, 0.10, ..., 0.95]$.

We compare our methods with Bernoulli-Gaussian Approximate Message Passing (BG-AMP) (Vila and Schniter, 2013), Orthogonal Matching Pursuit (OMP) (Needell and Tropp,

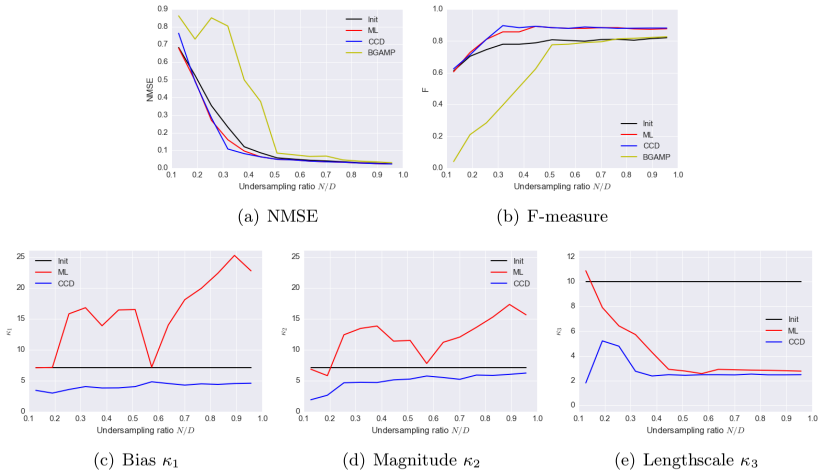
(a) NMSE (b) F-measure

(c) Iterations (d) Time per iterations

Figure 4: Performance of the methods as a function of undersampling ratio N/D for $T = 1$. We compare full EP (EP, Spatial), EP with diagonal prior covariance (IEP), the common precision approximation (CP-EP) and the low rank approximation (LR-EP). The results are averaged over 100 realization.

2010) and an "oracle" estimator, which computes a ridge regression estimate based on knowledge of the true support. In this work, we use the BG-AMP method as baseline. It uses a (generalized) approximate message passing algorithm (Sundeep, 2010) for inference in a probabilistic model with i.i.d. spike-and-slab priors and a Gaussian likelihood. The AMP algorithm is closely related to EP algorithm (Meng et al., 2015), and the phase transition curve for BG-AMP is state of the art to the best of our knowledge. The OMP algorithm is a non-probabilistic greedy method, that iteratively select the column of $\boldsymbol{A}$ that correlate best with the current residuals until a pre-specified number of columns have been selected. The regularization parameters for the ridge regression is fixed to $\lambda = 10^{-3}$ for all runs. Finally, for comparison we also apply the proposed EP algorithm with a diagonal prior covariance matrix, which correspond to the conventional independent spike-and-slab prior (IEP). We provide BG-AMP and OMP with prior knowledge of the true number of non-zero variables in $\boldsymbol{x}_0$ and the noise variance used to generate the observations. The results are shown in Figure 4.

The two black curves in Figure 4 show the results for BG-AMP (black, solid) and EP with diagonal prior covariance (black, dashed). Both of these methods are based on conventional independent spike-and-slab priors. It is seen that the methods with prior correlation, that is EP (blue), CP-EP (cyan), and LR-EP (red, dashed), are uniformly better than the methods with independent priors both in terms of NMSE and F-measure. In fact, these methods achieve as good performance as the support-aware oracle estimator around $N/D = 0.6$ in terms of NMSE. Furthermore, it is also seen that the two approximations CP-EP and LR-EP are indistinguishable from the full EP algorithm in terms of accuracy. Panel (c) and (d) show the number iterations and the run time per iteration for the EP-based methods. Here it is seen that IEP has the lowest computational complexity per iteration, but the CP-EP and LR-EP are almost as fast.



7.4 Experiment 4: Compressed Sensing of Optical Characters

In this experiment, we apply the structured spike-and-slab model with Gaussian likelihood to an application of compressed sensing (Donoho, 2006) of numerical characters from the MNIST data set (LeCun et al., 1998; Hernández-Lobato et al., 2013). The images of the numerical digits are 28 pixels $\times$ 28 pixels and they are represented as vectors $\boldsymbol{x}_0 \in \mathbb{R}^{784}$. The objective is to reconstruct $\boldsymbol{x}_0$ from a small set of linear and noisy measurements $\boldsymbol{y} = \boldsymbol{A}\boldsymbol{x}_0 + \boldsymbol{\epsilon}$. The sensing matrix $\boldsymbol{A}$ is sampled independently from a standardized Gaussian distribution, that is $A_{ni} \sim \mathcal{N}(0, 1)$ and the noise variance is scaled such that the SNR is fixed 10dB.

We use a squared exponential kernel with a single lengthscale defined on the 2D image grid to encourage the neighbourhood structure expected in the images. We impose a Gaussian prior distribution on ν_0 with zero mean and variance κ_1^2, that is $\nu_0 \sim \mathcal{N}(0, \kappa_1^2)$ and integrate over ν_0 analytically to get the kernel function

$$k(i, j) = \kappa_1^2 + \kappa_2^2 \exp\left(-\frac{\|\boldsymbol{d}_i - \boldsymbol{d}_j\|_2^2}{2\kappa_3^2}\right), \tag{73}$$

where $\boldsymbol{d}_i$ is the image grid coordinates of γ_i. We assume that the noise variance is known and we fix the prior mean and variance of the 'slab' component to a standardized Gaussian with $\rho_0 = 0$ and $\tau_0 = 1$. Thus, the hyperparameters to be learned are $\boldsymbol{\Omega} = \{\kappa_1, \kappa_2, \kappa_3\}$. For the CCD procedure, we have to choose prior distributions for the hyperparameters. For the lengthscale parameter, we can use the fact that the 'pen' is roughly a few pixels wide on average and choose a log-normal prior with mean 4 and standard deviation 2, that is $\kappa_3 \sim \mathcal{LN}\left(4, 2^2\right)$. The 10'th and 90'th percentiles for this distribution are approximately 2 and 7, respectively. For the remaining two hyperparameters, we will use the same prior distribution, that is $\kappa_1, \kappa_2 \sim \mathcal{LN}\left(4, 2^2\right)$, but for a different reason than for the lengthscale parameter κ_3. The mode of the distribution $\mathcal{LN}\left(4, 2^2\right)$ is approximate 2.9 and then the 10'th and 90'th percentiles of the distribution of $\phi(\gamma)$ for $\gamma \sim \mathcal{N}(0, 2.9^2)$ are approximately 0.0001 and 0.9999, respectively. Furthermore, the choice of lognormal priors generally works well for the CCD scheme, which can yield poor performance if the distributions have too heavy tails.

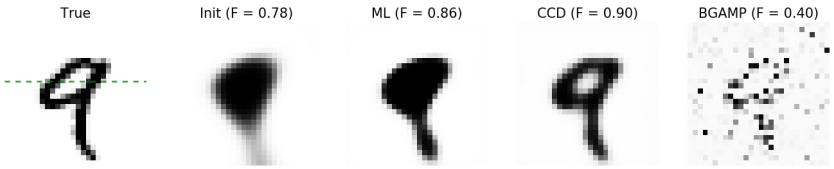
(a) NMSE (b) F-measure

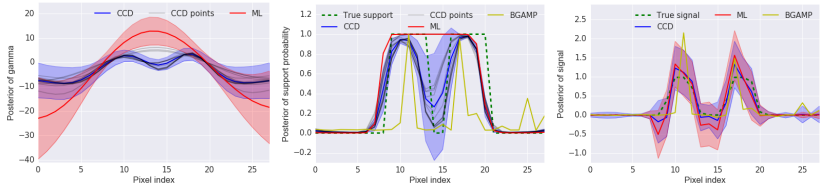
(c) Bias κ_1 (d) Magnitude κ_2 (e) Lengthscale κ_3

Figure 5: Performance of compressed sensing of numerical digits as a function of undersampling ratio. Panels (a) and (b) show the NMSE and F-measure, while panels (c)–(e) show the estimated values of the hyperparameters as a function of the undersampling ratio. For the CCD method, the panels (c)–(e) show the CCD-weighted average of the hyperparameters.

We use the low-rank approximation for all computations in this experiment. Figure 5(a)–(b) show the NMSE reconstruction error and F measure as a function of the undersampling ratio $\frac{N}{D}$. In this experiment, we also compare with the BGAMP method, which is informed about the noise level. We also use a standardized Gaussian as slab distribution for BGAMP. The black curves in panels (a) and (b) show the performance for the model when the hyperparameter are fixed to the initial values. It is seen that for small undersampling rates $N/D < 0.5$, we obtain slightly better results in terms of NMSE when adapting the hyperparameters, but we get a uniform improvement in terms of the F measure. Figure 5(c)–(e) show the estimated values for the hyperparameters as a function of the undersampling ratio. It is seen that the ML solution tends to overestimate the lengthscale for small sample sizes. In this case, only weak information are propagated from the observations to the prior of $\boldsymbol{\gamma}$ and thus the model becomes over-regularized. It is also seen that the bias and magnitude parameters are correlated as expected from the relationship in eq. 8, (see Appendix D for more details).

Figure 6 shows the posterior mean of the support for each method for $N/D \approx 0.3$, where it is seen that we obtain a qualitative and quantitative improvement of the support estimate by taking a priori knowledge into account and integrating over the uncertainty. Figure 7 shows the posterior distribution for $\boldsymbol{\gamma}$, $\boldsymbol{z}$ and $\boldsymbol{x}$ for the line indicated by the green dashed





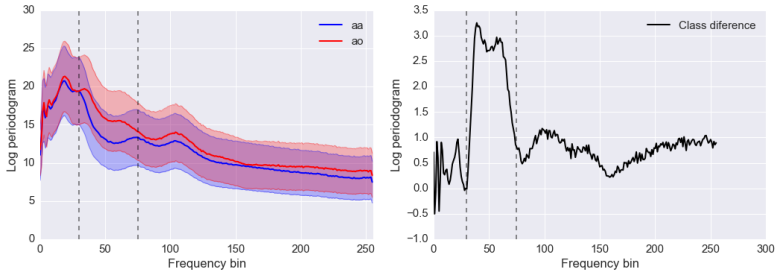


Figure 6: Posterior mean of $\boldsymbol{z}$ for compressed sensing of numerical digits, where $N/D \approx 0.3$. The panels in the top row show the posterior mean of the support, while the panels in the bottom row show the posterior mean of signal. Figure 7 shows the posterior distributions of the row indicated the dashed line.

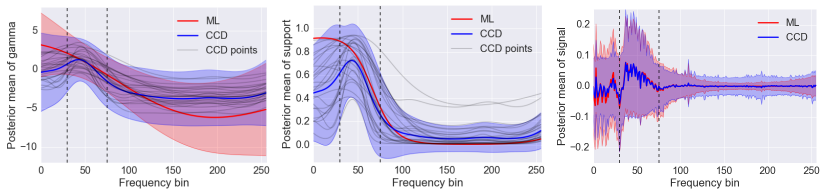
Table 2: Results for phoneme classification experiment

line in Figure 6(a). Recall, that the posterior distributions obtained using CCD are finite mixture models. The thin gray lines in left and center columns show the posterior mean of the individual mixture components, while the solid colored lines and the shaded areas show the mean and variance of the mixture distributions, respectively. From the center panel, it is seen all methods fail to capture the true support perfectly, but the mean of the support of the CCD solution are significantly improved compared to the ML solution and more interestingly, the CCD solution also has high variance in the region, where it is wrong. These uncertainties are not properly reflected in the NMSE and F metrics, but the log posterior density of the true support of the ML solution is −181.654, while the same quantity for the CCD method and BG-AMP evaluate to −74.181 and −339.065, respectively.

7.5 Experiment 5: Phoneme Recognition

In this experiment, we consider the task of phoneme recognition (Hastie et al., 2001; Hernandez-Lobato et al., 2011). In particular, we consider the problem of discriminating between the spoken vowels "aa" and "ao" using their log-periodograms as features. The data set consists of 695 and 1022 utterances of the vowels "aa" and "ao", respectively, along with their corresponding labels. The response variable in this experiment is binary and therefore we use the probit model rather than the Gaussian observation model.

Each log-periodogram has been sampled at 256 uniformly spaced frequencies. The left-most



panel in Figure 2 shows the frequency-wise mean and standard deviation of the two classes and the right-most panel shows the difference of the two mean signals. We choose a squared exponential kernel for $\boldsymbol{\gamma}$ since it is assumed that frequency bands rather than single frequencies are relevant for discriminating between the two classes. The total number of observations is 1717 and we use $N = 150$ examples for training and the remaining 1567 examples for testing. We repeat the experiment 100 times using different partitions into training and test sets. The training and test sets are generated such that the prior odds of the two classes are the same for both training and test. The number of input features is $D = 257$ (256 frequencies + bias).

We use the low rank approximation for this experiment, and we choose the number of eigenvectors such that 99% of the total variance in $\boldsymbol{\Sigma}_0$ is explained. We use the maximum likelihood method and the CCD marginalization method for the hyperparameter inference. We choose the prior mean of $\boldsymbol{x}$ as $\rho_0 = 0$ to reflect our ignorance on the sign of the active weights and we impose a half Student's t distribution on the prior standard deviation of the $\boldsymbol{x}$, that is $\sqrt{\tau_0} \sim t^+(\mathrm{df} = 4)$, which is considered to be weakly informative.

As in the compressed sensing experiment, we impose a zero-mean normal distribution on the prior mean of $\boldsymbol{\gamma}$ and integrate it out analytically to obtain a kernel of the form given in eq. (73). Compared to the compressed sensing example, our a priori knowledge of the structure of the support are more diffuse, but we expect that the lengthscale is significantly smaller than the number of frequency bins. Therefore, we choose a log-normal prior with mean 40 and standard deviation 30, that is $\kappa_3 \sim \mathcal{LN}\left(40, 30^2\right)$. The 5'th and 95'th percentiles for this distribution is approximately 10 and 100, respectively. For the remaining two hyperparameters, we use the same two prior distributions as in the previous experiment, that is $\kappa_1, \kappa_2 \sim \mathcal{LN}\left(4, 2^2\right)$. To predict the label of a new observation, we compute the predictive distribution by integrating the probit likelihood with respect to the approximate posterior distribution of the weights.

We compare our method against the network-based sparse Bayesian classification (NBSBC) method, which also uses EP to approximate the posterior distribution of linear model with coupled spike-and-slab priors. Instead of using a Gaussian process to encode the structure of the support, the NBSBC model encodes the structure in a network using a Markov random field prior. This method has been shown to outperform competing method on this specific problems (Hernandez-Lobato et al., 2011).

Table 2 summarizes the performance of the methods based on the average number of misclassifications and average log posterior predictive density (LPPD). It is seen that the LR-EP (ML) method achieves similar performance in terms test error as the NBSBC method, but it performs marginally better in terms of test LPPD. On the other hand, it is seen that the LR-EP (CCD) method outperforms both other methods. The panels in Figure 9 shows the posterior distributions of $\boldsymbol{\gamma}$, $\boldsymbol{z}$ and $\boldsymbol{x}$. The posterior distribution for the CCD approximation is a finite mixture model and each of the thin black lines shows the posterior mean for each individual mixture component. However, these are omitted for the posterior of $\boldsymbol{x}$ to improve the visual clarity of the figure. Based on Figure 2(b), we expect the weights for the frequencies between bin 35 and bin 70 to most discriminative of the two classes and

(a) Posterior $\boldsymbol{\gamma}$ (b) Posterior support (c) Posterior signal

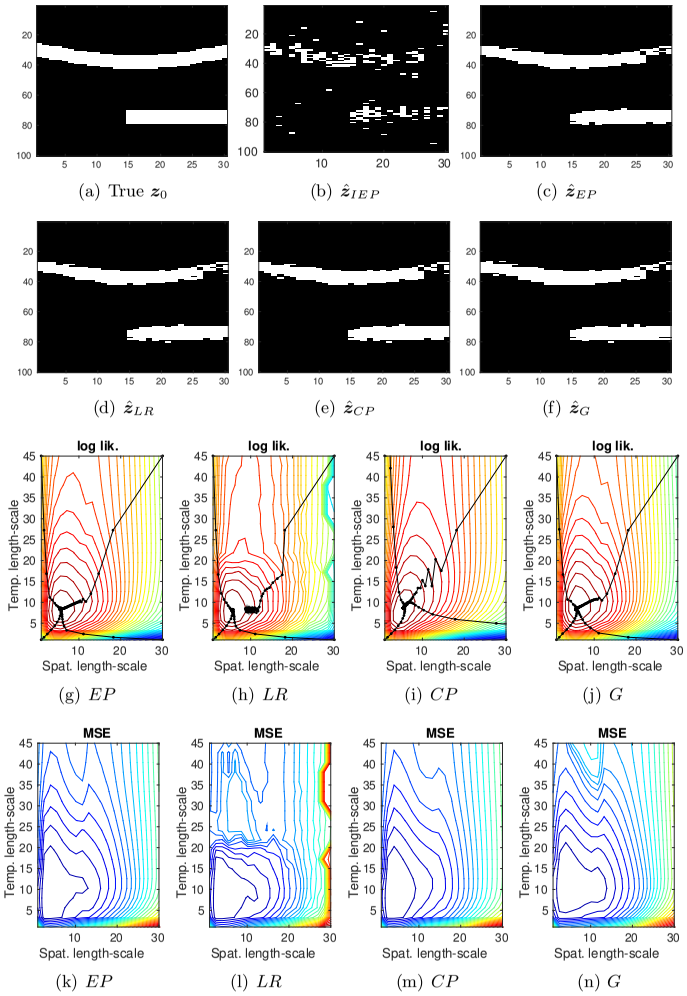
Figure 9: Comparison of the posterior distribution of $\boldsymbol{\gamma}$, $\boldsymbol{z}$ and $\boldsymbol{x}$ for ML and CCD hyperparameter inference. These are omitted for the posterior of the signal to improve visual clarity.

it is seen that both the ML method and the CCD method have high posterior probabilities for the support in the region.

7.6 Experiment 6: Spatio-temporal Example

In the previous experiments the focus was on problems with only one measurement vector, whereas in this and the following experiments we consider problems with multiple measurement vectors. Specifically, in this experiment we qualitatively study the properties of the proposed algorithm in the spatio-temporal setting using simulated data. We have synthesized a signal, where the support set satisfies the following three properties: 1) non-stationarity, 2) spatiotemporal correlation, and 3) the number of active coefficients change over time. The support of the signal is shown in panel (a) in Figure 10. Based on the support set, we sample the active coefficients from a zero-mean isotropic Gaussian distribution. We then observe the desired signal $\boldsymbol{X}$ through linear measurements $\boldsymbol{Y} = \boldsymbol{A}\boldsymbol{X} + \boldsymbol{E}$, where both the forward model $\boldsymbol{A}$ and the noise $\boldsymbol{E}$ is sampled from a zero-mean isotropic Gaussian distribution. The noise variance is scaled such that the SNR is 5dB. We apply our proposed method to estimate $\boldsymbol{X}$ given the forward model $\boldsymbol{A}$ and the observations $\boldsymbol{Y}$.

Panel (b) in Figure 10 shows the reconstructed support $\boldsymbol{Z}$ using the proposed EP algorithm with a diagonal prior covariance matrix on $\boldsymbol{\Gamma}$, which implies no prior correlation in the support. The panels (c)–(f) shows the reconstructed support for full EP, low rank EP, common precision EP and group EP, which all assumes that the prior covariance matrix for $\boldsymbol{\Gamma}$ is a Kronecker product of two squared exponential components. For the group approximation the group size is chosen to 5 and 10 in the spatial and temporal dimension, respectively, and for the low-rank approximation the rank is chosen such that the minimum number of eigenvectors explain 99% of the variance in the prior. All hyperparameters are chosen by maximizing the approximate marginal likelihood. By inspecting the panels (a)–(f) it is seen that the reconstructed support is qualitatively improved by modeling the additional



structure. Furthermore, the reconstructions using the approximation schemes do not differ significantly from the result using full EP.

Panels (g)–(j) shows the marginal likelihood approximation as a function of the spatial and temporal length scale of the prior covariance matrix for the proposed methods, while the panels (k)–(g) show the corresponding NMSE between the reconstructed coefficients $\hat{\boldsymbol{X}}$ and the true coefficient $\boldsymbol{X}$. The black curves superimposed on the marginal likelihood plots show the trajectories of the optimization path for the length-scales of the prior distribution starting from four different initial values. It is seen that the marginal likelihood approximation is unimodal and correlates strongly with the NMSE surface, which suggests that it is reasonable to tune the length-scales of the prior covariance using the marginal likelihood approximation. However, we emphasize that this is not always the case and for some problems this indeed leads to suboptimal results.

7.7 Experiment 7: Phase Transitions for Multiple Measurement Vectors

The multiple measurement vector problem also exhibits a phase transition analogously to the single measurement vector problem described in Experiment 3 (Cotter et al., 2005; Ziniel and Schniter, 2013a; Andersen et al., 2015). In this experiment, we investigate how the location of the phase transition of the EP algorithms improves when the sparsity pattern of the underlying signal is smooth both in space and time and multiple measurement vectors are available. Using a similar setup as in Experiment 3, we generate 100 realizations of $\boldsymbol{X}$ from the prior specified in eq. (10)–(12) such that the total number of active components is fixed to $K = \frac{1}{4}DT = 2500$. The covariance structure is of the form $\boldsymbol{\Sigma}_0 = \boldsymbol{\Sigma}_{\text{temporal}} \otimes \boldsymbol{\Sigma}_{\text{spatial}}$, where both the temporal and spatial components are chosen to be squared exponential kernels. Figure 11 shows an example of a sample realization of $\boldsymbol{\Gamma}$, $\boldsymbol{Z}$ and $\boldsymbol{X}$ from the prior distribution. For each of the realizations of $\boldsymbol{X}$, we generate a set of linear observations $Y = \boldsymbol{A}\boldsymbol{X} + \boldsymbol{E}$, where the forward model $\boldsymbol{A}$ is Gaussian i.i.d. and $E_{nt} \sim \mathcal{N}\left(0, \sigma^2\right)$ is zero-mean Gaussian scaled such that the SNR is fixed to 20dB. For reference we compare our methods against BG-AMP (Vila and Schniter, 2013) and DCS-AMP (Ziniel and Schniter, 2013a). The DCS-AMP method is a temporal extension to the BG-AMP method (see Experiment 3 for a brief description), and it uses approximate message passing inference based on spatially i.i.d. spike-and-slab priors, but assumes that the binary support variables evolve in time according to a first order Markov process. Both BG-AMP and DCS-AMP methods are informed about the true number of active coefficients and the true noise level. The results are shown in Figure 12.

The method LR-EP (blue) assumes that the sparsity pattern is spatially correlated, but independent in time. The method LR-K-EP (red, dashed) applies the low rank approximation to EP and assumes that the sparsity pattern is spatio-temporally correlated and that the prior covariance for $\boldsymbol{\Gamma}$ is described by a Kronecker product (hence the prefix "-K"). Similarly, the methods CP-K-EP (cyan) and G-K-EP (magenta) have the same assumptions about the sparsity pattern, but use the common precision approximation and the group approximation, respectively. For G-K-EP we use groups of 5 in both the spatial dimension and temporal dimension. In this experiment, we do not run full EP with the spatiotemporal prior because it would be prohibitively slow.

Panels (a)–(f) compare the true sparsity pattern and the reconstructed sparsity patterns and panels (g)–(n) show the approximate marginal likelihood and the MSE error metric as a function of the spatial and temporal length-scale. For the low rank approximation (LR-EP), the number of eigenvectors is chosen to explain 99% of the variance and the group size for group approximation (G-EP) is chosen to 5 and 10 in the spatial and temporal dimensions, respectively.

(a) Sample of $\mathbf{\Gamma}$ (b) Sample of $\boldsymbol{Z}$ (c) Sample of $\boldsymbol{X}$

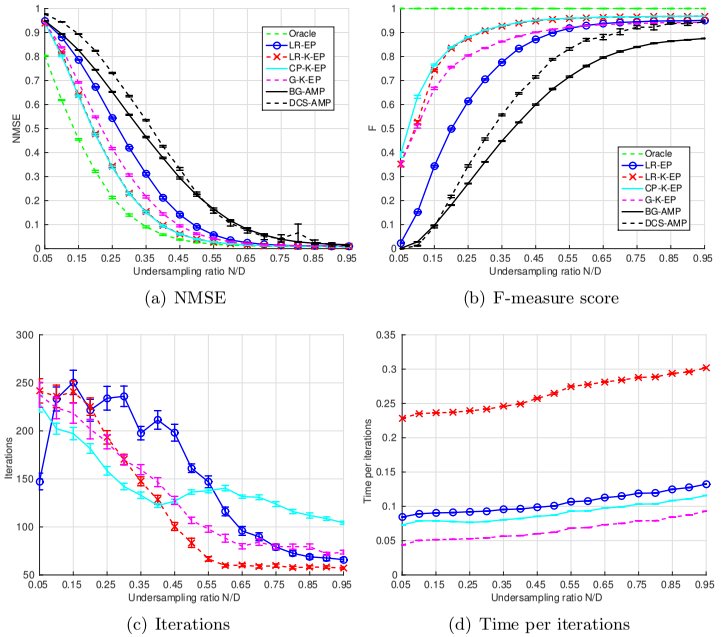

Figure 11: Example of a realization of the synthetic signals in Experiment 6.

On panel (a) in Figure 12 it is seen that as the number of measurements increase, all methods eventually reach the NMSE level of the support-aware oracle estimator, but the general picture is that the more structure a method takes into account (i.i.d. sparsity vs. spatial sparsity vs. spatio-temporal sparsity), the better it performs in terms of NMSE. In particular, at $N/D \approx 0.3$ BG-AMP achieves NMSE ≈ 0.63 and LR-EP achieves NMSE ≈ 0.44 while LR-K-EP and CP-K-EP achieve NMSE ≈ 0.24. Panel (b) shows a similar picture for F-measure. Furthermore, it is seen that the performance of LR-K-EP and CP-K-EP are similar and slightly better than the performance of G-K-EP both in terms of NMSE and F-measure. However, the G-K-EP approximation has the lowest computational complexity per iteration as seen in panel (d). In terms of run time the EP-methods are slower compared to the AMP-based methods, which have linear time complexity in all dimensions. However, the EP methods are not limited to Gaussian i.i.d. ensembles as the AMP-based methods are.

7.8 Experiment 8: EEG Source Localization

In the final experiment, we apply the proposed method to an EEG source localization problem (Baillet et al., 2001), where the objective is to infer the locations of the active sources on the cortical surface of the human brain based on electroencephalogram (EEG) measurements. The brain is modelled using a discrete set of current dipoles distributed on the cortical surface and Maxwell's equations then describe how the magnitudes of the dipole sources relate to the EEG signals measured at the scalp. We apply the proposed method to an EEG data set, where the subjects are presented with pictures of faces and scrambled faces. The data set is publicly available and the experimental paradigm is described in (Henson et al., 2003). The data set has $N = 128$ electrodes and contains a total of 304 epochs evenly distributed between the two conditions: face or scrambled face. Each epoch has a duration of $800ms$ corresponding to $T = 161$ samples in time and the stimuli are presented at $t = 0s$. We generated a forward model[1] with 5124 dipole sources, that is $\boldsymbol{A} \in \mathbb{R}^{128\times 5124}$. To encourage spatio-temporal coherence of the sources, we choose the covariance matrix for $\mathbf{\Gamma}$ to be of the form $\mathbf{\Sigma}_0 = \kappa^2 \cdot \mathbf{\Sigma}_{\text{temporal}} \otimes \mathbf{\Sigma}_{\text{spatial}}$, where both the temporal component and spatial component are squared exponential kernels with individual length-scales. For simplicity, we use the Euclidean distance to compute the pairwise distances among the

(c) Iterations (d) Time per iterations

Figure 12: Performance of the methods as a function of undersampling ratio N/D for $T = 100$. We compare low-rank EP with spatial structure only (LR-EP, Spatial), low rank EP spatio-temporal kronecker structure (LR-L-EP), the common precision EP with spatio-temporal kronecker structure (CP-K-EP), group EP with spatio-temporal kronecker structure (G-K-EP), the low rank approximation (LR-EP) with BGAMP and DCSAMP. The results are averaged over 100 realization.

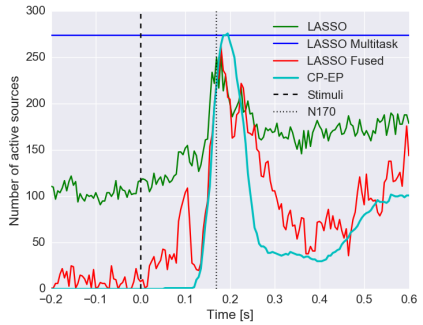

Figure 13: The number of active dipoles sources as a function of the time for the common precision approximation (CP-EP) and the LASSO, the Multi-task LASSO and the fused LASSO for a face perception experiment. The stimuli were presented at time $t = 0$.

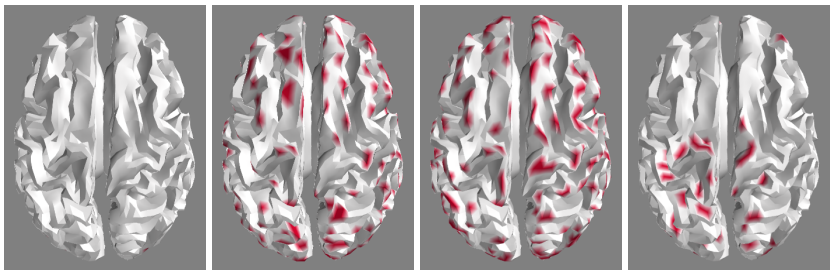
dipole sources as opposed to the more advances approach, where the distances are computed within the manifold defined by the cortex.

The resulting inverse problem has $N = 128$ measurements, $T = 161$ measurement vectors and $D = 5124$ unknowns per time point and a total of $DT = 5124 \cdot 151 = 824964$ unknowns. The forward model has a condition number of $\text{cond}(\boldsymbol{A}) = 3.1099 \cdot 10^{15}$. Thus, the problem instance is both heavily ill-posed and ill-conditioned. Because of the dimensions of this problem we use the common precision approximation for this data set. In fact, a low rank approximation of the prior covariance matrix $\boldsymbol{\Sigma}_0$ will require 3961 eigenvectors to explain 90% of the variance and the matrix low rank eigenvector matrix $\boldsymbol{U} \in \mathbb{R}^{824964 \times 3691}$ would then require more than $20GB$ of memory to store in 64 bit double precision.

Tuning the hyperparameters using the approximate marginal likelihood estimate leads to poor solutions for this data set. In particular, the length-scales were significantly overestimated, which is consistent with what we observed in the compressed sensing experiment for very small samples sizes (see Figure 5(e)). However, manually specifying the hyperparameters using prior knowledge (spatial lengthscale $10mm$, temporal lengthscale $50ms$ and magnitude $\kappa^2 = 10$, prior mean 0), yields a posterior approximation with several interesting aspects. Ideally, we would compare the findings with the same posterior quantities for the BG-AMP and DCS-AMP methods as discussed earlier, but the highly correlated columns of the forward model make the AMP-approximations break down as they assume that the entries of the forward model are sampled from an Gaussian i.i.d. distribution. Instead, we compare with the LASSO[2] (Tibshirani, 1994), the multi-task LASSO [2](Obozinski et al., 2006) and

2. We used the implementation in scikit-learn toolbox (Pedregosa et al., 2011).



the fused LASSO[3] (Tibshirani et al., 2005). The LASSO, the multi-task LASSO and the fused LASSO all minimize a quadratic reconstruction error subject to an ℓ_1 constraint, but the multi-task LASSO also assumes that the sparsity pattern is constant in time (joint sparsity) and the fused LASSO has an additional constraint on the temporal first-order difference of the solution $\sum_{i,t} |x_{i,t} - x_{i,t-1}|$.

The CP-EP method has been informed with appropriate values of the kernel hyperparameters. This is possible because the structure of the sparsity pattern is encoded using generic covariance functions that are easily interpretable. However, this is not an option for the LASSSO methods as the regularization parameters of these methods are more difficult to interpret in terms of the geometry of the problem. To compensate, we used the estimated solution obtained using the CP-EP method to inform the LASSO methods as follows. For the regular LASSO and the multi-task LASSO, we chose the value of the regularization parameter such that the number of active sources matches the CP-EP solution at the time point with the largest number of active sources (see Figure 13). For the fused LASSO, we also matched the average autocorrelation across all sources.

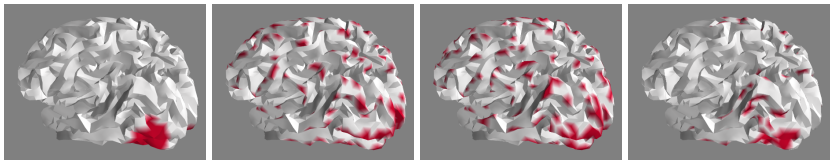


Figure 13 shows the number of active dipole sources as a function of time for each method. The reconstructed support for both CP-EP and the fused LASSO are well-localized in time, whereas the distribution of active sources for LASSO are very diffuse in time. For the CP-EP method, it is seen that the number of active sources is zero until roughly time $t \approx 150ms$, where the number of active sources increase and peaks at $t \approx 180ms$, which is consistent with the known time delay of approximately 170ms for the face perception, that is the so-called N170 ERP component (Itier and Taylor, 2004). Figure 14 shows a visualization of the estimated sets of active sources for time $t = 180ms$ from a top view, a side view and a bottom view, respectively. Interestingly, CP-EP detects four spatially coherent areas: left and right occipital and fusiform face areas that are associated with the face perception (Henson et al., 2009). The LASSO, the Multi-task LASSO and the fused LASSO also detect several active dipoles in the left and right occipital areas, but they also detect active sources distributed over the entire cortex as seen in the top row.

Thus, from this experiment we conclude that this problem is too ill-posed for learning the hyperparameters of the model, but we can still extract meaningful information from the data using the model if we have access to additional a priori information. We note that learning hyperparameters is often difficult in neuroimaging due to high-dimensional signals and poor signal to noise conditions (Varoquaux et al., 2017).

8. Summary and Outlook

In this work, we have addressed the problem of solving multiple underdetermined linear inverse problems subject to a sparsity constraint. We have proposed a new generalization of the spike-and-slab prior distribution to encode a priori correlation of the support of the solution in both space and time by imposing a transformed Gaussian process on the spike-and-slab probabilities. An expectation propagation (EP) algorithm for posterior inference under the proposed model has been derived. Computations involved in EP updates scale like $\mathcal{O}\left(D^3T^3\right)$ where D is the number of features and T is number of inverse problems, hence for large scale problems, the standard EP algorithm can be prohibitively slow. We therefore introduced three different approximation schemes for the covariance structure to reduce the computational complexity. First, assuming that the prior has a Kronecker decomposition brings complexity $\mathcal{O}\left(D^3 + T^3\right)$, based on this decomposition, a further K-rank approximation brings a reduction of complexity to $\mathcal{O}\left(K^2DT\right)$, we also proposed a common precision approximation of complexity $\mathcal{O}\left(D^2T + T^2D\right)$, and finally a scheme based on spatio-temporal grouping of variables effectively reducing D and T by the grouping factor. We also discussed several ways to handle unknown hyperparameters, including maximum likelihood estimates, maximum a posterior estimates and efficient numerical integration using central composite design (CCD) approach.

We investigated the role of the spatio-temporal prior and the approximation schemes in a series of experiments. First we studied a simple 1D problem with spatial, translational invariant smoothness of the support (single measurement case, $T = 1$). For a signal with two small connected components in the support, we illustrate the solutions for variable smoothness of the prior. For a wide range of prior parameters the correct form of the support is recovered, while the two support regions were found to merge in a single region as the smoothness length scale approaches the distance between the two regions. In the second experiment we investigated the role of the three covariance function approximations, also in a single measurement setup ($T = 1$). We found that all approaches accurately reconstruct the true simulated support and inverse problem solutions despite the approximation of the Gaussian process posterior. It is well-known that the quality of the inferred solutions strongly depends on both the undersampling ratio and the sparsity level of the true solution. We investigated how the location of the phase transition is improved by invoking the smoothness prior. We found that the methods based on assumed prior correlation, were uniformly better than the methods with independent priors both in terms of the quality of normalized mean square error and in terms of their accuracy of support recovery (F-measure). The covariance approximation schemes are almost as fast as the scheme without smoothness, while yielding greatly improved performance.

In the experiments 4 and 5, we investigated two applications: compressed sensing of numerical characters and phoneme recognition, respectively. In the former, we demonstrated how the quality of the reconstructed digits was improved using the structured prior. We also found that for the severely undersampled problems, maximum likelihood learning tends to overestimate the lengthscale of the kernel, which in turn lead to poor estimates of the support of and the weight. However, we also demonstrated how this could be alleviated by

imposing a proper prior distribution to the lengthscale parameter and integrating over the uncertainty using CCD. In the latter experiment, we demonstrated how the probit likelihood can be used to extend to model binary sparse classification problems and we found that our algorithm compare well with published benchmarks.

In a sixth experiment we studied the properties of the proposed algorithms in the spatio-temporal setting using simulated data. Signals were synthesized so that the support set showed non-stationarity, spatio-temporal correlation and so that the cardinality of the support set changed over time. We estimated prior hyperparameters by optimizing the approximate marginal likelihood and found they converged to optimal settings in all cases. We found that there was a good correspondence between the approximate marginal likelihood and the solution's quantitative performance measure (NMSE).

Also for the multiple measurement vector problem it is known that there is a phase transition-like dependence of the solution quality on undersampling ratio. In the sixth experiment we investigated how the location of the phase transition of the EP algorithms improved when the sparsity pattern of the underlying signal is smooth in both space and time for the multiple measurements case. We compare our various approximate solvers with the state-of-the-art tools based on approximate message passing: BG-AMP, DCS-AMP, both of which were informed about the true number of active coefficients and the true noise level. The full EP was too demanding to run for this problem. Significant improvement were found for the methods that exploited sparsity structure. Comparing performance with AMP methods, the EP methods performed best both in terms of identifying the support (F measure) and in terms of NMSE. Run times for the EP-methods were longer compared to the AMP-based methods, which have linear complexity in all dimensions. We noted importantly that the EP methods also can be used for more general forward model ensembles (A), while the AMP-based methods assume a Gaussian i.i.d. ensemble.

In the final experiment, we applied the proposed methods to the hard problem of EEG source localization; data for this experiment was derived from a publicly available brain imaging data set designed to detect brain areas involved in face perception (Henson et al., 2003). This was a larger scale application with $N = 128$ measurements and a total number of 824964 unknowns, hence, only the common precision approximation was feasible. Furthermore, the forward model was very ill-conditioned in contrast to the well-conditioned i.i.d. ensembles considered in the simulations. For this data set, the hyperparameters of the kernel, for example, spatial and temporal lengthscale, could not be estimated from the data and thus, additional prior knowledge was required to perform inference. In spite of these challenges highly interesting results were obtained: All four main foci of activation as earlier detected by fMRI, but not in these EEG data by other inference schemes, were here found to have well-defined and spatially extended support by the new approximate inference scheme. In contrast to fMRI EEG allowed us to monitor the dynamics in these areas in high temporal resolution.

This work has led to several interesting lines of research. First of all, from the the compressed sensing experiment as well as the source localization experiment, we concluded that the

lengthscale parameter of the kernel cannot be learned from the data if the problem is too ill-posed. Thus, in future work we will extend the model to handle EEG data for multiple subjects simultaneously in a hierarchical manner, which allows us to use much more data to estimate the hyperparameters. Future studies also include an analysis of the phase transitions of the approximate log marginal likelihood in the hyperparameter space of the spatiotemporal prior as discussed in Experiment 1. Furthermore, we also plan to apply the proposed algorithms to brain decoding problems, for example, in classification of fMRI task pattern data sets. Finally, we also plan to investigate the use of spatio-temporal sparsity priors for factor models like PCA and ICA.

Appendix A. Moments Computations for $f_{2,t,j}$

In this section, we consider the update for the terms $\tilde{f}_{2,t,j}\left(x_{t,j}, z_{t,j}\right)$. First we compute the so-called cavity distribution $Q^{\backslash 2,t,j}\left(x_{t,j}, z_{t,j}\right)$ by removing the contribution of $f_{2,t,j}(x_{t,j}, t, j)$ from the marginals of the joint approximation $Q\left(\boldsymbol{x}, \boldsymbol{z}, \boldsymbol{\gamma}\right)$

$$\begin{aligned} Q^{\backslash 2,t,j}(x_{t,j}, z_{t,j}) &= \frac{Q\left(x_{t,j}, z_{t,j}\right)}{\tilde{f}_{2,t,j}\left(x_{t,j}, z_{t,j}\right)} = \frac{\mathcal{N}\left(x_{t,j} \middle| \hat{m}_{t,j}, \hat{V}_{t,j}\right) \mathrm{Ber}\left(z_{t,j} \middle| \phi\left(\hat{\gamma}_{t,j}\right)\right)}{\mathcal{N}\left(x_{t,j} \middle| \hat{m}_{2,t,j}, \hat{V}_{2,t,j}\right) \mathrm{Ber}\left(z_{t,j} \middle| \phi\left(\hat{\gamma}_{2,t,j}\right)\right)} \\ &= K^{\backslash 2,t,j} \cdot \mathcal{N}\left(x_{t,j} \middle| \hat{m}^{\backslash 2,t,j}, \hat{V}^{\backslash 2,t,j}\right) \mathrm{Ber}\left(z_{t,j} \middle| \phi\left(\hat{\gamma}^{\backslash 2,t,j}\right)\right), \end{aligned} \tag{74}$$

where

$$\hat{v}^{\backslash 2,t,j} = \left[\hat{V}_{jj}^{-1} - \hat{v}_{2,t,j}^{-1}\right]^{-1}, \tag{75}$$

$$\hat{m}^{\backslash 2,t,j} = \hat{v}^{\backslash 2,t,j}\left[\hat{V}_{t,jj}^{-1}\hat{m}_{t,j} - \hat{v}_{2,t,j}^{-1}\hat{m}_{2,t,j}\right], \tag{76}$$

$$\hat{\gamma}^{\backslash 2,t,j} = \hat{\gamma}_{3,t,j}. \tag{77}$$

Note that the cavity parameter for γ for $f_{2,t,j}$ is simply equal to $\hat{\gamma}_{3,t,j}$ (and vice versa) since $\hat{\gamma}_{2,t,j}$ and $\hat{\gamma}_{3,t,j}$ are the only two terms contributing to $\gamma_{t,j}$.

Next, we minimize the KL-divergence between $f_{2,t,j}Q^{\backslash 2,t,j}$ and q or equivalently matching the moments between the two distributions. Following the latter approach we first compute the (unnormalized) moment w.r.t. $z_{t,j}$

$$\begin{aligned} Z_1 &= \sum_{z_{t,j}} \int z_{t,j} f_{2,t,j}\left(x_{t,j}, z_{t,j}\right) Q^{\backslash 2,t,j}\left(x_{t,j}, z_{t,j}\right) \mathrm{d}x_{t,j} \\ &= \phi\left(\hat{\gamma}^{\backslash 2,t,j}\right) \mathcal{N}\left(0 \middle| \hat{m}^{\backslash 2,i} - \rho_0, \hat{V}^{\backslash 2,t,j} + \tau_0\right). \end{aligned} \tag{78}$$

Next, the zeroth moment w.r.t $x_{t,i}$ or the normalization constant of $f_{2,t,j}Q^{\setminus 2,t,j}$

$$\begin{aligned} X_0 &= \sum_{z_{t,j}} \int f_{2,t,j}\left(x_{t,j}, z_{t,j}\right) Q^{\setminus 2,t,j}\left(x_{t,j}, z_{t,j}\right) \mathrm{d}x_{t,j} \qquad (79)\\ &= \sum_{z_{t,j}} \int \left[\left(1 - z_{t,j}\right)\delta(x_{t,j}) + z_{t,j}\mathcal{N}\left(x_{t,j}\middle|\rho_0, \tau_0\right)\right] \\ &\quad \mathcal{N}\left(x_{t,j}\middle|\hat{m}^{\setminus 2,t,j}, \hat{V}^{\setminus 2,t,j}\right) \mathrm{Ber}\left(z_{t,j}\middle|\phi\left(\hat{\gamma}^{\setminus 2,t,j}\right)\right) \mathrm{d}x_{t,j} \\ &= \left(1 - \phi\left(\hat{\gamma}^{\setminus 2,t,j}\right)\right)\mathcal{N}\left(0\middle|\hat{m}^{\setminus 2,i}, \hat{V}^{\setminus 2,i}\right) + \phi\left(\hat{\gamma}^{\setminus 2,t,j}\right)\mathcal{N}\left(0\middle|\hat{m}^{\setminus 2,t,j} - \rho_0, \hat{V}^{\setminus 2,t,j} + \tau_0\right) \\ &= \left(1 - \phi\left(\hat{\gamma}^{\setminus 2,t,j}\right)\right)\mathcal{N}\left(0\middle|\hat{m}^{\setminus 2,i}, \hat{V}^{\setminus 2,i}\right) + Z_1 \qquad (80) \end{aligned}$$

We now compute the (unnormalized) first moment w.r.t. $x_{t,j}$

$$\begin{aligned} X_1 &= \sum_{z_{t,j}} \int x_{t,j} f_{2,t,j}\left(x_{t,j}, z_{t,j}\right) Q^{\setminus 2,i}\left(x_{t,j}, z_{t,j}\right) \mathrm{d}x_{t,j} \\ &= \phi\left(\hat{\gamma}^{\setminus 2,t,j}\right)\mathcal{N}\left(0\middle|\hat{m}^{\setminus 2,t,j} - \rho_0, \hat{V}^{\setminus 2,t,j} + \tau_0\right) \frac{\frac{\hat{m}^{\setminus 2,t,j}}{\hat{V}^{\setminus 2,t,j}} + \frac{\rho_0}{\tau_0}}{\frac{1}{\tau_0} + \frac{1}{\hat{V}^{\setminus 2,t,j}}} \\ &= Z_1 \frac{\hat{m}^{\setminus 2,t,j}\tau_0 + \rho_0 \hat{V}^{\setminus 2,t,j}}{\tau_0 + \hat{V}^{\setminus 2,t,j}} \qquad (81) \end{aligned}$$

and the second (unnormalized) moment w.r.t. $x_{t,j}$

$$\begin{aligned} X_2 &= \sum_{z_{t,j}} \int x_i^2 f_{2,i}\left(x_i, z_i\right) Q^{\setminus 2,i}\left(x_i, z_i\right) \mathrm{d}x_i \\ &= \phi\left(\hat{\gamma}^{\setminus 2,i}\right)\mathcal{N}\left(0\middle|\hat{m}^{\setminus 2,i} - \rho_0, \hat{V}^{\setminus 2,i} + \tau_0\right)\left[\left(\frac{\frac{\hat{m}^{\setminus 2,i}}{\hat{V}^{\setminus 2,i}} + \frac{\rho_0}{\tau_0}}{\frac{1}{\tau_0} + \frac{1}{\hat{V}^{\setminus 2,i}}}\right)^2 + \frac{1}{\frac{1}{\tau_0} + \frac{1}{\hat{V}^{\setminus 2,i}}}\right] \\ &= Z_1\left[\left(\frac{\hat{m}^{\setminus 2,t,j}\tau_0 + \rho_0\hat{V}^{\setminus 2,t,j}}{\tau_0 + \hat{V}^{\setminus 2,t,j}}\right)^2 + \frac{\tau_0\hat{V}^{\setminus 2,i}}{\hat{V}^{\setminus 2,i} + \tau_0}\right] \qquad (82) \end{aligned}$$

The central moments for Q^* in eq. (21) are given by

$$E\left[x_{t,j}\right] = \frac{X_1}{X_0}, \qquad V\left[x_{t,j}\right] = \frac{X_2}{X_0} - \frac{X_1^2}{X_0^2}, \qquad E\left[z_{t,j}\right] = \frac{Z}{X_0}. \qquad (83)$$

Appendix B. Moment Computations for $\tilde{f}_{3,t,j}$

The moments matching for $\tilde{f}_{3,t,j}$ is derived in a similar manner as for $\tilde{f}_{2,t,j}$ (see appendix A for details). First we compute the cavity distribution $Q^{\setminus 3,t,j}\left(z_{t,j}, \gamma_{t,j}\right)$ by removing the

contribution of $f_{3_t,j}(z_{t,j}, \gamma_{t,j})$ from the marginals of the joint approximation Q

$$\begin{aligned} Q^{\setminus 3,t,j}(z_{t,j}, \gamma_{t,j}) &= \frac{Q\left(z_{t,j}, \gamma_{t,j}\right)}{\tilde{f}_{3,t,j}\left(z_{t,j}, \gamma_{t,j}\right)} = \frac{\mathrm{Ber}\left(z_{t,j}\middle|\phi\left(\hat{\gamma}_{t,j}\right)\right)\mathcal{N}\left(\gamma_{t,j}, \hat{\mu}_{t,j}, \hat{\Sigma}_{t,jj}\right)}{\mathrm{Ber}\left(z_{t,j}\middle|\phi\left(\hat{\gamma}_{3,t,j}\right)\right)\mathcal{N}\left(\gamma_{t,j}, \hat{\mu}_{3,t,j}, \hat{\Sigma}_{3,t,j}\right)} \\ &= K^{\setminus 3,t,j} \cdot \mathrm{Ber}\left(z_{t,j}\middle|\phi\left(\hat{\gamma}^{\setminus 3,t,j}\right)\right)\mathcal{N}\left(\gamma_{t,j}\middle|\hat{\mu}^{\setminus 3,t,j}, \hat{\Sigma}^{\setminus 3,t,j}\right), \qquad (84) \end{aligned}$$

where

$$\hat{\Sigma}^{\setminus 3,t,j} = \left(\hat{\Sigma}_{t,jj}^{-1} - \Sigma_{3,t,j}^{-1}\right)^{-1}, \qquad (85)$$

$$\hat{\mu}^{\setminus 3,t,j} = \hat{\Sigma}^{\setminus 3,t,j}\left(\hat{\Sigma}_{t,jj}^{-1}\hat{\mu}_{t,j} - \hat{\Sigma}_{3,t,j}^{-1}\hat{\mu}_{3,t,j}\right), \qquad (86)$$

$$\hat{\gamma}^{\setminus 3,t,j} = \hat{\gamma}_{2,t,j}. \qquad (87)$$

Once again we minimize the KL-divergence between $f_{3,t,j}Q^{\setminus 3,t,j}$ and Q or equivalently matching the moments between the two distributions. We now compute the moments w.r.t. $\gamma_{j,t}$ and $z_{j,t}$ of the (unnormalized) tilted distribution

$$G_m = \sum_{z_{j,t}} \int \gamma_{j,t}^m \cdot f_{3,t,j}\left(z_{j,t}, \gamma_{j,t}\right) Q^{\setminus 3,t,j}\left(z_{j,t}, \gamma_{j,t}\right) \mathrm{d}\gamma_{j,t} \quad \text{for} \quad m = 0, 1, 2, \qquad (88)$$

$$Z_1 = \sum_{z_{j,t}} \int z_{j,t} \cdot f_{3,t,j}\left(z_{j,t}, \gamma_{j,t}\right) Q^{\setminus 3,t,j}\left(z_{j,t}, \gamma_{j,t}\right) \mathrm{d}\gamma_{j,t} \qquad (89)$$

We first compute the normalization constant of $f_{3,t,j}Q^{\setminus 3,t,j}$

$$\begin{aligned} G_0 &= \sum_{z_{t,j}} \int f_{3,t,j}\left(z_{t,j}, \gamma_{t,j}\right) Q^{\setminus 3,t,j}\left(z_{t,j}, \gamma_i\right) \mathrm{d}\gamma_{t,j} \\ &= \sum_{z_{t,j}} \int \mathrm{Ber}\left(z_{t,j}\middle|\phi\left(\gamma_{t,j}\right)\right)\mathrm{Ber}\left(z_{t,j}\middle|\phi\left(\hat{\gamma}^{\setminus 3,t,j}\right)\right)\mathcal{N}\left(\gamma_{t,j}\middle|\hat{\mu}^{\setminus 3,t,j}, \hat{\Sigma}^{\setminus 3,t,j}\right)\mathrm{d}\gamma_{t,j} \\ &= \sum_{z_i} \int \left[\left(1 - z_i\right)\left(1 - \phi\left(\gamma_i\right)\right)\left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right) + z_i\phi\left(\gamma_i\right)\phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right]\mathcal{N}\left(\gamma_i\middle|\hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right)\mathrm{d}\gamma_i \\ &= \left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right)\int\left(1 - \phi\left(\gamma_i\right)\right)\mathcal{N}\left(\gamma_i\middle|\hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right)\mathrm{d}\gamma_i \\ &\quad + \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\int\phi\left(\gamma_i\right)\mathcal{N}\left(\gamma_i\middle|\hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right)\mathrm{d}\gamma_i \end{aligned}$$

Integrals of the form $\int \phi\left(\gamma_i\right)\mathcal{N}\left(\gamma_i\middle|\hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right)\mathrm{d}\gamma_i$ can be solved analytically (Rasmussen and Williams, 2006),

$$\int \phi\left(\gamma_i\right)\mathcal{N}\left(\gamma_i\middle|\hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right)\mathrm{d}\gamma_i = \phi\left(c_{3,i}\right), \quad c_{3,i} \triangleq \frac{\hat{\mu}^{\setminus 3,i}}{\sqrt{1 + \hat{\Sigma}^{\setminus 3,i}}}. \qquad (90)$$

Inserting this result back into the expression for G_0 yields

$$G_0 = \left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right)\left(1 - \phi\left(c_{3,i}\right)\right) + \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\phi\left(c_{3,i}\right). \qquad (91)$$

We can now compute the moments of the unnormalized distribution

$$\begin{aligned} Z_1 &= \sum_{z_i} \int z_i f_{3,i}\left(z_i, \gamma_i\right) Q^{\setminus 3,i}\left(z_i, \gamma_i\right) \mathrm{d}\gamma_i \\ &= \phi\left(\hat{\gamma}^{\setminus 3,i}\right) \phi\left(c_{3,i}\right), \end{aligned} \tag{92}$$

Then the first moment w.r.t. to $z_{i,t}$ is obtained as $E\left[z_{i,t}\right] = Z_1/G_0$.

For the moments w.r.t. γ_i, we get

$$\begin{aligned} G_1 &= \sum_{z_i} \int \gamma_i f_{3,i}\left(z_i, \gamma_i\right) Q^{\setminus 3,i}\left(z_i, \gamma_i\right) \mathrm{d}\gamma_i \\ &= \sum_{z_i} \int \gamma_i \left[\left(1 - z_i\right)\left(1 - \phi\left(\gamma_i\right)\right)\left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right) + z_i \phi\left(\gamma_i\right) \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right] \\ &\quad \mathcal{N}\left(\gamma_i \middle| \hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right) \mathrm{d}\gamma_i \\ &= \left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right) \int \gamma_i \left(1 - \phi\left(\gamma_i\right)\right) \mathcal{N}\left(\gamma_i \middle| \hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right) \mathrm{d}\gamma_i \\ &\quad + \phi\left(\hat{\gamma}^{\setminus 3,i}\right) \int \gamma_i \phi\left(\gamma_i\right) \mathcal{N}\left(\gamma_i \middle| \hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right) \mathrm{d}\gamma_i \\ &= \left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right) \left[\hat{\mu}^{\setminus 3,i} - \int \gamma_i \phi\left(\gamma_i\right) \mathcal{N}\left(\gamma_i \middle| \hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right) \mathrm{d}\gamma_i\right] \\ &\quad + \phi\left(\hat{\gamma}^{\setminus 3,i}\right) \int \gamma_i \phi\left(\gamma_i\right) \mathcal{N}\left(\gamma_i \middle| \hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right) \mathrm{d}\gamma_i \end{aligned} \tag{93}$$

Again we turn to (Rasmussen and Williams, 2006) for the analytical solution of the above integrals

$$\begin{aligned} \int \gamma_i \phi\left(\gamma_i\right) \mathcal{N}\left(\gamma_i \middle| \hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right) \mathrm{d}\gamma_i &= \phi\left(c_{3,i}\right) \hat{\mu}^{\setminus 3,i} + \phi\left(c_{3,i}\right) \frac{\hat{\Sigma}^{\setminus 3,i} \mathcal{N}\left(c_{3,i} \middle| 0, 1\right)}{\phi\left(c_{3,i}\right) \sqrt{1 + \hat{\Sigma}^{\setminus 3,i}}} \\ &= \phi\left(c_{3,i}\right) \hat{\mu}^{\setminus 3,i} + \phi\left(c_{3,i}\right) d_{3,i}, \end{aligned} \tag{94}$$

where we have defined

$$d_{3,i} \triangleq \frac{\hat{\Sigma}^{\setminus 3,i} \mathcal{N}\left(c_{3,i} \middle| 0, 1\right)}{\phi\left(c_{3,i}\right) \sqrt{1 + \hat{\Sigma}^{\setminus 3,i}}}. \tag{95}$$

Plugging eq. (94) back into eq. (93) and simplifying yields

$$\begin{aligned} G_1 &= \left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right) \left[\left(1 - \phi\left(c_{3,i}\right)\right) \hat{\mu}^{\setminus 3,i} - \phi\left(c_{3,i}\right) d_{3,i}\right] + \phi\left(\hat{\gamma}^{\setminus 3,i}\right) \phi\left(c_{3,i}\right) \left[\hat{\mu}^{\setminus 3,i} + d_{3,i}\right] \\ &= \left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right) \left(1 - \phi\left(c_{3,i}\right)\right) \hat{\mu}^{\setminus 3,i} - \left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right) \phi\left(c_{3,i}\right) d_{3,i} + Z_1 \left[\hat{\mu}^{\setminus 3,i} + d_{3,i}\right] \\ &= \left(G_0 - Z_1\right) \hat{\mu}^{\setminus 3,i} - \left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right) \phi\left(c_{3,i}\right) d_{3,i} + Z_1 \left[\hat{\mu}^{\setminus 3,i} + d_{3,i}\right] \\ &= G_0 \hat{\mu}^{\setminus 3,i} + \left(2 Z_1 - \phi\left(c_{3,i}\right)\right) d_{3,i} \end{aligned} \tag{96}$$

Thus, the first moment w.r.t. $\gamma_{i,t}$ is given by $\mathbb{E}\left[\gamma_{i,t}\right] = G1/G0$.

Similarly, we compute the second moment w.r.t. γ_i

$$\begin{aligned} G_2 &= \sum_{z_i} \int \gamma_i^2 f_{3,i}\left(z_i, \gamma_i\right) Q^{\setminus 3,i}\left(z_i, \gamma_i\right) \mathrm{d}\gamma_i \\ &= \left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right) \int \gamma_i^2 \left(1 - \phi\left(\gamma_i\right)\right) \mathcal{N}\left(\gamma_i \middle| \hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right) \mathrm{d}\gamma_i \\ &\quad + \phi\left(\hat{\gamma}^{\setminus 3,i}\right) \int \gamma_i^2 \phi\left(\gamma_i\right) \mathcal{N}\left(\gamma_i \middle| \hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right) \mathrm{d}\gamma_i \end{aligned} \tag{97}$$

The solution to the above integrals are given by (Rasmussen and Williams, 2006)

$$\begin{aligned} &\int \gamma_i^2 \phi\left(\gamma_i\right) \mathcal{N}\left(\gamma_i \middle| \hat{\mu}^{\setminus 3,i}, \hat{\Sigma}^{\setminus 3,i}\right) \mathrm{d}\gamma_i \\ &= \phi\left(c_{3,i}\right) \left[2 \hat{\mu}^{\setminus 3,i} \left(\hat{\mu}^{\setminus 3,i} + d_{3,i}\right) + \left(\hat{\Sigma}^{\setminus 3,i} - \left(\hat{\mu}^{\setminus 3,i}\right)^2\right) - b_{3,i}\right] \end{aligned} \tag{98}$$

where

$$b_{3,i} \triangleq \frac{\left(\hat{\Sigma}^{\setminus 3,i}\right)^2 c_{3,i} \mathcal{N}\left(c_{3,i} \middle| 0, 1\right)}{\phi\left(c_{3,i}\right)\left(1 + \hat{\Sigma}^{\setminus 3,i}\right)} \tag{99}$$

Furthermore, we define

$$w_{3,i} \triangleq 2 \hat{\mu}^{\setminus 3,i} \left(\hat{\mu}^{\setminus 3,i} + d_{3,i}\right) + \left(\hat{\Sigma}^{\setminus 3,i} - \left(\hat{\mu}^{\setminus 3,i}\right)^2\right) - b_{3,i} \tag{100}$$

Substituting the above result back into eq. (97) and rearranging yields

$$\begin{aligned} G_2 &= \left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right) \left[\left(\hat{\mu}^{\setminus 3,i}\right)^2 + \hat{\Sigma}^{\setminus 3,i} - \phi\left(c_{3,i}\right) w_{3,i}\right] + \phi\left(\hat{\gamma}^{\setminus 3,i}\right) \phi\left(c_{3,i}\right) w_{3,i} \\ &= \left(1 - \phi\left(\hat{\gamma}^{\setminus 3,i}\right)\right) \left[\left(\hat{\mu}^{\setminus 3,i}\right)^2 + \hat{\Sigma}^{\setminus 3,i} - \phi\left(c_{3,i}\right) w_{3,i}\right] + Z_1 w_{3,i} \end{aligned} \tag{101}$$

Thus, the second moment is given by $\mathbb{E}\left[\gamma_{i,t}^2\right] = G2/G0$. Finally, the central moments of Q^* then becomes

$$\mathbb{E}\left[\gamma_{j,t}\right] = \frac{G_1}{G_0}, \qquad \mathbb{V}\left[\gamma_{j,t}\right] = \frac{G_2}{G_0} - \frac{G_1^2}{G_0^2}, \qquad \mathbb{E}\left[z_{j,t}\right] = \frac{Z_1}{G_0}. \tag{102}$$

These moments completely determine the distribution $Q^{3,\text{new}}$ and thus, we compute the updates for $f_{3,i}$ as follows

$$\hat{\Sigma}_{3,i}^{\text{new}} = \left[\mathbb{V}\left[\gamma_i\right]^{-1} - \left(\hat{\Sigma}^{\setminus 3,i}\right)^{-1}\right]^{-1}, \tag{103}$$

$$\hat{\mu}_{3,i}^{\text{new}} = \hat{\Sigma}_{3,i}^{\text{new}} \left[\mathbb{V}\left[\gamma_i\right]^{-1} \mathbb{E}\left[\gamma_i\right] - \left(\hat{\Sigma}^{\setminus 3,i}\right)^{-1} \hat{\mu}^{\setminus 3,i}\right], \tag{104}$$

$$\hat{\gamma}_{3,i}^{\text{new}} = d\left(\phi\left(\mathbb{E}\left[z_i\right]\right), \hat{\gamma}^{\setminus 3,i}\right), \tag{105}$$

Appendix C. Moments Computations for Probit Likelihood

The purpose of this section is to describe the details of the EP approximation of the structured spike-and-slab prior with a probit likelihood. Using the notation described in Section 4, the probit likelihood term is given by

$$f_{1,t}\left(\boldsymbol{x}_t\right) = p(\boldsymbol{y}_t|\boldsymbol{x}_t) = \prod_{n=1}^{N} \phi\left(y_{n,t}\boldsymbol{A}_{n,\cdot}\boldsymbol{x}_t\right). \tag{106}$$

First we compute the cavity distribution $Q^{\backslash 1,t,n}\left(\boldsymbol{x}\right)$ by removing the contribution of $\tilde{f}_{1t,n}(\boldsymbol{x})$ from the marginals of the joint approximation Q

$$Q^{\backslash 1,t,n}(\boldsymbol{x}_t) = \frac{\mathcal{N}\left(\boldsymbol{x}_t|\boldsymbol{m}_t, \boldsymbol{V}_t\right)}{\tilde{f}_{1,t,n}(\boldsymbol{x}_t)} = K^{\backslash 1,t,n}\mathcal{N}\left(\boldsymbol{x}_t|\boldsymbol{m}^{\backslash 1,t,n}, \boldsymbol{V}^{\backslash 1,t,n}\right), \tag{107}$$

where

$$\boldsymbol{V}^{\backslash 1,t,n} = \left(\hat{\boldsymbol{V}}_t^{-1} - \hat{\boldsymbol{V}}_{1,t,n}^{-1}\right)^{-1}, \tag{108}$$

$$\boldsymbol{m}^{\backslash 1,t,n} = \boldsymbol{V}^{\backslash 1,t,n}\left(\hat{\boldsymbol{V}}_t^{-1}\hat{\boldsymbol{m}}_t - \hat{\boldsymbol{V}}_{1,t}^{-1}\hat{\boldsymbol{m}}_{1,t,n}\right). \tag{109}$$

for diagonal matrices $\boldsymbol{V}_t$ and $\boldsymbol{V}^{\backslash 1,t,n}$. The tilted distribution then becomes

$$\hat{q}_{1,t,n}\left(\boldsymbol{x}_t\right) = \frac{1}{z_{1,t,n}}\phi\left(y_{n,t}\boldsymbol{A}_{n,\cdot}\boldsymbol{x}_t\right)\mathcal{N}\left(\boldsymbol{x}_t|\boldsymbol{m}^{\backslash 1,t,n}, \boldsymbol{V}^{\backslash 1,t,n}\right),$$

First we compute the normalization constant, which is given by

$$z_{1,t,n} = \int \phi\left(y_{n,t}\boldsymbol{A}_{n,\cdot}\boldsymbol{x}_t\right)\mathcal{N}\left(\boldsymbol{x}_t|\boldsymbol{m}^{\backslash 1,t,n}, \boldsymbol{V}^{\backslash 1,t,n}\right)\mathrm{d}\boldsymbol{x}_t \tag{110}$$

$$= \int \phi\left(u\right)\mathcal{N}\left(u|a_{1,t,n}, b_{1,t,n}\right)\mathrm{d}u \tag{111}$$

$$= \phi\left(c_{1,t,n}\right), \tag{112}$$

where $a_{1,t,n} = y_{n,t}\boldsymbol{A}_{n,\cdot}\boldsymbol{m}^{\backslash 1,t,n}$, $b_{1,t,n} = \boldsymbol{A}_{n,\cdot}\boldsymbol{V}^{\backslash 1,t,n}\boldsymbol{A}_{n,\cdot}^T$ and $c_{1,t,n} = \frac{a_{1,t,n}}{\sqrt{1+b_{1,t,n}}}$. Since $y_{n,t} \in \{-1, 1\}$, $y_{n,t}$ does not appear in the expression for $b_{1,t,n}$ due to square form. Define the row-vector $\tilde{\boldsymbol{A}}_n = y_{n,t}\boldsymbol{A}_{n,\cdot} \in \mathbb{R}^{1\times D}$, then the first moment w.r.t. $x_{t,j}$ is given by

$$\mathbb{E}\left[x_{t,j}\right] = \frac{1}{z_{1,t,n}}\int x_{t,j}\phi\left(y_{n,t}\boldsymbol{A}_{n,\cdot}\boldsymbol{x}_t\right)\mathcal{N}\left(\boldsymbol{x}_t|\boldsymbol{m}^{\backslash 1,t,n}, \boldsymbol{V}^{\backslash 1,t,n}\right)\mathrm{d}\boldsymbol{x}_t \tag{113}$$

$$= \frac{1}{z_{1,t,n}}\int x_{t,j}\phi\left(\tilde{\boldsymbol{A}}_{n,\cdot}\boldsymbol{x}_t\right)\mathcal{N}\left(\boldsymbol{x}_t|\boldsymbol{m}^{\backslash 1,t,n}, \boldsymbol{V}^{\backslash 1,t,n}\right)\mathrm{d}\boldsymbol{x}_t \tag{114}$$

$$= \frac{1}{z_{1,t,n}}\int x_{t,j}\int \phi\left(\tilde{\boldsymbol{A}}_{n,-j}\boldsymbol{x}_{-j} + \tilde{a}_{n,j}x_{t,j}\right)\mathcal{N}\left(\boldsymbol{x}_{t,-j}|\boldsymbol{m}_{-j}^{\backslash 1,t,n}, \boldsymbol{V}_{-j}^{\backslash 1,t,n}\right)\mathrm{d}\boldsymbol{x}_{t,-j}$$
$$\mathcal{N}\left(x_{t,j}|\boldsymbol{m}_j^{\backslash 1,t,n}, \boldsymbol{V}_{jj}^{\backslash 1,t,n}\right)\mathrm{d}x_{t,j} \tag{115}$$

Performing a change of variable, $z = \tilde{A}_{n,-j}\boldsymbol{x}_{t,-j}$, reduces the inner integral to a one-dimensional integral and thus, the resulting two nested one-dimensional integrals can be solved using standard results for Gaussian integrals Rasmussen and Williams (2006). The resulting moment becomes:

$$\mathbb{E}\left[x_{t,j}\right] = m_j^{\backslash 1,t,n} + \alpha_{1,t,n}\tilde{a}_{n,j}V_{jj}^{\backslash 1,t,n}, \tag{116}$$

where we have defined $\alpha_{1,t,n} = \frac{\mathcal{N}(z)}{\sqrt{1+b_{1,t,n}}\phi(z)}$. Therefore,

$$\mathbb{E}\left[\boldsymbol{x}_t\right] = \boldsymbol{m}^{\backslash 1,t,n} + \alpha_{1,t,n}\cdot\left(\tilde{\boldsymbol{A}}_{n,\cdot}\circ\mathrm{diag}\left(\boldsymbol{V}^{\backslash 1,t,n}\right)\right). \tag{117}$$

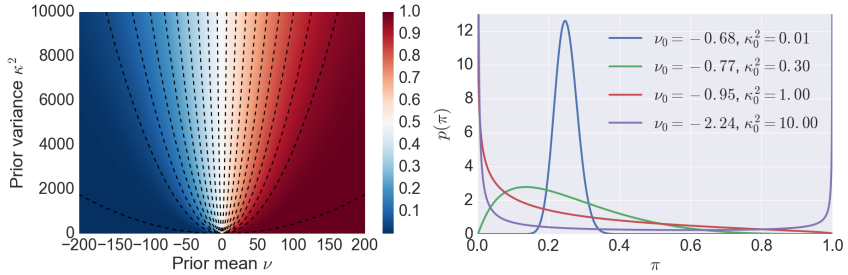
Carrying out similar calculations for $\boldsymbol{x}\boldsymbol{x}^T$ yields

$$\mathbb{V}\left[\boldsymbol{x}_t\right] = \mathrm{diag}\left(\boldsymbol{V}^{\backslash 1,t,n}\right)$$
$$- \alpha_{1,t,n}\cdot\frac{\left(\tilde{\boldsymbol{A}}_{n,\cdot}\mathbb{E}\left[\boldsymbol{x}_t\right] + \alpha_{1,t,n}\right)}{1+b_{1,t,n}}\left(\tilde{\boldsymbol{A}}_{n,\cdot}\circ\mathrm{diag}\left(\boldsymbol{V}^{\backslash 1,t,n}\right)\right)\circ\left(\tilde{\boldsymbol{A}}_{n,\cdot}\circ\mathrm{diag}\left(\boldsymbol{V}^{\backslash 1,t,n}\right)\right). \tag{118}$$

Using these moments, we compute the updates for $\tilde{f}_{1,t,n}$ as follows

$$\hat{\boldsymbol{V}}_{1,t,n}^{\mathrm{new}} = \left[\boldsymbol{V}\left[\boldsymbol{x}_t\right]^{-1} - \left(\boldsymbol{V}^{\backslash 1,t,n}\right)^{-1}\right]^{-1}, \tag{119}$$

$$\hat{\boldsymbol{m}}_{1,t,n}^{\mathrm{new}} = \hat{\boldsymbol{V}}_{1,t,n}^{\mathrm{new}}\left[\boldsymbol{V}\left[\boldsymbol{x}_t\right]^{-1}\mathbb{E}\left[\boldsymbol{x}_t\right] - \left(\boldsymbol{V}^{\backslash 1,t,n}\right)^{-1}\boldsymbol{m}^{\backslash 1,t,n}\right]. \tag{120}$$



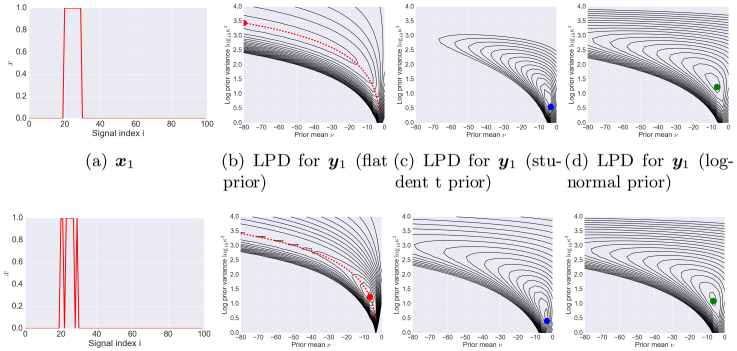
Appendix D. On the Prior Mean and Variance of Γ

The purpose of this appendix is to elaborate on the interplay between the prior mean and the prior variance of $\boldsymbol{\Gamma}$. For this analysis we will assume that the $\boldsymbol{\Gamma}$ has constant mean $\boldsymbol{\mu}_0 = \nu_0\mathbf{1}$ for $\nu_0 \in \mathbb{R}$, and covariance $\boldsymbol{\Sigma}_0 = \kappa_0^2\boldsymbol{R}_0$, where $\mathbf{1} \in \mathbb{R}^D$ is a column vector of ones and $\boldsymbol{R}_0 \in \mathbb{R}^{D\times D}$ is a correlation matrix. Recall from eq. (8) that the marginal prior probability of $z_i = 1$ is given by

$$\hat{p} = p(z_i = 1) = \int p(z_i = 1|\gamma_i)p(\gamma_i)\mathrm{d}\gamma_i = \int \phi(\gamma_i)\mathcal{N}\left(\gamma_i|\mu_i, \Sigma_{0,ii}\right)\mathrm{d}\gamma_i = \phi\left(\frac{\nu_0}{\sqrt{1+\kappa_0^2}}\right). \tag{121}$$

It is seen from the above expression that the marginal expected sparsity level is controlled by ν_0 and κ_0^2. Figure 15(a) shows the surface of $p(z_i = 1)$ as a function of ν_0 and κ_0^2, where the black dashed isocontours confirm that the same level of marginal expected sparsity can be obtained for any combination of (ν_0, κ_0^2) that satisfies the relationship in eq. (121) for some $\hat{p} \in (0, 1)$. Also, note that the prior probability $\hat{p}$ is by definition equal to the expectation of $\phi(\gamma_i)$, that is $\hat{p} = \mathbb{E}_{p(\gamma_i)}\left[\phi(\gamma_i)\right]$. However, as ϕ is a monotonic function, we can derive the full distribution of $\pi = \phi(\gamma)$ through a change of variable as follows

$$p(\pi) = p_\gamma(\phi^{-1}(\pi))\left|\frac{\mathrm{d}\phi^{-1}(\pi)}{\mathrm{d}\pi}\right| = \mathcal{N}\left(\phi^{-1}(\pi)|\nu_0, \kappa_0^2\right)\left|\frac{\mathrm{d}\phi^{-1}(\pi)}{\mathrm{d}\pi}\right| = \frac{\mathcal{N}\left(\phi^{-1}(\pi)|\nu_0, \kappa_0^2\right)}{\mathcal{N}\left(\phi^{-1}(\pi)|0, 1\right)}. \tag{122}$$



(a) Expected sparsity vs. prior mean and variance

(b) Distribution of $\phi(\gamma_i)$ for $p(z_i = 1) = \frac{1}{4}$

Figure 15: Properties of the prior distribution. (a) Marginal prior probability $p(z_i = 1)$ as a function of (ν_0, κ_0^2). The black dashed lines are isocontours. (b) Distribution of $\pi = \phi(\gamma_i)$ for 4 different pairs of (ν_0, κ_0^2), but for fixed value of $p(z_i = 1)$.

Figure 15(b) shows a plot of the density of π for 4 pairs of (ν_0, κ_0^2) that all satisfy $\hat{p} = \mathbb{E}[\pi] = \frac{1}{4}$. Thus, increasing κ_0^2 while keeping $\mathbb{E}[\pi]$ fixed pushes the mass of $p(\pi)$ to the boundary values. Informally, the distribution of $p(\pi)$ will approach a mixture of two Dirac distributions at 0 and 1 with weights $1 - \mathbb{E}[\pi]$ and $\mathbb{E}[\pi]$, respectively, for very large values of κ_0^2 relative to $\nu_0 \neq 0$. In Section 6, we discussed maximum likelihood among other methods for learning the hyperparameters of the structured spike-and-slab model. However, maximum likelihood learning of ν and κ can in some instances give rise to the similar problems as encountered in maximum likelihood learning of logistic regression models on data sets, that are completely separated in one or more dimensions (Gelman et al., 2008). The following small example illustrates the problem. Consider an instance of $\boldsymbol{y}_1 = \boldsymbol{A}\boldsymbol{x}_1 + \boldsymbol{\epsilon}$, where $\boldsymbol{x}_1$ is the signal shown in Figure 16(a) and where the signal to noise ratio is such that the true support of the signal can be recovered exactly. The dimensions of the forward model is $\boldsymbol{A} \in \mathbb{R}^{50\times 100}$. Let $\mathbf{R}$ be the squared exponential kernel with lengthscale fixed to 8. Figure 16(c) shows the surface of the marginal likelihood approximation as a function of ν_0 and κ_0^2 while the remaining hyperparameters are kept fixed. The red dot indicates the maximum likelihood solution constrained to the domain shown in the figure. The red dashed line shows a plot of the implicit function $\hat{p}_{ML} = p(z_i = 1) = \phi\left(\frac{\nu_0}{\sqrt{1+\kappa_0^2}}\right)$ that intersects the maximum likelihood solution. It is clear that the likelihood surface has a ridge along the curve satisfying $\hat{p}_{ML} = \phi\left(\frac{\nu_0}{\sqrt{1+\kappa_0^2}}\right)$ and that the likelihood is increasing along that ridge as the magnitude of ν_0 and κ_0^2 increase. Thus, the maximum likelihood solutions pushes to magnitude of ν_0 and κ_0^2 to larger and larger values while keeping the sparsity level $\hat{p}_{ML}$ fixed and therefore, gradient-based optimization of the maximum likelihood w.r.t. (ν_0, κ_0^2) will never converge. However, this problem only occurs when the support is separated as in Figure 16(a). Figure 16(f) shows the marginal likelihood approximation surface for $\boldsymbol{y}_2 = \boldsymbol{A}\boldsymbol{x}_2 + \boldsymbol{\epsilon}$, where $\boldsymbol{x}_2$ in Figure 16(b). It is now seen that the maximum likelihood solution is well-defined within the

(a) $\boldsymbol{x}_1$

(b) LPD for $\boldsymbol{y}_1$ (flat prior)

(c) LPD for $\boldsymbol{y}_1$ (student t prior)

(d) LPD for $\boldsymbol{y}_1$ (log-normal prior)

(e) $\boldsymbol{x}_2$

(f) LPD for $\boldsymbol{y}_2$ (flat prior)

(g) LPD for $\boldsymbol{y}_2$ (student t prior)

(h) LPD for $\boldsymbol{y}_2$ (log-normal prior)

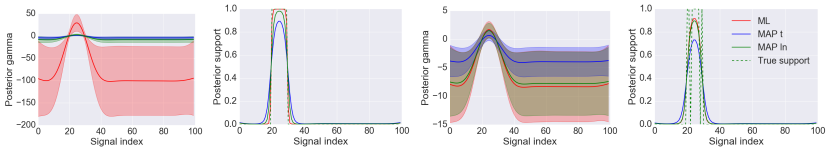


Figure 16: (a) Signal, where the support is contiguous. (b), (c), (d): Log posterior density for $\boldsymbol{y}_1 = \boldsymbol{A}\boldsymbol{x}_1 + \boldsymbol{\epsilon}$ with a flat prior, half student t prior (df = 4) and a log normal prior (mean 6, std. dev 3) for κ_0, respectively. (e) Signal, where the support is not contiguous.(f), (g), (h): Log posterior density (LPD) for $\boldsymbol{y}_2 = \boldsymbol{A}\boldsymbol{x}_2 + \boldsymbol{\epsilon}$ with a flat prior, half student t prior (df = 4) and a log normal prior (mean 6, std. dev 3) for κ_0, respectively. The red dashed line shows a plot of the implicit function $\hat{p}_{ML} = p(z_i = 1) = \phi\left(\nu_0 (1 + \kappa_0^2)^{-\frac{1}{2}}\right)$ that intersects the maximum likelihood solution.

interior of $\mathbb{R}^2$. The problem is easily fixed by imposing a weakly informative prior on κ_0 to ensure that the solution is always well-defined. To illustrate this, we re-run this experiment shown in Figure 16(c) with two different priors on κ_0. Figures 16(d)-(e) show the results for a standardized half student t prior with 4 degrees of freedom and a log-normal prior with mean 6 and standard deviation 3, respectively. Figures 16(g)-(h) show the same plots for the signal $\boldsymbol{x}_2$. Figure 17 shows the resulting posterior distribution for both signals with and without priors distributions.

Abstract

The scalability of statistical estimators is of increasing importance in modern applications. One approach to implementing scalable algorithms is to compress data into a low dimensional latent space using dimension reduction methods. In this paper, we develop an approach for dimension reduction that exploits the assumption of low rank structure in high dimensional data to gain both computational and statistical advantages. We adapt recent randomized low-rank approximation algorithms to provide an efficient solution to principal component analysis (PCA), and we use this efficient solver to improve estimation in large-scale linear mixed models (LMM) for association mapping in statistical genomics. A key observation in this paper is that randomization serves a dual role, improving both computational and statistical performance by implicitly regularizing the covariance matrix estimate of the random effect in an LMM. These statistical and computational advantages are highlighted in our experiments on simulated data and large-scale genomic studies.

Keywords: dimension reduction, generalized eigendecompositon, low-rank, genomics, linear mixed models, supervised, random projections, randomized algorithms, Krylov subspace methods

1. Introduction

In the current era of information, large amounts of complex high dimensional data are routinely generated across science and engineering disciplines. One perspective is that the signal in high dimensional data is often concentrated in low dimensional structure, and estimating and exploring this latent structure is of fundamental importance in a variety of applications. As the size of the data sets increases, the problem of statistical inference and computational feasibility become inextricably linked. Dimension reduction is a natural approach to summarizing massive data and has historically played a central role in data analysis, visualization, and predictive modeling. Dimension reduction has had a significant impact on both statistical inference (Adcock, 1878; Edegworth, 1884; Fisher, 1922; Hotelling, 1933; Young, 1941), and on numerical analysis research and applications (Golub, 1969; Golub and Van Loan, 1996; Gu and Eisenstat, 1996; Golub et al., 2000); for a recent review see Mahoney (2011). Historically, statisticians have focused on the study of theoretical properties of estimators often in the context of asymptotically large number of samples. Numerical analysts and computational mathematicians, on the other hand, have been instrumental in the development of useful and tractable algorithms with provable stability and convergence guarantees. Naturally, many of these algorithms have been successfully applied to compute estimators grounded on solid statistical foundations. A classic example of this interplay is principal component analysis (PCA) (Hotelling, 1933). In PCA, an objective function is defined based on statistical considerations about the sample variance, which can then be efficiently computed using a variety of singular value decomposition (SVD) algorithms developed by the numerical analysis community.

In this paper, we consider the problem of dimension reduction, focusing on the integration of i) statistical considerations of *estimation accuracy* and out-of-sample prediction error of matrices with latent low-rank, and ii) computational considerations of run time and *numerical accuracy*. The methodology that we develop builds on a classical approach to modeling large data, which first compresses the data, minimizing the loss of relevant information, and then applies statistical estimators appropriate for small-scale problems. In particular, we focus on dimension reduction via generalized eigendecomposition as the means for data compression, and on out-of-sample residual error as the measure of information loss. The scope of this work includes applications to a large number of dimension reduction methods, which can be implemented as solutions to truncated generalized eigendecomposition problems (Hotelling, 1933; Fisher, 1936; Li, 1991; Wu et al., 2010). In this paper our first focus is on the increasing need to compute an SVD of massive data using randomized algorithms developed in the numerical analysis community (Drineas et al., 2006; Sarlos, 2006; Liberty et al., 2007; Boutsidis et al., 2009; Rokhlin et al., 2009; Halko et al., 2011) to simultaneously reduce the dimension and regularize, or control the impact of independent random noise.

The second focus in this paper is to provide efficient solvers for the linear mixed models that arise in statistical and quantitative genomics. In high-throughput genomics experiments, a vast amount of sequencing data is collected—on the order of tens of millions of genetic variants. The goal of genome-wide association studies (GWAS) is to test for a statistical association at each genetic variant (polymorphic position) to a response of interest (e.g., gene expression levels or disease status) in a sample cohort. However, as the dimension of these genomic data and sample sizes continue to increase, there is an urgent need to improve the statistical and computational performance of standard tests.

It is typical to collect several thousand individuals for one study. These individuals may come from several genetically heterogeneous populations. It has been recognized since 2001 (Pritchard and Donnelly, 2001) that the ancestry makeup of the individuals in the study has great potential to influence study results—in particular, spurious associations arise when genetic variants with differential frequencies may appear to be associated with the biased response variable via latent population structure.

The earliest methods (e.g., genomic control) accounted for population structure by using covariate estimates to correct for these confounding signals. More recently, linear mixed models have been used successfully to correct spurious results in the presence of population structure. LMMs

have been shown to improve power in association studies while reducing false positives (Yang et al., 2014). However, mixed models incur a high computational cost when performing association studies because of the computational burden of computing and inverting the covariance matrix for the random effect controlling for population structure. Significant work has gone into mitigating such costs using spectral decompositions for efficient covariance estimation (Kang et al., 2008, 2010; Yang et al., 2011; Zhou and Stephens, 2012; Listgarten et al., 2012).

In this work we show, using simulations of genomic data with latent population structure and real data from large-scale genomic studies, that our approach, adaptive randomized SVD (ARSVD), is effective in terms of both computational efficiency and numerical accuracy. Under certain settings, we find that the LMM using ARSVD outperforms current state-of-the-art approaches by implicitly performing regularization of the covariance matrix.

There are three key contributions of this paper:

(i) We develop an adaptive algorithm for randomized singular value decomposition (SVD) in which both the number of relevant singular vectors and the number of iterations of the algorithm are inferred from the data based on informative statistical criteria.

(ii) We use our adaptive randomized SVD (ARSVD) algorithm to construct truncated generalized eigendecomposition estimators for PCA and linear mixed models (LMMs) (Listgarten et al., 2012; Zhou and Stephens, 2012).

(iii) We demonstrate on simulated and real data examples that the randomized estimators provide a computationally efficient solution, and, furthermore, often improve statistical accuracy of the predictions. We show that, in an over-parametrized setting, this improvement in accuracy is due to implicit regularization imposed by the randomized approximation.

In Section 2, we describe the adaptive randomized SVD procedure we use for the various dimension reduction methods. In Section 2.5, we provide randomized estimators for linear mixed models used in statistical genetics. In Section 3, we give an explanation for why the randomized estimator for linear (mixed) models imposes regularization. In Section 4, we validate the proposed methodology on simulated and real data and compare our approach with state-of-the-art approaches. In particular, we show results from our approach for estimating low dimensional geographic structure in genomic data and for genetic association mapping applications.

2. Randomized Algorithms for Dimension Reduction

In this section, we develop algorithmic extensions for PCA. We state an algorithm that provides a numerically efficient and statistically robust estimate of the highest variance directions in the data using a randomized algorithm for singular value decomposition (Randomized SVD) (Rokhlin et al., 2009; Halko et al., 2011). In this problem, the objective is linear unsupervised dimension reduction with the low-dimensional subspace estimated via an eigendecomposition. Randomized SVD will serve as the core computational engine for the other estimators we develop in this paper.

2.1 Notation

Given positive integers p and d with $p \gg d$, $\mathbb{R}^{p\times d}$ denotes the class of all matrices of dimension $p \times d$ with real entries. We denote symmetric positive semi-definite matrices as $\mathbb{S}_+^p$. For $B \in \mathbb{R}^{p\times d}$,

span(B) denotes the subspace of $\mathbb{R}^p$ spanned by the columns of B. A *basis matrix* for a subspace $\mathcal{S}$ is any full column rank matrix $B \in \mathbb{R}^{p\times d}$ such that $\mathcal{S} = \text{span}(B)$, where $d = \dim(\mathcal{S})$. We denote the data matrix $X = (x_1, \ldots, x_n)^T \in \mathbb{R}^{n\times p}$ with observations drawn from p-dimensional marginal distribution, $x_i \sim \mathcal{P}_X$. When we consider supervised problems such as regression we denote the response vector as either a quantitative response $Y \in \mathbb{R}^m$ or a categorical response $Y \in \{1, \ldots, C\}$, here C is the number of categories. For the joint setting of response and predictor variables we assume a joint distribution, $(X, Y) \sim \mathcal{P}_{X\times Y}$. We denote the orthonormal left eigenvector basis of the data matrix X as eigen-basis(X).

2.2 Computational Considerations

The main computational tool we use is a randomized algorithm for approximate eigendecompositon, which factorizes a $n \times p$ matrix of rank r in time $\mathcal{O}(npr)$ using randomized methods that take advantage of the intrinsic low-rank of the input matrix, rather than the $\mathcal{O}(np \times \min(n, p))$ time required by deterministic approaches. This is relevant to statistical applications to high dimensional data but reflects a highly constrained process (e.g., from genomic or financial applications), which suggests that the data have low intrinsic dimensionality, i.e., $r \ll n < p$. Further improvements have been made to randomized algorithms for approximate eigendecomposition by noting that a structured random projection (such as the subsampled random Fourier transform) can achieve computational complexity of $O(np\log(r)+(m+p)r^2)$ assuming the input matrix fits in main memory (Halko et al., 2011). Since we use power iterations to decay the eigenspectrum and achieve a numerically accurate result independent of the particular spectral gaps, most of the computational gains from subsampling methods would be lost when applied in our framework. Furthermore, since matrix-matrix multiplies are highly optimized on many computational architectures, parallel implementations can reduce our asymptotic complexity to yield excellent run times in practice (Halko et al., 2011).

An appealing characteristic of our randomized algorithm is the explicit control of the trade-off between estimation accuracy relative to the exact estimates and computational efficiency. Rapid convergence to the exact estimates has been shown both empirically as well as in theory (Rokhlin et al., 2009). From the perspective of theoretical computer science and numerical analysis, the objective of randomized SVD algorithms is, given a matrix X, to efficiently compute an approximate eigendecomposition that is close to the exact eigendecomposition; we call this view the *approximation perspective*.

2.3 Statistical Considerations

A *statistical perspective* will deviate from the approximation perspective in two ways: the data matrix X is not fixed, but a noisy random sample drawn from a population, and the inferential objective is to obtain estimates of population quantities from the sample X, not estimates of the eigendecomposition of X itself. Taking a statistical perspective will drive two central concepts in this paper. The first concept is that there is utility in considering randomized algorithms as statistical models. The second concept is that many formulations of ARSVD implicitly impose regularization constraints.

The acceptable error for the approximation perspective and the statistical perspective differ; typically larger error is tolerated in the statistical perspective. For many statistical estimators, the error between the estimator and the population quantity scales as $\varepsilon = O(\frac{1}{\sqrt{n}})$ where n is the sample

size. This is much coarser than the approximation error sought in numerical analysis, where the desired error between the exact and approximate algorithms scales as ε^2, the squared error in the statistical estimate. This observation highlights that, in the statistical setting, one can use fewer computations than are typically considered in the numerical analysis setting because the accuracy of the finer approximation will be lost to the error due to sampling.

This observation about error will impact the parameters of the randomized estimators that we propose in in this paper. An important parameter in our ARSVD algorithms is the number of power iterations t that the randomized algorithm executes (Section 2.4). Increasing the number of power iterations results in a closer approximation to the exact solution (Rokhlin et al., 2009), but also increases the runtime of the algorithm. The observation that we can afford coarser error rates between the exact and approximate solutions suggests that very few power iterations may be required. We provide empirical evidence (Section 4) that fewer power iterations of the approximate algorithm provide results that are both faster and also more accurate with respect to out-of-sample predictions. This observation suggests that the approximation induced by the randomized algorithm is a form of regularization.

2.4 Adaptive Randomized Low-Rank Approximation

In this section, we provide a brief description of a randomized estimator for the best low-rank matrix approximation, introduced by Rokhlin et al. (2009); Halko et al. (2011), which combines random projections with numerically stable matrix factorization. We consider this numerical framework as implementing a computationally efficient shrinkage estimator of the subspace capturing the largest variance directions in the data. The procedure is well suited for matrices that are low rank or matrices where the signal is low rank. Detailed discussion of the estimation accuracy of Randomized SVD in the absence of noise is provided in Rokhlin et al. (2009).

The idea of random projection was first developed as a proof technique to study the distortion induced by the low dimensional embedding of high-dimensional vectors (Johnson and Lindenstrauss, 1984), with much literature simplifying and sharpening the results (Frankl and Maehara, 1987; Indyk and Motwani, 1998; Achlioptas, 2001; Dasgupta and Gupta, 2003). More recently, the theoretical computer science and the numerical analysis communities discovered that random projections can be used for efficient approximation algorithms for a variety of applications (Drineas et al., 2006; Sarlos, 2006; Liberty et al., 2007; Boutsidis et al., 2009; Rokhlin et al., 2009; Halko et al., 2011). We focus on one such approach proposed by Rokhlin et al. (2009); Halko et al. (2011), which targets the accurate low-rank approximation of a given large data matrix $X \in \mathbb{R}^{n\times p}$. In particular, we extend the randomization methodology to the noisy setting, in which the estimation error is due to both the approximation of the low-rank structure in X and also added noise. A simple working model capturing this scenario is

$$X = X_{d^*} + E, \quad X_{d^*} \in \mathbb{R}^{n\times p}, \quad \text{rank}(X_{d^*}) = d^*,$$

where X_{d^*} captures the low dimensional signal and E is independent additive noise.

2.4.1 ALGORITHM FOR ARSVD

Given an upper bound on the target rank $d_{\max}$ and the number of necessary power iterations $t_{\max}$ ($t_{\max} \in \{5, \dots 10\}$ is sufficient in most cases), the algorithm proceeds in two stages: (1) estimate a

basis for the range of X_{d^*}, (2) project the data onto this basis and apply SVD:

Algorithm: *Adaptive Randomized SVD*(X, $t_{\max}$, $d_{\max}$, Δ)

(1) Find orthonormal basis for the range of X;

  (i) Set the number working directions: $\ell = d_{\max} + \Delta$;

  (ii) Generate random matrix: $\Omega \in \mathbb{R}^{n\times\ell}$ with $\Omega_{ij} \overset{iid}{\sim} \text{N}(0, 1)$;

  (iii) Construct blocks: $F^{(t)} = XX^TF^{(t-1)}$ with $F^{(0)} = \Omega$ for $t \in \{1, \dots, t_{\max}\}$;

  (iv) Select the optimal block $t^* \in \{1, \dots, t_{\max}\}$ and rank estimate $d^* \in \{1, \dots, d_{\max}\}$, using the stability criterion and Bi-Cross-Validation stated in Section 2.4.3;

  (v) Compute a basis for the selected block: $F^{(t^*)} = QR \in \mathbb{R}^{n\times\ell}, Q^TQ = I$;

(2) Project data onto the range basis and compute the SVD;

  (i) Project onto the basis: $B = X^TQ \in \mathbb{R}^{p\times\ell}$;

  (ii) Factorize: $B \overset{\text{svd}}{=} U\Sigma W^T$, where $\Sigma = \text{diag}(\sigma_1, \dots, \sigma_\ell)$;

  (iii) Compute the rank d^* approximation: $\widehat{X}_{d^*} = U_{d^*}\Sigma_{d^*}V_{d^*}^T$
  $U_{d^*} = (U_1|\dots|U_{d^*}) \in \mathbb{R}^{n\times d^*}$
  $\Sigma_{d^*} = \text{diag}(\sigma_1, \dots, \sigma_{d^*}) \in \mathbb{R}^{d^*\times d^*}$
  $V_{d^*} = Q \times (W_1|\dots|W_{d^*}) \in \mathbb{R}^{p\times d^*}$;

In stage (1), we set the number of working directions $\ell = d_{\max} + \Delta$ to be the sum of the upper bound on the rank of the data $d_{\max}$, and a small oversampling parameter Δ, which ensures a more stable approximation of the top $d_{\max}$ sample variance directions; the estimator tends to be robust to changes in Δ, so we use $\Delta = 10$ as a suggested default. In step (1.iii), the random projection matrix Ω is applied to powers of XX^T to randomly sample linear combinations of eigenvectors of the data weighted by powers of the eigenvalues:

$$\underbrace{F^{(t)}}_{n\times\ell} = (XX^T)^t\Omega = US^{2t}U^T\Omega = US^{2t}\Omega^*, \quad \text{where } X \overset{\text{svd}}{=} USV^T.$$

The power iterations shrink small eigenvalues and increase large eigenvalues while leaving the eigenvectors unchanged. Observe that each column of $F^{(t)}$ can be thought of as drawn from a multivariate normal, $F_j^{(t)} \sim \mathcal{N}(0, US^{4t}U^T)$. The covariance structure of this matrix is biased towards higher directions of variation as t increases. The fact that the power iterations shrink noise directions shows that power iterations impose a form of regularization. The multivariate normal structure of this shrinkage is related to local shrinkage priors developed in Polson and Scott (2010). In step (iv), we select an optimal block $F^{(t^*)}$ for $t^* \in \{1, \dots, t_{\max}\}$ and estimate an orthonormal basis for the column space. For numerical stability, each block in the intermediate power iterations should be orthgonalized (Halko et al., 2011; Gu, 2015). In previous work (Rokhlin et al., 2009), the authors assumed fixed target rank d^* and approximated X rather than X_{d^*}. They showed that the optimal strategy is to set $t^* = t_{\max}$, which typically achieves excellent d^*-rank approximation accuracy for X, even for relatively small values of $t_{\max}$.

In stage (2), we rotate the orthogonal basis Q computed in stage (1) to the canonical eigenvector basis and scale according to the corresponding eigenvalues. In step (2.i) the data is projected onto the low dimensional orthogonal basis Q. Step (2.ii) computes the exact SVD in the projected space.

In this work, we focus on the noisy case, where $E \neq 0$, and propose to adaptively set both d^* and t^*, aiming to optimize the generalization or out-of-sample performance of the randomized estimator. The estimation strategy for d^* and t^* is described in detail in Section 2.4.3.

2.4.2 COMPUTATIONAL COMPLEXITY

The computational complexity of the randomization step is $\mathcal{O}(np \times d_{\max} \times t_{\max})$ and the factorizations in the lower dimensional space have complexity $\mathcal{O}(np \times d_{\max} + n \times d_{\max}^2)$. With $d_{\max}$ small relative to n and p, the runtime in both steps is dominated by the multiplication by the data matrix; in the case of sparse data, fast multiplication can further reduce the run time. We use a normalized version of the above algorithm that has the same run time complexity but is numerically more stable (Martinsson et al., 2010).

2.4.3 ADAPTIVE METHOD TO ESTIMATE d^* AND t^*

We propose to use ideas of stability under random projections in combination with cross-validation to estimate the intrinsic dimensionality of the reduced subspace d^* and the optimal value of the eigenvalue shrinkage parameter t^*.

2.4.4 ESTIMATION OF t^* USING BI-CROSS-VALIDATION

We propose a procedure for selecting an optimal value for $t \in \{1, \ldots, t_{\max}\}$ by using the Bi-Cross-Validation procedure of Owen and Perry (2009), which was used to estimate the rank or cutoff for SVD. For our procedure, we consider a Bi-Cross-Validation formulation that uses the generalized Gabriel holdout pattern (Gabriel, 2002) to partition the data matrix by partitioning the rows and columns into $r = 2$ and $c = 2$ groups respectively that are non-overlapping as suggested in Owen and Perry (2009). We then compute the following Bi-Cross-Validation error by holding out each of the four blocks and estimating a block using the other three blocks

$$\begin{aligned}\text{BiCV}(t) =& \frac{1}{4}\Big[\|A - BD_t^\dagger C|\|_F^2 + \|B - AC_t^\dagger D\|_F^2 + \|B - AC_t^\dagger D\|_F^2 + \\ & \|C - DB_t^\dagger A\|_F^2 + \|D - CA_t^\dagger B\|_F^2\Big], \quad \text{here } X = \begin{pmatrix} A & B \\ C & D \end{pmatrix}.\end{aligned} \tag{1}$$

In the above equation, $\|\cdot\|_F^2$ is the Frobenius norm, $U_t^\dagger$ is the Moore-Penrose pseudoinverse of U where the SVD of U is computed using Adaptive Randomized SVD$(t, d(t), \delta = 10)$, and $d(t)$ is set using the stability criterion developed in the next section. We optimize over the range $\{1, \ldots, t_{\max}\}$ to estimate t^*

$$\hat{t} \;=\; \underset{t \in \{1,\ldots,t_{\max}\}}{\arg\min}\; \text{BiCV}(t).$$

In our simulation results, the value of t^* is estimated small enough to not incur much computational overhead, yet still yields accurate results (Results Section). The original formulation of Bi-Cross-Validation defined the hold-out error to be the Frobenius norm between the predicted and

true submatrix (Owen and Perry, 2009). While the Frobenius and spectral norms both have upper bounds with respect to approximation accuracy of truncated spectral decompositions, more recent results suggest that the spectral norm may generalize better if the goal is to produce an accurate dimension reduction of massive data such as principal components analysis (Mahoney, 2011; Szlam et al., 2014). We recognize the limitation of the Frobenius norm in this context, and acknowledge that it may be wise for Bi-Cross-Validation error to use the spectral norm.

2.4.5 ESTIMATION OF d^* USING STABILITY CRITERION

Given the number of power iterations t, we describe a procedure to estimate the rank parameter $d^*(t)$ using a stability criterion based on random projections of the data. We start with rough upper-bound estimate $d_{\max}$ for the dimension parameter d^*. We then apply a small number ($B = 5$) of independent Gaussian random projections $\Omega^{(b)} \in \mathbb{R}^{n \times d_{\max}}$, $\Omega_{ij}^{(b)} \overset{iid}{\sim} \text{N}(0, 1)$, for $b \in \{1, \ldots, B\}$. Given the projections, we compute an estimate of the eigenvector basis of the column space onto the projected data. We then denoise the estimate by raising all the eigenvalues to the power t:

$$U_b^{(t)} \equiv (U_{b1}^{(t)}|\ldots|U_{bd}^{(t)}) = \text{SVD}[(XX^T)^t\Omega^{(b)}] \;\text{ for }\; b \in \{1, \ldots, B\}.$$

The k-th principal basis left singular vector estimate ($k \in \{1, \ldots, d\}$) is assigned a *stability score*:

$$\text{stab}(t, k, B) = \frac{1}{N}\sum_{j_1=1}^{B-1}\sum_{j_2=j_1+1}^{B}\left|\text{cor}\left(U_{j_1k}^{(t)}, U_{j_2k}^{(t)}\right)\right|, \quad \text{where } N = \frac{B(B-1)}{2}.$$

Here $U_{rk}^{(t)}$ is the estimate of the k^{th} principal eigenvector of X^TX based on the r-th random projection and cor $\left(U_{j_1k}^{(t)}, U_{j_2k}^{(t)}\right)$ denotes the Spearman rank-sum correlation between $U_{j_1k}^{(t)}$ and $U_{j_2k}^{(t)}$. Eigenvector directions that are not dominated by independent noise are expected to have higher stability scores. When the data has approximately low-rank, we expect a sharp transition in the eigenvector stability between the directions corresponding to signal and to noise. In order to estimate this change point, we apply a non-parametric location shift test (Wilcoxon rank-sum) to each of the $d_{\max} - 2$ stability score partitions of eigenvectors with larger versus smaller eigenvalues. The subset of principal eigenvectors that can be stably estimated from the data for the given value of t is determined by the change point with smallest p-value among all $d_{\max} - 2$ non-parametric tests.

$$\hat{d}_t = \underset{k \in \{2,\ldots,d_{\max}-1\}}{\arg\min}\; \text{p-value}(k, t),$$

where p-value(k,t) is the p-value from the Wilcoxon rank-sum test applied to the $\{\text{stab}(t, i, B)\}_{i=1}^{k-1}$ and $\{\text{stab}(t, i, B)\}_{i=k}^{d_{\max}}$.

2.5 Fast Linear Mixed Models

Multivariate linear mixed models (LMMs) are a workhorse in statistical and quantitative genetics because they allow for the regression of explanatory variables on outcome variables while capturing potentially confounding relatedness between samples (Henderson, 1984; Price et al., 2011; Krote et al., 2012). In the context of the genetic association mapping of complex traits, LMMs are used to control for observed (known covariates) and unobserved (random effects) statistical confounding, particularly the presence of population structure amongst samples.

The linear mixed models in this paper take the form

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u} + e,$$

where $\mathbf{y}$ is an $n \times 1$ response vector of observed phenotypes, $\mathbf{X}$ is an $n \times q$ matrix of fixed effects that includes the genotypes (SNPs) and other confounding variables, $\boldsymbol{\beta}$ is a $q \times 1$ vector representing coefficients of the fixed effects, $\mathbf{u} \sim N(0, \sigma_g^2 K)$ is the random vector of additive genetic effects with incidence matrix $\mathbf{Z}$, and the vector $e \sim \mathcal{N}(0, \sigma_e^2 I_n)$ is the residual error. The matrix K is the kinship or genetic relatedness matrix and may be computed from genotype data. Parameter σ_g^2 is the proportion of variance in the phenotypes explained by genetic factors. The overall phenotypic variance-covariance matrix, integrating out the random effects, is $\mathbf{V} = \sigma_g^2 \mathbf{Z} K \mathbf{Z}^T + \sigma_e^2 I_n$.

The main goal in genetic association studies is to test every genetic locus for significant association to the phenotype based on the effect size of the coefficient $\boldsymbol{\beta}_j$. For each genetic locus, we apply the following hypothesis test:

$$\text{null } H_0 : \boldsymbol{\beta}_j = 0 \quad \text{alternative } H_1 : \boldsymbol{\beta}_j \neq 0, \qquad \text{for } j = 1, \ldots, p.$$

The standard procedure for inferring SNPs associated with a phenotype while correcting for population structure using an LMM proceeds in the following steps:

(1) *Construct the genetic relatedness matrix (GRM)*: The GRM captures the genetic relationship between individuals in the study to model population structure, family structure, and cryptic relatedness. There are cases where the GRM may be obtained directly if the pedigree of the individuals in the sample is known (see Thompson, 1976). In the more common setting, we are not given pedigree information, but instead we have the p dimensional genotype vector G for each of the n individuals. Given the genotype matrix, we can compute the GRM matrix as $\text{GRM} = GG^T$. In the machine learning literature, the GRM would be defined as the Gram matrix for a linear kernel. The biological interpretation of a GRM computed from genotype data differs slightly from the one specified by a pedigree.

(2) *Estimate variance components*: We first use the restricted maximum likelihood estimation (REML) method to estimate σ_g^2, the proportion of phenotypic variance attributable to additive genetic effects. Given the estimate $\hat{\sigma}_g^2$, we estimate σ_ϵ^2, the proportion of phenotypic variance attributable to environmental factors. There are several efficient algorithms for computing the REML (Johnson and Thompson, 1995; Gilmour et al., 1995; Lin et al., 2013; Matilainen et al., 2013). If one computes the random effects first and then the fixed effects, unbiased estimates of the random effects can be found; this is typically the order of computations in genomics.

(3) *Compute an association statistic at each genotype location*: There are a variety of procedures to test for the significance of a genotype j using coefficients $\widehat{\boldsymbol{\beta}}_j$. One approach is to use an F-statistic to test for whether $(G\boldsymbol{\beta})_j = 0$ for each $j = 1, \ldots, p$ (Kang et al., 2008; Kennedy et al., 1992; Henderson, 1984). Another approach is to use a likelihood ratio test considering the variance components. Denote $\ell_1(\hat{\sigma}_1$ as the likelihood under the alternate hypothesis with $\hat{\sigma}_1 = \hat{\sigma}_g^2$ as the estimate of the additive genetic variance component under the alternate model. Then denote $\ell_0(\hat{\sigma}_0)$ as the likelihood under the null ($\boldsymbol{\beta} = 0$) with $\hat{\sigma}_0 = \hat{\sigma}_g^2$ the estimate of the additive genetic variance component under the null model. The log ratio test statistic $2 \log \frac{\ell_1(\hat{\sigma}_1)}{\ell_0(\hat{\sigma}_0)}$ follows a χ^2 distribution and may be used as a test statistic (Kang et al., 2008, 2010; Zhou and Stephens, 2012).

Reducing the computational complexity of the LMM has been an active area of research driven by the increasing size of association studies. A variety of methods have been proposed to increase computational speed (see Kang et al., 2008, 2010; Lippert et al., 2011; Zhou and Stephens, 2012; Lippert et al., 2013). The software we implemented for the results in this paper as well as our methodology is based on EMMAX (Kang et al., 2010). EMMAX improved on EMMA (Kang et al., 2008), which dramatically reduced the computational cost of a standard LMM by exploiting properties of a spectral decomposition of the genotype matrix. EMMAX improves on EMMA by approximating the variance component for each SNP based on an estimate that is computed only once rather than for each SNP. Although we will speed up the model used in EMMAX, our approach can be applied to other fast LMM solvers.

Our contribution to accelerating parameter estimation is using ARSVD to reduce the computational complexity of estimating the random effect $\mathbf{u}$ associated with the design matrix $\mathbf{Z}$. An SVD of the matrix $\mathbf{Z}$ has complexity $\mathcal{O}(n^3)$. If we instead apply ARSVD to $\mathbf{Z}$, we reduce the computational complexity to $\mathcal{O}(np \times d_{\max} + n \times d_{\max}^2)$. In addition, using ARSVD to decompose the design matrix serves to denoise the GRM by retaining the low-rank structure present in the GRM. This avoids the need to manually or heuristically subset the data to achieve a low-rank representation. We will observe in both simulated and real data examples that this application of the ARSVD leads to both a substantial acceleration of the computational speed and an implicit regularization of the design matrix, which reduces type I errors substantially.

3. Regularization of ARSVD

The idea of adding randomness or noise to algorithms for the purpose of regularization has been repeatedly rediscovered (Bishop, 1995; Simard et al., 1993; Mahoney, 2011; Srivastava et al., 2014). Adding independent and identical noise to input variables was observed and rigorously shown to be identical to Tikhonov regularization (Bishop, 1995). Furthermore, Tikhonov regularization is closely related to early stopping, as both regularization methods act as low pass filters (Yao et al., 2007). On the other hand, early stopping is not subject to saturation (Vito et al., 2005; Smale and Zhou, 2007; Yao et al., 2007). In this section we explain why principal components regression (PCR) using ARSVD is a form of regularization. We are confident more refined analyses as well as sharper statements and bounds can be made; our results are more motivational than a detailed analysis.

We will use the spectral filtering framework. In particular, we will use kernel least squares ridge regression (KRR) to illustrate spectral filtering. We then show that PCR using ARSVD is also a spectral filter, and regularization is imposed by weighting and truncating eigenvalues of a positive semidefinite matrix that the algorithm constructs.

3.1 Kernel Ridge Regression

We consider the regression setting, where the number of variables is much larger than the number of observations, $p \gg n$. Given an $n \times p$ design matrix X, the ordinary least squares solution (OLS) is computed based on the normal equations:

$$\hat{\beta} = (X^T X)^{-1} X^T Y,$$

where Y is an $n \times 1$ vector of responses and $\hat{\beta}$ is the OLS estimate for the regression coefficients. When $p \gg n$, the OLS estimator does not work because $X^T X$ is not invertible. In this high-dimensional $p \gg n$ setting, ridge regression (Hoerl and Kennard, 1970) addresses many of the shortcomings of OLS. The estimation problem in ridge regression is formulated as

$$\hat{\alpha} = (XX^T + n\lambda I)^{-1} Y,$$

where λ is a regularization parameter and the induced regression function is

$$\hat{y} = \sum_{j=1}^{p} \hat{\alpha}_j x_j^T x = \hat{\beta}^T x, \quad \hat{\beta} = \sum_{j=1}^{p} \hat{\alpha}_j x_j.$$

When $\lambda = 0$, we recover the OLS estimator, and, when $\lambda = \infty$, one obtains the zero solution $\hat{\alpha} = 0$; λ trades off between fitting the observations and shrinking the solution towards zero.

A standard nonlinear extension to ridge regression is kernel ridge regression (Poggio and Girosi, 1990; Williams and Seeger, 2001) where the regression function takes the form

$$f(x) = \sum_{i=1}^{n} \alpha_i k(x, x_i),$$

and $k(u, v)$ is a positive (semi) definite function called a *kernel*. One example of a kernel function is the Gaussian kernel, $k(u, v) = \exp(-h^2 \|u - v\|^2)$. The parameters α to be estimated in kernel ridge regression (KRR) are given by the formula

$$\hat{\alpha} = (K + n\lambda I)^{-1} Y,$$

where the kernel matrix K is defined as $K_{ij} = k(x_i, x_j)$.

3.2 KRR as a Spectral Filter

For the purposes of this paper we will consider spectral filtering as a procedure to filter or smooth a signal (vector) by filtering the eigenvalues of a positive (semi) definite matrix. A signal processing perspective of KRR as a filtering operation is as follows: given the response signal Y and matrix K, the filtering procedure is a map $F(K) : \mathbb{R}^n \to \mathbb{R}^n$, where

$$\hat{Y} = FY, \quad F = K(K + n\lambda I)^{-1}. \tag{2}$$

The basic idea behind spectral filtering is that the filter F operates on the spectrum of the positive (semi) definite matrix, K. In the KRR setting, a natural basis for the matrix F is the eigenvectors of K, and we define the orthonormal matrix $V = [v_1 \cdots v_m]$ with $(v_j)_{j=1}^m$ the m eigenvectors of K with nonzero eigenvalues. The filter F can be written as

$$F = (v_1\ v_2\ \cdots\ v_m) \begin{pmatrix} f(\sigma_1) & & & \\ & f(\sigma_2) & & 0 \\ & & \ddots & \\ & 0 & & \ddots \\ & & & f(\sigma_m) \end{pmatrix} \begin{pmatrix} v_1^T \\ v_2^T \\ \vdots \\ v_m^T \end{pmatrix}, \tag{3}$$

where the spectrum of K is filtered by the function $f(\sigma_i) = \frac{\sigma_i}{\sigma_i + \lambda}$. The filter given in equation (3) can be thought of as a low pass filter that is smoothing the signal Y by shrinking higher frequency eigenvectors—those eigenvectors corresponding to small eigenvalues. In the case of the linear kernel, which is the focus of our paper, K is the Gram matrix, $K_{ij} = x_i^T x_j$.

3.3 Randomized Principal Component Regression as a Spectral Filter

The standard formulation of principal components regression (PCR) is specified by the model

$$y_i = \beta^T z_i + \varepsilon_i, \quad \varepsilon_i \overset{iid}{\sim} \mathrm{N}(0, \sigma^2), \tag{4}$$

where $z_i = x_i^T V$ with x_i an observation in $\mathbb{R}^p$ and $V = [v_1 \cdots v_m]$ are the m eigenvectors corresponding to the top eigenvalues of the empirical covariance matrix. The idea of PCR is that projection onto the top principal component reduces variance without much loss in bias. The nonzero eigenvalues of the Gram matrix and the empirical covariance matrix are identical, so one can compute V from the Gram matrix $K_{ij} = x_i^T x_j$.

Again, we consider the case where $p \gg n$ and assume that the ARSVD procedure sets the maximum rank $d_{\max} \ll n \ll p$. In the following, we will formulate principal components regression as a spectral filter analogous to a filtering formulation of KRR in (2). We will make some approximations in this analysis as the form of the filter in the case of ARSVD is not straightforward due to randomization. The randomization and power iterations of ARSVD impact the spectral filter F in two ways: The filter no longer operates on the eigenvalues of the Gram matrix, and the eigenvectors of the spectral filter are not given by the eigenvalues of the Gram matrix.

Our analysis will consist of two observations. The first is that the eigenvectors of the exact gram matrix K and the eigenvectors of the Gram matrix induced by the ARSVD procedure are close approximations. This observation will allow us to use the eigenvectors of the exact Gram matrix in our analysis of the spectral filter. The second observation is based on a series of papers (Gerfo et al., 2008; Rudi et al., 2013, 2015) that illustrated a common regularization framework for some families of truncation-based algorithms including truncated SVD and PCR, early stopping of iterative procedures, and regularization algorithms such as ridge regression. The filter function for PCR is

$$f(\sigma) = \begin{cases} 1 & \sigma \geq \tau \\ 0 & \text{otherwise,} \end{cases}$$

here τ is the eigenvalue cutoff.

In the case of ARSVD, we generate a random matrix Ω with $\Omega_{ij} \overset{iid}{\sim} \mathrm{N}(0, 1)$. The following power iterations are then taken of a random projection onto the Gram matrix

$$G^{(t)} = (XX^T)^t \Omega = U\Sigma^{2t} U^T \Omega = U\Sigma^{2t} \Omega^*, \quad \text{with } X = U\Sigma V^T,$$

where U, Σ, and V correspond to a standard SVD of X. A basis is computed from matrix $G^{(t)}$ via QR decomposition,

$$G^{(t)} = QR \in \mathbb{R}^{n \times \ell}, \quad Q^T Q = I.$$

The data are then projected onto this basis $B = X^T Q \in \mathbb{R}^{p \times \ell}$ and a standard SVD is run on the much lower rank matrix B. If the eigenvectors of XX^T and BB^T are equal, then the following

spectral filter can be specified for the PCR with ARSVD based on the eigenvalues of the Gram matrix of the data

$$\hat{Y} = FY, \quad F = V\,\Lambda_{f(\sigma)}\,V^T, \quad \Lambda_{f(\sigma)} = \text{diag}(f(\sigma_1), ..., f(\sigma_n)), \quad f(\sigma_i) = \frac{\sigma_i^{2t}}{\sigma_i^{2t} + \tau}, \quad (5)$$

where τ is a threshold parameter. The derivation of this spectral filter is based on results in Gerfo et al. (2008) and Rudi et al. (2013). In the limit of infinite power iterations, the spectral filter is simply a hard thresholding algorithm

$$\lim_{t\to\infty} f(\sigma_i) = \begin{cases} 1 & \sigma_i > 1 \\ 0 & \sigma_i > 1. \end{cases}$$

This asymptotic analysis suggests that scaling each eigenvalue $\sigma_i := \sigma_i/\tau$ can be used to threshold at the level $1/\tau$.

We now show that the eigenvectors for XX^T and BB^T are equivalent, at least for eigenvectors corresponding to larger eigenvalues. This allows us to interpret the filter in terms of the eigenvalues of the Gram matrix XX^T. If the matrix Ω is orthogonal, then the eigenvectors corresponding to the top ℓ eigenvalues of XX^T and BB^T would be equivalent, modulo a constant scale term, which we can set without loss of generality. We argue that the matrix Ω is ε-quasiorthogonal. A set of unit norm vectors $\mu_1, ..., \mu_M \in \mathcal{R}^n$ is ε-quasiorthogonal (Kainen and Kůrková, 1993; Hecht-Nielsen and Kůrková, 1992) if their inner products are small $|\mu_i \cdot \mu_j| \leq \varepsilon$. In Indyk and Motwani (1998, Appendix A), it was shown that, for a random matrix with elements drawn exactly as Ω, the columns are ε-quasiorthogonal.

Beyond principal component regression, the top eigenvalues are important to estimate for many machine learning methods, including graph Laplacian objectives. Graph Laplacians form a key component of practically important algorithms including computing the heat kernel of a graph and PageRank (Mahoney and Orecchia, 2010). It has been shown that approximation algorithms such as ARSVD solve an exact optimization problem with an explicit regularization term (Mahoney and Orecchia, 2010; Perry and Mahoney, 2011).

3.4 Randomization and Leverage Scores

The idea of subsampling observations to generate the Gram matrix is at the heart of Nyström methods (Williams and Seeger, 2001; Drineas and Mahoney, 2005). For runtime considerations, a Gram matrix is constructed as the approximation $\tilde{G} = C^T W^{-1} C$, where C is a $p \times c$ matrix where c is a uniform subsample of the n observations and W is an $n \times n$ incidence matrix of which rows and columns are included in the subsample. There is a great deal of work in the machine learning literature arguing why it is that the Nyström method results in faster algorithms, and recent work illustrating why this numerical approximation can be formulated as a regularization method (Rudi et al., 2013, 2015). Another subsampling perspective is based on leverage scores. Given a design matrix X and the corresponding left singular vectors U the leverage score of a sample is $\ell_j = ||U_j||^2$ (Gittens and Mahoney, 2013) and can be thought of as a measure of relevance of the jth sample to the linear regression function. An alternative to uniformly sampling observations is to sample them according to the leverage score, $p_j \propto \ell_j = ||U_j||^2$, so points with higher leverage scores will more likely be sampled. Indeed, it has been shown that leverage scores drive the accuracy of the the Nyström method, and the uniform sampling approach is optimal when the leverage

scores are almost equal; in the case when the leverage scores are variable, importance sampling according to the leverage score has been used (Drineas et al., 2012). It has been shown previously that random projections project into a space where leverage scores are nearly uniform (Drineas et al., 2012; Mahoney, 2011).

4. Results on Real and Simulated Data

We use real and simulated data to highlight the following three major contributions of this paper

1. In the presence of informative *low-rank* structure in the data, randomized algorithms tend to be much faster than exact methods with minimal loss in approximation accuracy.

2. The *rank* and *subspace* containing information in the data can be reliably estimated and used to provide efficient solutions for dimension reduction.

3. The randomized algorithms implicitly impose regularization, which can be adaptively controlled in a computationally efficient manner to produce improved out-of-sample performance.

4.1 Simulated Data

4.1.1 UNSUPERVISED DIMENSION REDUCTION

We begin with unsupervised dimension reduction of data with low-rank structure contaminated with Gaussian noise, and we focus on evaluating the application of *Adaptive Randomized SVD* for PCA (see Section 2.4). In particular, we demonstrate that the proposed method estimates the sample singular values with exponentially decreasing relative error in t. Then we show that achieving similar low-rank approximation accuracy to a state-of-the-art Lanczos method requires the same run time complexity, which scales linearly in both dimensions of the input matrix. This makes our proposed method applicable to large data matrices. Lastly, we demonstrate the ability to adaptively estimate the underlying rank of the data, given a coarse upper bound. In all our simulations, we set the oversampling parameter in ARSVD, $\Delta = 10$.

We note that the oversampling parameter is crucial in scientific computing applications such as ours. In particular, setting this parameter will be application-specific and depend heavily on the structure of the input data, such as sparsity and distributional properties. For worst-case matrices, our algorithm has potential to produce sub-optimal results (Mahoney, 2011). In general, high quality results—both empirical and theoretical—are achieved by setting the oversampling parameter between five and ten (Halko et al., 2011).

4.1.2 SIMULATION MODEL

We first state the simulation model used for most of the results in this subsection. The data matrix $X \in \mathbb{R}^{n\times p}$, is generated as follows: $X = USV^T + E$, where $U^TU = V^TV = I_{d^*}$. The d^* columns of U and V are drawn uniformly at random from the corresponding unit sphere and the singular values S = diag$(s_1, \ldots, s_{d^*})$ are randomly generated starting from a baseline value, which is a fraction of the maximum noise singular value, with exponential increments separating consecutive

entries:

$$\begin{aligned} s_j &= s_{j-1} + \nu_j, \text{ for } j \in \{2, \ldots, d^*\} \\ \nu_j &\overset{\text{iid}}{\sim} \text{Exp}(\lambda), \quad \nu_0 = s_1^{(E)}. \end{aligned}$$

The noise is iid Gaussian: $E_{ij} \overset{\text{iid}}{\sim} N\left(0, \frac{1}{n}\right)$. The gaps between singular values, ν_j, follow an exponential distribution with rate parameter λ to control the signal-to-noise ratio (Table 1). The sample variance has the SVD decomposition $E \overset{\text{svd}}{=} U_E S_E V_E^T$, where $S_E = \text{diag}\left(s_1^{(E)}, \ldots, s_{\min(n,p)}^{(E)}\right)$ are the singular values in decreasing order. While there exist other working models for the noise structure, here we chose to investigate the current model and that of latent population structure because of its relevance to the genetic data that we wish to model (Section 4.1.4). Our simulations and genetic data experiments show that the assumptions we make on this particular noise model generalize well to genetics data.

4.1.3 RESULTS

The first objective is to show that we can accurately estimate singular values with very few power iterations. Our focus is on understanding the effect of the regularization parameter t controlling the singular value shrinkage. Larger values correspond to a stronger weighting on directions with large eigenvalues. In our first simulation we assume the rank d^* is fixed to 50 and the input matrix is $2,000 \times 5,000$. Studying the estimates of the percent relative error of the *singular values* averaged over ten simulated data sets. The relative error given a singular value estimate $\hat{\sigma}$ and singular value σ is $\left(\frac{\sigma - \hat{\sigma}}{\sigma}\right)$. We observed exponential convergence to the sample estimates with increasing t (Table 1). This suggests that we can capture the variation in the data with a few data matrix multiplications. We measure the error in our estimates using a signal-to-noise (S/N) metric

$$\frac{\|S\|_F^2}{\|E\|_F^2}, \quad S \text{ is the signal matrix and } E \text{ is the error or residual matrix.}$$

The signal matrix has a maximum of d^* non-zero singular values, and thus the calculation of the Frobenius norm only includes the top d^* singular values in computing both $\|S\|_F^2$ and $\|E\|_F^2$.

λ	S/N	$t = 1$	$t = 2$	$t = 3$	$t = 4$	$t = 5$
2	2.39	2.34 ± 1.23	1.18 ± 0.63	0.72 ± 0.43	0.48 ± 0.32	0.35 ± 0.25
4	0.61	3.32 ± 1.32	1.67 ± 0.47	1.00 ± 0.28	0.68 ± 0.20	0.50 ± 0.16
6	0.15	5.04 ± 1.53	2.97 ± 0.66	1.86 ± 0.41	1.30 ± 0.30	0.97 ± 0.24
8	0.13	6.26 ± 1.87	3.48 ± 0.42	2.14 ± 0.28	1.47 ± 0.21	1.08 ± 0.18

Table 1: **Singular values from ARSVD.** We report the relative error for singular value estimates with ± 1 standard deviation. A linear increase in the regularization parameter t results in a exponential decrease in the error. S/N is the signal to noise ratio and a function of λ.

It is also of interest to characterize the decay in accuracy in estimating singular values using the randomized method as the magnitude of the true singular values decreases. When we consider

the rank-ordered singular values for a fixed matrix as well as the distribution of the singular values computed via various runs of the ARSVD, an interesting observation is that the estimates are biased for small singular values (Figure 1). Data were generated from $n = 1,000$ and $p = 1,000$ with true rank $d^* = 50$. For the smallest singular values, ARSVD tends to underestimate the singular values, and the standard error is larger. This bias can be considered a form of regularization that shrinks directions corresponding to small singular values. We will discuss this property further in Section 4.1.4.

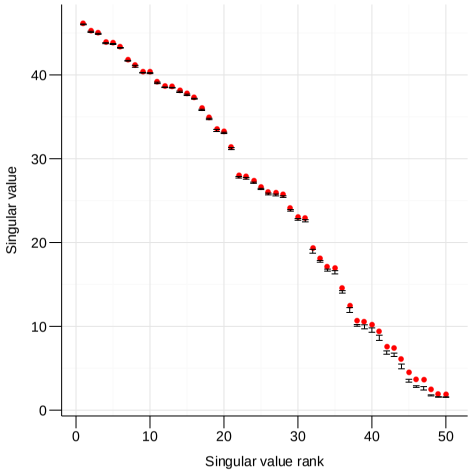

Figure 1: **Singular value accuracy of ARSVD.** Simulation results comparing estimation accuracy of singular values for ARSVD versus SVD on pseudo-random matrices of dimension $n = 1,000$ and $p = 1,000$. The exact singular values are in red and confidence intervals for the singular values computed using ARSVD are in blue.

We can compare the runtime of randomized SVD (RSVD) to two standard spectral decompositions methods. We denote the singular value decomposition of a data matrix X as SVD. We denote as eig the procedure first computing $\widehat{\Sigma} = XX^T$ and then computing the spectral decomposition of $\widehat{\Sigma}$. For this simulation, we generate pseudo-random matrices that are $n \times p$ such that $n = \frac{p}{10}$. For the RSVD procedure we will set the rank parameter to 100. We ran the SVD procedure on matrices with $p = [2000, 40000]$, we did not exceed 40,000 due to computational constraints. We ran the eigenvalue procedure on matrices with $p = [2000, 80000]$. We ran our RSVD procedure on matrices with $p = [2000, 100000]$. Examining the runtime of the three methods in terms of CPU-seconds compared to the size of the matrix, which we index as p, we see on a log scale that RSVD dramatically outperforms the other two methods (Figure 2).

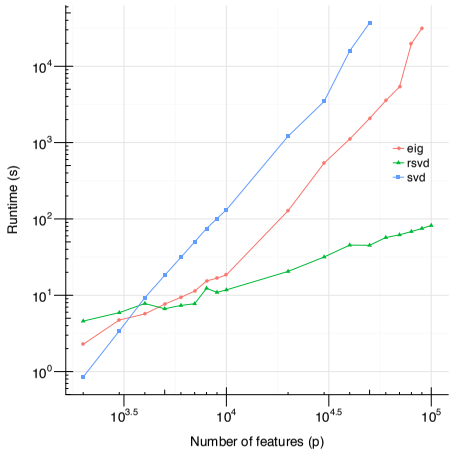

Figure 2: **Comparison of three spectral methods.** We compare RSVD, SVD, and eig. The x-axis indexes matrix size as p and the y-axis is the runtime in seconds. Both axes are on a log scale.

A natural question is whether the randomization offers any advantage over well developed efficient methods, such as Lanczos-Krylov Subspace estimation, which also operate on the data matrix only through matrix multiplies (Saad, 1992; Lehoucq et al., 1998; Stewart, 2001; Baglama and Reichel, 2006). These subspace methods are also iterative in nature, with the runtime complexity typically scaling as $O(qnp)$, where q is small. We compare the runtime ratio of our RSVD with a state-of-the-art low-rank approximation algorithm, the blocked Lanczos method implemented in the CRAN package `irlba` (Baglama and Reichel, 2006). Data were generated from $n = 1000$ and $p = 1000$ with true rank $d^* = 50$, and we varied t in ARSVD. We ran both ARSVD and blocked Lanczos until the Frobenius norm reconstruction error to the original matrix was equal to one degree of precision. We report the ratio of the runtime of ARSVD over blocked Lanczos computed on ten simulated data sets (Table 2). The relative runtime remains approximately constant with simultaneous increase in both data dimensions, which suggests similar order of complexity for both methods when the latent rank of the data (d^*) is supplied as a static parameter to each method. The relative runtime decreases exponentially when using ARSVD to dynamically estimate the latent rank versus using Bi-Cross-Validation to dynamically estimate the rank supplied to block Lanczos.

We now examine our ability to accurately estimate the rank of the matrix using the adaptive stability-based approach outlined in Section 2.4.3. We generated 50 random data sets with $n = 1000, p = 1000, d^* \overset{\text{iid}}{\sim} \text{Uniform}[10, 50]$. We set the initial rank upper bound estimate to be $2 \times d^*$ and used the stability based method (Section 2.4.3) to estimate both optimal t^* and the corresponding d^*. We compared the *true rank* and the corresponding estimates of the regularization parameter t^* for

n + p	6,000	7,500	9,000	10,500	12,000
relative time (static rank)	2.5 ± 0.05	1.84 ± 0.03	1.82 ± 0.03	1.83 ± 0.02	1.84 ± 0.04
n + p	2,000	3,500	5,000	6,500	8,000
relative time (dynamic rank)	3.49 ± 1.10	0.58 ± 0.26	0.46 ± 0.21	0.04 ± 0.01	0.25 ± 0.11

Table 2: **Runtime ratio of ARSVD versus block Lanczos.** We report the sample mean and standard error of ARSVD over block Lanczos based on ten random replicate data sets across dimensionality $n+p$. n is incremented by 500 and p is incremented by $1,000$. In the static rank experiments, the latent rank d^* is supplied as a static parameter to both methods. In the dynamic rank experiments, ARSVD estimates the latent rank using the algorithm previously described, and we use Bi-Cross-Validation to dynamically estimate the latent rank supplied to block Lanczos. ARSVD is run for as many iterations as needed until the sample error is equal to within one degree of precision, thus we do not dynamically estimate the number of power iterations, t^*, in these experiments.

two different signal-to-noise scenarios (Figure 3). In both scenarios, the rank estimates agreed with the true rank values. If the signal-to-noise ratio is low, then our procedure slightly underestimates the rank. We suspect this underestimate is due to the fact that the few smallest variance signal directions tend to be difficult to distinguish from the random noise and hence are less stable under random projections. Our approach tends to select small values for t^*, especially when there is a clear separation between the signal and the noise.

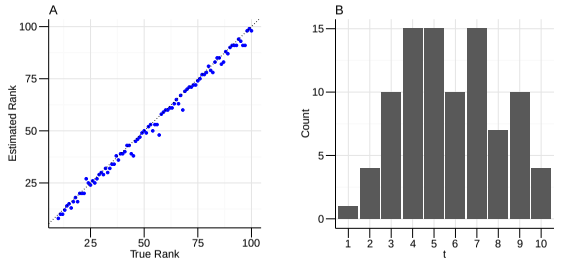

Figure 3: **Rank estimation of ARSVD.** Rank estimation results after performing ARSVD on 50 pseudo-random matrices of dimension $n = 10000$ and $p = 10000$, with true rank $d^* \overset{\text{iid}}{\sim} \text{Uniform}[10, 50]$. Matrices are generated as described in Section 4.1.1. Panel A: True rank (d^*) on the x-axis, and estimated rank ($\hat{d}^*$) on the y-axis. Panel B: estimations of t^* with max t set to ten.

4.1.4 LATENT POPULATION STRUCTURE

We examine how accurately ARSVD can be used to correct latent or cryptic population structure. Specifically, we compared the performance of an LMM using ARSVD versus a standard LMM. We simulated genotype and phenotype data where the genotypes have latent population structure that, once corrected for, there remains no association between genotype and phenotype. In other words, the phenotype is conditionally independent of the genotype given the latent (population) structure. This relation is sometimes called the confounding effect of cryptic structure in genomic data, and motivates the need for LMMs in genome-wide studies. Given that simulations are entirely under the null hypothesis of no association between genotype and phenotype, p-values should follow a uniform distribution if the random effect controls population structure appropriately. We consider any result exceeding an α-threshold a false positive, occurring at rate α.

We use the model stated in Mimno et al. (2014) to simulate admixed genotypes with K ancestral populations. The genotype of an individual is generated by the following hierarchical model

$$\begin{aligned}
\theta_i &\sim \text{Dir}_K(\alpha), \\
\phi_k &\sim \text{Beta}(1,1),\ k = 1, ..., K, \\
(z_{1,ij}, z_{2,ij}) &\sim \Big(\text{Mult}(\theta_i), \text{Mult}(\theta_i)\Big) \text{ for } j = 1, ..., p \\
(x_{1,ij}, x_{2,ij}) &\sim \Big(\text{Bin}(\phi_{z_{1,ij}}), \text{Bin}(\phi_{z_{2,ij}})\Big) \text{ for } j = 1, ..., p.
\end{aligned}$$

The first step samples the the admixture proportions for individual i. The second step samples the allele frequency distribution for populations $k = 1, \ldots, K$. The third step samples the population of origin for both allele copies over all loci, $j = 1, \ldots, p$. The final step samples both copies of the alleles at each locus j. We generated the phenotype using the following relation: $y_i \sim \text{Be}(0.5\theta_k + 0.1(1 - \theta_k))$.

We looked at four simulation settings $n = p = 1000$, $n = p = 5000$, $n = 1000, p = 5000$, and $n = 5000, p = 1000$. Using the p-values for a LMM using ARSVD with the rank parameter d^* of the ARSVD specified, we see that the standard LMM is recovered in the limit of $d^* = p$ (Figure 4). Of these settings, the case where $n = 1000, p = 5000$ is the most similar to the standard genomics case where the number of SNPs p is much larger than the number of observations n. A summary of these simulation results is that the ARSVD method is much faster than the standard LMM and performs similarly with respect to correcting for population structure and controlling false positives. We observed that, for the simulation with $n = 1000, p = 5000$, using ARSVD leads to a substantial reduction of computational complexity with similar performance. In general, we expect the tradeoff between computational efficiency and accuracy to depend on the data. In the case of structured genomic data, we report in these simulations and in Section 4.1.4 that massive computational savings are accompanied by numerical accuracy.

4.2 Association Mapping in Large Genomic Data

We applied our LMM with ARSVD to a large genomic data set to illustrate that we can achieve considerable computational efficiency without loss in accuracy. In particular, we applied our method to the Wellcome Trust Case Control Consortium (WTCCC) data (Consortium, 2007). The data we consider consist of a case-control study of $4,684$ individuals. The cases are individuals with Crohn's disease, and the number of features are 478,765 genetic variants across the 22 autosomal chromosomes in the genome. We compared our ARSVD method with state-of-the-art LMMs designed for

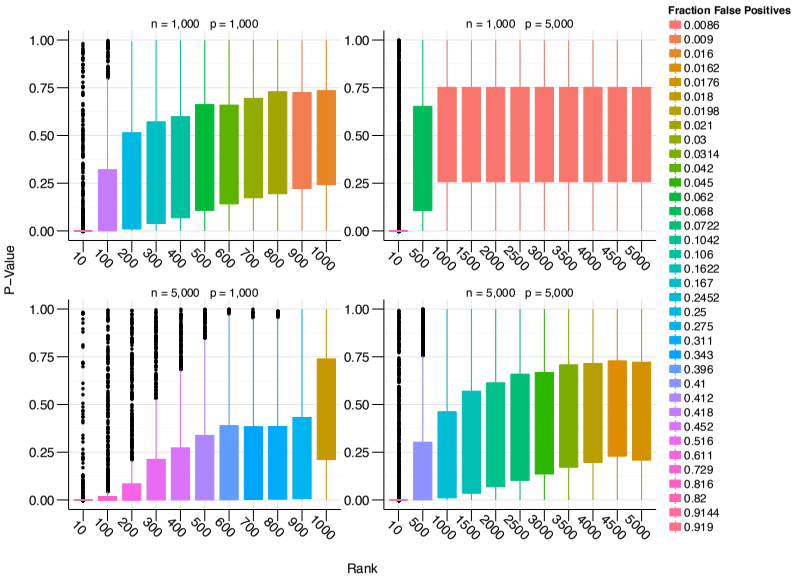

Figure 4: **Controlling for structure.** RSVD with pylmm is applied to four simulation settings with varying n and p. The x-axis is the setting of the ARSVD parameter d^*. The y-axis corresponds to the p-values from the LMM for each of the p features. The color of each box plot represents the fraction of false positive rate of the LMM using ARSVD.

association studies. Our LMM with ARSVD procedure uses EMMAX (pylmm) to solve the LMM. The two methods we compared to are EMMAX with the addition of ARSVD and GEMMA (Zhou et al., 2013) (GEMMA is executed with the `-lmm` option to most closely approximate the analysis that pylmm performs).

ARSVD on the whole genome took 82.2 seconds, while a traditional eigendecomposition of the covariance matrix in pylmm took 88 mins 23.9 seconds. In order to most accurately control for the test statistic computed in a LMM and to achieve maximal statistical power, it is suggested that a covariance matrix is constructed once per (22) chromosomes, performed by holding out the test chromosome and concatenating the remaining chromosomes (Yang et al., 2014). Our method performs the 22 decompositions in a total of 5 mins 4.8 secs, while the traditional decomposition method takes 4 hrs 24 mins.

In the remainder of this subsection, we denote the culling of EMMAX with ARSVD as pylmm. It has been observed (Zhou et al., 2013) that the effect sizes of the coefficients are similar whether one applies linear regression or logistic regression to most case-control genomic studies. Estimates

of β for pylmm and GEMMA are strongly correlated. The distributions of p-values computed by pylmm show enrichment in low p-values. This suggests that the regularization in pylmm may capture additional associations.

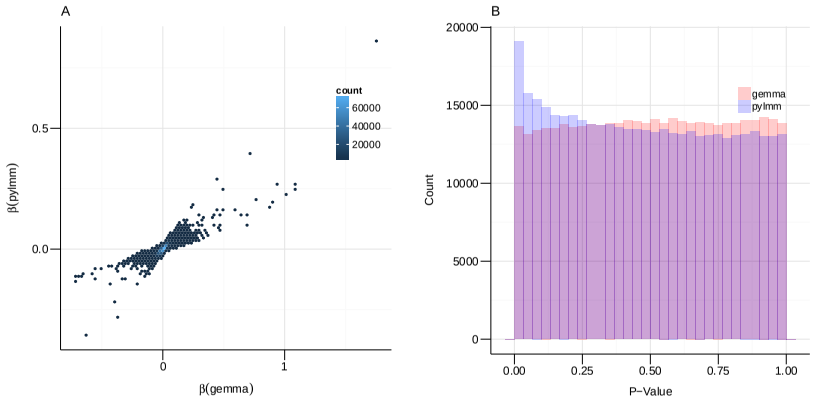

Figure 5: **Comparison of pylmm and GEMMA.** A) A scatter plot of the β-values for GEMMA on the x-axis versus the β-values for pylmm on the y-axis. B) Histogram of p-values for both methods, GEMMA in red and pylmm in blue.

We compared the most significant associations that we identified to results from other analyses of Crohn's disease. One source of associations is from a large-scale meta-analysis of Crohn's disease consisting of 6,333 affected individuals (cases) and 15,056 controls, and the top association signals were followed up on in 15,694 cases, 14,026 controls, and 414 parent-offspring trios (Franke et al., 2010). We denote this list as MA. In Listgarten et al. (2012), the list of associated genetic variants collected includes the MA list as well as the WTCCC list. The major histocompatibility complex (MHC) is a region that has been previously associated to Crohn's disease and autoimmune disease in general. We denote the list of variants in this region as MHC. We report the overlap between the results obtained from our method to the MA list, the union of the WTCCC and MA lists, and the union of the WTCCC, MA, and MHC lists. (Table 3). We select our top hits using two cutoffs: the top 0.5% with respect to negative log p-value, and the associations that pass a local false discovery rate (LFDR) of 5% (Strimmer, 2008).

We identified several potential genetic variants associated with Crohn's that were previously unidentified. In particular, there are a few genetic variants within the 3.6MB region that defines the MHC on chromosome 6 in the human genome (sequencing consortium, 1999) at an LFDR threshold of 10%. Genetic variant rs9269186 ($p \leq 7.03 \times 10^{-7}$) is below the LFDR threshold of 1% and lies within 5 kilobases (KB) of the start of the *HLA-DRB5* gene, putatively acting to regulate transcription of this protein-coding gene that produces a membrane-bound class II molecule. The

HLA-DRB5 protein is an antigen that has an important role in the human immune system, and thus may play a role in an autoimmune disorder such as Crohn's disease.

source	significant variants	top 0.5%	LFDR 5%
MA+WTCC+MHC	151	61	35
MA + WTCCC	93	48	30
MA	81	47	29

Table 3: **Overlap of genetic associations with prior studies.** Columns represent the number of associations (significant variants) in the MA, WTCCC studies and the number of variants in the MHC region; the overlap of our list with the associations in these lists with a cutoff of the top 0.5% of our associations; and overlap at an LFDR threshold of 5%.

5. Discussion

Massively high-dimensional data sets are ubiquitous in modern data analysis settings. In this paper, we provide a scale method for accurate computation using spectral decompositions for data analysis. The main computational tool we use is based on recent randomized algorithms developed by the numerical analysis community. To address the issue of noise, we provide an adaptive procedure to estimate both the rank d^* of the lower dimensional projection and the number of Krylov iterations t^* for the randomized approximate SVD. Using this adaptive estimator of low-rank structure, we implement efficient algorithms for PCA and linear mixed models. An interesting observation both from an empirical and theoretical perspective is that our randomized algorithm implicitly imposes regularization.

In simulated experiments we show high accuracy in recovering the true (latent) rank of matrices with low-rank substructure, without the need for many Krylov iterations. Additionally, we show in simulations that our method performs implicit regularization and improves quantitative properties of results under various types of data structure. Furthermore, our results on large genome-wide association studies show that our approach to using ARSVD in linear mixed models fills a critical need for methods with computational efficiency that do not sacrifice the desirable statistical properties of traditional LMMs.

Some important open questions still remain:

(1) There is need for a more refined theoretical framework to quantify what generalization guarantees the randomization algorithm can provide on out-of-sample data, and the dependence of this bound on the noise and the structure in the data on one hand and on the parameter settings on the other.

(2) A probabilistic interpretation of the algorithm could contribute additional insights (Mahoney, 2011) into the practical utility of the proposed approach under different assumptions. In particular, it would be interesting to relate our work to a Bayesian model with posterior modes that correspond to the subspaces estimated by the randomized approach.

(3) The implicit regularization on latent factors imposed by ARSVD should be further explored with respect to the structure of the noise, and its impact on estimates of random effects in LMMs (Runcie and Mukherjee, 2013).

Appendix A. Generalized Eigendecomposition and Dimension Reduction

The appendix states a variety of dimension reduction methods supervised, unsupervised, and non-linear that can use the ARSVD engine to scale to massive data. The key requirement is a formulation of the truncated generalized eigendecomposition problem that can be implemented by the *Adaptive Randomized SVD* from Section 2.4. The dimension reduction methods we will focus on are sliced inverse regression (SIR) and localized sliced inverse regression (LSIR).

A.1 Problem Formulation

Assume we are given $\Sigma \in \mathbb{S}^p_{++}, \Gamma \in \mathbb{S}^p_+$ that characterize pairwise relationships in the data and let $r \ll \min(n,p)$ be the "intrinsic dimensionality" of the information contained in the data. In the case of supervised dimension reduction methods this corresponds to the dimensionality of the linear subspace to which the joint distribution of (X,Y) assigns non-zero probability mass. Our objective is to find a basis for that subspace. For SIR and LSIR this corresponds to the span of the generalized eigenvectors $\{g_1,\dots,g_r\}$ with largest eigenvalues $\{\lambda_{\max} = \lambda_1 \geq \dots \geq \lambda_r\}$:

$$\Gamma g = \lambda \Sigma g. \tag{6}$$

An important structural constraint we impose on Γ, which is applicable to a variety of high-dimensional data settings, is that it has low-rank: $r \leq d^* \equiv \text{rank}(\Gamma) \ll p$. It is this constraint that we will take advantage of in the randomized methods. In the case of $\Sigma = \text{I}$ (unsupervised case), $r = d^*$.

A.2 Sufficient Dimension Reduction

Dimension reduction is often a first step in the statistical analysis of high-dimensional data and could be followed by data visualization or predictive modeling. If the ultimate goal is the latter, then the statistical quantity of interest is a low dimensional summary $Z \equiv R(X)$ which captures all the predictive information in X relevant to Y:

$$Y = f(X) + \varepsilon = h(Z) + \varepsilon, \quad X \in \mathbb{R}^p, Z \in \mathbb{R}^r,\ r \ll p.$$

Sufficient dimension reduction (SDR) is one popular approach for estimating Z (Li, 1991; Cook and Weisberg, 1991; Li, 1992; Li et al., 2005; Nilsson et al., 2007; Sugiyama, 2007; Cook, 2007; Wu et al., 2010). In this appendix we focus on linear SDRs: $G = (g_1,\dots,g_r) \in \mathbb{R}^{p\times r} \Rightarrow R(X) = G^T X$, which provide a prediction-optimal reduction of X.

$$(Y \mid X) \overset{d}{=} (Y \mid G^T X), \quad \overset{d}{=} \text{ is equivalence in distribution.}$$

We will consider two specific dimension reduction methods: Sliced Inverse Regression (SIR) (Li, 1991) and Localized Sliced Inverse Regression (LSIR) (Wu et al., 2010). SIR is effective when the predictive structure in the data is global, i.e., there is single predictive subspace over the support of the marginal distribution of X. In the case of local or manifold predictive structure in the data, LSIR can be used to compute a projection matrix G that contains this non-linear (manifold) structure.

A.3 Efficient Solutions and Approximate SVD

SIR and LSIR reduce to solving a truncated generalized eigendecomposition problem as formulated in (6). Since we consider estimating the dimension reduction based on sample data we focus on the sample estimators $\widehat{\Sigma} = \frac{1}{n}X^T X$ and $\widehat{\Gamma}_{XY} = X^T K_{XY} X$, where K_{XY} is symmetric and encodes the method-specific grouping of the samples based on the response Y. In the classic statistical setting, when $n > p$, both $\widehat{\Sigma}$ and $\widehat{\Gamma}_{XY}$ are positive definite almost surely. Then, a typical solution proceeds by first sphering the data: $Z = \widehat{\Sigma}^{-\frac{1}{2}} X$, e.g., using a Cholesky or SVD representation $\widehat{\Sigma} = \widehat{\Sigma}^{\frac{1}{2}}(\widehat{\Sigma}^{\frac{1}{2}})^T$. This is followed by eigendecomposition of $\widehat{\Gamma}_{ZY}$ Li (1991); Wu et al. (2010) and back-transformation of the top eigenvectors directions to the canonical basis. The computational time is $O(np^2)$. When $n < p$, $\hat{\Sigma}$ and $\hat{\Gamma}$ are rank-deficient and a unique solution to the problem (6) does not exist. One widely-used approach, which allows us to make progress in this problematic setting, is to restrict our attention to the directions in the data with positive variance. Then we can proceed as before, using an orthogonal projection onto the span of the data. The total computation time in this case is $O(n^2 p)$. In many modern data analysis applications both n and p are very large, and hence algorithmic complexity of $O[\max(n,p) \times \min(n,p)^2]$ could be prohibitive, rendering the above approaches unusable. We propose an approximate solution that explicitly recovers the low-rank structure in Γ using *Adaptive Randomized SVD* from Section 2.4. In particular, assume $\text{rank}\,(\Gamma) = d^* \geq r$ (where r is the dimensionality of the optimal dimension reduction subspace). Then $\Gamma \overset{\text{svd}}{=} US^2U^T$, where $U \in \mathbb{R}^{p\times d^*}$. The generalized eigendecomposition problem (6) solution becomes restricted to the subspace spanned by the columns of Γ:

$$S^{-1}U^T \Sigma U S^{-1} e \;=\; \frac{1}{\lambda} e, \qquad e \equiv SU^T g. \tag{7}$$

The dimension reduction subspace is contained in the span(G), where

$$G = (US^{-1}e_1,\dots,US^{-1}e_r).$$

Abstract

We study the problem of solving a quadratic system of equations, i.e., recovering a vector signal $\boldsymbol{x} \in \mathbb{R}^n$ from its magnitude measurements $y_i = |\langle \boldsymbol{a}_i, \boldsymbol{x}\rangle|, i = 1, ..., m$. We develop a gradient descent algorithm (referred to as RWF for reshaped Wirtinger flow) by minimizing the quadratic loss of the magnitude measurements. Comparing with Wirtinger flow (WF) (Candès et al., 2015), the loss function of RWF is nonconvex and nonsmooth, but better resembles the least-squares loss when the phase information is also available. We show that for random Gaussian measurements, RWF enjoys linear convergence to the true signal as long as the number of measurements is $\mathcal{O}(n)$. This improves the sample complexity of WF ($\mathcal{O}(n \log n)$), and achieves the same sample complexity as truncated Wirtinger flow (TWF) (Chen and Candès, 2015), but without any sophisticated truncation in the gradient loop. Furthermore, RWF costs less computationally than WF, and runs faster numerically than both WF and TWF. We further develop an incremental (stochastic) version of RWF (IRWF) and connect it with the randomized Kaczmarz method for phase retrieval. We demonstrate that IRWF outperforms existing incremental as well as batch algorithms with experiments.

Keywords: gradient descent, phase retrieval, nonconvex optimization, regularity condition, stochastic algorithms

1. Introduction

Many problems in machine learning and signal processing can be reduced to solving a quadratic system of equations. For instance, in phase retrieval applications, i.e., X-ray crystallography and coherent diffraction imaging (Drenth, 2007; Miao et al., 1999, 2008), the structure of an object is to be recovered from the measured far field diffracted intensity when the object is illuminated by a source light. Mathematically, such a problem amounts to recovering the signal from only the magnitudes of its linear measurements. Specifically, the problem is formulated as follows.

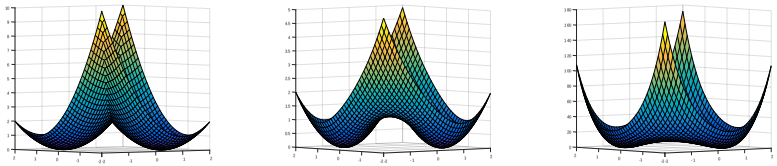
Problem 1 *Recover $\boldsymbol{x} \in \mathbb{R}^n/\mathbb{C}^n$ from the measurements given as*

$$y_i = |\langle \boldsymbol{a}_i, \mathbf{x}\rangle|, \quad \text{for } i = 1, \cdots, m, \tag{1}$$

where $\boldsymbol{a}_i \in \mathbb{R}^n/\mathbb{C}^n$ are known design vectors.

Various algorithms have been proposed to solve this problem since the 1970s. The error-reduction methods (Gerchberg, 1972; Fienup, 1982) work well empirically but lack theoretical guarantees. More recently, convex relaxation of the problem has been formulated, for example, via PhaseLift (Candès et al., 2013; Candès and Li, 2014; Chen et al., 2015) and PhaseCut (Waldspurger et al., 2015), and the correspondingly developed algorithms typically come with performance guarantees. The readers can refer to the review paper (Shechtman et al., 2015) to learn more about applications and algorithms of the phase retrieval problem.

Nonetheless, these convex approaches often suffer from high computational complexity particularly when the signal dimension is large. It is therefore desirable to develop more efficient nonconvex approaches that can provably recover the true signal. Netrapalli et al. (2013) proposed the *AltMinPhase* algorithm, which alternates between updates of the phase and the signal, and showed that it converges linearly and recovers the true signal with $\mathcal{O}(n \log^3 n)$ Gaussian measurements, when $\boldsymbol{a}_i$'s are composed of *independent and identically distributed* (i.i.d.) standard Gaussian entries. More recently, Candès et al. (2015) introduced the *Wirtinger flow* (WF) algorithm, which guarantees signal recovery via a simple gradient descent algorithm with only $\mathcal{O}(n \log n)$ Gaussian measurements and attains ϵ-accuracy within $\mathcal{O}(mn^2 \log 1/\epsilon)$ flops[1]. More specifically, WF obtains a good initialization by the spectral method, and then minimizes the following nonconvex loss function based on the quadratic loss of the squared magnitude measurements



$$\ell_{WF}(\boldsymbol{z}) := \frac{1}{4m}\sum_{i=1}^{m}(|\boldsymbol{a}_i^T \boldsymbol{z}|^2 - |y_i|^2)^2, \tag{2}$$

via the gradient descent scheme.

WF is further improved by *truncated Wirtinger flow* (TWF) (Chen and Candès, 2015), which adopts a Poisson loss function of $|\boldsymbol{a}_i^T \boldsymbol{z}|^2$, and keeps only well-behaved measurements based on carefully designed truncation thresholds for calculating the initialization and the gradient updates. Such truncation assists to achieve a linear convergence rate using a fixed step size; as a consequence, TWF reduces both the sample complexity to $\mathcal{O}(n)$ and the computational complexity to $\mathcal{O}(mn \log 1/\epsilon)$.

Furthermore, incremental/stochastic methods have been proposed to solve Problem 1. Specifically, the randomized Kaczmarz method has been adopted to solve the phase retrieval problem (Wei, 2015; Li et al., 2015), which was shown to have excellent empirical performance, but no nonasymptotic global convergence guarantee was established. Incremental truncated Wirtinger flow (ITWF) (Kolte and Özgür, 2016) is another stochastic algorithm developed based on TWF.

1. WF has computational cost $\mathcal{O}(mn^2 \log(1/\epsilon))$ (Candès et al., 2015, Theorem 3.1) because it needs $\log(1/\epsilon) \cdot \frac{1}{-\log(1-c/n)} \approx \frac{n}{c}\log(1/\epsilon)$ iterations to achieve ϵ-accuracy due to the convergence rate $\left(1 - \frac{c}{n}\right)^k$ and each iteration needs $\mathcal{O}(mn)$ flops. Contrastingly, RWF has computational cost $\mathcal{O}(mn \log 1/\epsilon)$ because it requires only $c \log(1/\epsilon)$ iterations to achieve ϵ-accuracy due to the convergence rate $(1-c)^k$.

(a) Expected loss of LS (b) Expected loss of RWF (c) Expected loss of WF

Figure 1: Surface of the expected loss function of (a) least-squares (mirrored symmetrically), (b) RWF, and (c) WF when $\boldsymbol{x} = [1, -1]^T$.

1.1 Our Contribution

This paper adopts the following loss function

$$\ell(\boldsymbol{z}) := \frac{1}{2m}\sum_{i=1}^{m}\left(|\boldsymbol{a}_i^T\boldsymbol{z}| - y_i\right)^2, \tag{3}$$

which is the quadratic loss of the magnitude measurements. Compared to the loss function (2) of WF that adopts the quadratic loss of $|\boldsymbol{a}_i^T\boldsymbol{z}|^2$, the above loss function adopts the quadratic loss of $|\boldsymbol{a}_i^T\boldsymbol{z}|$ and hence has lower-order variables. While both loss functions are nonconvex in $\boldsymbol{z}$, the WF loss function (2) is a fourth-order smooth function of $\boldsymbol{a}_i^T\boldsymbol{z}$ and our loss function (3) in contrast is nonsmooth.

To minimize such a nonconvex and nonsmooth loss function (3), we develop a gradient descent algorithm, which sets the "gradient" to zero corresponding to nonsmooth samples. We refer to such an algorithm together with an initialization using a new spectral method (different from that employed in TWF or WF) as *reshaped Wirtinger flow* (RWF). We show that the new loss function has great advantage in both statistical and computational efficiency, despite nonsmoothness. In fact, the curvature of such a loss function behaves similarly to that of a least-squares problem with phase information in the neighborhood of global optimizers, and hence yields faster convergence. To provide further insights, consider the standard problem of solving $\boldsymbol{x}$ from *linear measurements* $\langle \boldsymbol{a}_i, \mathbf{x}\rangle$, $i = 1, \cdots, m$, where $\boldsymbol{a}_i$'s are composed of i.i.d. standard Gaussian entries. In this case, it is natural to use the least-squares loss function

$$\ell_{LS}(\boldsymbol{z}) := \frac{1}{m}\sum_{i=1}^{m}\left(\boldsymbol{a}_i^T\boldsymbol{z} - \boldsymbol{a}_i^T\boldsymbol{x}\right)^2. \tag{4}$$

Examining the expected (with respect to $\boldsymbol{a}_i$'s) loss surface of $\min\{\ell_{LS}(\boldsymbol{z}), \ell_{LS}(-\boldsymbol{z})\}$ (to mimic sign ambiguity), $\ell(\boldsymbol{z})$, and $\ell_{WF}(\boldsymbol{z})$ in Figure 1, whose expressions can be found in Appendix A, it can be seen that the loss of RWF, rather than the loss of WF, has a similar curvature to the quadratic least-squares loss around the global optimizers, which justifies its better performance than WF.

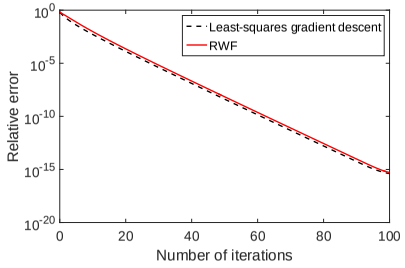


Figure 2: Comparison of convergence behavior between RWF and the least-squares gradient descent with the same initialization, the same parameters $n = 1000$, $m = 6n$, and the same step size $\mu = 0.8$.

The nonsmoothness of the loss function (3) does not negatively impact the performance of RWF because only with negligible probability the algorithm encounters nonsmooth points for some samples, which furthermore are set not to contribute to the gradient direction by RWF. The gradient of the RWF loss (3) is given as

$$\nabla\ell(\boldsymbol{z}) := \frac{1}{m}\sum_{i=1}^{m}\left(\boldsymbol{a}_i^T\boldsymbol{z} - y_i\cdot\mathrm{sgn}(\boldsymbol{a}_i^T\boldsymbol{z})\right)\boldsymbol{a}_i, \tag{5}$$

where $\mathrm{sgn}(0) = 0$ by convention. Comparing this with the gradient of the least-squares loss

$$\nabla\ell_{LS}(\boldsymbol{z}) = \frac{1}{m}\sum_{i=1}^{m}\left(\boldsymbol{a}_i^T\boldsymbol{z} - \boldsymbol{a}_i^T\boldsymbol{x}\right)\boldsymbol{a}_i, \tag{6}$$

one can see that RWF uses estimated phase information $\mathrm{sgn}(\boldsymbol{a}_i^T\boldsymbol{z})$ to generate the gradient updates, and the convergence behavior of RWF is much similar to that of least-squares with phase information if initialized properly. Indeed, Figure 2 illustrates that RWF takes almost the *same* number of iterations for recovering a signal (with only the magnitude information) as the least-squares gradient descent method for recovering a signal (with both the magnitude and the sign information).

We further develop incremental/stochastic versions of RWF using mini-batches of measurements, called incremental RWF (IRWF), and show that IRWF also enjoys the advantageous local curvature of RWF, and achieves excellent statistical and computational performance. Along the way, we establish the performance guarantee of the Kaczmarz-PR update rule by interpreting it as a variant of IRWF. We conduct extensive numerical experiments to demonstrate that IRWF performs better than other competitive incremental algorithms (ITWF and Kaczmarz-PR) as well as batch algorithms (RWF, TWF, WF and AltMinPhase).

We summarize our main results as follows.

- Statistically, we show that RWF recovers the true signal with $\mathcal{O}(n)$ Gaussian measurements, which is order-wise optimal. Thus, RWF improves the sample complexity

$\mathcal{O}(n \log n)$ of WF, and achieves the same sample complexity as TWF but without truncation in the gradient descent step.

- Computationally, RWF converges linearly to the true signal with a constant step size, requiring $\mathcal{O}(mn \log(1/\epsilon))$ flops to reach ϵ-accuracy. Again, without truncation in the gradient descent step, RWF improves the computational cost $\mathcal{O}(mn^2 \log(1/\epsilon))$ of WF and achieves the same computational cost as TWF.

- We also show that RWF is robust to bounded additive noise. The estimation error is shown to diminish at a linear rate with respect to the noise level up to a scaling difference. Experiments on Poisson noise further corroborate the stability guarantee.

- The incremental versions of RWF (IRWF) is shown to shrink the estimation error in expectation for one update, which implies the linear convergence of the algorithm if the iteration path lies in the neighborhood of the true signal. Furthermore, we show that Kaczmarz-PR can be viewed as IRWF under a specific choice of step size, and establish a similar convergence result for Kaczmarz-PR under the same sample complexity.

- Numerically, RWF and its incremental versions require fewer parameters, e.g., truncation thresholds, than TWF in practice. RWF is generally two times faster than TWF and four to six times faster than WF in terms of both the number of iterations and time cost. IRWF also outperforms existing incremental as well as batch algorithms.

Compared to WF and TWF, the nonsmoothness in the loss function requires new bounding techniques in order to establish the theoretical guarantees. On the other hand, our technical proof is much simpler, because the lower-order loss function allows to bypass higher-order moments of variables as well as truncation of samples in the gradient descent steps.

1.2 Related Work

The quadratic loss function of magnitudes (3) was also used in the early literature of phase retrieval (Fienup, 1982) with Fourier magnitude measurements. However, no global convergence guarantee was available in (Fienup, 1982). Along the line of developing nonconvex algorithms with global performance guarantees for the phase retrieval problem, Netrapalli et al. (2013) and Waldspurger (2016) developed alternating minimization algorithms, Candès et al. (2015); Chen and Candès (2015); Zhang et al. (2016); Cai et al. (2016) developed first-order algorithms, and a recent study Sun et al. (2016) characterized the geometric structure of the nonconvex objective and designed a second-order trust-region algorithm. This paper is closely related to (Candès et al., 2015; Chen and Candès, 2015; Zhang et al., 2016), but develops a new gradient descent algorithm based on a lower-order nonsmooth (as well as nonconvex) loss function that yields advantageous statistical and computational efficiency.

Stochastic algorithms were also developed for the phase retrieval problem. Kolte and Özgür (2016) studied the incremental truncated Wirtinger flow (ITWF) and showed that ITWF needs much fewer passes of data than TWF to reach the same accuracy. Wei (2015) adapted the Kaczmarz method to solve the phase retrieval problem and demonstrated its

fast empirical convergence. We show that IRWF is closely related to Kaczmarz-PR, and empirically runs faster than ITWF thanks to the advantageous curvature of the loss function.

After our work was posted on arXiv, an independent work (Wang et al., 2016) was subsequently posted, which also adopts the same loss function but develops a slightly different algorithm called TAF (i.e., truncated amplitude flow). One major difference is that RWF does not require truncation in the gradient loops while TAF still employs truncation. Hence, RWF has fewer parameters to tune, and is easier to implement than TAF in practice. Furthermore, RWF demonstrates the performance advantage of adopting a lower-order loss function even without truncation, which cannot be observed from TAF. The two algorithms also employ different initialization strategies. Moreover, we analyze stochastic algorithms based on the new loss function while Wang et al. (2016) do not.

More generally, various high-dimensional signal estimation problems have been studied by minimizing nonconvex loss functions. For example, a partial list of these studies include matrix completion (Keshavan et al., 2010; Jain et al., 2013; Sun and Luo, 2016; Hardt, 2014; Sa et al., 2015; Zheng and Lafferty, 2016; Jin et al., 2016; Ge et al., 2016), low-rank matrix recovery (Bhojanapalli et al., 2016; Chen and Wainwright, 2015; Tu et al., 2015; Zheng and Lafferty, 2015; Park et al., 2016; Wei et al., 2016; Li et al., 2017), robust PCA (Netrapalli et al., 2014), robust tensor decomposition (Anandkumar et al., 2016), dictionary learning (Arora et al., 2015; Sun et al., 2015), community detection (Bandeira et al., 2016), phase synchronization (Boumal, 2016), blind deconvolution (Lee et al., 2016b; Li et al., 2016), etc.

For minimizing a general nonconvex nonsmooth objective, various algorithms have been proposed, such as gradient sampling (Burke et al., 2005; Kiwiel, 2007) and majorization-minimization (Ochs et al., 2015). These algorithms are often shown to converge to critical points which may be local minimizers or saddle points, without an explicit characterization of convergence rates. In contrast, our algorithm is specifically designed for the phase retrieval problem, and can be shown to converge linearly to the global optimum under an appropriate initialization.

The advantage of using nonsmooth loss functions in our study is analogous in spirit to that of the rectifier activation function (of the form $\max\{0, \cdot\}$) in neural networks. It has been shown that rectified linear unit ($ReLU$) enjoys superb advantage in reducing the training time (Krizhevsky et al., 2012) and promoting sparsity (Glorot et al., 2011) over its counterparts of sigmoid and hyperbolic tangent functions, in spite of non-linearity and non-differentiability at zero. Our results in fact also demonstrate that a nonsmooth but simpler loss function yields improved performance.

1.3 Paper Organization and Notations

The rest of this paper is organized as follows. Section 2 describes the RWF algorithm in detail and establishes its performance guarantee. Section 3 introduces the IRWF algorithm, establishes its performance guarantee and compares it with existing stochastic algorithms. Section 4 compares RWF and IRWF with other competitive algorithms numerically. Finally, Section 5 concludes the paper with comments on future directions.

Throughout the paper, boldface lowercase letters such as $\boldsymbol{a}_i, \boldsymbol{x}, \boldsymbol{z}$ denote vectors, and boldface capital letters such as $\boldsymbol{A}, \boldsymbol{Y}$ denote matrices. For two matrices, $\boldsymbol{A} \prec \boldsymbol{B}$ means that $\boldsymbol{B} - \boldsymbol{A}$ is positive definite. For a complex matrix and a vector, $\boldsymbol{A}^*$ and $\boldsymbol{z}^*$ denote conjugate

transposes of $\boldsymbol{A}$ and $\boldsymbol{z}$, respectively. For a real matrix and a vector, $\boldsymbol{A}^T$ and $\boldsymbol{z}^T$ denote transposes of $\boldsymbol{A}$ and $\boldsymbol{z}$, respectively. We let $\odot$ denotes element-wise product. The indicator function $\mathbf{1}_A = 1$ if the event A occurs, and $\mathbf{1}_A = 0$ otherwise. We let $\|\boldsymbol{x}\|_1$ and $\|\boldsymbol{x}\|$ denote the l_1 norm and l_2 norm of a vector $\boldsymbol{x}$, respectively. Moreover, let $\|\boldsymbol{A}\|_F$ and $\|\boldsymbol{A}\|$ denote the Frobenius norm and the spectral norm of a matrix $\boldsymbol{A}$, respectively. We note that the constants c, C, c_0, c_1, c_2 may be different in different equations, for the sake of notational simplicity.

2. Reshaped Wirtinger Flow

Consider the Problem 1 for the complex case. It can be observed that if $\boldsymbol{z}$ is a solution, i.e., satisfying Equation (1), then $\boldsymbol{z}e^{-j\phi}$ is also the solution of the problem where ϕ is an arbitrary phase constant. Therefore, the recovery is up to a phase difference. Thus, we define the Euclidean distance between two complex vectors up to a global phase difference (Candès et al., 2015) as,

$$\operatorname{dist}(\boldsymbol{z}, \boldsymbol{x}) := \min_{\phi \in [0, 2\pi)} \|\boldsymbol{z}e^{-j\phi} - \boldsymbol{x}\|, \tag{7}$$

which is simply $\min \|\boldsymbol{z} \pm \boldsymbol{x}\|$ for the real case.

In this paper, we focus on the real-valued case in our analysis, but the algorithm designed below is applicable to the complex-valued case and the case with other measurement vectors such as *coded diffraction pattern* (CDP) as we demonstrate via numerical experiments in Section 4.

We design RWF (see Algorithm 1) for solving the phase retrieval problem, which contains two stages: spectral initialization and gradient loop. The suggested values for the parameters[2] are given by $\alpha_l = 1, \alpha_u = 5$ and $\mu = 0.8$. The rescaling coefficient in λ_0 and the conjugate transpose $\boldsymbol{a}_i^*$ allow the algorithm readily applicable to the complex and CDP cases. We next describe the two stages of RWF in details in Sections 2.1 and 2.2, respectively, and establish the convergence guarantee in Section 2.3. Finally, we provide the stability guarantee of RWF in Section 2.4.

2.1 Initialization via the Spectral Method

When solving nonconvex problems by iterative algorithms, the starting point is critical. The spectral method is a popular choice in the literature (Keshavan et al., 2010; Netrapalli et al., 2013; Candès et al., 2015; Chen and Candès, 2015), which often provides a good initialization. Different from the spectral initialization used in AltMinPhase (Netrapalli et al., 2013), WF (Candès et al., 2015) and TWF (Chen and Candès, 2015), which are based on the squared magnitudes as the weight of each rank-one matrix $\boldsymbol{a}_i\boldsymbol{a}_i^*$, we propose an alternative initialization in Algorithm 1 that uses the magnitudes instead, and truncates samples that are either too large or too small. We show that such an initialization achieves a smaller sample complexity than WF and the same sample complexity as TWF order-wise, and furthermore, performs better than both WF and TWF numerically.

Our initialization consists of estimation of both the norm and the direction of $\boldsymbol{x}$. The norm estimation of $\boldsymbol{x}$ is given by λ_0 in Algorithm 1. Intuitively, with real-valued Gaussian

2. For the complex Gaussian case, we suggest $\mu = 1.2$.

Algorithm 1 Reshaped Wirtinger Flow

Input: $\boldsymbol{y} = \{y_i\}_{i=1}^m$, $\{\boldsymbol{a}_i\}_{i=1}^m$;

Parameters: Lower and upper thresholds α_l, α_u for truncation in initialization, step size μ;

Initialization: Let $\boldsymbol{z}^{(0)} = \lambda_0 \tilde{\boldsymbol{z}}$, where $\lambda_0 = \frac{mn}{\sum_{i=1}^m \|\boldsymbol{a}_i\|_1} \cdot \left(\frac{1}{m}\sum_{i=1}^m y_i\right)$ and $\tilde{\boldsymbol{z}}$ is the leading eigenvector of

$$\boldsymbol{Y} := \frac{1}{m}\sum_{i=1}^m y_i \boldsymbol{a}_i \boldsymbol{a}_i^* \mathbf{1}_{\{\alpha_l \lambda_0 < y_i < \alpha_u \lambda_0\}}. \tag{8}$$

Gradient loop: for $t = 0 : T-1$ do

$$\boldsymbol{z}^{(t+1)} = \boldsymbol{z}^{(t)} - \frac{\mu}{m}\sum_{i=1}^m \left(\boldsymbol{a}_i^*\boldsymbol{z}^{(t)} - y_i \cdot \frac{\boldsymbol{a}_i^*\boldsymbol{z}^{(t)}}{|\boldsymbol{a}_i^*\boldsymbol{z}^{(t)}|}\right)\boldsymbol{a}_i. \tag{9}$$

Output $\boldsymbol{z}^{(T)}$.

measurement vectors (i.e., $\boldsymbol{a}_i \sim \mathcal{N}(0, \boldsymbol{I}_{n\times n})$), the scaling coefficient $\frac{mn}{\sum_{i=1}^m \|\boldsymbol{a}_i\|_1} \approx \sqrt{\frac{\pi}{2}}$. Moreover, for $i = 1, \ldots, m$, $y_i = |\boldsymbol{a}_i^T\boldsymbol{x}|$ are independent sub-Gaussian random variables with mean $\sqrt{\frac{2}{\pi}}\|\boldsymbol{x}\|$, and thus $\frac{1}{m}\sum_{i=1}^m y_i \approx \sqrt{\frac{2}{\pi}}\|\boldsymbol{x}\|$. Combining these two facts yields the desired argument.

The direction of $\boldsymbol{x}$ is approximated by the leading eigenvector of $\boldsymbol{Y}$, because $\boldsymbol{Y}$ approaches $\mathrm{E}[\boldsymbol{Y}]$ by concentration of measure arguments, and the leading eigenvector of $\mathrm{E}[\boldsymbol{Y}]$ takes the form $c\boldsymbol{x}$ for some scalar $c \in \mathbb{R}$. We note that (8) involves truncation of samples from both sides, in contrast to truncation only by an upper threshold in TWF (Chen and Candès, 2015). The truncation parameters α_l and α_u are related to the eigenvalue gap between the top two eigenvalues of $\boldsymbol{Y}$, which determines the estimation accuracy of the eigenvector after running k iterations of the power method[3]. The larger the eigenvalue gap, the better the accuracy of the power method given a number of iterations. We note that $\alpha_l = 1, \alpha_u = \infty$ yield the largest eigenvalue gap from the developments in Appendix B. We explicitly set a bounded α_u for the development of the proof and for numerical stability.

We next provide the formal statement that with high probability, the proposed initialization lands in a small neighborhood around the true signal.

Proposition 1 *Fix $\delta > 0, \alpha_l = 1$ and $\alpha_u \gg 1$. The initialization step in Algorithm 1 yields $\boldsymbol{z}^{(0)}$ satisfying $dist(\boldsymbol{z}^{(0)}, \boldsymbol{x}) \le \delta\|\boldsymbol{x}\|$ with the probability at least $1 - \exp(-cm\epsilon^2)$, if $m > C(\delta, \epsilon)n$, where c is some positive constant and C is a positive constant affected by δ and ϵ.*

Proof. See Appendix B. ■

Finally, we numerically compare different initialization methods in Figure 3. It is demonstrated that RWF achieves better initialization accuracy in terms of the relative error $\operatorname{dist}(\boldsymbol{z}^{(0)}, \boldsymbol{x})/\|\boldsymbol{x}\|$ than WF, TWF, as well as the initialization method proposed in TAF (Wang et al., 2016).

3. Numerical linear algebra shows that after k iterations of the power method, the estimation accuracy of the eigenvector is given by $\mathcal{O}((\lambda_2/\lambda_1)^k)$, where λ_1 and λ_2 are the top two eigenvalues.

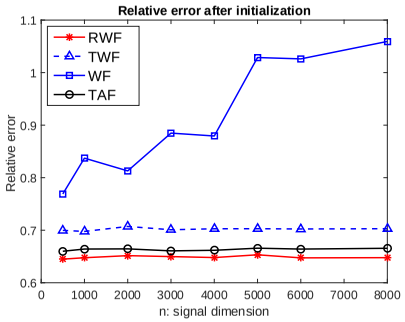

Figure 3: Comparison of different initialization methods with $m = 6n$ and under 50 iterations of power method.

2.2 Gradient Loop

The gradient loop of Algorithm 1 is based on the loss function (3), and the update rule (9) makes itself suitable for the complex case. For the real case the update direction is given as follows:

$$\nabla \ell(\boldsymbol{z}) := \frac{1}{m}\sum_{i=1}^{m}\left(\boldsymbol{a}_i^T\boldsymbol{z} - y_i\cdot \mathrm{sgn}(\boldsymbol{a}_i^T\boldsymbol{z})\right)\boldsymbol{a}_i = \frac{1}{m}\sum_{i=1}^{m}\left(\boldsymbol{a}_i^T\boldsymbol{z} - y_i\cdot \frac{\boldsymbol{a}_i^T\boldsymbol{z}}{|\boldsymbol{a}_i^T\boldsymbol{z}|}\right)\boldsymbol{a}_i, \tag{10}$$

where $\mathrm{sgn}(\cdot)$ is the sign function for nonzero arguments. We further set $\mathrm{sgn}(0) = 0$ and $\frac{0}{|0|} = 0$. In fact, $\nabla\ell(\boldsymbol{z})$ equals the gradient of the loss function (3) over the samples that satisfy $\boldsymbol{a}_i^T\boldsymbol{z} \neq 0$. For samples corresponding to the nonsmooth point, i.e., $\boldsymbol{a}_i^T\boldsymbol{z} = 0$, we adopt the Fréchet superdifferential (Kruger, 2003) for nonconvex functions to set the gradient component to be zero (as zero is an element in the Fréchet superdifferential). With abuse of terminology, we still refer to $\nabla\ell(\boldsymbol{z})$ in Equation (10) as the "gradient" for simplicity, which rather represents the update direction in the gradient loop of Algorithm 1.

2.3 Linear Convergence of RWF

We characterize the convergence guarantee of RWF in the following theorem.

Theorem 2 *Consider the problem of solving any given $\boldsymbol{x} \in \mathbb{R}^n$ from a system of equations (1) with Gaussian measurement vectors. There exist some universal constants $\mu_0 > 0$ (μ_0 can be set as 0.8 in practice), $0 < \rho, \nu < 1$ and $c_0, c_1, c_2 > 0$ such that if $m \geq c_0 n$ and $\mu < \mu_0$, then with probability at least $1 - c_1\exp(-c_2 m)$, Algorithm 1 yields*

$$dist(\boldsymbol{z}^{(t)}, \boldsymbol{x}) \leq \nu(1-\rho)^t\|\boldsymbol{x}\|, \quad \forall t \in \mathbb{N}. \tag{11}$$

Proof We outline the proof here with the details delegated to Appendix C. Compared to WF and TWF, our proof is much simpler due to the lower-order loss function that RWF relies on. We first introduce a global phase notation for the real case as follows:

$$\Phi_{\boldsymbol{x}}(\boldsymbol{z}) := \begin{cases} 0, & \text{if } \|\boldsymbol{z}-\boldsymbol{x}\| \leq \|\boldsymbol{z}+\boldsymbol{x}\|, \\ \pi, & \text{otherwise.} \end{cases} \tag{12}$$

For the sake of simplicity, we let $\boldsymbol{z}$ be $e^{-j\Phi_{\boldsymbol{x}}(\boldsymbol{z})}\boldsymbol{z}$, which indicates that $\boldsymbol{z}$ is always in the neighborhood of $\boldsymbol{x}$.

Here, the central idea is to show that within the neighborhood of the global minimizer, RWF satisfies the *Regularity Condition* $\mathsf{RC}(\mu, \lambda, c)$ (Chen and Candès, 2015), i.e.,

$$\langle \nabla\ell(\boldsymbol{z}), \boldsymbol{z}-\boldsymbol{x}\rangle \geq \frac{\mu}{2}\|\nabla\ell(\boldsymbol{z})\|^2 + \frac{\lambda}{2}\|\boldsymbol{z}-\boldsymbol{x}\|^2 \tag{13}$$

for all $\boldsymbol{z}$ obeying $\|\boldsymbol{z}-\boldsymbol{x}\| \leq c\|\boldsymbol{x}\|$, where $0 < c < 1$ is some small constant. Then, as shown in (Candès et al., 2015; Chen and Candès, 2015), once the initialization lands into this neighborhood, linear convergence can be guaranteed with a proper choice of the constant step size, i.e.,

$$\mathrm{dist}^2\left(\boldsymbol{z} - \mu\nabla\ell(\boldsymbol{z}), \boldsymbol{x}\right) \leq (1-\mu\lambda)\mathrm{dist}^2(\boldsymbol{z}, \boldsymbol{x}), \tag{14}$$

for any $\boldsymbol{z}$ satisfying $\|\boldsymbol{z}-\boldsymbol{x}\| \leq c\|\boldsymbol{x}\|$.

Lemmas 6 and 7 in Appendix C yield that for all $\boldsymbol{z}$ satisfying $\|\boldsymbol{z}-\boldsymbol{x}\| \leq c\|\boldsymbol{x}\|$,

$$\langle \nabla\ell(\boldsymbol{z}), \boldsymbol{z}-\boldsymbol{x}\rangle \geq (1-0.26-3\epsilon)\|\boldsymbol{z}-\boldsymbol{x}\|^2 = (0.74-3\epsilon)\|\boldsymbol{z}-\boldsymbol{x}\|^2$$

with high probability. Moreover, Lemma 8 in Appendix C further yields that

$$\|\nabla\ell(\boldsymbol{z})\| \leq (1+\delta)\cdot 2\|\boldsymbol{z}-\boldsymbol{x}\| \tag{15}$$

with high probability. Therefore, the above two bounds imply that the Regularity Condition (13) holds for μ and λ satisfying

$$0.74 - 3\epsilon \geq \frac{\mu}{2}\cdot 4(1+\delta)^2 + \frac{\lambda}{2} \tag{16}$$

for sufficiently small ϵ and δ. ■

We note that Equation (16) implies an upper bound for the step size $\mu \leq \frac{0.74}{2} = 0.37$, by taking ϵ and δ to be sufficiently small. However, in practice, the step size μ can be set much larger than such a bound, say 0.8, while still keeping the algorithm convergent. This is because the coefficients in the proof are set for the convenience of the proof rather than being tightly chosen.

Theorem 2 indicates that RWF recovers the true signal with $\mathcal{O}(n)$ samples, which is order-wise optimal. Such an algorithm improves the sample complexity $\mathcal{O}(n\log n)$ of WF. Furthermore, RWF does not require truncation of samples in the gradient step to achieve the same sample complexity as TWF. This is mainly because RWF benefits from the lower-order loss function given in Equation (3), the curvature of which behaves similarly to the least-squares loss function locally as we explain in the introduction.

Theorem 2 also suggests that RWF converges linearly with a constant step size. To reach ϵ-accuracy, it requires a computational cost of $\mathcal{O}(mn\log(1/\epsilon))$ flops, which is better than WF ($\mathcal{O}(mn^2\log(1/\epsilon))$ and on par with TWF. Numerically, as we demonstrate in Section 4, RWF is two times faster than TWF and four to six times faster than WF in terms of both the iteration counts and the time cost in various examples.

2.4 Stability to Bounded Noise

We have established that RWF guarantees exact recovery at a linear convergence rate for noise-free measurements. We now study RWF in the presence of noise. Suppose the measurements are corrupted by bounded noise, and are given by

$$y_i = |\boldsymbol{a}_i^T\boldsymbol{x}| + w_i, \quad 1 \le i \le m, \tag{17}$$

where $\boldsymbol{w} = \{w_i\}_{i=1}^m$ denote the additive noise. Then the following theorem shows that RWF is robust under bounded noise.

Theorem 3 *Consider the model* (17). *Suppose that the measurement vectors are independently Gaussian, i.e., $\boldsymbol{a}_i \sim \mathcal{N}(0, \boldsymbol{I})$ for $1 \le i \le m$, and the noise is bounded, i.e., $\|\boldsymbol{w}\|/\sqrt{m} \le c\|\boldsymbol{x}\|$ where c is a positive constant. Then there exist some universal constants $\mu_0 > 0$ (μ_0 can be set as 0.8 in practice), $0 < \rho < 1$ and $c_0, c_1, c_2 > 0$ such that if $m \ge c_0 n$ and $\mu < \mu_0$, then with probability at least $1 - c_1\exp(-c_2 m)$, Algorithm 1 yields*

$$dist(\boldsymbol{z}^{(t)}, \boldsymbol{x}) \lesssim \frac{\|\boldsymbol{w}\|}{\sqrt{m}} + (1-\rho)^t\|\boldsymbol{x}\|, \quad \forall t \in \mathbb{N}. \tag{18}$$

Proof See Appendix D. ■

Theorem 3 shows that under the same sample complexity, RWF converges at a linear rate to a neighborhood around the true signal, whose radius is on the level of the noise. The numerical result under the Poisson noise model in Section 4 further corroborates the stability of RWF.

3. Incremental Reshaped Wirtinger Flow

In large-sample and online scenarios, stochastic algorithms are preferred due to their potential advantage of faster convergence and lower memory requirement. Thus, in this section, we develop stochastic versions of RWF, referred to as incremental reshaped Wirtinger flow (IRWF). We show that IRWF guarantees exact recovery at a linear convergence rate under the same sample complexity. We further draw the connection between IRWF and the randomized Kaczmarz method recently developed for phase retrieval (Wei, 2015; Li et al., 2015; Chi and Lu, 2016), and establish its global convergence as a side product.

3.1 (Mini-batch) IRWF: Algorithm and Convergence

In oder to fully exploit the processing throughput of CPU/GPU, we develop a mini-batch IRWF, described in Algorithm 2. The mini-batch IRWF applies the same initialization step as in RWF, and uses a mini-batch of measurements for each gradient update.

Algorithm 2 Mini-batch Incremental Reshaped Wirtinger Flow (mini-batch IRWF)

Input: $\boldsymbol{y} = \{y_i\}_{i=1}^m$, $\{\boldsymbol{a}_i\}_{i=1}^m$, mini-batch size k;
Initialization: Same as in RWF (Algorithm 1);
Gradient loop: for $t = 0 : T-1$ do
Choose Γ_t uniformly at random from the subsets of $\{1, 2, \ldots, m\}$ with the cardinality k, and let

$$\boldsymbol{z}^{(t+1)} = \boldsymbol{z}^{(t)} - \mu \cdot \boldsymbol{A}_{\Gamma_t}^* \left(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)} - \boldsymbol{y}_{\Gamma_t} \odot \mathrm{Ph}(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)})\right), \tag{19}$$

where $\boldsymbol{A}_{\Gamma_t}$ is a matrix stacking $\boldsymbol{a}_i^*$ for $i \in \Gamma_t$ as its rows, $\boldsymbol{y}_{\Gamma_t}$ is a vector stacking y_i for $i \in \Gamma_t$ as its elements, and $\mathrm{Ph}(\boldsymbol{z})$ denotes the phase vector of $\boldsymbol{z}$.
Output $\boldsymbol{z}^{(T)}$.

If the gradient update uses only a single sample, i.e., $k = 1$, we refer to Algorithm 2 as IRWF, where the step (19) becomes

$$\boldsymbol{z}^{(t+1)} = \boldsymbol{z}^{(t)} - \mu\left(\boldsymbol{a}_{i_t}^*\boldsymbol{z}^{(t)} - y_{i_t} \cdot \frac{\boldsymbol{a}_{i_t}^*\boldsymbol{z}^{(t)}}{|\boldsymbol{a}_{i_t}^*\boldsymbol{z}^{(t)}|}\right)\boldsymbol{a}_{i_t}. \tag{20}$$

We characterize the convergence of mini-batch IRWF in the following theorem.

Theorem 4 *Consider the problem of solving any given $\boldsymbol{x} \in \mathbb{R}^n$ from a system of equations* (1) *with independent Gaussian measurement vectors $\boldsymbol{a}_i \sim \mathcal{N}(0, \boldsymbol{I})$. There exist some universal constants $0 < \rho, \rho_0 < 1$ and $c_0, c_1, c_2 > 0$ such that if $m \ge c_0 n$ and $\mu = \rho_0/n$ for the update rule* (19), *then with probability at least $1 - c_1\exp(-c_2 m)$, we have that*

$$\mathrm{E}_{\Gamma_t}\left[dist^2(\boldsymbol{z}^{(t+1)}, \boldsymbol{x})\right] \le \left(1 - \frac{k\rho}{n}\right) \cdot dist^2(\boldsymbol{z}^{(t)}, \boldsymbol{x}) \tag{21}$$

holds for all $\boldsymbol{z}^{(t)}$ satisfying $\frac{dist(\boldsymbol{z}^{(t)}, \boldsymbol{x})}{\|\boldsymbol{z}\|} \le \frac{1}{10}$.

Proof See Appendix E.1. ■

We suggest that $\rho_0 = 1$ and hence the step size $\mu = \frac{1}{n}$ in practice. Theorem 4 characterizes that the error decays exponentially fast in expectation if the estimate lands into the neighborhood of the global minimizer. For a generic optimization objective, it is not anticipated that incremental/stochastic first-order methods achieve linear convergence due to the variance of stochastic gradients. However, for our specific problem, the variance of stochastic gradients reduces as the estimate approaches the true signal, and hence a fixed step size can be employed and exponential decay can be established. A result similar in spirit was also established for the stochastic algorithm based on TWF (referred to as ITWF) (Kolte and Özgür, 2016). We provide further comparisons between IRWF and ITWF in Section 3.3. On the other hand, it was shown in (Moulines and Bach, 2011; Needell et al., 2016) that stochastic gradient methods yield linear convergence to the minimizer $\boldsymbol{x}_\star$ if the objective $F(\boldsymbol{x}) = \sum_i f_i(\boldsymbol{x})$ is a smooth and strongly convex function and $\boldsymbol{x}_\star$ minimizes

all components $f_i(\boldsymbol{x})$. The summands of our objective (3) also share the same minimizer (although it is neither convex nor smooth), which also helps to explain the convergence property of the IRWF.

3.2 Connection to the Kaczmarz Method for Phase Retrieval

The *Kaczmarz method* was originally developed for solving systems of linear equations (Kaczmarz, 1937). In literature (Wei, 2015; Li et al., 2015), it was adapted to solve the phase retrieval problem, which we refer to as *Kaczmarz-PR*. It has been demonstrated in Wei (2015) that Kaczmarz-PR exhibits better empirical performance than error reduction (ER) (Gerchberg, 1972; Fienup, 1982) and WF (Candès et al., 2015). However, global convergence of Kaczmarz-PR has not been well established yet, although the randomized Kaczmarz method for the least-squares problem is known to converge at a linear rate (Strohmer and Vershynin, 2009; Zouzias and Freris, 2013). For instance, Wei (2015) obtained a bound on the estimation error which can be as large as the signal energy no matter how many iterations are taken. Li et al. (2015) established the asymptotic convergence in the regime when both m and n go to infinity but their ratio is fixed.

In this section, we draw connection between IRWF and Kaczmarz-PR, which enables us to establish the theoretical guarantee of Kaczmarz-PR by adapting that of IRWF. This is analogous to the connection made in Needell et al. (2016) between the Kaczmarz method and the stochastic gradient method for solving the least-squares problem. Here, the connection is made possible due to the lower-order loss function of RWF, which was not evident in previous studies of WF and TWF.

To be more specific, the Kaczmarz-PR (Wei, 2015, Algorithm 3) employs the following update rule

$$\boldsymbol{z}^{(t+1)} = \boldsymbol{z}^{(t)} - \frac{1}{\|\boldsymbol{a}_{i_t}\|^2}\left(\boldsymbol{a}_{i_t}^*\boldsymbol{z}^{(t)} - y_{i_t}\cdot\frac{\boldsymbol{a}_{i_t}^*\boldsymbol{z}^{(t)}}{|\boldsymbol{a}_{i_t}^*\boldsymbol{z}^{(t)}|}\right)\boldsymbol{a}_{i_t}, \tag{22}$$

where i_t is selected either in a deterministic manner or randomly. We focus on the randomized case where i_t is selected uniformly at random from $\{1,\dots,m\}$.

Comparing Equation (22) and Equation (20), the update rule of Kaczmarz-PR becomes equivalent to IRWF, if we replace the step size μ by $\frac{1}{\|\boldsymbol{a}_{i_t}\|^2}$. Moreover, these two update rules are close if μ is set as suggested, i.e., $\mu = \frac{1}{n}$, because for Gaussian measurements, $\|\boldsymbol{a}_{i_t}\|^2$ concentrates around n by the law of large numbers. As we demonstrate in the numerical experiments (see Table 1), Kaczmarz-PR and IRWF have similar performance as anticipated. Thus, following the convergence guarantee for IRWF in Theorem 4, we establish the convergence guarantee for the randomized Kaczmarz-PR as follows.

Theorem 5 *Assume the measurement vectors are independent and each $\boldsymbol{a}_i \sim \mathcal{N}(0,\boldsymbol{I})$. There exist some universal constants $0<\rho<1$ and $c_0,c_1,c_2>0$ such that if $m \ge c_0 n$, then with probability at least $1-c_1 m\exp(-c_2 n)$, the randomized Kaczmarz-PR update rule* (22) *yields*

$$\mathrm{E}_{i_t}\left[dist^2(\boldsymbol{z}^{(t+1)},\boldsymbol{x})\right] \le \left(1-\frac{\rho}{n}\right)\cdot dist^2(\boldsymbol{z}^{(t)},\boldsymbol{x}) \tag{23}$$

for all $\boldsymbol{z}^{(t)}$ satisfying $\frac{dist(\boldsymbol{z}^{(t)},\boldsymbol{x})}{\|\boldsymbol{z}\|} \le \frac{1}{10}$.

Proof See Appendix E.2. ■

Theorem 5 implies that as long as the iteration sequence $\boldsymbol{z}^{(t)}$ lies in the neighborhood of the true signal, the error decays exponentially fast in expectation. However, Theorem 5 does not guarantee the full trajectory of the estimates to be in the neighborhood of the true signal. After submission of our work, more recent studies (Jeong and Gunturk, 2017; Tan and Vershynin, 2017) established the convergence of full trajectory by employing martingale theory.

Furthermore, Wei (2015) also provided a *block* Kaczmarz-PR (similar to the mini-batch version), whose update rule is given by

$$\boldsymbol{z}^{(t+1)} = \boldsymbol{z}^{(t)} - \boldsymbol{A}_{\Gamma_t}^{\dagger}\left(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)} - \boldsymbol{y}_{\Gamma_t}\odot \mathrm{Ph}(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)})\right), \tag{24}$$

where Γ_t is a selected block at iterate t containing row indices, and $\dagger$ represents *Moore-Penrose pseudoinverse*, which is computed as follows:

$$\boldsymbol{A}^{\dagger} = \begin{cases} (\boldsymbol{A}^*\boldsymbol{A})^{-1}\boldsymbol{A}^*, & \text{if } \boldsymbol{A} \text{ has linearly independent columns;} \\ \boldsymbol{A}^*(\boldsymbol{A}\boldsymbol{A}^*)^{-1}, & \text{if } \boldsymbol{A} \text{ has linearly independent rows.} \end{cases} \tag{25}$$

Comparing Equation (24) and the mini-batch IRWF update in Equation (19), these two update rules are similar to each other if $\boldsymbol{A}_{\Gamma_t}\boldsymbol{A}_{\Gamma_t}^*$ approaches $\frac{n}{\rho_0}\boldsymbol{I}_{|\Gamma_t|}$. For the case with Gaussian measurements, $\boldsymbol{A}_{\Gamma_t}$ has linearly independent rows with high probability if $|\Gamma_t| \le n$ and hence $\boldsymbol{A}_{\Gamma_t}\boldsymbol{A}_{\Gamma_t}^*$ is not far from $n\boldsymbol{I}_{|\Gamma_t|}$. Our numerical experiments (see Table 1) further suggest similar convergence rates for these two algorithms with the same block/mini-batch size.

Next, we argue that for the CDP setting, block Kaczmarz-PR is the same as the mini-batch IRWF with $\mu = 1$. The CDP measurements are collected in the following form

$$\boldsymbol{y}^{(l)} = |\boldsymbol{F}\boldsymbol{D}^{(l)}\boldsymbol{x}|, \quad 1 \le l \le L, \tag{26}$$

where $\boldsymbol{F}$ represents the discrete Fourier transform (DFT) matrix, $\boldsymbol{D}^{(l)}$ denotes a diagonal matrix (mask), and L denotes the number of masks. We choose the block size $|\Gamma_t|$ to be the dimension n of the signal for the convenience of Fourier transform. Then $\boldsymbol{A}_{\Gamma_t}$ becomes the Fourier transform composed with $\boldsymbol{D}^{(l)}$ (mask effect) and $\boldsymbol{A}_{\Gamma_t}^*$ becomes $\boldsymbol{D}^{(l)*}$ multiplied by the inverse Fourier transform. Therefore, $(\boldsymbol{A}_{\Gamma_t}\boldsymbol{A}_{\Gamma_t}^*) = \boldsymbol{I}$ if the diagonal elements of $\boldsymbol{D}^{(l)}$ have unit magnitude. Taking the step size $\mu = 1$, the two algorithms are identical.

On the other hand, since the block Kaczmarz-PR needs to calculate the matrix inverse or to solve an inverse problem, the block size cannot be too large. However, mini-batch IRWF works well for a wide range of the mini-batch sizes, which can even grow with the signal dimension n as long as a batch of data is loadable into the memory.

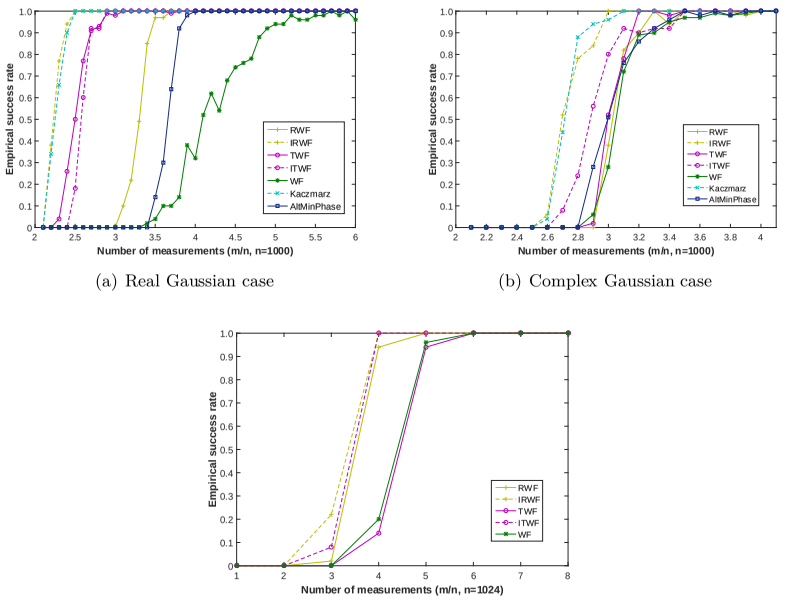
3.3 Comparison with Incremental Truncated Wirtinger Flow (ITWF)

Recently, (Kolte and Özgür, 2016) designed and analyzed an incremental algorithm based on TWF, which is referred to as ITWF. More specifically, ITWF employs the same initialization procedure as TWF and randomly chooses one sample with the index i_t selected uniformly

at random from $\{1, 2, \ldots, m\}$ for the gradient update as follows:

$$\boldsymbol{z}^{(t+1)} = \boldsymbol{z}^{(t)} - \mu \cdot \frac{|\boldsymbol{a}_{i_t}^T \boldsymbol{z}|^2 - y_{i_t}^2}{\boldsymbol{a}_{i_t}^T \boldsymbol{z}} \boldsymbol{a}_{i_t} \mathbf{1}_{\mathcal{E}_{1,t}^{i_t} \cap \mathcal{E}_3^{i_t}}, \tag{27}$$

where $\mathbf{1}_{\mathcal{E}_{1,t}^{i_t} \cap \mathcal{E}_3^{i_t}}$ represents the truncation rule determined by the events $\mathcal{E}_{1,t}^{i_t}$ and $\mathcal{E}_3^{i_t}$. As a comparison, the update rule of IRWF is much simpler due to the use of the lower-order loss function and does not require any truncation in the gradient loop. Kolte and Özgür (2016) proved that the update (27) shrinks the estimate error as long as m/n is large enough and the estimate $\boldsymbol{z}$. Compared to ITWF, the IRWF update (19) also shrinks the estimate error, but runs faster than ITWF numerically as demonstrated in Section 4.



4. Numerical Experiments

In this section, we demonstrate the numerical efficiency of RWF and (mini-batch) IRWF by comparing their performance with other competitive algorithms. Our experiments are conducted not only for the real Gaussian case but also for the complex Gaussian and the CDP cases. All the experiments are implemented in Matlab 2015b and conducted on a computer equipped with Intel Core i7 3.4GHz CPU and 12GB RAM.

We first compare the sample complexity of RWF and IRWF with those of TWF, WF, Kaczmarz-PR and AltMinPhase via the empirical successful recovery rate versus the number of measurements. For RWF, we follow Algorithm 1 with the suggested parameters. For IRWF, we adopt a block size 64 for efficiency and set the step size $\mu = 1/n$. For WF, TWF, we use the code provided in the original papers with the suggested parameters. For ITWF, we also adopt a block size 64 and set the step size $\mu = 0.6/n$ (optimal step size). We conduct the experiments for the real Gaussian, complex Gaussian and CDP cases respectively. For the real and complex cases, we set the signal dimension n to be 1000, and set the ratio m/n to take values from 2 to 6 with a step 0.1. For each m, we run 100 trials and count the number of successful trials. For each trial, we run a maximal number of iterations/passes $T = 10000$ for all algorithms, and a trial is declared to be successful whenever the iterate satisfies $\text{dist}(\boldsymbol{z}^{(T)}, \boldsymbol{x})/\|\boldsymbol{x}\| \leq 10^{-5}$. For the real Gaussian case, we generate the signal $\boldsymbol{x} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_{n\times n})$, and generate the measurement vectors $\boldsymbol{a}_i \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_{n\times n})$ i.i.d. for $i = 1, \ldots, m$. For the complex Gaussian case, we generate the signal $\boldsymbol{x} \sim \mathcal{N}(0, \boldsymbol{I}_{n\times n}) + j\mathcal{N}(0, \boldsymbol{I}_{n\times n})$ and the measurement vectors $\boldsymbol{a}_i \sim \frac{1}{2}\mathcal{N}(0, \boldsymbol{I}_{n\times n}) + j\frac{1}{2}\mathcal{N}(0, \boldsymbol{I}_{n\times n})$ i.i.d. for $i = 1, \ldots, m$. For the CDP case (26), we set $n = 1024$ for the convenience of FFT and $m/n = L = 1, 2, \ldots, 8$. All other settings are the same as those for the real case.

We note that for the CDP case, the Kaczmarz-PR algorithm is identical to the IRWF with step size $\mu = 1/n$ due to the argument in Section 3.2. Moreover under the CDP case, the AltMinPhase algorithm is identical to the RWF with step size $\mu = 1$ because the inverse of the Fourier measurement matrix is nothing but its conjugate transpose. In the following experiments for the CDP case, we choose the step size $\mu = 1/n$ for the IRWF and $\mu = 1$ for the RWF, under which the Kaczmarz-PR algorithm coincides with the IRWF and the AltMinPhase algorithm coincides with the RWF.

Figure 4 plots the fraction of successful trials out of 100 trials for all algorithms, with respect to m/n. It can be seen that IRWF and Kaczmarz-PR exhibit a similar sample

(a) Real Gaussian case

(b) Complex Gaussian case

(c) CDP case

Figure 4: Comparison of sample complexity among RWF, IRWF, TWF, ITWF, WF, Karzmarz-PR and AltMinPhase.

complexity, which is the best for all three cases, and is close to the theoretical limit (Bandeira et al., 2014). It can also be seen that the two incremental methods (IRWF and ITWF) outperform the batch methods (RWF, TWF, AltMinPhase and WF). This can be due to the inherent noise in incremental methods, which helps to escape bad local minima. This can be extremely helpful in the regime with a small number of samples, where local minima do exist near the global minima. Comparing among the batch methods (RWF, TWF AltMinPhase and WF), it can be seen that although RWF outperforms only WF and AltMinPhase (not TWF) for the real Gaussian case, it has a comparable performance for the complex case and outperforms TWF and WF in the CDP case. An intuitive explanation for the real case is that a substantial number of samples with small $|\boldsymbol{a}_i^T \boldsymbol{z}|$ can deviate the gradient direction so that truncation indeed helps to stabilize the algorithm if the number of measurements is not large.

We next compare the convergence rate of RWF, IRWF with those of TWF, ITWF, WF, Kaczmarcz and AltMinPhase. We run all of the algorithms with the suggested parameters in the original code. We generate the signal and measurements in the same way as those

Table 1: Comparison of iteration count and time cost among algorithms ($n = 5000, m = 8n$).

		Real Gaussian		Complex Gaussian	
		#passes	time(s)	# passes	time(s)
Batch methods	RWF	72	**12.66**	176	**122.4**
	TWF	186	32.36	487	395.1
	WF	319	54.83	932	887.8
	AltMinPhase	**6**	79.58	**159**	9637
Incremental methods	IRWF	9	44.77	21	233.2
	mini-batch IRWF (64)	9	**8.076**	**21**	**48.58**
	mini-batch ITWF (64)	16	37.38	29	149.5
	Kaczmarz-PR	9	50.68	21	248.4
	block Kaczmarz-PR (64)	**8**	28.50	22	89.31

in the first experiment with $n = 5000, m = 8n$. All algorithms are seeded with the RWF initialization. In Table 1, we list the number of passes and the time cost for all the algorithms to achieve a relative error of 10^{-14} averaged over 10 trials. For the incremental methods, one update passes k samples and one pass amounts to m/k updates. Clearly, IRWF with mini-batch size 64 runs the fastest for both the real and complex cases. Moreover, among the batch (deterministic) algorithms, RWF takes much fewer passes as well as runs much faster than TWF and WF. Although RWF takes more iterations than AltMinPhase, it runs much faster than AltMinPhase due to the fact that each iteration of AltMinPhase needs to solve a least-squares problem that takes much longer than a simple gradient update in RWF.

We also compare the performance of the above algorithms on the recovery of a real image from the Fourier intensity measurements (the two dimensional CDP case). The image (see Figure 5) is the Milky Way Galaxy with resolution 1920×1080. Table 2 lists the number of passes and the time cost for the above six algorithms to achieve the relative error of 10^{-15} for one R/G/B channel. All algorithms are seeded with the RWF initialization. To explore the advantage of FFT, we run the incremental/stochastic methods with the mini-batch size equal to the number of pixels for one R/G/B channel. We note that with such a mini-batch size, IRWF is equivalent to block Kaczmarz-PR from the discussion in Section 3.2. It can be seen that in general, the incremental/stochastic methods (IRWF and ITWF) run faster than the batch methods (RWF, TWF, WF). Moreover, among the batch methods, RWF outperforms the other three algorithms in both the number of passes and the computational time. In particular, RWF runs two times faster than TWF and six times faster than WF in terms of both the number of iterations and the computational time.

We next demonstrate the robustness of RWF to noise and compare it with TWF. We consider the phase retrieval problem in imaging applications, where Poisson noise is often used to model the sensor and electronic noise (Fogel et al., 2016). Specifically, the noisy measurements of intensity can be expressed as $y_i = \sqrt{\alpha \cdot \text{Poisson}\left(|\boldsymbol{a}_i^T \boldsymbol{x}|^2/\alpha\right)}$, for

Figure 5: Milky way Galaxy.

Table 2: Comparison of iterations and time cost among algorithms on recovery of Galaxy image (shown in Figure 5), where $L = m/n$ denotes the number of CDP masks.

	Algorithms	RWF	IRWF	TWF	ITWF	WF
$L = 6$	#passes	140	**24**	410	41	fail
	time cost(s)	110	**21.2**	406	43	fail
$L = 12$	#passes	70	**8**	190	12	315
	time cost(s)	107	**13.7**	363.6	25.9	426

$i = 1, 2, ...m$ where α denotes the level of the input noise, and Poisson(λ) denotes a random sample generated by the Poisson distribution with mean λ. It can be observed from Figure 6 that RWF performs better than TWF in terms of the recovery accuracy under two different noise levels.

5. Conclusion

In this paper, we proposed RWF and its incremental version IRWF to recover a signal for the phase retrieval problem, based on a *nonconvex and nonsmooth* quadratic loss function of magnitude measurements. This loss function sacrifices the smoothness but enjoys advantages in statistical and computational efficiency. It has potential to be extended in various scenarios. One interesting direction is to extend such an algorithm to exploit signal structures (e.g., non-negativity, sparsity, etc) to assist the recovery. The lower-order loss function may offer great simplicity to prove the performance guarantee in such cases.

Another interesting direction is to study the convergence of algorithms from random initialization. In the regime with a large sample size ($m \gg n$), the empirical loss surface

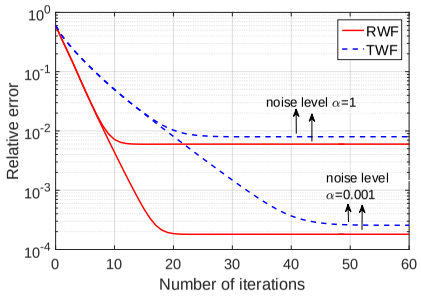


Figure 6: Comparison of relative error under Poisson noise between RWF and TWF.

approaches the asymptotic loss Figure 1(b) and hence has no spurious local minima. Due to the result (Lee et al., 2016a), it is conceivable that the gradient descent algorithm converges from any random starting point. Similar phenomena have been observed in (Sun et al., 2016; Ge et al., 2016). However, under a moderate number of measurements ($m < 10n$), we observe that genuine local minima do exist and often locate not far from the global minima. In such a regime, the batch gradient method often fails with random initialization. As anticipated, stochastic algorithms are efficient in escaping bad local minima or saddle points in nonconvex optimization because of the inherent noise (Ge et al., 2015; Sa et al., 2015). We observe numerically that IRWF and block IRWF from a random starting point still converge to a global minimum even with a very small sample size which is close to the theoretical limit. It is of interest to analyze theoretically why stochastic methods escape these local minima (not just saddle points) efficiently.

Appendices

Appendix A. Expected Loss Surfaces

It is easy to check that the expectation of the least-squares loss is given by $\mathrm{E}[\ell_{LS}(\boldsymbol{z})] = \|\boldsymbol{z}-\boldsymbol{x}\|^2$. The expectation of the WF loss function (2) is given by (Sun et al., 2016) as

$$\mathrm{E}[\ell_{WF}(\boldsymbol{z})] = \frac{3}{4}\|\boldsymbol{x}\|^4 + \frac{3}{4}\|\boldsymbol{z}\|^4 - \frac{1}{2}\|\boldsymbol{x}\|^2\|\boldsymbol{z}\|^2 - |\boldsymbol{z}^T\boldsymbol{x}|^2. \tag{28}$$

We next show that the expectation of the RWF loss function (3) has the following form:

$$\mathrm{E}[\ell(\boldsymbol{z})] = \frac{1}{2}\|\boldsymbol{x}\|^2 + \frac{1}{2}\|\boldsymbol{z}\|^2 - \|\boldsymbol{x}\|\|\boldsymbol{z}\| \cdot \mathrm{E}\left[\frac{|\boldsymbol{a}_i^T\boldsymbol{z}|}{\|\boldsymbol{z}\|} \cdot \frac{|\boldsymbol{a}_i^T\boldsymbol{x}|}{\|\boldsymbol{x}\|}\right], \tag{29}$$

where

$$\mathrm{E}\left[\frac{|\boldsymbol{a}_i^T\boldsymbol{z}|}{\|\boldsymbol{z}\|} \cdot \frac{|\boldsymbol{a}_i^T\boldsymbol{x}|}{\|\boldsymbol{x}\|}\right] = \begin{cases} \frac{(1-\rho^2)^{3/2}}{\pi}\int_0^\infty t(e^{\rho t}+e^{-\rho t})K_0(t)dt, & \text{if } |\rho|<1; \\ 1, & \text{if } |\rho|=1; \end{cases} \tag{30}$$

where $\rho = \frac{\boldsymbol{z}^T\boldsymbol{x}}{\|\boldsymbol{x}\|\|\boldsymbol{z}\|}$ and $K_0(\cdot)$ is the modified Bessel function of the second kind.

In order to derive (30), we first define

$$u := \frac{\boldsymbol{a}_i^T\boldsymbol{z}}{\|\boldsymbol{z}\|} \text{ and } v := \frac{\boldsymbol{a}_i^T\boldsymbol{x}}{\|\boldsymbol{x}\|},$$

and it suffices to drive $\mathrm{E}[|uv|]$. Note that $(u,v) \sim \mathcal{N}(0,\Sigma)$, where

$$\Sigma = \begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix}, \quad \text{and} \quad \rho = \frac{\boldsymbol{z}^T\boldsymbol{x}}{\|\boldsymbol{x}\|\|\boldsymbol{z}\|}.$$

Following (Donahue, 1964), the density function of uv is given by

$$\phi_{uv}(x) = \frac{1}{\pi\sqrt{1-\rho^2}}\exp\left(\frac{\rho x}{1-\rho^2}\right)K_0\left(\frac{|x|}{1-\rho^2}\right), \quad x \neq 0.$$

Thus, the density function of $|uv|$ is given by

$$\psi_{|uv|}(x) = \frac{1}{\pi\sqrt{1-\rho^2}}\left[\exp\left(\frac{\rho x}{1-\rho^2}\right)+\exp\left(-\frac{\rho x}{1-\rho^2}\right)\right]K_0\left(\frac{|x|}{1-\rho^2}\right), \quad x>0, \tag{31}$$

for $|\rho|<1$. Therefore, if $|\rho|<1$, we have

$$\begin{aligned}\mathrm{E}[|uv|] &= \int_0^\infty x\cdot\psi_\rho(x)dx \\ &= \int_0^\infty x\cdot\frac{1}{\pi\sqrt{1-\rho^2}}\left[\exp\left(\frac{\rho x}{1-\rho^2}\right)+\exp\left(-\frac{\rho x}{1-\rho^2}\right)\right]K_0\left(\frac{|x|}{1-\rho^2}\right)dx \\ &= \frac{(1-\rho^2)^{3/2}}{\pi}\int_0^\infty t(e^{\rho t}+e^{-\rho t})K_0(t)dt,\end{aligned}$$

where the last step follows from change of variables.

If $|\rho| = 1$, then $|uv|$ becomes a χ_1^2 random variable, with the density given by

$$\psi_{|uv|}(x) = \frac{1}{\sqrt{2\pi}} x^{-1/2} \exp(-x/2), \quad x > 0,$$

and hence $\mathrm{E}[|uv|] = 1$.

Appendix B. Proof of Proposition 1

The idea of using truncation to bound some non-sub-Gaussian sequences has appeared in the literature (Candès et al., 2013, Lemma 2.3) and (Chen and Candès, 2015). Compared to the proof of the initialization for TWF (Chen and Candès, 2015), new technical developments are needed to address the magnitude measurements and truncation from both sides.

We first estimate the norm of $\boldsymbol{x}$ as

$$\lambda_0 = \frac{mn}{\sum_{i=1}^m \|\boldsymbol{a}_i\|_1} \cdot \left(\frac{1}{m} \sum_{i=1}^m y_i \right). \tag{32}$$

Since $\boldsymbol{a}_i \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{I}_{\mathbf{n}\times\mathbf{n}})$, by Hoeffding-type inequality, it can be shown that

$$\left| \frac{\sum_{i=1}^m \|\boldsymbol{a}_i\|_1}{mn} - \sqrt{\frac{2}{\pi}} \right| < \frac{\epsilon}{3} \tag{33}$$

holds with probability at least $1 - 2\exp(-c_1 mn\epsilon^2)$ for some constant $c_1 > 0$.

Moreover, for a fixed $\boldsymbol{x}$, y_i's are independent sub-Gaussian random variables. Thus, by Hoeffding-type inequality, it can be shown that

$$\left| \sqrt{\frac{\pi}{2}} \left(\frac{1}{m} \sum_{i=1}^m y_i \right) - \|\boldsymbol{x}\| \right| < \frac{\epsilon}{3} \|\boldsymbol{x}\| \tag{34}$$

holds with probability at least $1 - 2\exp(-c_1 m\epsilon^2)$ for some constant $c_1 > 0$.

On the event $E_1 = \{\text{both (33) and (34) hold}\}$, it can be argued that

$$|\lambda_0 - \|\boldsymbol{x}\|| < \epsilon \|\boldsymbol{x}\|. \tag{35}$$

Without loss of generality, we let $\|\boldsymbol{x}\| = 1$. Then on the event E_1, the truncation function satisfies the following bounds

$$\mathbf{1}_{\{\alpha_l(1+\epsilon) < |\boldsymbol{a}_i^T \boldsymbol{x}| < \alpha_u(1-\epsilon)\}} \le \mathbf{1}_{\{\alpha_l \lambda_0 < y_i < \alpha_u \lambda_0\}} \le \mathbf{1}_{\{\alpha_l(1-\epsilon) < |\boldsymbol{a}_i^T \boldsymbol{x}| < \alpha_u(1+\epsilon)\}}.$$

Thus, define

$$\begin{aligned}
\boldsymbol{Y}_1 :=& \frac{1}{m} \sum_{i=1}^m \boldsymbol{a}_i \boldsymbol{a}_i^T |\boldsymbol{a}_i^T \boldsymbol{x}| \mathbf{1}_{\{\alpha_l(1+\epsilon) < |\boldsymbol{a}_i^T \boldsymbol{x}| < \alpha_u(1-\epsilon)\}} \\
\boldsymbol{Y}_2 :=& \frac{1}{m} \sum_{i=1}^m \boldsymbol{a}_i \boldsymbol{a}_i^T |\boldsymbol{a}_i^T \boldsymbol{x}| \mathbf{1}_{\{\alpha_l(1-\epsilon) < |\boldsymbol{a}_i^T \boldsymbol{x}| < \alpha_u(1+\epsilon)\}},
\end{aligned}$$

and we have $\boldsymbol{Y}_1 \prec \boldsymbol{Y} \prec \boldsymbol{Y}_2$. We further compute the expectations of $\boldsymbol{Y}_1$ and $\boldsymbol{Y}_2$ and obtain

$$\mathrm{E}[\boldsymbol{Y}_1] = (\beta_1 \boldsymbol{x}\boldsymbol{x}^T + \beta_2 \boldsymbol{I}), \quad \mathrm{E}[\boldsymbol{Y}_2] = (\beta_3 \boldsymbol{x}\boldsymbol{x}^T + \beta_4 \boldsymbol{I}), \tag{36}$$

where

$$\begin{aligned}
\beta_1 &:= \mathrm{E}[|\xi|^3 \mathbf{1}_{\{\alpha_l(1+\epsilon) < |\xi| < \alpha_u(1-\epsilon)\}}] - \mathrm{E}[|\xi| \mathbf{1}_{\{\alpha_l(1+\epsilon) < |\xi| < \alpha_u(1-\epsilon)\}}], \\
\beta_2 &:= \mathrm{E}[|\xi| \mathbf{1}_{\{\alpha_l(1+\epsilon) < |\xi| < \alpha_u(1-\epsilon)\}}] \\
\beta_3 &:= \mathrm{E}[|\xi|^3 \mathbf{1}_{\{\alpha_l(1-\epsilon) < |\xi| < \alpha_u(1+\epsilon)\}}] - \mathrm{E}[|\xi| \mathbf{1}_{\{\alpha_l(1-\epsilon) < |\xi| < \alpha_u(1+\epsilon)\}}], \\
\beta_4 &:= \mathrm{E}[|\xi| \mathbf{1}_{\{\alpha_l(1-\epsilon) < |\xi| < \alpha_u(1+\epsilon)\}}]
\end{aligned}$$

where $\xi \sim \mathcal{N}(0,1)$. For given α_l and α_u, a small value of ϵ yields arbitrarily close β_1 and β_3, as well as arbitrarily close β_2 and β_4. For example, taking $\alpha_l = 1, \alpha_u = 5$ and $\epsilon = 0.01$, we have $\beta_1 = 0.9678, \beta_2 = 0.4791, \beta_3 = 0.9688, \beta_4 = 0.4888$.

Now applying the standard results on random matrices with non-isotropic sub-Gaussian rows (Vershynin, 2012, equation (5.26)) and noticing that $\boldsymbol{a}_i \boldsymbol{a}_i^T |\boldsymbol{a}_i^T \boldsymbol{x}| \mathbf{1}_{\{\alpha_l(1+\epsilon) < |\boldsymbol{a}_i^T \boldsymbol{x}| < \alpha_u(1-\epsilon)\}}$ can be rewritten as $\boldsymbol{b}_i \boldsymbol{b}_i^T$ for a sub-Gaussian vector $\boldsymbol{b}_i := \boldsymbol{a}_i \sqrt{|\boldsymbol{a}_i^T \boldsymbol{x}|} \mathbf{1}_{\{\alpha_l(1+\epsilon) < |\boldsymbol{a}_i^T \boldsymbol{x}| < \alpha_u(1-\epsilon)\}}$, one can derive

$$\|\boldsymbol{Y}_1 - \mathrm{E}[\boldsymbol{Y}_1]\| \le \delta, \quad \|\boldsymbol{Y}_2 - \mathrm{E}[\boldsymbol{Y}_2]\| \le \delta \tag{37}$$

with probability at least $1 - 4\exp(-c_1(\delta)m)$ for some positive c_1 which is only affected by δ, provided that m/n exceeds a certain constant. Furthermore, when ϵ is sufficiently small, one further has $\|\mathrm{E}[\boldsymbol{Y}_1] - \mathrm{E}[\boldsymbol{Y}_2]\| \le \delta$. Combining the above facts together, one can show that

$$\|\boldsymbol{Y} - (\beta_1 \boldsymbol{x}\boldsymbol{x}^T + \beta_2 \boldsymbol{I})\| \le 3\delta. \tag{38}$$

Let $\tilde{\boldsymbol{z}}^{(0)}$ be the normalized leading eigenvector of $\boldsymbol{Y}$. Following the arguments in (Candès et al., 2015, Section 7.8) and taking δ and ϵ to be sufficiently small, one has

$$\mathrm{dist}(\tilde{\boldsymbol{z}}^{(0)}, \boldsymbol{x}) \le \tilde{\delta}, \tag{39}$$

for a given $\tilde{\delta} > 0$, as long as m/n exceeds a certain constant.

Appendix C. Proof of Theorem 2

The general structure of the proof follows that for WF in (Candès et al., 2015) and TWF in (Chen and Candès, 2015). However, the proof requires the development of new bounds due to the nonsmoothness of the loss function and the magnitude measurements. On the other hand, the proof is much simpler due to the lower-order loss function adopted in RWF.

The idea of the proof is to show that within the neighborhood of the global optimizers, RWF satisfies the *Regularity Condition* $\mathsf{RC}(\mu, \lambda, c)$, i.e.,

$$\langle \nabla \ell(\boldsymbol{z}), \boldsymbol{h} \rangle \ge \frac{\mu}{2} \|\nabla \ell(\boldsymbol{z})\|^2 + \frac{\lambda}{2} \|\boldsymbol{h}\|^2 \tag{40}$$

for all $\boldsymbol{z}$ and $\boldsymbol{h} = \boldsymbol{z} - \boldsymbol{x}$ obeying $\|\boldsymbol{h}\| \le c\|\boldsymbol{x}\|$, where $0 < c < 1$ is some constant. Then, as shown in (Chen and Candès, 2015), once the initialization lands into the neighborhood that satisfies $\|\boldsymbol{z} - \boldsymbol{x}\| \le c\|\boldsymbol{x}\|$, linear convergence can be guaranteed, i.e.,

$$\mathrm{dist}^2\left(\boldsymbol{z} - \mu\nabla\ell(\boldsymbol{z}), \boldsymbol{x}\right) \le (1 - \mu\lambda)\mathrm{dist}^2(\boldsymbol{z}, \boldsymbol{x}), \tag{41}$$

for any $\boldsymbol{z}$ with $\|\boldsymbol{z} - \boldsymbol{x}\| \le c\|\boldsymbol{x}\|$.

To show the regularity condition, we first define a set $\mathcal{S} := \{i : 1 \le i \le m, (\boldsymbol{a}_i^T\boldsymbol{z})(\boldsymbol{a}_i^T\boldsymbol{x}) < 0\}$ (which depends on $\boldsymbol{x}$ and $\boldsymbol{z}$), and then derive the following bound:

$$\begin{aligned}
\langle\nabla\ell(\boldsymbol{z}), \boldsymbol{h}\rangle &= \frac{1}{m}\sum_{i=1}^{m}\left(\boldsymbol{a}_i^T\boldsymbol{z} - |\boldsymbol{a}_i^T\boldsymbol{x}|\mathrm{sgn}(\boldsymbol{a}_i^T\boldsymbol{z})\right)(\boldsymbol{a}_i^T\boldsymbol{h}) \\
&= \frac{1}{m}\left[\sum_{i=1}^{m}(\boldsymbol{a}_i^T\boldsymbol{h})^2 + 2\sum_{i\in\mathcal{S}}(\boldsymbol{a}_i^T\boldsymbol{x})(\boldsymbol{a}_i^T\boldsymbol{h})\right] \\
&\ge \frac{1}{m}\left[\sum_{i=1}^{m}(\boldsymbol{a}_i^T\boldsymbol{h})^2 - 2\left|\sum_{i\in\mathcal{S}}(\boldsymbol{a}_i^T\boldsymbol{x})(\boldsymbol{a}_i^T\boldsymbol{h})\right|\right] \\
&\ge \frac{1}{m}\left[\sum_{i=1}^{m}(\boldsymbol{a}_i^T\boldsymbol{h})^2 - \sum_{i\in\mathcal{S}}2\left|(\boldsymbol{a}_i^T\boldsymbol{x})(\boldsymbol{a}_i^T\boldsymbol{h})\right|\right].
\end{aligned} \tag{42}$$

The first term in (42) can be bounded using Lemma 3.1 in (Candès et al., 2013), which we state below.

Lemma 6 *For any $0 < \epsilon < 1$, there exist constants $c_0, c_1 > 0$ such that if $m > c_0 n\epsilon^{-2}$, then with probability at least $1 - 2\exp(-c_1\epsilon^2 m)$,*

$$(1 - \epsilon)\|\boldsymbol{h}\|^2 \le \frac{1}{m}\sum_{i=1}^{m}(\boldsymbol{a}_i^T\boldsymbol{h})^2 \le (1 + \epsilon)\|\boldsymbol{h}\|^2 \tag{43}$$

holds for all non-zero vectors $\boldsymbol{h} \in \mathbb{R}^n$.

For the second term in (42), we derive

$$\begin{aligned}
\sum_{i\in\mathcal{S}}2\left|\boldsymbol{a}_i^T\boldsymbol{x}\right|\left|\boldsymbol{a}_i^T\boldsymbol{h}\right| &\le \sum_{i\in\mathcal{S}}\left[(\boldsymbol{a}_i^T\boldsymbol{x})^2 + (\boldsymbol{a}_i^T\boldsymbol{h})^2\right] \\
&= \sum_{i=1}^{m}[(\boldsymbol{a}_i^T\boldsymbol{x})^2 + (\boldsymbol{a}_i^T\boldsymbol{h})^2]\cdot\mathbf{1}_{\{(\boldsymbol{a}_i^T\boldsymbol{x})(\boldsymbol{a}_i^T\boldsymbol{z})<0\}} \\
&= \sum_{i=1}^{m}[(\boldsymbol{a}_i^T\boldsymbol{x})^2 + (\boldsymbol{a}_i^T\boldsymbol{h})^2]\cdot\mathbf{1}_{\{(\boldsymbol{a}_i^T\boldsymbol{x})^2 + (\boldsymbol{a}_i^T\boldsymbol{x})(\boldsymbol{a}_i^T\boldsymbol{h})<0\}} \\
&\le \sum_{i=1}^{m}[(\boldsymbol{a}_i^T\boldsymbol{x})^2 + (\boldsymbol{a}_i^T\boldsymbol{h})^2]\cdot\mathbf{1}_{\{|\boldsymbol{a}_i^T\boldsymbol{x}|<|\boldsymbol{a}_i^T\boldsymbol{h}|\}} \\
&\le 2\sum_{i=1}^{m}(\boldsymbol{a}_i^T\boldsymbol{h})^2\cdot\mathbf{1}_{\{|\boldsymbol{a}_i^T\boldsymbol{x}|<|\boldsymbol{a}_i^T\boldsymbol{h}|\}}.
\end{aligned} \tag{44}$$

The right hand side of the above equation can be further upper bounded by the following lemma.

Lemma 7 *For any $\epsilon > 0$, there exist constants $c_0, c_1, C > 0$ such that if $m > c_0 n\epsilon^{-2}\log\epsilon^{-1}$, then with probability at least $1 - C\exp(-c_1\epsilon^2 m)$,*

$$\frac{1}{m}\sum_{i=1}^{m}(\boldsymbol{a}_i^T\boldsymbol{h})^2\cdot\mathbf{1}_{\{|\boldsymbol{a}_i^T\boldsymbol{x}|<|\boldsymbol{a}_i^T\boldsymbol{h}|\}} \le (0.13 + \epsilon)\|\boldsymbol{h}\|^2 \tag{45}$$

holds for all non-zero vectors $\boldsymbol{h} \in \mathbb{R}^n$ satisfying $\|\boldsymbol{h}\| \le \frac{1}{10}\|\boldsymbol{x}\|$.

Proof See Section C.1. ■

Therefore, combining Lemmas 6 and 7 with (42) yields

$$\langle\nabla\ell(\boldsymbol{z}), \boldsymbol{h}\rangle \ge (1 - 0.26 - 3\epsilon)\|\boldsymbol{h}\|^2 = (0.74 - 3\epsilon)\|\boldsymbol{h}\|^2. \tag{46}$$

We further provide an upper bound on $\|\nabla\ell(\boldsymbol{z})\|$ in the following lemma.

Lemma 8 *Fix $\delta > 0$. There exist constatnts $c_0, c, C > 0$ such that if $m \ge c_0 n$ then with probability at least $1 - C\exp(-cm)$,*

$$\|\nabla\ell(\boldsymbol{z})\| \le (1 + \delta)\cdot 2\|\boldsymbol{h}\| \tag{47}$$

holds for all non-zero vectors $\boldsymbol{h}, \boldsymbol{z} \in \mathbb{R}^n$ satisfying $\boldsymbol{z} = \boldsymbol{x} + \boldsymbol{h}$ and $\|\boldsymbol{h}\| \le \frac{1}{10}\|\boldsymbol{x}\|$.

Proof See Section C.2. ■

Thus, applying Lemma 8 and (46) to (40), we conclude that *Regularity Condition* holds for μ and λ satisfying

$$0.74 - 3\epsilon \ge \frac{\mu}{2}\cdot 4(1 + \delta)^2 + \frac{\lambda}{2}, \tag{48}$$

which concludes the proof.

C.1 Proof of Lemma 7

We first prove bounds for any fixed $\boldsymbol{h} \le \frac{1}{10}\|\boldsymbol{x}\|$, and then develop a uniform bound later on. We introduce a series of auxiliary random Lipschitz functions to approximate the indicator functions. For $i = 1, \ldots, m$, define

$$\chi_i(t) := \begin{cases} t, & \text{if } t > (\boldsymbol{a}_i^T\boldsymbol{x})^2; \\ \frac{1}{\delta}(t - (\boldsymbol{a}_i^T\boldsymbol{x})^2) + (\boldsymbol{a}_i^T\boldsymbol{x})^2, & \text{if } (1-\delta)(\boldsymbol{a}_i^T\boldsymbol{x})^2 \le t \le (\boldsymbol{a}_i^T\boldsymbol{x})^2; \\ 0, & \text{else;} \end{cases} \tag{49}$$

and then $\chi_i(t)$'s are random Lipschitz functions with Lipschitz constant $\frac{1}{\delta}$. We further have

$$|\boldsymbol{a}_i^T\boldsymbol{h}|^2\mathbf{1}_{\{|\boldsymbol{a}_i^T\boldsymbol{x}|<|\boldsymbol{a}_i^T\boldsymbol{h}|\}} \le \chi_i(|\boldsymbol{a}_i^T\boldsymbol{h}|^2) \le |\boldsymbol{a}_i^T\boldsymbol{h}|^2\mathbf{1}_{\{(1-\delta)|\boldsymbol{a}_i^T\boldsymbol{x}|^2<|\boldsymbol{a}_i^T\boldsymbol{h}|^2\}}. \tag{50}$$

For convenience, we denote $\gamma_i := \frac{|\boldsymbol{a}_i^T\boldsymbol{h}|^2}{\|\boldsymbol{h}\|^2}\mathbf{1}_{\{(1-\delta)|\boldsymbol{a}_i^T\boldsymbol{x}|^2<|\boldsymbol{a}_i^T\boldsymbol{h}|^2\}}$ and $\theta := \|\boldsymbol{h}\|/\|\boldsymbol{x}\|$. We next estimate the expectation of γ_i, by the following conditional expectation,

$$\mathrm{E}[\gamma_i] = \int_\Omega \gamma_i d\mathbb{P} = \iint_{-\infty}^{\infty} \mathrm{E}\left[\gamma_i | \boldsymbol{a}_i^T\boldsymbol{x} = \tau_1\|\boldsymbol{x}\|, \boldsymbol{a}_i^T\boldsymbol{h} = \tau_2\|\boldsymbol{h}\|\right] \cdot f(\tau_1,\tau_2)d\tau_1 d\tau_2, \tag{51}$$

where $f(\tau_1,\tau_2)$ is the density of two joint Gaussian random variables with the correlation $\rho = \frac{\boldsymbol{h}^T\boldsymbol{x}}{\|\boldsymbol{h}\|\|\boldsymbol{x}\|} \neq \pm 1$. We then continue to derive

$$\begin{aligned}
\mathrm{E}[\gamma_i] &= \iint_{-\infty}^{\infty} \tau_2^2 \cdot \mathbf{1}_{\{\sqrt{1-\delta}|\tau_1|<|\tau_2|\theta\}} \cdot f(\tau_1,\tau_2)d\tau_1 d\tau_2 \\
&= \frac{1}{2\pi\sqrt{1-\rho^2}} \int_{-\infty}^{\infty} \tau_2^2 \exp\left(-\frac{\tau_2^2}{2}\right) \cdot \int_{\frac{-|\tau_2|\theta}{\sqrt{1-\delta}}}^{\frac{|\tau_2|\theta}{\sqrt{1-\delta}}} \exp\left(-\frac{(\tau_1-\rho\tau_2)^2}{2(1-\rho^2)}\right) d\tau_1 d\tau_2 \qquad (52) \\
&= \frac{1}{2\pi} \int_{-\infty}^{\infty} \tau_2^2 \exp\left(-\frac{\tau_2^2}{2}\right) \cdot \int_{\frac{-\frac{|\tau_2|\theta}{\sqrt{1-\delta}}-\rho\tau_2}{\sqrt{1-\rho^2}}}^{\frac{\frac{|\tau_2|\theta}{\sqrt{1-\delta}}-\rho\tau_2}{\sqrt{1-\rho^2}}} \exp\left(-\frac{\tau^2}{2}\right) d\tau d\tau_2 \qquad \text{by change of variables} \\
&= \frac{1}{2\pi} \int_{-\infty}^{\infty} \tau_2^2 \exp\left(-\frac{\tau_2^2}{2}\right) \cdot \sqrt{\frac{\pi}{2}} \left(\mathrm{erf}\left(\frac{\frac{|\tau_2|\theta}{\sqrt{1-\delta}}-\rho\tau_2}{\sqrt{1-\rho^2}}\right) - \mathrm{erf}\left(\frac{-\frac{|\tau_2|\theta}{\sqrt{1-\delta}}-\rho\tau_2}{\sqrt{1-\rho^2}}\right)\right) d\tau_2 \\
&= \frac{1}{\sqrt{2\pi}} \int_0^{\infty} \tau_2^2 \exp\left(-\frac{\tau_2^2}{2}\right) \cdot \left(\mathrm{erf}\left(\frac{(\frac{\theta}{\sqrt{1-\delta}}-\rho)\tau_2}{\sqrt{1-\rho^2}}\right) + \mathrm{erf}\left(\frac{(\frac{\theta}{\sqrt{1-\delta}}+\rho)\tau_2}{\sqrt{1-\rho^2}}\right)\right) d\tau_2. \qquad (53)
\end{aligned}$$

For $|\rho|<1$, $\mathrm{E}[\gamma_i]$ is a continuous function of ρ. For $|\rho|=1$, $\mathrm{E}[\gamma_i]=0$. The last integral (53) can be calculated numerically. Figure 7 plots $\mathrm{E}[\gamma_i]$ for $\theta=0.1$ and $\delta=0.01$ over $\rho\in[-1,1]$. Furthermore, (52) indicates that $\mathrm{E}[\gamma_i]$ is monotonically increasing with both θ and δ. Thus, we obtain a universal bound

$$\mathrm{E}[\gamma_i] \leq 0.13 \quad \text{for } \theta<0.1 \text{ and } \delta = 0.01, \tag{54}$$

which implies $\mathrm{E}[\chi_i(|\boldsymbol{a}_i^T\boldsymbol{h}|^2)] \leq 0.13\|\boldsymbol{h}\|^2$ for $\theta<0.1$ and $\delta=0.01$.

Furthermore, $\chi_i(|\boldsymbol{a}_i^T\boldsymbol{h}|^2)$'s are sub-exponential with the sub-exponential norm $\mathcal{O}(\|\boldsymbol{h}\|^2)$. By the sub-exponential tail bound (Bernstein type) (Vershynin, 2012), we have

$$\mathbb{P}\left[\frac{1}{m}\sum_{i=1}^m \frac{\chi_i(|\boldsymbol{a}_i^T\boldsymbol{h}|^2)}{\|\boldsymbol{h}\|^2} > (0.13+\epsilon)\right] < \exp(-cm\epsilon^2), \tag{55}$$

for some universal constant c, as long as $\|\boldsymbol{h}\| \leq \frac{1}{10}\|\boldsymbol{x}\|$.

We have proved so far that the claim holds for a fixed $\boldsymbol{h}$. We next obtain a uniform bound over all $\boldsymbol{h}$ satisfying $\|\boldsymbol{h}\| \leq \frac{1}{10}\|\boldsymbol{x}\|$. We first show the claim holds for all $\boldsymbol{h}$ with $\|\boldsymbol{h}\| = \frac{1}{10}\|\boldsymbol{x}\|$ and then argue that the claim holds when $\|\boldsymbol{h}\| < \frac{1}{10}\|\boldsymbol{x}\|$ towards the end of the proof. Let $\epsilon' = \epsilon\frac{\|\boldsymbol{x}\|}{10}$ and we construct an ϵ'-net $\mathcal{N}_{\epsilon'}$ covering the sphere with the radius $\frac{1}{10}\|\boldsymbol{x}\|$ in $\mathbb{R}^n$ with the cardinality $|\mathcal{N}_{\epsilon'}| \leq (1+\frac{2}{\epsilon})^n$. Then for any $\|\boldsymbol{h}\| = \frac{1}{10}\|\boldsymbol{x}\|$, there exists an $\boldsymbol{h}_0 \in \mathcal{N}_{\epsilon'}$ such that $\|\boldsymbol{h}-\boldsymbol{h}_0\| \leq \epsilon\|\boldsymbol{h}\|$. Taking the union bound for all the points on the net, we claim that

$$\frac{1}{m}\sum_{i=1}^m \chi_i\left(|\boldsymbol{a}_i^T\boldsymbol{h}_0|^2\right) \leq (0.13+\epsilon)\|\boldsymbol{h}_0\|^2, \quad \forall \boldsymbol{h}_0 \in \mathcal{N}_{\epsilon'} \tag{56}$$

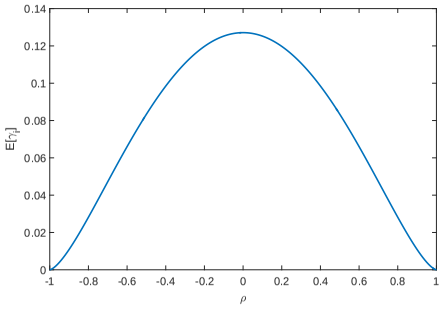

Figure 7: $\mathrm{E}[\gamma_i]$ with respect to ρ.

holds with probability at least $1-(1+2/\epsilon)^n\exp(-cm\epsilon^2)$.

Since $\chi_i(t)$'s are Lipschitz functions with the constant $1/\delta$, we have the following bound

$$\left|\chi_i(|\boldsymbol{a}_i^T\boldsymbol{h}|^2) - \chi_i(|\boldsymbol{a}_i^T\boldsymbol{h}_0|^2)\right| \leq \frac{1}{\delta}||\boldsymbol{a}_i^T\boldsymbol{h}|^2 - |\boldsymbol{a}_i^T\boldsymbol{h}_0|^2|. \tag{57}$$

Moreover, by (Chen and Candès, 2015, Lemma 1), we have

$$\frac{1}{m}\sum_{i=1}^m |\boldsymbol{a}_i^T\boldsymbol{M}\boldsymbol{a}_i| \leq c_2\|\boldsymbol{M}\|_F, \qquad \text{for all symmetric rank-2 matrices } \boldsymbol{M}\in\mathbb{R}^{n\times n}, \tag{58}$$

holds with probability at least $1-C\exp(-c_1m)$ as long as $m>c_0n$ for some constants $C, c_0, c_1, c_2>0$. Consequently, on the event that (58) holds, we have

$$\begin{aligned}
&\left|\frac{1}{m}\sum_{i=1}^m \chi_i\left(|\boldsymbol{a}_i^T\boldsymbol{h}|^2\right) - \frac{1}{m}\sum_{i=1}^m \chi_i\left(|\boldsymbol{a}_i^T\boldsymbol{h}_0|^2\right)\right| \\
&\leq \frac{1}{m}\sum_{i=1}^m \left|\chi_i\left(|\boldsymbol{a}_i^T\boldsymbol{h}|^2\right) - \chi_i\left(|\boldsymbol{a}_i^T\boldsymbol{h}_0|^2\right)\right| \\
&\leq \frac{1}{\delta}\cdot\frac{1}{m}\sum_{i=1}^m \left|\boldsymbol{a}_i^T(\boldsymbol{h}\boldsymbol{h}^T-\boldsymbol{h}_0\boldsymbol{h}_0^T)\boldsymbol{a}_i\right| \qquad \text{because of (57)} \\
&\leq \frac{1}{\delta}\cdot c_2\|\boldsymbol{h}\boldsymbol{h}^T-\boldsymbol{h}_0\boldsymbol{h}_0^T\|_F \qquad \text{because of (58)} \\
&\leq \frac{1}{\delta}\cdot 3c_2\|\boldsymbol{h}-\boldsymbol{h}_0\|\cdot\|\boldsymbol{h}\| \\
&\leq \frac{3c_2\epsilon}{\delta}\|\boldsymbol{h}\|^2,
\end{aligned}$$

where the second to last inequality is due to (Chen and Candès, 2015, Lemma 2).

On the intersection of the events over which (56) and (58) hold respectively, we have

$$\frac{1}{m}\sum_{i=1}^m \chi_i\left(|\boldsymbol{a}_i^T\boldsymbol{h}|^2\right) \leq (0.13+\epsilon+3c_2\epsilon/\delta)\|\boldsymbol{h}\|^2, \tag{59}$$

for all $\boldsymbol{h}$ with $\|\boldsymbol{h}\| = \frac{1}{10}\|\boldsymbol{x}\|$.

For the case when $\|\boldsymbol{h}'\| < \frac{1}{10}\|\boldsymbol{x}\|$, $\boldsymbol{h}' = \omega\boldsymbol{h}$ for some $\boldsymbol{h}$ satisfying $\|\boldsymbol{h}\| = \frac{1}{10}\|\boldsymbol{x}\|$ and $0 < \omega < 1$. By the definition of $\chi_i(\cdot)$, it can be verified that

$$\chi_i(|\boldsymbol{a}_i^T\boldsymbol{h}'|^2) = \chi_i(|\boldsymbol{a}_i^T(\omega\boldsymbol{h})|^2) \le \omega^2\chi_i(|\boldsymbol{a}_i^T\boldsymbol{h}|^2). \tag{60}$$

Applying (59), on the same event over which (56) and (58) hold, we have

$$\frac{1}{m}\sum_{i=1}^m \chi_i\left(|\boldsymbol{a}_i^T\boldsymbol{h}'|^2\right) \le (0.13 + \epsilon + 3c_2\epsilon/\delta)\,\|\boldsymbol{h}'\|^2, \tag{61}$$

for all $\|\boldsymbol{h}'\| < \frac{1}{10}\|\boldsymbol{x}\|$. Since ϵ can be arbitrarily small, the proof is completed.

C.2 Proof of Lemma 8

Denote $v_i := \boldsymbol{a}_i^T\boldsymbol{z} - |\boldsymbol{a}_i^T\boldsymbol{x}|\mathrm{sgn}(\boldsymbol{a}_i^T\boldsymbol{z})$ for $i = 1, \cdots, m$. Then

$$\nabla\ell(\boldsymbol{z}) = \frac{1}{m}\boldsymbol{A}^T\boldsymbol{v}, \tag{62}$$

where $\boldsymbol{A}$ is a matrix with each row being $\boldsymbol{a}_i^T$ and $\boldsymbol{v} = [v_1, \cdots, v_m]^T$. Thus,

$$\|\nabla\ell(\boldsymbol{z})\| = \left\|\frac{1}{m}\boldsymbol{A}^T\boldsymbol{v}\right\| \le \frac{1}{m}\|\boldsymbol{A}\|\cdot\|\boldsymbol{v}\| \le (1+\delta)\frac{\|\boldsymbol{v}\|}{\sqrt{m}} \tag{63}$$

as long as $m \ge c_1 n$ for some sufficiently large $c_1 > 0$, where the spectral norm bound $\|\boldsymbol{A}\| \le \sqrt{m}(1+\delta)$ follows from (Vershynin, 2012, Theorem 5.32).

We next bound $\|\boldsymbol{v}\|$. Let $\boldsymbol{v} = \boldsymbol{v}^{(1)} + \boldsymbol{v}^{(2)}$, where $v_i^{(1)} = \boldsymbol{a}_i^T\boldsymbol{h}$ and $v_i^{(2)} = 2\boldsymbol{a}_i^T\boldsymbol{x}\mathbf{1}_{\{(\boldsymbol{a}_i^T\boldsymbol{z})(\boldsymbol{a}_i^T\boldsymbol{x})<0\}}$. By the triangle inequality, we have $\|\boldsymbol{v}\| \le \|\boldsymbol{v}^{(1)}\| + \|\boldsymbol{v}^{(2)}\|$. Furthermore, given $m > c_0 n$, following from (Candès et al., 2013, Lemma 3.1), with probability at least $1 - \exp(-cm)$, we have

$$\frac{1}{m}\|\boldsymbol{v}^{(1)}\|^2 = \frac{1}{m}\sum_{i=1}^m(\boldsymbol{a}_i^T\boldsymbol{h})^2 \le (1+\delta)\|\boldsymbol{h}\|^2. \tag{64}$$

By Lemma 7, we have with probability at least $1 - C\exp(-c_1 m)$

$$\frac{1}{m}\|\boldsymbol{v}^{(2)}\|^2 = \frac{1}{m}\sum_{i=1}^m 4(\boldsymbol{a}_i^T\boldsymbol{x})^2\cdot\mathbf{1}_{\{(\boldsymbol{a}_i^T\boldsymbol{x})(\boldsymbol{a}_i^T\boldsymbol{z})<0\}} \le 4(0.13+\epsilon)\|\boldsymbol{h}\|^2. \tag{65}$$

Hence,

$$\frac{\|\boldsymbol{v}\|}{\sqrt{m}} \le \left(\sqrt{1+\delta} + 2\sqrt{0.13+\epsilon}\right)\|\boldsymbol{h}\|. \tag{66}$$

This concludes the proof.

Appendix D. Proof of Theorem 3

The initialization analysis is similar to Appendix B and is hence omitted. To analyze the gradient loop, we consider the following two regimes.

• **Regime 1**: $c_4\|\boldsymbol{z}\| \ge \|\boldsymbol{h}\| \ge c_3\frac{\|\boldsymbol{w}\|}{\sqrt{m}}$. In this regime, the error contraction by each gradient descent step is given by

$$\mathrm{dist}\left(\boldsymbol{z} - \mu\nabla\ell(\boldsymbol{z}), \boldsymbol{x}\right) \le (1-\rho)\mathrm{dist}(\boldsymbol{z}, \boldsymbol{x}). \tag{67}$$

It suffices to justify that $\nabla\ell(\boldsymbol{z})$ satisfies the RC. We first have

$$\begin{aligned}\nabla\ell(\boldsymbol{z}) &= \frac{1}{m}\sum_{i=1}^m\left(\boldsymbol{a}_i^T\boldsymbol{z} - y_i\cdot\frac{\boldsymbol{a}_i^T\boldsymbol{z}}{|\boldsymbol{a}_i^T\boldsymbol{z}|}\right)\boldsymbol{a}_i \\ &= \underbrace{\frac{1}{m}\sum_{i=1}^m\left(\boldsymbol{a}_i^T\boldsymbol{z} - |\boldsymbol{a}_i^T\boldsymbol{x}|\cdot\frac{\boldsymbol{a}_i^T\boldsymbol{z}}{|\boldsymbol{a}_i^T\boldsymbol{z}|}\right)\boldsymbol{a}_i}_{\nabla^{clean}\ell(\boldsymbol{z})} - \underbrace{\frac{1}{m}\sum_{i=1}^m\left(w_i\cdot\frac{\boldsymbol{a}_i^T\boldsymbol{z}}{|\boldsymbol{a}_i^T\boldsymbol{z}|}\right)\boldsymbol{a}_i}_{\nabla^{noise}\ell(\boldsymbol{z})}.\end{aligned} \tag{68}$$

All the proofs for Lemmas 6, 7 and 8 are still valid for $\nabla^{clean}\ell(\boldsymbol{z})$, and thus we have

$$\langle\nabla^{clean}\ell(\boldsymbol{z}), \boldsymbol{h}\rangle \ge 0.74\|\boldsymbol{h}\|^2, \tag{69}$$

$$\left\|\nabla^{clean}\ell(\boldsymbol{z})\right\| \le 2(1+\delta)\|\boldsymbol{h}\|. \tag{70}$$

Next, we analyze the contribution of the noise. Let $\tilde{w}_i = w_i\frac{\boldsymbol{a}_i^T\boldsymbol{z}}{|\boldsymbol{a}_i^T\boldsymbol{z}|}$, and then for sufficiently large m/n, we have

$$\|\nabla^{noise}\ell(\boldsymbol{z})\| = \left\|\frac{1}{m}\boldsymbol{A}^T\tilde{\boldsymbol{w}}\right\| \le \left\|\frac{1}{\sqrt{m}}\boldsymbol{A}^T\right\|\left\|\frac{\tilde{\boldsymbol{w}}}{\sqrt{m}}\right\| \le (1+\delta)\frac{\|\tilde{\boldsymbol{w}}\|}{\sqrt{m}} \le (1+\delta)\frac{\|\boldsymbol{w}\|}{\sqrt{m}}, \tag{71}$$

where the second inequality is due to the spectral norm bound $\|\boldsymbol{A}\| \le \sqrt{m}(1+\delta)$ (Vershynin, 2012, Theorem 5.32). Given the regime condition $\|\boldsymbol{h}\| \ge c_3\frac{\|\boldsymbol{w}\|}{\sqrt{m}}$, we further have

$$\|\nabla^{noise}\ell(\boldsymbol{z})\| \le \frac{(1+\delta)}{c_3}\|\boldsymbol{h}\|, \tag{72}$$

$$\left|\left\langle\nabla^{noise}\ell(\boldsymbol{z}), \boldsymbol{h}\right\rangle\right| \le \left\|\nabla^{noise}\ell(\boldsymbol{z})\right\|\cdot\|\boldsymbol{h}\| \le \frac{(1+\delta)}{c_3}\|\boldsymbol{h}\|^2. \tag{73}$$

Combining these together, one has

$$\langle\nabla\ell(\boldsymbol{z}), \boldsymbol{h}\rangle \ge \left\langle\nabla^{clean}\ell(\boldsymbol{z}), \boldsymbol{h}\right\rangle - \left|\left\langle\nabla^{noise}\ell(\boldsymbol{z}), \boldsymbol{h}\right\rangle\right| \ge \left(0.74 - \frac{(1+\delta)}{c_3}\right)\|\boldsymbol{h}\|^2, \tag{74}$$

and

$$\|\nabla\ell(\boldsymbol{z})\| \le \left\|\nabla^{clean}\ell(\boldsymbol{z})\right\| + \left\|\nabla^{noise}\ell(\boldsymbol{z})\right\| \le (1+\delta)\left(2 + \frac{1}{c_3}\right)\|\boldsymbol{h}\|. \tag{75}$$

The RC is guaranteed if μ, λ are chosen properly, c_3 is sufficiently large, and δ is sufficiently small.

• **Regime 2**: Once the iterate enters the regime with $\|\boldsymbol{h}\| \le \frac{c_3\|\boldsymbol{w}\|}{\sqrt{m}}$, the gradient descent update may not reduce the estimation error. However, in this regime, the size $\mu\nabla\ell(\boldsymbol{z})$ of each move is at most $\mathcal{O}(\|\boldsymbol{w}\|/\sqrt{m})$. Then the estimation error cannot increase by more than $\|\boldsymbol{w}\|/\sqrt{m}$ with a constant factor. Thus, one has

$$\operatorname{dist}\left(\boldsymbol{z}+\mu\nabla\ell(\boldsymbol{z}),\boldsymbol{x}\right) \le c_5\frac{\|\boldsymbol{w}\|}{\sqrt{m}} \tag{76}$$

for some constant c_5. As long as $\|\boldsymbol{w}\|/\sqrt{m}$ is sufficiently small, it is guaranteed that $c_5\frac{\|\boldsymbol{w}\|}{\sqrt{m}} \le c_4\|\boldsymbol{x}\|$. If the iterate jumps out of *Regime 2*, it falls back into *Regime 1*.

Appendix E. Convergence of Mini-batch IRWF and Kaczmarz-PR

E.1 Proof of Theorem 4

Without loss of generality, we assume $\boldsymbol{z}^{(t)}$ is in the neighborhood of $\boldsymbol{x}$ (otherwise it is in the neighborhood of $-\boldsymbol{x}$). Let $\boldsymbol{h}=\boldsymbol{z}^{(t)}-\boldsymbol{x}$. We follow the notations in Appendix C and let $\mathcal{S}=\{i:(\boldsymbol{a}_i^T\boldsymbol{x})(\boldsymbol{a}_i^T\boldsymbol{z}^{(t)})<0\}$. Then we have

$$\begin{aligned}
&\mathrm{E}_{\Gamma_t}\left[\operatorname{dist}^2\left(\boldsymbol{z}^{(t+1)},\boldsymbol{x}\right)\right]\\
&=\mathrm{E}_{\Gamma_t}\left[\left\|\boldsymbol{z}^{(t)}-\mu\boldsymbol{A}_{\Gamma_t}^T\left(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)}-\boldsymbol{y}_{\Gamma_t}\odot\operatorname{sgn}(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)})\right)-\boldsymbol{x}\right\|^2\right]\\
&=\|\boldsymbol{h}\|^2-2\mu\mathrm{E}_{\Gamma_t}\left[\left(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)}-\boldsymbol{y}_{\Gamma_t}\odot\operatorname{sgn}(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)})\right)^T\boldsymbol{A}_{\Gamma_t}\boldsymbol{h}\right]\\
&\quad+\mu^2\mathrm{E}_{\Gamma_t}\left[\left(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)}-\boldsymbol{y}_{\Gamma_t}\odot\operatorname{sgn}(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)})\right)^T\boldsymbol{A}_{\Gamma_t}\boldsymbol{A}_{\Gamma_t}^T\left(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)}-\boldsymbol{y}_{\Gamma_t}\odot\operatorname{sgn}(\boldsymbol{A}_{\Gamma_t}\boldsymbol{z}^{(t)})\right)\right]\\
&\overset{(a)}{=}\|\boldsymbol{h}\|^2-\frac{2\mu k}{m}\sum_{i=1}^m\boldsymbol{a}_i^T\boldsymbol{h}\left(\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}-y_i\cdot\frac{\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}}{|\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}|}\right)+\frac{\mu^2k}{m}\sum_{i=1}^m\|\boldsymbol{a}_i\|^2\left(\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}-y_i\cdot\frac{\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}}{|\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}|}\right)^2\\
&=\|\boldsymbol{h}\|^2-\frac{2\mu k}{m}\left(\sum_{i=1}^m(\boldsymbol{a}_i^T\boldsymbol{h})^2+\sum_{i\in\mathcal{S}}2(\boldsymbol{a}_i^T\boldsymbol{h})(\boldsymbol{a}_i^T\boldsymbol{x})\right)\\
&\quad+\frac{\mu^2k}{m}\left(\sum_{i=1}^m\|\boldsymbol{a}_i\|^2(\boldsymbol{a}_i^T\boldsymbol{h})^2+4\sum_{i\in\mathcal{S}}\|\boldsymbol{a}_i\|^2(\boldsymbol{a}_i^T\boldsymbol{x})(\boldsymbol{a}_i^T\boldsymbol{z}^{(t)})\right)\\
&\le\|\boldsymbol{h}\|^2-\frac{2\mu k}{m}\sum_{i=1}^m(\boldsymbol{a}_i^T\boldsymbol{h})^2+\frac{4\mu k}{m}\sum_{i\in\mathcal{S}}\left|(\boldsymbol{a}_i^T\boldsymbol{h})(\boldsymbol{a}_i^T\boldsymbol{x})\right|+\frac{\mu^2k}{m}\sum_{i=1}^m\|\boldsymbol{a}_i\|^2(\boldsymbol{a}_i^T\boldsymbol{h})^2,
\end{aligned}\tag{77}$$

where (a) is due to the fact that Γ_t is uniformly chosen from all subsets of $\{1,2,\ldots,m\}$ with the cardinality k.

By Lemma 6, we have that if $m\ge c_0\epsilon^{-2}n$ then with probability $1-2\exp(-c_1m\epsilon^2)$

$$(1-\epsilon)\|\boldsymbol{h}\|^2\le\frac{1}{m}\sum_{i=1}^m(\boldsymbol{a}_i^T\boldsymbol{h})^2\le(1+\epsilon)\|\boldsymbol{h}\|^2.$$

holds for all vectors $\boldsymbol{h}$. By Lemma 7, we have that with probability $1-C\exp(-c_1m\epsilon^2)$

$$\frac{1}{m}\sum_{i\in\mathcal{S}}\left|(\boldsymbol{a}_i^T\boldsymbol{h})(\boldsymbol{a}_i^T\boldsymbol{x})\right|\le(0.13+\epsilon)\|\boldsymbol{h}\|^2$$

holds for all $\boldsymbol{h}$ satisfying $\|\boldsymbol{h}\|/\|\boldsymbol{x}\|\le\frac{1}{10}$.

Define an event $E_1:=\{\max_{1\le i\le m}\|\boldsymbol{a}_i\|^2\le 6n\}$. It can be shown that E_1 holds with probability $1-m\exp(-1.5n)$. Then on the event E_1, Equation (77) is further upper bounded by

$$\begin{aligned}
\mathrm{E}_{\Gamma_t}\left[\operatorname{dist}^2\left(\boldsymbol{z}^{(t+1)},\boldsymbol{x}\right)\right]&\le\left(1-2\mu k(1-\epsilon)+4\mu k(0.13+\epsilon)+\mu^2k\cdot6n(1+\epsilon)\right)\|\boldsymbol{h}\|^2\\
&\le\left(1-2\mu k(0.74-3\epsilon-3n\mu(1+\epsilon))\right)\|\boldsymbol{h}\|^2.
\end{aligned}\tag{78}$$

By choosing the step size $\mu\le\frac{0.24}{n}$, the proposition is proved.

E.2 Proof of Theorem 5

Without loss of generality, we assume the $\boldsymbol{z}^{(t)}$ is in the neighborhood of $\boldsymbol{x}$ (otherwise it is in the neighborhood of $-\boldsymbol{x}$). Let $\boldsymbol{h}=\boldsymbol{z}^{(t)}-\boldsymbol{x}$. We follow the notations in Appendix C and let $\mathcal{S}=\{i:(\boldsymbol{a}_i^T\boldsymbol{x})(\boldsymbol{a}_i^T\boldsymbol{z}^{(t)})<0\}$. Then we have

$$\begin{aligned}
&\mathrm{E}_{i_t}\operatorname{dist}^2\left(\boldsymbol{z}^{(t+1)},\boldsymbol{x}\right)\\
&=\mathrm{E}_{i_t}\left\|\boldsymbol{z}^{(t)}-\frac{1}{\|\boldsymbol{a}_{i_t}\|^2}\left(\boldsymbol{a}_{i_t}^T\boldsymbol{z}^{(t)}-y_{i_t}\cdot\frac{\boldsymbol{a}_{i_t}^T\boldsymbol{z}^{(t)}}{|\boldsymbol{a}_{i_t}^T\boldsymbol{z}^{(t)}|}\right)\boldsymbol{a}_{i_t}-\boldsymbol{x}\right\|^2\\
&=\|\boldsymbol{h}\|^2-2\mathrm{E}_{i_t}\frac{(\boldsymbol{a}_{i_t}^T\boldsymbol{h})}{\|\boldsymbol{a}_{i_t}\|^2}\left(\boldsymbol{a}_{i_t}^T\boldsymbol{z}^{(t)}-y_{i_t}\cdot\frac{\boldsymbol{a}_{i_t}^T\boldsymbol{z}^{(t)}}{|\boldsymbol{a}_{i_t}^T\boldsymbol{z}^{(t)}|}\right)+\mathrm{E}_{i_t}\frac{1}{\|\boldsymbol{a}_{i_t}\|^2}\left(\boldsymbol{a}_{i_t}^T\boldsymbol{z}^{(t)}-y_{i_t}\cdot\frac{\boldsymbol{a}_{i_t}^T\boldsymbol{z}^{(t)}}{|\boldsymbol{a}_{i_t}^T\boldsymbol{z}^{(t)}|}\right)^2\\
&\overset{(a)}{=}\|\boldsymbol{h}\|^2-\frac{2}{m}\sum_{i=1}^m\frac{(\boldsymbol{a}_i^T\boldsymbol{h})}{\|\boldsymbol{a}_i\|^2}\left(\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}-y_i\cdot\frac{\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}}{|\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}|}\right)+\frac{1}{m}\sum_{i=1}^m\frac{1}{\|\boldsymbol{a}_i\|^2}\left(\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}-y_i\cdot\frac{\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}}{|\boldsymbol{a}_i^T\boldsymbol{z}^{(t)}|}\right)^2\\
&=\|\boldsymbol{h}\|^2-\frac{2}{m}\left(\sum_{i=1}^m\frac{(\boldsymbol{a}_i^T\boldsymbol{h})^2}{\|\boldsymbol{a}_i\|^2}+\sum_{i\in\mathcal{S}}\frac{2(\boldsymbol{a}_i^T\boldsymbol{h})(\boldsymbol{a}_i^T\boldsymbol{x})}{\|\boldsymbol{a}_i\|^2}\right)+\frac{1}{m}\left(\sum_{i=1}^m\frac{(\boldsymbol{a}_i^T\boldsymbol{h})^2}{\|\boldsymbol{a}_i\|^2}+4\sum_{i\in\mathcal{S}}\frac{(\boldsymbol{a}_i^T\boldsymbol{x})(\boldsymbol{a}_i^T\boldsymbol{z}^{(t)})}{\|\boldsymbol{a}_i\|^2}\right)\\
&=\|\boldsymbol{h}\|^2-\frac{1}{m}\sum_{i=1}^m\frac{(\boldsymbol{a}_i^T\boldsymbol{h})^2}{\|\boldsymbol{a}_i\|^2}+\frac{4}{m}\sum_{i\in\mathcal{S}}\frac{(\boldsymbol{a}_i^T\boldsymbol{x})^2}{\|\boldsymbol{a}_i\|^2}
\end{aligned}\tag{79}$$

where (a) is due to the fact that i_t is sampled uniformly at random from $\{1,2,\cdots,m\}$. By the special case of Lemma 5.20 in (Vershynin, 2012), $\{\sqrt{n}\frac{\boldsymbol{a}_i}{\|\boldsymbol{a}_i\|}\}_{i=1}^m$ are independent isotropic random vectors in $\mathbb{R}^n$ and hence

$$\mathrm{E}\left[n\frac{(\boldsymbol{a}_i^T\boldsymbol{h})^2}{\|\boldsymbol{a}_i\|^2}\right]=\|\boldsymbol{h}\|^2.$$

Moreover, $\{\sqrt{n}\frac{\boldsymbol{a}_i}{\|\boldsymbol{a}_i\|}\}_{i=1}^m$ are sub-Gaussian and the sub-Gaussian norm is bounded by an absolute constant. Thus, we have that if $m\ge c_0\epsilon^{-2}n$, then with probability $1-2\exp(-c_1m\epsilon^2)$,

$$\frac{1}{m}\sum_{i=1}^m\frac{(\boldsymbol{a}_i^T\boldsymbol{h})^2}{\|\boldsymbol{a}_i\|^2}\ge\frac{(1-\epsilon)}{n}\|\boldsymbol{h}\|^2.$$

holds for all vectors $\boldsymbol{h}$. By Lemma 7, we have that with probability $1-C\exp(-c_1m\epsilon^2)$

$$\frac{1}{m}\sum_{i\in\mathcal{S}}\left|\boldsymbol{a}_i^T\boldsymbol{x}\right|^2\le\frac{1}{m}\sum_{i=1}^m\left|\boldsymbol{a}_i^T\boldsymbol{h}\right|^2\mathbf{1}_{\{|\boldsymbol{a}_i^T\boldsymbol{x}|<|\boldsymbol{a}_i^T\boldsymbol{h}|\}}\le(0.13+\epsilon)\|\boldsymbol{h}\|^2$$

holds for all $\boldsymbol{h}$ satisfying $\|\boldsymbol{h}\|/\|\boldsymbol{x}\| \le \frac{1}{10}$.

Define an event $E_2 := \{\min_{1\le i\le m} \|\boldsymbol{a}_i\|^2 \ge \frac{2}{3}n\}$. It can be shown that $\mathbb{P}\{E_2\} \ge 1 - m\exp(-n/12)$. Then on the event E_2, (79) is further upper bounded by

$$\mathrm{E}_{i_t}\left[\mathrm{dist}^2\left(\boldsymbol{z}^{(t+1)},\boldsymbol{x}\right)\right] \le \left(1 - \frac{1-\epsilon}{n} + \frac{6(0.13+\epsilon)}{n}\right)\|\boldsymbol{h}\|^2 \le \left(1 - \frac{0.22-7\epsilon}{n}\right)\|\boldsymbol{h}\|^2, \quad (80)$$

which concludes the proof.

Abstract

The robust improper maximum likelihood estimator (RIMLE) is a new method for robust multivariate clustering finding approximately Gaussian clusters. It maximizes a pseudo-likelihood defined by adding a component with improper constant density for accommodating outliers to a Gaussian mixture. A special case of the RIMLE is MLE for multivariate finite Gaussian mixture models. In this paper we treat existence, consistency, and breakdown theory for the RIMLE comprehensively. RIMLE's existence is proved under non-smooth covariance matrix constraints. It is shown that these can be implemented via a computationally feasible Expectation-Conditional Maximization algorithm.

Keywords: Robustness, Improper density, Mixture models, Model-based clustering, Maximum likelihood, ECM-algorithm

1. Introduction

Maximum likelihood estimation (MLE) in a Gaussian mixture model with mixture components interpreted as clusters is a popular approach to cluster analysis (see, e.g., Fraley and Raftery (2002)). In many datasets not all observations can be assigned appropriately to clusters that can be properly modelled by a Gaussian distribution, and it is also well known that the MLE can be strongly affected by outliers (Hennig (2004)). In this paper we investigate the recently introduced "robust improper maximum likelihood estimator" (RIMLE, see Coretto and Hennig, 2016), a method for robust clustering with clusters that can be approximated by multivariate Gaussian distributions. The basic idea of RIMLE is to fit an improper density to the data that is made up by a Gaussian mixture density and a "pseudo mixture component" defined by a small constant density, which is meant to capture outliers and observations in low density areas of the data that cannot properly be assigned to a Gaussian mixture component (called "noise" in the following). This is inspired by the addition of a uniform "noise component" to a Gaussian mixture suggested by Banfield and Raftery (1993). Hennig (2004) showed that using an improper density improves the breakdown robustness of this approach for one-dimensional datasets. As in many other statistical problems, violations of the model assumptions may cause problems in cluster analysis. Our general attitude to the use of statistical models in cluster analysis is that the models should not be understood as reflecting some underlying but in practice unobservable "truth", but rather as thought constructs implying a certain behaviour of methods derived from them (e.g., maximizing the likelihood), which may or may not be appropriate in a given application (more details on the general philosophy of clustering can be found in Hennig and Liao (2013); Hennig (2015b)). Using a model such as a mixture of multivariate Gaussian distributions, interpreting every mixture component as a "cluster", implies that we look for clusters that are approximately "Gaussian-shaped", but we do not want to rely on whether the data really were generated i.i.d. by a Gaussian mixture. We focus on situations in which the number of clusters G is fixed.

There is a number of proposals already in the literature for accounting for the presence of noise and outliers in model-based clustering problems. The contributions can be divided in two groups: methods based on mixture modelling, and methods based on fixed partition models. Within the first group Banfield and Raftery (1993) and Coretto and Hennig (2011) dealt with uniform distributions added as "noise components" to a finite Gaussian mixture. Peel and McLachlan (2000) proposed to model data based on Student t-distributions. Cuesta-Albertos et al. (1997) and García-Escudero and Gordaliza (1999) introduced and studied trimming in order to robustify the k-means partitioning method. Robust partitioning methods with homoscedastic clusters based on ML–type procedures where proposed in Gallegos (2002) and Gallegos and Ritter (2005). Heteroscedasticity in ML-type partitioning methods has been introduced with the TCLUST algorithm of García-Escudero et al. (2008) and the "k–parameters clustering" of Gallegos and Ritter (2013). More references and an in-depth overview are given in García-Escudero et al. (2015). Different from the methods based on fixed partition models, mixture models and RIMLE allow a smooth transition between different clusters and between clustered observations and noise, which improves parameter estimation in the presence of overlap between mixture components. The one-dimensional version of the RIMLE was introduced in Coretto and Hennig (2010) and was investigated based on Monte Carlo experiments. Extension of the methods to the multivariate setting is not straightforward. Existence and consistency of the MLE for the multivariate Gaussian mixtures is a long standing problem due to the ill-posedness of the likelihood function. Even for ML for plain multivariate Gaussian mixtures (i.e. the RIMLE with the improper constant density set to zero), consistency theory is limited to the situation in which the model is assumed to hold precisely, and restrictive conditions are required (e.g., Redner and Walker (1984)). Chen and Tan (2009) and Alexandrovich (2014) propose and study a penalized ML estimator. García-Escudero et al. (2014) studied a classification ML estimator for Gaussian mixture that is based on the TCLUST idea.

In this paper we study the theoretical properties of the RIMLE as well as its computation. A comprehensive treatment of existence, consistency and robustness is given. This treatment includes the case of ML for multivariate Gaussian mixture as special case. Particularly, the robustness properties of RIMLE are superior to those of the mixture-based methods proposed by Banfield and Raftery (1993) and Peel and McLachlan (2000), as demonstrated later in the paper. For fitting plain Gaussian mixtures, some issues that are treated here arise as well, particularly the need to constrain the covariance matrices in order to avoid degeneration of the likelihood. Some literature on this is cited in Section

3.2. The consistency results given here in Section 4 are of a nonparametric nature and show the consistency of the RIMLE for the RIMLE-functional defined for a general class of sampling distributions. Similar results have been shown for a partition likelihood model (Gallegos and Ritter (2013)) and for alternative, trimming-based approaches to robust clustering (e.g., García-Escudero et al. (2008); Gallegos and Ritter (2009)). Compared to these results, there is an additional difficulty for the RIMLE, namely that degeneration of the likelihood needs to be prevented also in the case that almost all observations are assigned to the noise component and the remaining observations are fitted arbitrarily well. This may look like a disadvantage, but in the literature cited above such problems are only avoided by fixing the trimming rate. An analysis like the one given here, and in Coretto and Hennig (2016), is required for understanding the case in which both the proportion of points considered as "noise" and the density level at which this happens are flexible. Coretto and Hennig (2016) introduce the OTRIMLE, a data-adaptive choice of the improper constant density, the method's tuning constant for achieving robustness. That paper also includes a comprehensive simulation study comparing the different approaches to robust clustering. In the study, every method turns out to be superior for one or more setups, but the OTRIMLE achieves the most satisfactory overall performance.

The paper is organized as follows. We first discuss in Section 2 an artificial dataset to illustrate the issues RIMLE is meant to deal with. The RIMLE is introduced and defined in Section 3. In Section 4 existence and consistency of the RIMLE are proved. Section 5 treats the computation of the RIMLE and the choice of input parameters for the algorithms. Section 6 studies the breakdown robustness of RIMLE. Numerical experiments are presented in Section 7. Section 8 concludes the paper.

2. Artificial data examples

Every clustering method is designed to recover certain types of clusters even when they are based on methods and algorithms that apply universally. For instance, the well known k-means method aims to discover spherical balanced clusters, although the algorithm will find a solution when this is not the case. In this section we introduce some issues in robust clustering by showing examples of data affected by noise that cause trouble to most clustering methods, including those that supposedly explicitly account for it. These examples will illustrate the kind of clustering problem that the method investigated in this paper aims to address. Two artificial data sets are generated in dimension $p = 20$ from two sampling designs, called AsyNoise and GEM respectively, also considered for the numerical experiments presented in Section 7. The two data sets are shown in Figure 1 and 3. A detailed description of the sampling designs is given in Section 7.

In AsyNoise (Figure 1) there are 500 observations in 5 moderately separated clusters from student-t distributions with varying degrees of freedom, 187 observations (37.4%) are background noise. We have symmetric and elliptical clusters that are not well separated along all directions, and they are of different size. Although there is a deviation from Gaussianity in the tails of the clusters' distribution, methods based on Gaussian shapes are candidates to reconstruct such groups. Plain Gaussian mixture clustering (without noise component) fixing the number of clusters at $G = 5$ using the popular R package mclust of Fraley et al. (2012) puts the clustered points into two big clusters and assigns the noise to the

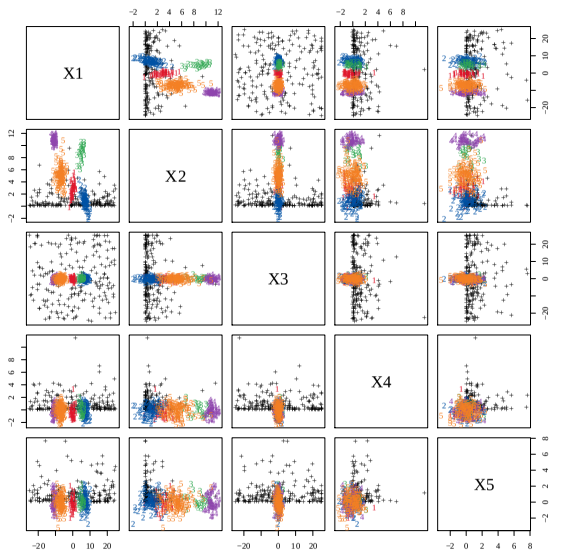

Figure 1: Scatter plots of $n = 500$ data points sampled from the AsyNoise design defined in Section 7. Marginals 1 to 5 are represented, further dimensions show a similar pattern. Colors denote the 5 clusters, while noise is represented by the "+" symbol.

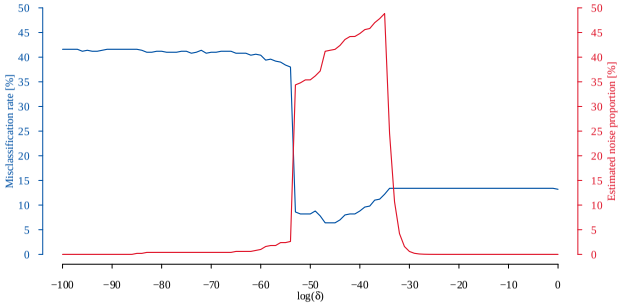

Figure 2: Misclassification rates (blue), and estimated noise proportions (red) by RIMLE over a grid of $\log(\delta)$ values for the data set in Figure 1.

remaining clusters achieving a misclassification rate of 61.4% (i.e., the best misclassification rate that can be achieved by permutation of the cluster labels so that no cluster is identified with the noise). Note that in this paper, mclust always automatically chooses an optimal covariance matrix parametrization by the BIC (see Fraley et al., 2012; Celeux and Govaert, 1995). One could wonder whether the data set may be an easy job for clustering methods that take into account outliers, but this is not the case as shown in Section 7. All robust methods require tuning that, directly or indirectly, controls the amount of noise present in the data set. Perhaps the only exception is the MLE for Gaussian mixtures with uniform noise of Banfield and Raftery (1993) implemented in the mclust package, but this can be led astray if the noise in fact behaves very differently from a uniform distribution. In real situations a priori information on the level of the noise is rarely available. The RIMLE method treated in this paper also requires tuning. The level of the noise is essentially controlled by the level of the improper noise density, called δ. For a given value of δ, the noise proportion then is estimated from the data.

For the data set in Figure 1 we computed the RIMLE for several values of $\log(\delta)$ (there are other constants required, chosen as $\gamma = 100$ and $\pi_{\max} = 0.5$, see Algorithm 2 and Sections 3). When choosing $\log(\delta)$ appropriately, namely $\log(\delta) \in [-53, -36]$, the RIMLE gets the structure of the data set right, and it stably produces a misclassification rate in the range [6.4%, 11%] with an estimated noise proportion in the range [34.38%, 45.8%]. This is clearly better than most other robust clustering methods we tried, see Section 7. Values of $\log(\delta)$ below -100 do not change the results. For large values of $\log(\delta)$ too much noise is found, hence the RIMLE's noise proportion constraint (see Section 3) becomes active and the resulting estimated noise proportion gets close to zero. The OTRIMLE criterion of Coretto and Hennig (2016) selects an optimal value $\log(\delta) = -40$, which is in the region where RIMLE shows its best performance. The RIMLE at $\log(\delta) = -40$ produces a misclassification rate of 8.8% with estimated noise proportion equal to 44.8%. Figure 2 shows how solutions change with changing values of $\log(\delta)$.

Another experimental situation considered in this paper is the GEM ("Gross Error Model") sampling design (Figure 3). In the GEM, 100 points are sampled from two normal populations with extremely different scatters, 2 points (2%) are outliers almost lying on a hyperplane. These outliers are not extremely separated from the regular points, and this can cause trouble to robust methods. Surprisingly, in a situation like this, some non-robust methods perform better than some robust alternatives. In fact, ML for plain Gaussian mixtures performed with mclust (without the noise component) assigns the two outliers to cluster 1 and achieves a misclassification rate of 2%, although the estimated mixture parameters are strongly biased. Robust methods may do worse if not well tuned (see Section 7). As for the previous data set the RIMLE has been computed for several values of $\log(\delta)$ maintaining all other parameters as before. The result can be seen in Figure 4. For any $-\infty < \log(\delta) \leq -46$ the RIMLE is 100% accurate and estimates a noise proportion of 2%. The OTRIMLE method for the data-driven choice of δ selects $\log(\delta) = -200$, which is in the region where the RIMLE achieves the best results.

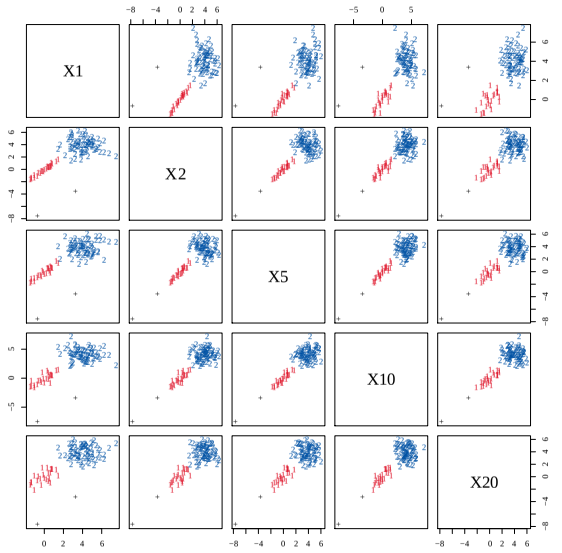

Figure 3: Scatter plots of $n = 100$ points sampled from the GEM sampling design defined in Section 7. Marginals 1,2,5,10, and 20 are represented, further dimensions show a similar pattern. Colors denote the 2 clusters, while noise is represented by the "+" symbol.

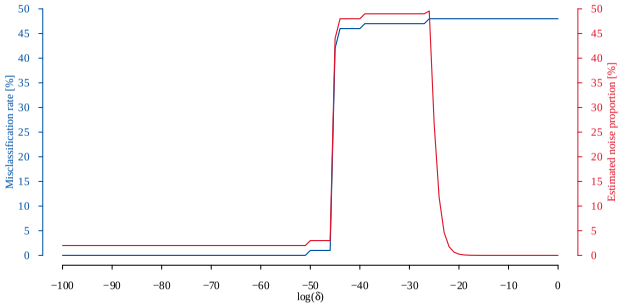

Figure 4: Misclassification rates (blue), and estimated noise proportions (red) by RIMLE over a grid of $\log(\delta)$ values for the data set in Figure 3.

3. Basic definitions

In this section we define the robust improper maximum likelihood estimator (RIMLE) along with its constrained parameter space.

3.1 RIMLE and clustering

The RIMLE is based on the "noise component" idea for robustification of the MLE based on the Gaussian mixture model. This models the noise by a uniform distribution, but in fact we are interested in more general patterns of noise or outliers. However, regions of high density are rather associated with clusters than with noise, so the noise regions should be those with the lowest density. This kind of distinction can be achieved by using the uniform density as in Banfield and Raftery (1993), but in the presence of gross outliers the dependence of the uniform distribution on the convex hull of the data causes a robustness problem (Hennig (2004)). The uniform distribution is not really used here as a model for the noise, but rather as a technical device to account for whatever goes on in low density regions. The RIMLE drives this idea further by using an improper uniform distribution the density value of which does not depend on how far awy extreme points in the data are from the main bulk. In the following, assume an observed sample $x_1, x_2, \ldots, x_n$, where x_i is the realization of a random variable $X_i \in \mathbb{R}^p$ with $p > 1$; $X_1, \ldots, X_n$ i.i.d. The goal is to cluster the sample points into G distinct groups. RIMLE then maximizes a pseudo-likelihood, which is based on the improper pseudo-density

$$\psi_\delta(x, \theta) = \pi_0 \delta + \sum_{j=1}^{G} \pi_j \phi(x; \mu_j, \Sigma_j), \tag{1}$$

where $\phi(\cdot, \mu, \Sigma)$ is the Gaussian density with mean μ and covariance matrix Σ, $\pi_0, \pi_j \in [0, 1]$ for $j = 1, 2, \ldots, G$, $\pi_0 + \sum_{i=1}^{G} \pi_j = 1$, while δ is the improper constant density. The parameter vector θ contains all Gaussian parameters plus all proportion parameters including π_0, ie. $\theta = (\mu_1, \ldots, \mu_G, \text{vect}(\Sigma_1), \ldots, \text{vect}(\Sigma_G), \pi_0, \ldots, \pi_G)$, where vect$(A)$ is the vectorized upper (or lower) triangle including the main diagonal of the symmetric square matrix A. δ and the number of Gaussian components G are considered fixed and known. Although this does not define a proper probability model, it yields a useful procedure for data modelled as a proportion of $(1 - \pi_0)$ of a mixture of Gaussian distributions, which have high enough density peaks to be interpreted as clusters plus a proportion π_0 times something unspecified with density smaller than or equal to δ (which may even contain further Gaussian components with so few points and/or so large within-component variation that they are not considered as "clusters"). The definition of the pseudo-model in (1) requires that the value of δ is fixed in advance. The choice of δ will be discussed in Section 5.2.

Given the sample improper pseudo-log-likelihood function

$$l_n(\theta) = \frac{1}{n} \sum_{i=1}^{n} \log \psi_\delta(x_i, \theta), \tag{2}$$

the RIMLE is defined as

$$\theta_n(\delta) = \underset{\theta \in \Theta_n}{\arg\max}\, l_n(\theta), \tag{3}$$

where Θ_n is a constrained parameter space defined in Section 3.2. $\theta_n(\delta)$ is then used to cluster points using pseudo posterior probabilities for belonging to the Gaussian components or the improper uniform. These pseudo posterior probabilities are given by

$$\tau_j(x_i, \theta) := \begin{cases} \frac{\pi_0 \delta}{\psi_\delta(x_i, \theta)} & \text{if } j = 0 \\ \frac{\pi_j \phi(x_i, \mu_j, \Sigma_j)}{\psi_\delta(x_i, \theta)} & \text{if } j = 1, 2, \ldots, G; \end{cases} \qquad \text{for } i = 1, 2, \ldots, n.$$

Points are assigned to the component for which the pseudo posterior probability is maximized. The assignment rule is then given by

$$J(x_i, \theta) := \underset{j \in \{0,1,2,\ldots,G\}}{\arg\max}\, \tau_j(x_i, \theta). \tag{4}$$

The assignment based on maximum posterior probabilities is common to all model-based clustering methods. Here, an improper density is involved, and so these are "pseudo posterior probabilities".

We also define a population version of the RIMLE for later deriving consistency results for the sequence $\{\theta_n(\delta)\}_{n \in \mathbb{N}}$. Let $\text{E}_P f(x)$ be the expectation of $f(x)$ under P. The RIMLE population target function and the constrained parameter set can be obtained by replacing the empirical measure with P, and the population version of $l_n(\theta)$ is given by

$$L(\theta) = \text{E}_P \log(\psi_\delta(x, \theta)).$$

Define $L_G = \sup_{\theta \in \Theta_G(P)} L(\theta)$, where $\Theta_G(P)$ is a constrained parameter space defined in Section 3.2.

3.2 The constrained parameter space

Some notation: the kth element of μ_j is denoted by $\mu_{j,k}$ for $k = 1, 2, \ldots, p$ and $j = 1, 2, \ldots, G$. Let $\lambda_{j,k}$ be the kth eigenvalue of Σ_j, define $\Lambda(\theta) = \{\lambda_{j,k} : \ j = 1, 2, \ldots, G; \ k = 1, 2, \ldots, p\}$, $\lambda_{\min}(\theta) = \min_{j,k}\{\Lambda(\theta)\}$, $\lambda_{\max}(\theta) = \max_{j,k}\{\Lambda(\theta)\}$.

Remark 1 *The p-dimensional Gaussian density can be written in terms of the eigen-decomposition of the covariance matrix:*

$$\phi(x; \mu, \Sigma) = (2\pi)^{-\frac{p}{2}} \left(\prod_{k=1}^{p} \lambda_k \right)^{-\frac{1}{2}} \exp\left(-\frac{1}{2} \sum_{k=1}^{p} \lambda_k^{-1} (x - \mu)' v_k v_k' (x - \mu) \right),$$

where λ_k is the k-th eigenvalue of Σ, and v_k is its associated eigenvector, for $k = 1, 2, \ldots, p$. Let $\lambda_0 = \min\{\lambda_k; \ k = 1, 2, \ldots, p\}$. Then, $\lim_{\lambda_0 \searrow 0} \phi(\mu; \mu, \Sigma) = \infty$, with $\phi(\mu; \mu, \Sigma) = O(\lambda_0^{-p/2})$ as $\lambda_0 \searrow 0$. On the other hand $\lim_{\lambda_0 \searrow 0} \phi(x; \mu, \Sigma) = 0$ for all $x \neq \mu$, with $\phi(x; \mu, \Sigma) = o(\lambda_0^q)$ for any fixed q as $\lambda_0 \searrow 0$. This implies that

$$\lim_{\lambda_0 \searrow 0} \ \phi(\mu; \mu, \Sigma) \phi(x; \mu, \Sigma) \to 0 \quad \text{for any } x \neq \mu$$

Furthermore, each of the density components in $\psi_\delta(\cdot)$ can be bounded above in terms of $\lambda_{\max}(\theta)$ and $\lambda_{\min}(\theta)$:

$$\phi(x; \mu_j, \Sigma_j) \leq (2\pi \lambda_{\min}(\theta))^{-\frac{p}{2}} \exp\left\{ -\frac{1}{2} \lambda_{\max}(\theta)^{-1} \|x - \mu_j\|^2 \right\} \leq (2\pi \lambda_{\min}(\theta))^{-\frac{p}{2}}. \tag{5}$$

The optimization problem in (3) requires that Θ_n is suitably defined, otherwise $\theta_n(\delta)$ may not exist. Consider a sequence $(\theta_m)_{m\in\mathbb{N}}$, as discovered by Kiefer and Wolfowitz (1956), the likelihood of a Gaussian mixtures degenerates if $\lambda_{1,1,m} \searrow 0$ if $\mu_{1,m} = x_1$, and this holds for (2), too. We here use the eigenratio constraint

$$\lambda_{\max}(\theta)/\lambda_{\min}(\theta) \leq \gamma < +\infty \tag{6}$$

with a constant $\gamma \geq 1$, where $\gamma = 1$ constrains all component covariance matrices to be spherical and equal, as in k-means clustering. This type of constraint has been proposed by Jr (1981), while Hathaway (1985) showed consistency of the scale-ratio constrained MLE for one-dimensional Gaussian mixtures. Ingrassia (2004) and Ingrassia and Rocci (2007) introduced EM algorithms for implementing these constraints for multivariate datasets. TCLUST by García-Escudero et al. (2008) and García-Escudero et al. (2014) also makes use of eigenratio constraints. Moreover there are a number of alternative constraints, see Ingrassia and Rocci (2011); Gallegos and Ritter (2009). It may be seen as a disadvantage of (6) that the resulting estimator will not be affine equivariant (this would require allowing $\lambda_{\max}(\theta)/\lambda_{\min}(\theta) \to \infty$ within any component). Affine equivariance can be achieved by defining a sphered version of the RIMLE as

$$\theta_n^*(\delta) = \theta_n^*(\delta, x_1, \ldots, x_n) = \theta_n(\delta, x_1^*, x_2^*, \ldots, x_n^*)$$

with $x_i^* = A(x_i - m),\ i = 1, \ldots, n$, where $S(x_1, \ldots, x_n)^{-1} = A'A$; $S(x_1, \ldots, x_n)$ could be the sample covariance matrix or another scale matrix and m the mean vector or another location estimator. This yields affine equivariance because the sphered versions of $\{x_1, \ldots, x_n\}$ and $\{Bx_1 + b, \ldots, Bx_n + b\}$ with some invertible $p \times p$-matrix B and $b \in \mathbb{R}^p$ are the same. Affine equivariance is not necessarily desirable though, see Hennig (2015a), Sec. 31.3.4.

This defines the parameter space

$$\tilde{\Theta} := \left\{\theta :\ \pi_j \geq 0\ \forall j \geq 1,\ \pi_0 + \sum_{j=1}^{G} \pi_j = 1;\ \frac{\lambda_{\max}(\theta)}{\lambda_{\min}(\theta)} \leq \gamma\right\}. \tag{7}$$

Occasionally, later, the notation $\|\theta\|$ will refer to the Euclidean norm of a vector pieced together from all the parameters collected in θ, in which all covariance matrices are interpreted as subvectors of all the matrix entries.

Although (6) ensures the boundedness of the likelihood in standard mixture models and TCLUST, for RIMLE this is not enough. The Gaussian components could degenerate on a few points and all other points could be fitted by the improper uniform component. Therefore we impose an additional constraint:

$$\frac{1}{n}\sum_{i=1}^{n} \tau_0(x_i, \theta) \leq \pi_{\max}, \tag{8}$$

for fixed $0 < \pi_{\max} < 1$. The quantity $n^{-1}\sum_{i=1}^{n} \tau_0(x_i, \theta)$ can be interpreted as the estimated proportion of noise points. This constraint depends on the dataset. Unfortunately the similar looking constraint $\pi_0 \leq \pi_{\max}$ independent of the data will not do, because this could not stop more than a portion of π_0 points to be fitted by the improper uniform component.

There is therefore a constrained effective parameter space for RIMLE estimation depending on the dataset:

$$\Theta_n := \left\{\theta \in \tilde{\Theta} :\ \pi_j \geq 0\ \forall j \geq 1,\ \pi_0 + \sum_{j=1}^{G} \pi_j = 1;\ \frac{1}{n}\sum_{i=1}^{n} \tau_0(x_i, \theta) \leq \pi_{\max};\ \frac{\lambda_{\max}(\theta)}{\lambda_{\min}(\theta)} \leq \gamma\right\}. \tag{9}$$

Analogously, existence and consistency of the RIMLE functional can only be showed on a parameter subset of $\tilde{\Theta}$ that depends on the underlying distribution and enforces that enough probability mass is fitted by Gaussian components rather than the improper uniform:

$$\Theta_G(P) := \left\{\theta \in \tilde{\Theta} :\ \pi_j \geq 0\ \forall j \geq 1;\ \pi_0 + \sum_{j=1}^{G} \pi_j = 1;\ \mathrm{E}_P \frac{\pi_0 \delta}{\psi_\delta(x, \theta)} \leq \pi_{\max};\ \frac{\lambda_{\max}(\theta)}{\lambda_{\min}(\theta)} \leq \gamma\right\}. \tag{10}$$

4. RIMLE existence and consistency

We first show existence of the RIMLE for finite samples Let $\#(A)$ denote the cardinality of the set A. Let $\underline{x_n} = \{x_1, x_2, \ldots, x_n\}$. Lemma 2 concerns the important case of plain Gaussian mixtures ($\delta = 0$) and requires a weaker assumption A0(a) for existence than A0 required for the RIMLE with $\delta > 0$. Here are some assumptions:

A0(a) $\#(\underline{x_n}) > G$.

A0 $\#(\underline{x_n}) > G + \lceil n\pi_{\max}\rceil$.

Lemma 2 *Assume A0(a), $\delta = 0$. Let $(\theta_m)_{m\in\mathbb{N}}$ be a sequence such that $\lambda_{\max}(\theta_m)/\lambda_{\min}(\theta_m) \leq \gamma$. Assume also that for some $j = 1, 2, \ldots, G$ and $k = 1, 2, \ldots, p$, $\lambda_{k,j,m} \searrow 0$ as $m \to \infty$; then* $\sup l_n(\theta_m) \to -\infty$.

Proof $\lambda_{k,j,m} \searrow 0$ implies $\lambda_{\max}(\theta_m) \searrow 0$, $\lambda_{\min}(\theta_m) \searrow 0$ at the same speed because of (6). Assume w.l.o.g. (otherwise consider a suitable subsequence) that $(\theta_m)_{m\in\mathbb{N}}$ is such that $\mu_{j,m},\ j = 1, 2, \ldots, G$ either leave every compact set for m large enough or converge, and assume w.l.o.g., that if their limits are in $\{x_1, \ldots, x_n\}$, they are in $\underline{x_G} = \{x_1, \ldots, x_G\}$. A0(a) implies that $\exists\ x_i \notin \underline{x_G}$, and $\exists \nu > 0$ such that for all such $x_i,\ j = 1, 2, \ldots, G$ and large enough $m : \|x_i - \mu_{j,m}\| \geq \nu$. Because the likelihood

$$\mathcal{L}_n(\theta_m) = \prod_{x_i \in \underline{x_G}} \left\{\sum_{j=1}^{G} \pi_j \phi(x_i; \mu_{j,m}, \Sigma_{j,m})\right\} \prod_{x_i \notin \underline{x_G}} \left\{\sum_{j=1}^{G} \pi_j \phi(x_i; \mu_{j,m}, \Sigma_{j,m})\right\}, \tag{11}$$

and Remark 1, the first product is of order $O(\lambda_{\min}(\theta_m)^{-p/2})^G$, and the second one of order $o(\lambda_{\min}(\theta_m)^q)$ for any fixed q, which implies that $\mathcal{L}_n(\theta_m) \to 0$ and $l_n(\theta_m) \to -\infty$. ■

Lemma 3 *Assume A0, $\delta > 0$. $(\theta_m)_{m\in N}$ is a sequence in Θ_n. Assume also that for some $j = 1, 2, \ldots, G$ and $k = 1, 2, \ldots, p$, $\lambda_{k,j,m} \searrow 0$ as $m \to \infty$. Then $l_n(\theta_m) \to -\infty$.*

Proof Using the definitions of the proof of Lemma 2, instead of (11) now

$$\mathcal{L}_n(\theta_m) = \prod_{x_i \in \underline{x_G}} \left\{ \pi_{0,m}\delta + \sum_{j=1}^{G} \pi_j \phi(x_i; \mu_{j,m}, \Sigma_{j,m}) \right\} \prod_{x_i \notin \underline{x_G}} \left\{ \pi_{0,m}\delta + \sum_{j=1}^{G} \pi_j \phi(x_i; \mu_{j,m}, \Sigma_{j,m}) \right\} \tag{12}$$

has to be considered, so that the limit behaviour of $(\pi_{0,m})_{m\in\mathbb{N}}$ is relevant. (8) implies

$$\frac{1}{n} \sum_{x_i \in \underline{x_G}} \left(1 + \sum_{j=1}^{G} \frac{\pi_j \phi(x_i, \mu_{j,m}, \Sigma_{j,m})}{\pi_{0,m}\delta} \right)^{-1} + \frac{1}{n} \sum_{x_i \notin \underline{x_G}} \left(1 + \sum_{j=1}^{G} \frac{\pi_j \phi(x_i, \mu_{j,m}, \Sigma_{j,m})}{\pi_{0,m}\delta} \right)^{-1} \leq \pi_{\max}. \tag{13}$$

Suppose that $(\pi_{0,m})_{m\in\mathbb{N}}$ does not converge to zero as $O(\phi(x_i, \mu_{j,m}, \Sigma_{j,m}))$ for at least one $x_i \notin \underline{x_G}$. For $m \to \infty$, the left term of (13) is ≥ 0, and the right term (at least a subsequence) converges to $\frac{\#(x_n \setminus \underline{x_G})}{n}$, which A0 requires to be $> \pi_{\max}$ with contradiction, thus $\pi_{0,m} = O(\phi(x_i, x_j, \Sigma_{j,m}))$. Therefore, by the same argument as in the proof of Lemma 2, the right product in (12) vanishes fast enough so that $l_n(\theta_m) \to -\infty$. ■

From these Lemmas:

Theorem 4 (Finite Sample Existence) *Assume A0. Then $\theta_n(\delta)$ exists for all $\delta \geq 0$.*

Proof Θ_n depends on δ via (8). Θ_n is not empty for any δ, because for any fixed values of the other parameters, small enough π_0 will fulfil (8). Next show that there exists a compact set $K_n \subset \Theta_n$ such that $\sup_{\theta\in K_n} l_n(\theta) = \sup_{\theta\in\Theta_n} l_n(\theta)$.
Step A: consider θ such that $\pi_1 = 1$, $\mu_1 = x_1$, $\Sigma_j = I_p$ for all $j = 1, 2, \ldots, G$, arbitrary μ_j and $\pi_j = 0$ for all $j \neq 1$. For this, $l_n(\theta) = \sum_{i=1}^{n} \log \phi(x_i; x_1, \Sigma_1) > -\infty$, thus $\sup_{\theta\in\Theta_n} l_n(\theta) > -\infty$.
Step B: consider a sequence $(\dot{\theta}_m)_{m\in N}$. It needs to be proved that if $(\dot{\theta}_m)_{m\in N}$ leaves a suitably chosen compact set K_n, it cannot achieve as large values of l_n as one could find within K_n. Lemma 3 (Lemma 2 for $\delta = 0$) rules out the possibility of any $\lambda_{k,j,m} \searrow 0$.
Step C: (5) implies that $l_n(\theta)$ can be bounded from above in terms of $\pi_0, \lambda_{\min}$ and δ:

$$l_n(\theta) = \frac{1}{n} \sum_{i=1}^{n} \log \left(\pi_0\delta + \sum_{j=1}^{G} \pi_j \phi(x_i; \mu_j, \Sigma_j) \right) \leq \log \left(\pi_0\delta + (1-\pi_0)(2\pi\lambda_{\min}(\theta))^{-\frac{p}{2}} \right).$$

Consider $\dot{\theta} \in \Theta_n$ such that $\dot{\lambda}_{k,j} < +\infty$ for all $k = 1, 2, \ldots, p$ and $j = 1, 2, \ldots, G$ (using the obvious notation of components of "dotted" parameter vectors). Also consider a sequence $(\ddot{\theta}_m)_{m\in\mathbb{N}}$ such that $\ddot{\theta}_m \to \ddot{\theta}$ where $\ddot{\theta}$ is equal to $\dot{\theta}$ except that $\ddot{\lambda}_{k,j,m} \to +\infty$ for some $k \in \{1, \ldots, p\}$ and $j \in \{1, \ldots, G\}$. By (6), $\lambda_{\min}(\ddot{\theta}_m) \to +\infty$ and thus $l_n(\ddot{\theta}_m) \to \log(\ddot{\pi}_0\delta)$. Clearly $\ddot{\pi}_0 < 1$ because otherwise $n^{-1}\sum_{i=1}^{n} \tau_0(x_i, \ddot{\theta}) = 1$, violating (8). Therefore $\lim_{m\to\infty} l_n(\ddot{\theta}_m) \leq l_n(\dot{\theta})$.
Step D: now consider $||\dot{\mu}_{j,m}|| \to +\infty$, for $j = 1$, w.l.o.g. Choose $\ddot{\theta}_m$ equal to $\dot{\theta}_m$ except now $\ddot{\mu}_{1,m} = 0$ for all m. Note that $\phi(x_i; \dot{\mu}_{1,m}, \dot{\Sigma}_1) \to 0$ for all $i = 1, 2, \ldots, n$, which implies that $\psi_\delta(x_i, \dot{\theta}_m) < \psi_\delta(x_i, \ddot{\theta}_m)$ for large enough m, for which then $l_n(\dot{\theta}_m) < l_n(\ddot{\theta}_m)$. Applying this argument to all j with $||\dot{\mu}_{j,m}|| \to +\infty$ shows that better l_n can be achieved inside a compact set.

Continuity of l_n now guarantees existence of $\theta_n(\delta)$. ■

We now derive consistency for the sequence $\{\theta_n(\delta)\}_{n\in\mathbb{N}}$ as estimator of L_G. Consistency of the RIMLE can be achieved only if L_G exists. In order to ease the notation we define $\eta(x, \theta) = \sum_{j=1}^{G} \pi_j \phi(x; \mu_j, \Sigma_j)$. Consider the following assumptions on P:

A1 For every $x_1, \ldots, x_G \in \mathbb{R}^p : P\{x_1, \ldots, x_G\} < 1 - \pi_{max}$.

A2 $L_G > L_{G-1}$, where for $G \in \mathbb{N}$ let $L_G = \sup_{\theta\in\Theta_G(P)} L(\theta)$.

A3 There exist $\epsilon_1, \epsilon_2 > 0$ so that for every θ with $\pi_0 < \epsilon_1 : L(\theta) \leq L_G - \epsilon_2$.

Remark 5 *Assumption A1 requires that no set of G points carries probability $1 - \pi_{\max}$ or more. Otherwise the log-likelihood can be driven to ∞ by fitting G mixture components to G points with all covariance matrix eigenvalues converging to zero. The improper noise component could take care of all other points.*

Note that assumptions A2 and A3 are not both required, but only any single one of them. A2 states that G mixture components fit the data better than $G-1$ components. If this is not the case, there is at least one redundant component, and one cannot make sure that $L(\theta)$ is bounded away from L_G for large n in some distance from the "true" RIMLE-functional as the redundant component can be moved around, see Theorem 11. In case that A2 is not fulfilled, a weaker result can still be achieved, namely the existence of a not necessarily unique consistent sequence of local maximizers of l_n. This requires A3, which states that a noise proportion bounded away from zero is required for maximizing L. If neither A2 nor A3 are fulfilled, P can be fitted perfectly by fewer than G mixture components and no noise. In this case one cannot stop the remaining mixture components from leaving every compact set, and therefore one cannot expect consistency of all components for any method; as long as there is still noise bounded away from zero, those mixture components still can contribute to fitting what otherwise would be noise, and fits become worse if these degenerate.

Note that this is less often the case than one might expect; for example, a plain Gaussian mixture with $G-1$ components may still fulfill A3: if the density of one of the components is uniformly smaller than δ, a better pseudo-likelihood can obviously be achieved by assigning its proportion to the noise component than by choosing $\pi_0 = \pi_G = 0$ and otherwise the true parameters. A Gaussian component that "looks like noise" rather than like a "cluster" will be treated as noise.

Lemma 6 *For any probability measure P on $\mathbb{R}^p$, $L_G > -\infty$.*

Proof Choose compact $K \subset \mathbb{R}^p$ with $P(K) > 0$. Let $q = 1-P(K)$ and choose K big enough that $\pi_{\max} > q$. Choose $\mu_1 = \mathrm{E}_P(x|x \in K)$, $\Sigma_1 = \mathrm{Cov}_P(x|x \in K)$, $\pi_2 = \ldots = \pi_G = 0$. If all eigenvalues of Σ_1 are zero, choose $\Sigma_1 = I_p$. Let $\lambda_{\max,1}$ be the largest eigenvalue of Σ_1. If $\lambda_{\max,1}/\lambda_{i,1} > \gamma$ for any eigenvalue $\lambda_{i,1}$ of Σ_1, modify Σ_1 by replacing all eigenvalues smaller

than $\gamma\lambda_{\max,1}$ by $\gamma\lambda_{\max,1}$ in its spectral decomposition. Let $\phi_{\min} = \min_{x\in K}\phi(x,\mu_1,\Sigma_1) > 0$. Choose

$$\pi_0 = \frac{(\pi_{\max}-q)\phi_{\min}}{2((1-\pi_{\max})\delta + (\pi_{\max}-q)\phi_{\min})} > 0,\ \pi_1 = 1-\pi_0.$$

Observe that the resulting $\theta \in \Theta_G(P)$ (with all other parameters chosen arbitrarily) by

$$\mathrm{E}_P\frac{\pi_0\delta}{\psi_\delta(x,\theta)} = \int_K \frac{\pi_0\delta}{\pi_0\delta+\eta(x,\theta)}dP(x) + \int_{K^c}\frac{\pi_0\delta}{\pi_0\delta+\eta(x,\theta)}dP(x) \leq$$
$$\leq (1-q)\frac{\pi_0\delta}{\pi_0\delta+(1-\pi_0)\phi_{\min}} + q.$$

This is smaller than $\pi_{\max}$ if $\pi_0 < \frac{(\pi_{\max}-q)\phi_{\min}}{(1-\pi_{\max})c+(\pi_{\max}-q)\phi_{\min}}$. Furthermore, $L(\theta) \geq (1-q)\log(\pi_0\delta+(1-\pi_0)\phi_{\min}) + q\log(\pi_0\delta) > -\infty$. ■

Lemma 7 *Assume A1. There are $\lambda^*_{\min} > 0,\ \lambda^*_{\max} < \infty,\ \epsilon > 0$, so that*

(a) *$L(\theta) \leq L_G - \epsilon$ for every θ with $\lambda_{\min}(\theta) < \lambda^*_{\min}$ or $\lambda_{\max}(\theta) > \lambda^*_{\max}$,*

(b) *for $x_1, x_2, \ldots$ i.i.d. with $\mathcal{L}(x_1) = P$, for sequences $(\theta_n)_{n\in\mathbb{N}}$ with $\lambda_{\min}(\theta_n) < \lambda^*_{\min}$ or $\lambda_{\max}(\theta_n) > \lambda^*_{\max}$ for large enough n: $l_n(\theta_n) \leq l_n(\theta_n(\delta)) - \epsilon$ a.s.*

Proof Start with part (a). First consider a sequence $\{\theta_m\}_{m\in\mathbb{N}} \in \Theta_G(P)^{\mathbb{N}}$ with $\lambda_{\max}(\theta_m) \to \infty$. The eigenvalue ratio constraint forces all covariance matrix eigenvalues to infinity, and therefore $\sup_x \phi(x,\mu_{j,m},\Sigma_{j,m}) \searrow 0$. But this means that $\mathrm{E}_P\frac{\pi_0\delta}{\psi_\delta(x,\theta)} \to 1 > \pi_{\max}$ and $\theta_m \notin \Theta_G(P)$ eventually, unless $\pi_{0,m} \searrow 0$, too. If the latter is the case, $\psi_\delta(x,\theta) \searrow 0$ uniformly over all x and $L(\theta_m) \searrow -\infty$, which together with Lemma 6 makes it impossible that $L(\theta_m)$ is close to L_G for m large enough and $\lambda_{\max}(\theta_m)$ too large, proving the existence of the upper bound $\lambda^*_{\max} < \infty$ as required.
Now consider a sequence $\{\theta_m\}_{m\in\mathbb{N}} \in \Theta_G(P)^{\mathbb{N}}$ with $\lambda_{\min}(\theta_m) \to 0$. Define

$$A_{m,\epsilon} = \left\{x : \min_{j=1,2,\ldots,G}\|x-\mu_{j,m}\| > \epsilon\right\}.$$

A1 ensures that for $0 < \epsilon_3$ there exists $\epsilon > 0$ so that for all $m \in \mathbb{N} : P(A_{m,\epsilon}) \geq \pi_{\max} + \epsilon_3$. Based on (5) derive an upper bound for $\pi_{0,m}$ from the constraint $\int \frac{\pi_{0,m}\delta}{\pi_{0,m}\delta+\eta(x,\theta_m)}dP(x) \leq \pi_{\max}$:

$$\int \frac{\pi_{0,m}\delta}{\pi_{0,m}\delta+\eta(x,\theta_m)}dP(x) = \int_{A_{m,\epsilon}}\frac{\pi_{0,m}\delta}{\pi_{0,m}\delta+\eta(x,\theta_m)}dP(x) + \int_{A^c_{m,\epsilon}}\frac{\pi_{0,m}\delta}{\pi_{0,m}\delta+\eta(x,\theta_m)}dP(x) \geq$$
$$\geq P(A_{m,\epsilon})\frac{\pi_{0,m}\delta}{\pi_{0,m}\delta+\max_{x\in A_{m,\epsilon}}\eta(x,\theta_m)},$$

which by (5) implies

$$\pi_{0,m} \leq \frac{\pi_{\max}\max_{x\in A_{m,\epsilon}}\eta(x,\theta_m)}{\delta(P(A_{m,\epsilon})-\pi_{\max})} \leq \frac{\pi_{\max}\exp(-\frac{\epsilon^2}{2\gamma\lambda_{\min}(\theta_m)})}{\delta\epsilon_3(2\pi)^{p/2}\lambda_{\min}(\theta_m)^{p/2}}.$$

For the log-likelihood,

$$L(\theta_m) = \int_{A_{m,\epsilon}}\log(\pi_{0,m}\delta+\eta(x,\theta_m))dP(x) + \int_{A^c_{m,\epsilon}}\log(\pi_{0,m}\delta+\eta(x,\theta_m))dP(x) \leq$$
$$\leq \int_{A_{m,\epsilon}}\log\left(\frac{\delta\pi_{\max}\exp(-\frac{\epsilon^2}{2\gamma\lambda_{\min}(\theta_m)})}{\delta\epsilon_3(2\pi)^{p/2}\lambda_{\min}(\theta_m)^{p/2}} + \frac{\exp(-\frac{\epsilon^2}{2\gamma\lambda_{\min}(\theta_m)})}{(2\pi)^{p/2}\lambda_{\min}(\theta_m)^{p/2}}\right)dP(x) +$$
$$+ \int_{A^c_{m,\epsilon}}\log\left(\frac{\delta\pi_{\max}\exp(-\frac{\epsilon^2}{2\gamma\lambda_{\min}(\theta_m)})}{\delta\epsilon_3(2\pi)^{p/2}\lambda_{\min}(\theta_m)^{p/2}} + \frac{1}{(2\pi)^{p/2}\lambda_{\min}(\theta_m)^{p/2}}\right)dP(x) \leq$$
$$\leq P(A_{m,\epsilon})\left(-\frac{c_1}{\lambda_{\min}(\theta_m)} - c_2\log(\lambda_{\min}(\theta_m)) + c_3\right) +$$
$$+ P(A^c_{m,\epsilon})\left(o(1) - c_4\log(\lambda_{\min}(\theta_m)) + c_5\right) =$$
$$= -\frac{c_6}{\lambda_{\min}(\theta_m)} - c_7\log(\lambda_{\min}(\theta_m)) + c_8$$

for positive constants c_1, c_2, c_4, c_6, c_7 and constants c_3, c_5, c_8, all independent of θ_m. If $\lambda_{\min}(\theta_m) \searrow 0$, this implies $L(\theta_m) \searrow -\infty$, proving together with Lemma 6 the existence of the lower bound $\lambda^*_{\min} > 0$.

Part (b) holds because if $(\theta_m)_{m\in\mathbb{N}}$ is chosen as above for $m = n \to \infty$ and P is replaced by the empirical distribution P_n, Glivenko-Cantelli enforces $P_n(A_{n,\epsilon}) - P(A_{n,\epsilon}) \to 0$ a.s. Glivenko-Cantelli applies because the class of all $A_{n,\epsilon}$ is a subset of the class of intersections of the complements of all closed balls, and therefore a Vapnik-Chervonenkis class, see van der Vaart and Wellner (1996). The argument carries over using all other integrals in the finite sample-form, i.e., w.r.t. P_n. Lemma 6 carries over because $l_n(\theta) \to L(\theta)$ a.s. by the strong law of large numbers for θ with $L(\theta) > -\infty$. ■

Remark 8 *Lemma 7 (a) and (5) imply that for all θ with $L(\theta) > L_G - \epsilon$, $j = 1, 2, \ldots, G$ and all x:*

$$\phi(x,\mu_j,\Sigma_j) \leq \phi_{\max} = \frac{1}{(2\pi)^{p/2}(\lambda^*_{\min})^{p/2}}.$$

This implies $L_G < \infty$.

The same holds because of Lemma 7 (b) for $x_1, x_2, \ldots$ i.i.d. with $\mathcal{L}(x_1) = P$ for large enough n a.s. for all θ with $l_n(\theta) > l_n(\theta_n(\delta)) - \epsilon$.

Lemma 9 *Assume A1 and A2. There is a compact set $K \subset \mathbb{R}^p$ so that*

(a) *L reaches its supremum for $\mu_1, \ldots, \mu_G \in K$ and is bounded away from the supremum if not all of $\mu_1, \ldots, \mu_G \in K$ (i.e., $\exists\epsilon_4 > 0$ so that L in this case is bounded from above by $\sup L - \epsilon_4$),*

(b) *for $x_1, x_2, \ldots$ i.i.d. with $\mathcal{L}(x_1) = P$ for large enough n, l_n reaches its supremum for $\mu_1, \ldots, \mu_G \in K$ and is bounded away from the supremum if not all of $\mu_1, \ldots, \mu_G \in K$, a.s.*

Proof Start with part (a). Consider a sequence $\{\theta_m\}_{m\in\mathbb{N}} \in \Theta_G(P)^{\mathbb{N}}$ with $\|\mu_{jm}\| \to \infty$ for $j = 1,\ldots,k,\ 1 \le k < G$ and a compact set K with $\mu_{jm} \in K$ for $j > k$. Let

$$A_m = \left\{ x:\ \forall j \in \{1,\ldots,k\} : \phi(x,\mu_{j,m},\Sigma_{j,m}) \le \epsilon_m \sum_{l=k+1}^{G} \pi_{l,m}\phi(x,\mu_{l,m},\Sigma_{l,m}) \right\},$$

where $\epsilon_m \searrow 0$ slowly enough that $P(A_m) \to 1$. Let $\pi_m^* = \sum_{j=1}^{k}\pi_{j,m}$. Let $\theta_{(G-k),m}$ for $m \in \mathbb{N}$ be defined by $\pi_{0,(G-k),m} = \pi_{0,m},\ \pi_{(j-k),(G-k),m} = \pi_{j,m}(1-\pi_{0,m})(1-\pi_m^*-\pi_{0,m})^{-1}$ for $j = k+1,\ldots,G$ accompanied by the μ_j,Σ_j-parameters belonging to the components $k+1,\ldots,G$ of θ_m. Observe, using Remark 8,

$$\begin{aligned} L(\theta_m) &= \int_{A_m} \log(\psi_\delta(x,\theta_m))dP(x) + \int_{A_m^c} \log(\psi_\delta(x,\theta_m))dP(x) \le \\ &\le \int_{A_m} \log((1+\epsilon_m)\psi_\delta(x,\theta_{(G-k)m}))dP(x) + P(A_m^c)\log(\delta+\phi_{max}) \end{aligned}$$

implying $L(\theta_{(G-k)m}) - L(\theta_m) \to 0$. $\mathrm{E}_P[\pi_{0,(G-k),m}\delta(\psi_\delta(x,\theta_{(G-k)m}))^{-1}] \le \pi_{\max}$ will be fulfilled for m large enough because it is fulfilled for θ_m by definition and $\psi_\delta(x,\theta_{(G-k),m}) > \psi_\delta(x,\theta_m)$ on A_m with $P(A_m) \to 1$. $L(\theta_{(G-k)m}) < L_{G-1}$ implies that, because of A2, θ_m is bounded away from L_G.

Regarding existence of a maximum with $\mu_1,\ldots,\mu_G \in K$, observe that with Remark 8, $\psi_\delta(x,\theta)$ can be bounded by $\delta+\phi_{max}$ for all θ for which $L(\theta) > L_G - \epsilon$. Now consider a sequence $(\theta_m)_{m\in\mathbb{N}}$ so that $\forall m:\ \mu_{1m},\ldots,\mu_{Gm} \in K$, with the notation of Lemma 7, $\lambda_{min}^* \le \lambda_{min}(\theta_m) \le \lambda_{max}(\theta_m) \le \lambda_{max}^*$ and $L(\theta_m) \to L_G$. Because of compactness, w.l.o.g., $\theta_m \to \theta_+$ and, using Fatou's Lemma, $L_G = \lim_{m\to\infty} L(\theta_m) \le E_P \limsup_m \psi_\delta(x,\theta_m) = L(\theta_+) \le L_G$.

Part (b) holds because if $(\theta_m)_{m\in\mathbb{N}}$ is chosen as above for $m = n \to \infty$ and P is replaced by the empirical distribution P_n, Glivenko-Cantelli enforces $P_n(A_n) - P(A_n) \to 0$ a.s. Glivenko-Cantelli applies here because a sequence of closed balls $(B_n)_{n\in\mathbb{N}}$ can be constructed so that $B_n \subseteq A_n,\ P(B_n) \to 1$ a.s.; the closed balls are a Vapnik-Chervonenkis class, and $P_n(A_n) \ge P_n(B_n) \to 1$ a.s. Furthermore, for $\theta \in \Theta_G(P)$ with $L(\theta) > L_{G-1}$: $l_n(\theta) \to L(\theta)$ a.s. by the strong law of large numbers, so that for large enough n: $\sup_{\theta\in\Theta_G(P)} l_n(\theta) > L_{G-1}$ a.s. On the other hand, $\theta_{(G-k),n}$ can be chosen optimally in a compact set K because of Lemma 7, within which l_n converges uniformly to L a.s. (Theorem 2 in Jennrich (1969)), and therefore, $\limsup_{n\to\infty} l_n(\theta_{(G-k),n}) \le L_{G-1}$. With these ingredients, the argument of part (a) carries over. ■

Lemma 10 *Assume A1 and A3. There is a compact set $K \subset \mathbb{R}^p$ so that*

(a) *L reaches its supremum for $\mu_1,\ldots,\mu_G \in K$,*

(b) *for $x_1,x_2,\ldots$ i.i.d. with $\mathcal{L}(x_1) = P$, there exists a sequence $(\tilde{\theta}_n)_{n\in\mathbb{N}}$ maximizing l_n locally for $\mu_1,\ldots,\mu_G \in K$ so that $l_n(\tilde{\theta}_n) \to L_G$ a.s., and a.s. there is no sequence $\theta_n \in \Theta_G(P)$ so that $\limsup_{n\to\infty} l_n(\theta_n) > L_G$.*

Proof Start with part (a). Consider a sequence $\{\theta_m\}_{m\in\mathbb{N}} \in \Theta_G(P)^{\mathbb{N}}$ with $\|\mu_{j,m}\| \to \infty$ for $j = 1,\ldots,k,\ 1 \le k < G$ (the case $k = G$ is treated at the end), and a compact set K with $\mu_{j,m} \in K$ for $j > k$. By selecting a subsequence if necessary, assume that there exists $\mu_j = \lim_{m\to\infty}\mu_{j,m}$, $\Sigma_j = \lim_{m\to\infty}\Sigma_{j,m}$ for $k+1 \le j \le G$ and that $\pi_{j,m}$ converge for $j = 0,\ldots,G$. Let $j^* = \arg\max_{k+1\le j\le G} \mathrm{E}_P\phi(x,\mu_j,\Sigma_j)$. Suppose $L(\theta_m) \nearrow L_G$ monotonically and, by A3, assume $\pi_{0,m} > \epsilon_1$.

Consider first the case $\sum_{j=1}^{k}\pi_{j,m} \to \epsilon_3 > 0$. Construct another sequence $\{\theta_{*m}\}_{m\in\mathbb{N}} \in \Theta_G(P)^{\mathbb{N}}$ for which $\mu_{1,*m} = \ldots = \mu_{k,*m} = \mu_{j^*} \in K$, $\Sigma_{1,*m} = \ldots = \Sigma_{k,*m} = \Sigma_{j^*}$. All other parameters are the same as in θ_m. Let $A_m = \{x:\ \forall j \in \{1,\ldots,k\} : 2\phi(x,\mu_{j,m},\Sigma_{j,m}) \le \phi(x,\mu_{j^*},\Sigma_{j^*})\}$. Observe $P(A_m) \to 1$. Now

$$L(\theta_{*m}) - L(\theta_m) = \int_{A_m} \log\frac{\psi_\delta(x,\theta_{*m})}{\psi_\delta(x,\theta_m)}dP(x) + \int_{A_m^c} \log\frac{\psi_\delta(x,\theta_{*m})}{\psi_\delta(x,\theta_m)}dP(x). \tag{14}$$

For large enough m,

$$\int_{A_m} \log\frac{\psi_\delta(x,\theta_{*m})}{\psi_\delta(x,\theta_m)}dP(x) \ge \epsilon_5 > 0,$$

whereas (using Remark 8)

$$\int_{A_m^c} \log\frac{\psi_\delta(x,\theta_{*m})}{\psi_\delta(x,\theta_m)}dP(x) \ge P(A_m^c)\log\frac{\epsilon_1\delta}{\delta+\phi_{\max}} \to 0. \tag{15}$$

Therefore $L(\theta_{*m}) - L(\theta_m) > 0$ for large enough m so that $L(\theta_m)$ is improved by a θ with $\mu_j \in K$ for $j = 1,2,\ldots,G$.

Consider now $\sum_{j=1}^{k}\pi_{jm} \to 0$. Construct another sequence $\{\theta_{*m}\}_{m\in\mathbb{N}} \in \Theta_G(P)^{\mathbb{N}}$ for which $\mu_{1,*m} = \ldots = \mu_{k,*m} = \mu_{j^*} \in K$, $\Sigma_{1,*m} = \ldots = \Sigma_{k,*m} = \Sigma_{j^*}$, $\pi_{1*m} = \ldots = \pi_{k*m} = 0$, $\pi_{0*m} = \sum_{j=0}^{k}\pi_{jm}$, all other parameters taken from θ_m. Set $A_m = \{x:\ \forall j \in \{1,\ldots,k\} : \phi(x,\mu_{jm},\Sigma_{jm}) < \delta\}$. Again $P(A_m) \to 1$. With this, (14) holds again. This time

$$\int_{A_m} \log\frac{\psi_\delta(x,\theta_{*m})}{\psi_\delta(x,\theta_m)}dP(x) > 0$$

and again (15).

Let $\theta_* = \lim_{m\to\infty}\theta_{*m}$ (this exists by construction). Continuity of L implies that $L(\theta_*) = L_G$ and therefore for all $m: L(\theta_*) \ge L(\theta_m)$. $\sum_{j=1}^{k}\pi_{j,m} \to 0$ is required here because $\pi_{0,*m} \ge \pi_{0,m}$ does not necessarily fulfill $\mathrm{E}_P\frac{\pi_{0,*m}c}{\psi_\delta(x,\theta_{*m})} \le \pi_{\max}$, but $\lim_{m\to\infty}\pi_{0,*m} = \lim_{m\to\infty}\pi_{0,m}$ does.

Finally, consider $k = G$. With $A_{m,\epsilon} = \{x:\ \forall j \in \{1,\ldots,k\} : \phi(x,\mu_{j,m},\Sigma_{j,m}) < \delta\epsilon\}$, observe

$$\mathrm{E}_P\frac{\pi_{0,m}\delta}{\psi_\delta(x,\theta_m)} \ge P(A_{m,\epsilon})\frac{\pi_{0,m}\delta}{\pi_{0,m}(c+\epsilon)} > \pi_{\max},$$

for small enough ϵ and large enough m, violating for large m the corresponding constraint in $\Theta_G(P)$ as long as $\pi_{0,m}$ is bounded from below, as was assumed. Existence follows in the same way as in the proof of Lemma 9.

For part (b) let θ^* have $\mu_1^*,\ldots,\mu_G^* \in K$ and $L(\theta^*) = L_G$, which exists because of part (a) and Lemma 7, which ensures further that θ^* is in a compact K^*. Then the strong law

of large numbers yields $l_n(\theta^*) \to L_G$ a.s., and Theorem 2 of Jennrich (1969) implies that for all sequences $(\theta_n)_{n\in\mathbb{N}} \in (K^*)^{\mathbb{N}} : \limsup_{n\to\infty} l_n(\theta_n) \leq L_G$. This also holds for sequences $(\theta_n)_{n\in\mathbb{N}}$ that are eventually outside K^* because of part (a) of Lemma 7 and the proof of part (a) above, because if $(\theta_m)_{m\in\mathbb{N}}$ is chosen as above for $m = n \to \infty$ and P is replaced by the empirical distribution P_n, Glivenko-Cantelli (which applies by the same argument as used in the proof of Lemma 9) enforces $P_n(A_n) - P(A_n) \to 0$ a.s., which means that as in part (a), a.s., eventually $l_n(\theta_n)$ cannot converge to anything larger than L_G. ■

Theorem 11 (RIMLE existence) *Assume A1 and any one of A2 or A3. There is a compact subset $K \subset \Theta_G(P)$ so that there exists $\theta \in K : \ \infty > L(\theta) = L_G > -\infty$. Assuming A2, for $\theta \notin K$, $L(\theta)$ is bounded away from L_G.*

Proof Pieced together from Lemmas 6-9 parts (a) and Remark 8. ■

Theorem 11 establishes existence of the RIMLE functional

$$\theta^\star(\delta) = \underset{\theta\in\Theta_G(P)}{\arg\max}\, L(\theta). \tag{16}$$

Unfortunately neither $L(\theta)$ nor $l_n(\theta)$ can be expected to have a unique maximum. If we take the vector θ and we permute some of the triples (π_j, μ_j, Σ_j) we still obtain the same value for $L(\theta)$ and $l_n(\theta)$. This known as "label switching" in the mixture literature. There could be other causes for multiple maxima. Without strong restrictions on P, we cannot identify any specific source of multiple optima in the target function. Instead we show that asymptotically the sequence of estimators is close to some maximum of the pseudo-loglikelihood, which amounts to consistency of the RIMLE with respect to a quotient space topology identifying all loglikelihood maxima, as done in Redner (1981). By $\theta^\star(\delta)$ in (16) we mean any of the maximizer of $L(\theta)$. Define the sets

$$S(\dot\theta) = \left\{\theta \in \Theta_G(P) : \int \log\psi_\delta(x;\theta)dP(x) = \int \log\psi_\delta(x;\dot\theta)dP(x)\right\},$$

$$\mathcal{K}(\dot\theta,\varepsilon) = \left\{\theta \in \Theta_G(P) : \|\theta - \ddot\theta\| < \varepsilon \ \forall\ \ddot\theta \in S(\dot\theta)\right\}, \quad \text{for any} \quad \varepsilon > 0.$$

The following theorem makes a stronger statement assuming A2 than A3, because if A2 does not hold, the Gth mixture component is asymptotically not needed and cannot be controlled for finite n outside a compact set.

Theorem 12 (Consistency) *Assume A1 and A2. Then for every $\varepsilon > 0$ and every sequence of maximizers $\theta_n(\delta)$ of l_n:*

$$\lim_{n\to\infty} P\left\{\theta_n(\delta) \in \mathcal{K}(\theta^\star(\delta),\varepsilon)\right\} = 1.$$

Assuming A3 instead of A2, for every compact $K \supset \mathcal{K}(\theta^\star(\delta),\varepsilon)$ there exists a sequence of θ_n that maximize l_n locally in K so that

$$\lim_{n\to\infty} P\left\{\theta_n \in \mathcal{K}(\theta^\star(\delta),\varepsilon)\right\} = 1.$$

Proof Under A2, because of the parts (b) of the Lemmas 7 and 9 it can be assumed that there is a compact set K so that all $\theta_n(\delta) \in K$ for large enough n a.s. Under A3, considerations are restricted to K anyway.

Based on Theorem 11 and related Lemmas $|\log\psi_\delta(x,\theta)| \leq C$ for some finite constant C for all $\theta \in K$. Sufficient conditions for Theorem 2 in Jennrich (1969) are satisfied, which implies uniform convergence of $l_n(\theta)$, that is $\sup_{\theta\in K}|l_n(\theta) - L(\theta)| \to 0$ P-a.s. Based on the latter, and applying the same argument as in proof of Theorem 5.7 in van der Vaart (2000), it holds true that $L(\theta_n(\delta)) \to L(\theta^\star(\delta))$ P-a.s. By continuity of $L(\theta)$ and Theorem 11 we have that for every $\varepsilon > 0$ there exists a $\beta > 0$ such that $L(\theta^\star(\delta)) - L(\theta) > \beta$ for all $\theta \in K \setminus \mathcal{K}(\theta^\star(\delta),\varepsilon)$. Denote $(\Omega, \mathcal{A}, P)$ the probability space where the sample random variables are defined and consider the following events

$$A_n = \{\omega \in \Omega : \ \theta_n(\delta) \in K \setminus \mathcal{K}(\theta^\star(\delta),\varepsilon)\},$$

and

$$B_n = \{\omega \in \Omega : \ L(\theta^\star(\delta)) - L(\theta_n(\delta)) > \beta\}.$$

Clearly $A_n \subseteq B_n$ for all n. $P(B_n) \to 0$ for $n \to \infty$ implies $P(A_n) \to 0$. The latter proves the result. ■

5. Algorithms and practical issues

Following the presentation of the proposed algorithm to compute the RIMLE, we discuss its initialization and tuning.

5.1 RIMLE computing

In this section we develop Expectation–Maximization type algorithms (EM) to compute the RIMLE (for a fixed δ). Let $s = 0, 1, \ldots$ be the iteration index. Let $a^{(s+1)}$ be the quantity a computed at the sth step of the EM algorithm. Define

$$\begin{aligned} Q(\theta,\theta^{(s)}) = &\sum_{i=1}^{n}\sum_{j=0}^{G}\tau_j(x_i,\theta^{(s)})\log\pi_j + \sum_{i=1}^{n}\tau_0(x_i,\theta^{(s)})\log\delta + \\ &+ \sum_{i=1}^{n}\sum_{j=1}^{G}\tau_j(x_i,\theta^{(s)})\log\phi(x_i;\mu_j,\Sigma_j). \end{aligned} \tag{17}$$

Increasing (17) by an appropriate choice of θ increases $l_n(\cdot)$. An approximate candidate maximum of $l_n(\theta)$ can be found by the EM Algorithm 1.

Proposition 13 *Assume A0. The sequence $\{\theta^{(s)}\}_{s\in\mathbb{N}}$ produced by Algorithm 1 converges to a point $\theta_n^{em} \in \Theta$, and $l_n(\theta^{(s)})$ is increased in every step.*

Proof Find a set $A_n \subset \mathbb{R}^p$ that contains all points in $\underline{x_n}$ with Lebesgue measure $M(A_n) = 1/\delta$. δ is then a proper uniform density function on A_n. Hence, for a given dataset the pseudo-density $\psi_\delta(\cdot)$ can be written as proper density function. Therefore the convergence

  E–step: compute $\tau_j(x_i, \theta^{(s)})$, for all $i = 1, 2, \ldots, n$ and $j = 0, 1, \ldots, G$
  M–step: $\theta^{(s+1)} \leftarrow \arg\max_{\theta\in\Theta} Q(\theta, \theta^{(s)})$
end
$\theta^{\text{em}} \leftarrow \theta^{(s+1)}$

Theorem 4.1 in Redner and Walker (1984) holds, with $Q(\theta, \theta^{(s)})$ playing the role of their $Q(\cdot)$ function. ■

Algorithm 1 is the analog of the EM algorithm for plain Gaussian mixtures (see Redner and Walker, 1984) except that now the M-step is a constrained optimization. Wu (1983) showed that the EM algorithm converges to the global maximum if the likelihood function is unimodal and certain differentiability conditions are satisfied. In general the limit of the EM algorithm is not guaranteed to coincide with a global maximum of likelihood function. However, Proposition 13 guarantees that θ_n^{em} is a stationary point of $l_n(\cdot)$. Running the EM algorithm for a large number of starting values increases the chances of finding the optimal solution. For finite Gaussian mixtures models it is well known that the likelihood surface is difficult to explore even when p is not too large, and the main advantage of the EM algorithm is that the M-step can be divided in a number of simpler optimization problems each of which has a closed form solution. However, for the RIMLE the constraints add some complexity, and in particular the noise proportion constraint does not allow to separate the M-step in simpler subprograms. One possibility is to perform the M-step using numerical optimization packages, but the eigenratio constraints requires to parameterize each Σ_j terms of its spectral components. The latter has the drawback to add $G{\times}p(1-p)/2$ parameters. Furthermore, the eigenratio constraint has a non-smooth nature that would make numerical techniques hard to adapt.

In Coretto and Hennig (2016) computations are based on Algorithm 1 where the M-step is performed as if the problem would be unconstrained, and breaking the iteration when updates drive the parameters outside the constrained parameter space. Coretto and Hennig (2016) also propose a heuristic method to enforce the constraints at the end of the iterations if necessary. Of course in such situations there would be no guarantee that the delivered solution is a stationary point of $l_n(\cdot)$. Here, we propose Algorithm 2 where constraints are applied exactly in each iteration. The M-step in Algorithm 1 is replaced with two conditional maximization (CM) steps. This transforms Algorithm 1 into an Expectation-Conditional Maximization algorithm (ECM) as introduced by Meng and Rubin (1993). For ease of notation, for $j = 0, 1, \ldots, G$ define $\tau_{i,j}^{(s)} = \tau_j(x_i, \theta^{(s)})$ and $T_j^{(s)} = \sum_{i=1}^n \tau_j(x_i, \theta^{(s)})$. Rewrite (17), using $\theta_1 = (\mu_1, \ldots, \mu_G, \text{vect}(\Sigma_1), \ldots, \text{vect}(\Sigma_G))$, $\theta_2 = (\pi_0, \pi_1, \ldots, \pi_G)'$, and $\theta = (\theta_1, \theta_2)'$, as

$$Q(\theta_1, \theta_2, \theta^{(s)}) = Q_1(\theta_1, \theta^{(s)}) + Q_2(\theta_2, \theta^{(s)}) + \text{const}, \tag{18}$$

where

$$Q_1(\theta_1, \theta^{(s)}) = \sum_{i=1}^n \sum_{j=1}^G \tau_{i,j}^{(s)} \log \phi(x_i; \mu_j, \Sigma_j), \quad Q_2(\theta_2, \theta^{(s)}) = \sum_{j=0}^G T_j^{(s)} \log \pi_j,$$

and const $= T_0^{(s)} \log(\delta)$ which does not depend on θ. Consider the following programs:

$$\underset{\theta_1}{\text{maximize}}\, Q_1(\theta_1, \theta^{(s)}) \quad \text{subject to} \quad \frac{\lambda_{\max}(\theta_1)}{\lambda_{\min}(\theta_1)} \leq \gamma, \tag{CM1}$$

and

$$\underset{\theta_2}{\text{maximize}}\, Q_2(\theta_2, \theta^{(s)}) \quad \text{subject to} \quad \sum_{j=0}^G \pi_j = 1,\ \sum_{i=1}^n \tau_0(x_i, \theta_1^{(s+1)}, \theta_2) \leq n\pi_{\max}. \tag{CM2}$$

The ECM algorithm consists of solving (**CM1**) and then (**CM2**). The sequence of optimizations replaces the M-step in Algorithm 1. Notice that in (**CM2**), $\pi_j = 0$ for some $j = 0, 1, \ldots, G$ would drive the objective function toward $-\infty$, so we do not need to restrict the π_j as > 0. $T_j^{(s)} = 0$ will not happen, see Remark 17. Also notice that for δ=0 the noise proportion constraint is automatically fulfilled, and for more analysis on these cases see Remark 17.

Before presenting the ECM Algorithm 2 we introduce additional notations. For $a \in R^d$ let diag(a) be the $d{\times}d$ diagonal matrix with elements of a on the main diagonal. For a matrix A let $\text{Spec}(A) = \Gamma\Lambda\Gamma'$ be the spectral decomposition of A, that is, Γ contains the normalized eigenvectors of A corresponding to the eigenvalues contained in the diagonal matrix Λ. Moreover for $a, m \in \mathbb{R}$ define the shrinkage operator $\ell_\gamma(a, m) = \min\{\max\{m, a\}, \gamma m\}$.
In each step of Algorithm 2 closed form expressions are computed except that for computing m_* in (CM1), and ω_* in (CM2). m_* is the solution of a one-dimensional convex problem. The resulting updates for the eigenvalues almost coincide with those of TCLUST. For TCLUST, Fritz et al. (2013) show that their analogue of m_* can be computed by $2pG + 1$ evaluations of the objective function. A similar result may hold here, however we do not consider it because in numerical experiments we found that the simple golden section search algorithm of Kiefer (1953) requires on average few objective function evaluations independently of p and G. Computation of ω_* can be performed by a one-dimensional root finder algorithm. Both are simple problems that do not require much computational effort.

Some additional results are given to show how the CM1–step and the CM2–step solve (**CM1**) and (**CM2**) respectively.

Lemma 14 *Assume Algorithm 2 has been run for s iterations. The vector $\theta_1^{(s+1)} = (\mu_1^{(s+1)}, \ldots, \mu_G^{(s+1)}, \text{vect}(\Sigma_1^{(s+1)}), \ldots, \text{vect}(\Sigma_G^{(s+1)}))'$ computed in the CM1–step is the global optimal solution to* (**CM1**). *Moreover, m_* exists and it is unique.*

Proof Based on standard normal likelihood theory, one can see that the unique maximum of $Q_1(\theta_1, \theta^{(s)})$ with respect to mean parameters is $\mu_j^{(s+1)}$ for all $j = 1, 2, \ldots, G$. Substituting $\mu_j^{(s+1)}$ into $Q_1(\cdot)$, and rearranging the exponent of the Gaussian density by using the cyclic

$$\pi_0^{(s+1)} \leftarrow \quad \omega_*$$

$$\pi_j^{(s+1)} \leftarrow \quad \frac{1-\omega_*}{n - T_0^{(s)}} T_j^{(s)}$$

end

end

$$\theta^{\text{ecm}} \leftarrow \theta^{(s+1)}$$

property of the matrix trace (see Anderson and Olkin, 1985), program (**CM1**) is completed by choosing $\Sigma_1, \ldots, \Sigma_G$ maximizing

$$Q_1(\dot{\theta}_1, \theta^{(s)}) = \text{const} - \frac{1}{2} \sum_{j=1}^{G} T_j^{(s)} \left(\operatorname{tr}(\Sigma_j^{-1} S_j^{(s+1)}) - \log\det(\Sigma_j^{-1}) \right) \tag{19}$$

under the eigenratio constraint, where $\dot{\theta}_1 = (\mu_1^{(s+1)}, \ldots, \mu_j^{(s+1)}, \operatorname{vect}(\Sigma_1), \ldots, \operatorname{vect}(\Sigma_G))$. Consider the spectral decompositions

$$\operatorname{Spec}(\Sigma_j) = \Gamma_j \Lambda_j \Gamma_j', \quad \text{and} \quad \operatorname{Spec}(S_j^{(s+1)}) = V_j^{(s+1)} E_j V_j^{(s+1)\prime},$$

where $\Lambda_j = \operatorname{diag}(\lambda_{j,1}, \ldots, \lambda_{j,p})$ and $E_j = \operatorname{diag}(e_{j,1}, \ldots, e_{j,p})$. Theorem 1 and Corollary 1 in Theobald (1975) imply that

$$\operatorname{tr}\left(\Lambda_j^{-1} E_j\right) - \log\det(\Lambda_j^{-1}) \leq \operatorname{tr}\left(\Sigma_j^{-1} S_j^{(s+1)}\right) - \log\det(\Sigma_j^{-1}), \tag{20}$$

with the previous holding with equality if and only if $\Gamma_j = V_j^{(s+1)}$. Therefore, $\Sigma_j^{(s+1)} = V_j^{(s+1)} \Lambda_j V_j^{(s+1)\prime}$ is plugged into (19), and (**CM1**) reduces to

$$\begin{aligned} &\underset{\lambda_{1,1},\ldots,\lambda_{G,p}}{\text{minimize}} \quad \sum_{j=1}^{G} T_j^{(s)} \sum_{k=1}^{p} \left(\log(\lambda_{j,k}) + \frac{e_{j,k}}{\lambda_{j,k}} \right), \\ &\text{subject to} \quad 0 < m \leq \lambda_{j,1}, \ldots, \leq \lambda_{j,p} \leq m\gamma \quad \forall j = 1, 2, \ldots, G. \end{aligned} \tag{21}$$

Program (21) is separable in the optimization variables, and therefore the summands of (21) can be minimized separately for a given m. Fix $m > 0$, then $\ell_\gamma(e_{j,k}, m)$ is the unique optimal solution to the minimization of $\log(\lambda_{j,k}) + e_{j,k}\, \lambda_{j,k}^{-1}$. Notice that $e_{j,k} \leq e_{j,t} \Longrightarrow \ell_\gamma(e_{j,k}, m) \leq \ell_\gamma(e_{j,t}, m)$ for any $m > 0$ and $t = 1, 2 \ldots, p$. This means that the relative ordering of the elements on the diagonal of E_j remains unchanged after having applied the shrinkage operator $\ell(\cdot)$. Replace $\lambda_{j,k}$ with $\ell_\gamma(e_{j,k}, m)$ and (21) is transformed into

$$\begin{aligned} &\underset{m}{\text{minimize}} \quad \sum_{j=1}^{G} T_j^{(s)} \sum_{k=1}^{p} \left(\log(\ell_\gamma(e_{j,k}, m)) + \frac{e_{j,k}}{\ell_\gamma(e_{j,k}, m)} \right), \\ &\text{subject to} \quad m > 0 \end{aligned} \tag{22}$$

(22) is now a convex program in m. Therefore (**CM1**) is solved by the unique m_* that solves (22). This implies that the CM1–step is solved by taking $\Sigma_j^{(s+1)} = V_j^{(s+1)} E_j^* V_j^{(s+1)\prime}$ where $E_j^* = \operatorname{diag}(\ell_\gamma(e_{j,1}, m_*), \ldots, \ell_\gamma(e_{j,p}, m_*))$. Notice that uniqueness of m_* implies the uniqueness of the solution to **CM1**. Observe that when the eigenvalues of $S_1^{(s+1)}, \ldots, S_G^{(s+1)}$ fulfill the eigenratio constraint, then $E_j^* = E_j$ and $\Sigma_j^{(s+1)} = S_j^{(s+1)}$ for all $j = 1, \ldots, G$. The latter completes the proof. (The result is connected to Lemma 1 in Won et al. (2013), by which the last part of the proof is inspired.)

■

Based on the previous Lemma, the constrained eigenvalues can be found by simply solving a convex one-dimensional problem. The optimal choice of the covariances is a form of Steinian-type nonlinear shrinkage (see Gavish and Donoho, 2017).

Lemma 15 *Assume Algorithm 2 has been run for s iterations. The vector* $\theta_2^{(s+1)} = (\pi_0^{(s+1)}, \ldots, \pi_G^{(s+1)})'$ *computed in the CM2–step is the global optimal solution to* (**CM2**)*. Moreover,* ω_* *exists and it is unique.*

Proof The objective function in (**CM2**) is strictly concave and the equality constraint is linear. Take $\theta_2', \theta_2'' \in \{\theta_2 : \ \pi_0 + \ldots, +\pi_G = 1, \ \pi_j \in [0,1] \ \forall j = 0, 1, \ldots, G\}$, if $\pi_0' \leq \pi_0''$ then $\tau_0(\cdot, \cdot, \theta_2') \leq \tau_0(\cdot, \cdot, \theta_2'')$. Therefore, for $\beta \in (0,1)$

$$\sum_{i=1}^{n} \tau_0(x_i, \theta_1^{(s+1)}, \ \beta\theta_2' + (1-\beta)\theta_2'') \leq \max\left\{\sum_{i=1}^{n} \tau_0(x_i, \theta_1^{(s+1)}, \theta_2'), \sum_{i=1}^{n} \tau_0(x_i, \theta_1^{(s+1)}, \theta_2'')\right\},$$

which implies that $\sum_{i=1}^{n} \tau_0(x_i, \theta_1^{(s+1)}, \theta_2)$ is quasiconvex in the optimization variable θ_2. It is concluded that Karush–Kuhn–Tucker (KKT) conditions are necessary for a global optimal solution (see Bertsekas, 1999). Such a solution will be a stationary point of the Langrangean function

$$H(\theta_2, h_1, h_2) \coloneqq Q_2(\theta_2, \theta^{(s)}) + h_1\left(1 - \sum_{j=0}^{G} \pi_j\right) + h_2\left(n\pi_{\max} - \sum_{i=1}^{n} \tau_0(x_i, \theta_1^{(s+1)}, \theta_2)\right),$$

where h_1 and h_2 are the dual variables. Let ∇_j denote derivatives with respect to the j component of θ_2. Let $\theta_2^\star$ the optimal solution, then based on KKT conditions there exists $h_1^\star, h_2^\star$ such that the following hold

$$\nabla_j Q_2(\theta_2^\star, \theta^{(s)}) - h_1^\star - h_2^\star \nabla_j \sum_{i=1}^{n} \tau_0(x_i, \theta_1^{(s+1)}, \theta_2^\star) = 0 \qquad \text{for all} \quad j = 0, 1, \ldots, G, \tag{23}$$

$$h_2^\star\left(\sum_{i=1}^{n} \tau_0(x_i, \theta_1^{(s+1)}, \theta_2^\star) - n\pi_{\max}\right) = 0, \quad h_2^\star \geq 0. \tag{24}$$

First consider the case when the noise proportion constraint does not bind, that is $h_2^\star = 0$. Than (23) becomes $T_j^{(s)}/\pi_j^\star - h_1^\star = 0$ for all $j = 0, 1, \ldots, G$. Solving the latter for $\pi_j^\star$, using the equality constraints and that $\sum_{j=0}^{G} T_j^{(s)} = n$, it results that $h_1^\star = n$ and $\pi_j^\star = T_j^{(s)}/n$ for all $j = 0, 1, \ldots, G$.
Now assume that the noise proportion constraints binds, hence $h_2^\star > 0$. Let $\pi_0^\star = \omega$ and rewrite the equality constraint as $\pi_1^\star +, \ldots, +\pi_G^\star = 1 - \omega$. Stationary points of $H(\cdot)$ satisfy $T_j^{(s)}/\pi_j^\star - h_1^\star = 0$. Solving the latter for $\pi_j^\star$ and using the equality constraints it results that $h_1^\star = \sum_{j=1}^{G} T_j^{(s)}/(1-\omega)$. Since $\sum_{j=1}^{G} T_j^{(s)} = n - T_0^{(s)}$, then

$$\pi_j^\star = \frac{1-\omega}{n - T_0^{(s)}} T_j^{(s)} \quad \text{for all} \quad j = 1, 2, \ldots, G.$$

Now the solution for $j = 1, 2, \ldots, G$ is a function of ω, which can be determined by using the fact that the inequality constraints binds. Define

$$g(\omega) = \left(\sum_{i=1}^{n} \frac{\omega\delta}{\omega\delta + \frac{1-\omega}{n-T_0^{(s)}} \sum_{j=1}^{G} T_j^{(s)} \phi(x_i; \mu_j^{(s+1)}, \Sigma_j^{(s+1)})}\right) - n\pi_{\max}.$$

$g(\omega)$ is bracketed on the interval $[0,1]$, in fact $g(0) = -n\pi_{\max} < 0$ and $g(1) = n(1-\pi_{\max}) > 0$. Moreover $g(\omega)$ is continuous, and it can be easily verified that it's derivative is continuous and positive at any $\omega \in (0,1)$. This implies that there exists a unique ω_* such that $g(\omega_*) = 0$. Setting $\pi_0^\star = \omega_*$ and replacing ω_* into $\pi_j^\star$ gives the optimal solution. We now compare the two solutions in terms of objective function, and we show that there is hierarchy between them. Define

$$\dot{\theta}_2 = \left(\frac{T_0^{(s)}}{n}, \frac{T_1^{(s)}}{n}, \ldots, \frac{T_1^{(s)}}{n}\right)', \qquad \ddot{\theta}_2 = \left(\omega_*, \frac{1-\omega_*}{n-T_0^{(s)}} T_1^{(s)}, \ldots, \frac{1-\omega_*}{n-T_0^{(s)}} T_G^{(s)}\right)'.$$

Using Wald's information inequality it can be shown that

$$\frac{T_0^{(s)}}{n} \log(\omega_*) + \sum_{j=1}^{G} \frac{T_j^{(s)}}{n} \log\left(\frac{1-\omega_*}{n-T_0^{(s)}} T_j^{(s)}\right) \ \leq \ \sum_{j=0}^{G} \frac{T_j^{(s)}}{n} \log\left(\frac{T_j^{(s)}}{n}\right),$$

with the previous holding with equality if and only if $\omega_* = T_0^{(s)}/n$. The latter implies that $Q_2(\ddot{\theta}_2, \theta^{(s)}) < Q_2(\dot{\theta}_2, \theta^{(s)})$ whenever $\ddot{\theta}_2 \neq \dot{\theta}_2$. Hence $\dot{\theta}_2$ is the global optimal solution whenever it is feasible, otherwise the global optimal solution is $\ddot{\theta}_2$. The latter proves that the updating in CM2-step selects the global optimal solution to (**CM2**). ■

Theorem 16 *Assume A0. The* $\{\theta^{(s)}\} s \in \mathbb{N}$ *produced by Algorithm 2 converges to a point* $\theta_n^{ecm} \in \Theta$*, and* $l_n(\theta^{(s)})$ *is increased in every step.*

Proof As consequence of Lemma 14 and 15, $Q(\theta, \theta^{(s)})$ is never decreased, in fact for all $s = 0, 1, \ldots$

$$Q(\theta_1^{(s+1)}, \theta_2^{(s+1)}, \theta^{(s)}) \geq Q(\theta_1^{(s+1)}, \theta_2^{(s)}, \theta^{(s)}) \geq Q(\theta_1^{(s)}, \theta_2^{(s)}, \theta^{(s)}),$$

A0 ensures existence of $\theta_n(\delta)$, and the convergence Theorem 4.1 in Redner and Walker (1984) holds with $Q(\theta, \theta^{(s)})$ playing the role of their $Q(\cdot)$ function. ■

Remark 17 *The eigenratio constraint together with the noise proportion constraint rule out the possibility that at some point along the iteration* $T_j^{(s)} = 0$ *for some* $j = 1, 2, \ldots, G$ *and updates in CM1-step are guaranteed to exist. In fact* $T_j^{(s)} = 0$ *means that according to* $\theta^{(s-1)}$ *none of points contributes to the* j*th Gaussian component. In theory this can only happen if the* j*th component has an infinite dispersion according to* $\theta^{(s-1)}$*. However, in*

that case the eigenratio constraint would force all eigenvalues in $\theta^{(s-1)}$ to diverge to $+\infty$ at the same rate so that $T_j^{(s)} \searrow 0$ for all $j = 1, 2, \ldots, G$, which is not possible because of the noise proportion constraint. Although in theory an appropriate choice of $\theta^{(0)} \in \Theta$ should not produce such a degeneracy, it may well be that in practice this is caused because of limited numerical resolution. Notice also that for δ=0 the noise proportion constraint is automatically fulfilled, and this would take the problem back to the EM algorithm for the MLE of a finite Gaussian mixture model with the additional eigenratio constraint. Therefore Algorithm 2 would become the EM Algorithm 1 where the M-step would coincide with CM1-step of Algorithm 2 plus the usual updating for the proportion parameters: $\pi_j^{(s+1)} \leftarrow T_j^{(s)}/n$ for all $j = 0, 1, \ldots, G$.

Remark 18 *There are substantial differences between Algorithm 2 and the one proposed in Coretto and Hennig (2016). Algorithm 2 implements the constraints of the RIMLE exactly and it is shown to converge under mild conditions on the data set. The algorithm presented in Coretto and Hennig (2016) handles the constraint heuristically as follows: (i) if the EM iteration converges, the eigenratio constraint is checked at the end of the iteration, and it is enforced simply increasing the eigenvalues smaller than $\lambda_{\max}(\theta)/\gamma$; (ii) if at some point along the EM iteration the estimated π_0 hits $\pi_{\max}$, the iteration is stopped and the solution discarded. Of course, this approximate algorithm is on average faster than Algorithm 2 for low values of γ and $\pi_{\max}$. In fact, in such a situation it is likely that Algorithm 2 needs to go through the additional computation of m_* and ω_* for most of the iterations. In order to give an idea to the reader, we estimated the relative speed for the AsyNoise data presented in Section 2 with $\gamma = 1, \pi_{\max} = 1\%$, and we found that on average the algorithm of Coretto and Hennig (2016) runs ten times faster. However, setting $\gamma = 100, \pi_{\max} = 50\%$ the difference becomes negligible. Furthermore, for low settings of $\pi_{\max}$ the algorithm of Coretto and Hennig (2016) is likely to record premature stops not leading to a solution (this happened in the previous experiment with $\pi_{\max} = 1\%$).*

5.2 Choice of initial values and input parameters

Algorithms 1 and 2 require the initial value $\theta^{(0)}$, and the input parameters $\pi_{\max}, \gamma$ and δ. The initial value $\theta^{(0)}$ can be set by randomly assigning points to G clusters and then computing cluster parameters. Initialization like this needs to be performed a number of times so that the solution with the largest pseudo-likelihood is selected. Implementation of the RIMLE given in the otrimle software of Coretto and Hennig (2017) relies on a more refined initialization strategy which consist in the following steps.

Initial denoising: for each data point compute its kth-nearest neighbors distance (k-NND), for some k. All points with k-NND larger than the $(1 - \pi_{\max})$-quantile of the k-NND are initialized as noise. The interpretation of k is that $(k-1)$, but not k, points close together may still be interpreted as noise/outliers, whereas k such points would constitute a cluster. The default value in the otrimle package is $k = 3$.

Initial clusters: agglomerative hierarchical clustering based on ML criteria for Gaussian mixture models as in Fraley (1998) is performed on the remaining $\lfloor n(1 - \pi_{\max}) \rfloor$ regular points to find the initial clusters. The sample mean and covariance matrix of points belonging to each cluster are computed to define $\theta^{(0)}$. This step is performed based on the `hc()` function from the mclust package.

The constraint defining quantities $\pi_{\max}$ and γ are regularization parameters that allow solving an otherwise ill-posed optimization problem. $\pi_{\max}$ also controls robustness because it specifies the maximum proportion of points assignable to the noise component. In order to be as robust as possible $\pi_{\max} = 1/2$ is a convenient choice that guarantees maximum protection. This implements a familiar condition in robust statistics that at most half of the data should be classified as "outliers/noise". A choice of $\pi_{\max}$ lower than the actual noise/outlier proportion will enforce some outliers to be assigned to clusters with potentially problematic implications. Hence, unless one has prior knowledge about the contamination process, we suggested to stick to $\pi_{\max} = 1/2$.

The role of the eigenratio can be twofold. If γ is set to a low-value, strong restrictions on clusters' shape are imposed. In this respect, the eigenratio constraint acts as a model selector. Unless one knows precisely the implications of a low choice of γ, it is suggested to use the eigenratio constraint as a regularization parameter. In fact, a large value of γ will regularize the covariance matrices without affecting clusters' shape too much. For example, a large γ would allow discovering an elongated concentrated cluster along with clusters having widespread spherical scatters. Ritter (2014) contains an in-depth analysis of constraints in model-based clustering. In Section 7 we present Monte Carlo experiments where the effect of different γ values is investigated.

Although through the presence of the product $\pi_0\delta$ in (1) the parameters π_0 and δ may seem confounded, they actually play a very different role in the RIMLE. δ is not treated as a model parameter to be estimated, but rather as a tuning device to enable a good robust clustering. The interpretation is that δ is the density value below which groups of observations should rather be treated as "noise" than as "cluster". This means that a larger value of δ will normally yield a larger estimate of π_0 because more observations will be classified as noise, as opposed to the intuition suggested by having the product $\pi_0\delta$ in (1). Whether small groups of observations of a certain size and with a certain density peak should rather count as "cluster" or rather as "group of outliers" cannot be identified from the data alone, but is rather a matter of interpretation. RIMLE may be sensitive to the choice of δ, and a good choice of δ is therefore important in practice. For instance, in the example of Figure 2 it has been shown that outside a certain interval of δ values the RIMLE does not perform well. Occasionally, subject matter knowledge may be available aiding the choice of a fixed value of δ, but often such knowledge may not exist. The OTRIMLE, a data dependent method ("optimally tuned RIMLE") to choose δ is presented in Coretto and Hennig (2016). The basic idea is to find a δ that optimizes a weighted Kolmogorov-type distance measure between the Mahalanobis distances of all objects to their corresponding cluster centers and the χ^2-distribution, which the Mahalanobis distances should follow if the clusters were indeed Gaussian. The current implementation of the OTRIMLE in the otrimle package selects the best RIMLE solution computed with algorithm 2 on a selected grid of 50 values of $\log(\delta)$. The default grid includes $\log(\delta) = -\infty$ so that a pure Gaussian mixture is always included in the competition (see the otrimle manual for more details).

6. Breakdown robustness of the RIMLE

Although robustness results for some clustering methods can be found in the literature, robustness theory in cluster analysis remains a tricky issue. Some work exists on breakdown points (García-Escudero and Gordaliza, 1999; Hennig, 2004; Gallegos and Ritter, 2005), addressing whether parameters can diverge to infinity (or zero, for covariance eigenvalues and mixture proportions) under small modifications of the data. An addition breakdown point of $r/(n+r)$ means that r, but not $r-1$, points can be added to a data set of size n so that at least one of the parameters "breaks down" in the above sense.

It is well known (García-Escudero and Gordaliza, 1999; Hennig, 2008), assuming the fitted number of clusters to be fixed, that robustness in cluster analysis has to be data dependent, for the following reasons:

- If there are two not well separated clusters in the data set, a very small amount of "contamination" can merge them, freeing up a cluster to fit outliers converging to infinity.
- Very small clusters cannot be robust because a group of outlying points can legitimately be seen as a "cluster" and will compete for fit with non-outlying clusters of the same size. Noise component-based and trimming methods are prone to trimming whole clusters if they are small enough.

Therefore, all nontrivial breakdown results (i.e., with breakdown point larger than the minimum $1/(n+1)$) in clustering require a condition that makes sure that the clusters in the data set are strongly clustered in some sense, which usually means that the clusters are homogeneous and strongly separated.

The theory for the RIMLE given here generalizes the argument given in Hennig (2004), Theorem 4.11, to the multivariate setup. We consider fixed datasets $\underline{x_n} = (x_1, x_2, \ldots, x_n)$ and sequences of estimators $(E_n)_{n\in\mathbb{N}}$ mapping observations from $(\mathbb{R}^p)^n$ to Θ. Denote the components of $E_n(\underline{x_n})$ by
$(\pi_{En0}, \pi_{En1}, \ldots, \pi_{EnG}, \mu_{En1}, \ldots, \mu_{EnG}, \Sigma_{En1}, \ldots, \Sigma_{EnG})$, G being the number of mixture components as usually.

The following assumption in the definition of the breakdown point makes sure that $E_n(\underline{x_n})$ indeed parametrizes G different mixture components; if there was a mixture component with proportion zero or two equal ones, one mixture component would be free to be driven to breakdown.

A4 For $j = 1, \ldots, G : \pi_{Enj} > 0$, and all $(\mu_{Enj}, \Sigma_{Enj})$ are pairwise different.

Definition 19 *Assume that $(E_n)_{n\in\mathbb{N}}$ and $\underline{x_n}$ fulfil A4. Then,*

$$
\begin{aligned}
B(E_n, \underline{x_n}) \;=\; & \min_r \left\{ \frac{r}{n+r} : \; \exists 1 \le j \le G \right. \\
& \forall D = [\pi_{min}, 1] \times C \text{ for which } \pi_{min} > 0, C \subset \mathbb{R}^p \times \mathcal{S}_p \text{ compact} \\
& \exists \underline{x_{n+r}} = (x_1, x_2, \ldots, x_n, x_{n+1}, \ldots x_{n+r}) \text{ so that for} \\
& \left. E_{n+g}(\underline{x_{n+g}}) : \; (\pi_{E(n+g)j}, \mu_{E(n+g)j}, \Sigma_{E(n+g)j}) \notin D \right\},
\end{aligned}
$$

where $\mathcal{S}_p$ is the set of all positive definite real valued $p\times p$-matrices, is called the **breakdown point** *of E_n at dataset $\underline{x_n}$.*

Denote the sequence of RIMLE estimators defined in (3) as $(\theta_{mH})_{m\in\mathbb{N}}$, write $l_{mH}(\underline{x_m}, \theta)$ for $l_m(\theta)$ with any $m \in \mathbb{N}$ and number of components H in (2), $l^o_{mH} = l_{mH}(\underline{x_m}, \theta_{mH}(\underline{x_m}))$. Let $\theta^* = \theta_{nG}(\underline{x_n})$ for the specific $\underline{x_n}$ and G considered here. Components of θ^* and later θ^+ are denoted with upper index "$*$" and "$+$", respectively. For $j = 1, \ldots, G$, let $\phi^*_j(x) = \phi(x, \mu^*_j, \Sigma^*_j)$, same with upper index "$+$". Assume $\delta > 0$ fixed throughout this section. We start with a straightforward extension of Lemma 3.

Lemma 20 *Assume A0 for $\underline{x_n}$. If $(\theta_m)_{m\in N}$ is any sequence in Θ so that for some $j = 1, 2, \ldots, G$ and $k = 1, 2, \ldots, p$, $\lambda_{k,j,m} \searrow 0$ as $m \to \infty$. For $\underline{x_{n+r}} = (x_1, x_2, \ldots, x_n, x_{n+1}, \ldots x_{n+r})$: $\sup_{(x_{n+1},\ldots,x_{n+r})\in(\mathbb{R}^p)^r} l_{(n+r)G}(\underline{x_{n+r}}, \theta_m) \to -\infty$.*

Proof The proof of Lemma 3 still applies because adding further observations only adds further positive terms to the sum in (13). ■

Corollary 21 *Assume that $\underline{x_n}$ is a fixed dataset fulfilling A0 and A4 for $E_n = \theta_{nG}$. Then there is a $\lambda_0 > 0$ bounding from below all λ_{min} for $\theta = \theta_{(n+r)G}(\underline{x_{n+r}})$ where $\underline{x_{n+r}} = (x_1, x_2, \ldots, x_n, x_{n+1}, \ldots x_{n+r})$ for any $(x_{n+1}, \ldots, x_{n+r}) \in (\mathbb{R}^p)^r$. Consequently $\phi_{max} = (2\pi)^{-\frac{p}{2}}\lambda_0^{-\frac{p}{2}}$ is an upper bound for all $\phi(x; \mu, \Sigma)$ with (μ, Σ) occurring as component parameters in any such θ.*

Proof Observe

$$
l_{(n+r)G}(\underline{x_{n+r}}, \theta^*) \ge \frac{1}{n+r}\left(\sum_{i=1}^{n} \log \psi_\delta(x_i, \theta^*) + r \log(\pi^*_0 \delta)\right) > -\infty. \tag{25}
$$

If the Corollary was wrong, it would be possible to construct a sequence $(\theta_m)_{m\in N}$ with $\lambda_{k,j,m} \searrow 0$ for some $j = 1, 2, \ldots, G$ and $k = 1, 2, \ldots, p$ so that each $\theta_m = \theta_{(n+r)G}(\underline{x_{n+r}})$ for an admissible $\underline{x_{n+r}}$. But (25) implies that there is a lower bound for $l_{(n+r)G}(\underline{x_{n+r}}, \theta_m)$, contradicting Lemma 20. ■

The following theorem gives conditions under which the RIMLE estimator is breakdown robust against adding r observation to $\underline{x_n}$. (26) states that the dataset needs to be fitted by G Gaussian components considerably better than by $G-1$ components, because otherwise the remaining mixture component would be available for fitting the added observations without doing much damage to the original fit. (27) makes sure that the noise proportion in $\underline{x_n}$ is low enough that the added observations can still be fitted by the noise component without exceeding π_{max}.

Theorem 22 *Assume that $\underline{x_n}$ fulfils A0 and A4 for $E_n = \theta_{nG}$. If*

$$
\begin{aligned}
l^o_{n(G-1)} \;<\; & \sum_{i=1}^{n} \log\left(\sum_{j=1}^{G} \pi^*_j \phi^*_j(x_i) + \left(\pi^*_0 + \frac{r}{n}\right)\delta\right) + \\
& r \log\left(\left(\pi^*_0 + \frac{r}{n}\right)\delta\right) + (n+r)\log\frac{n}{n+r} - r\log\phi_{max},
\end{aligned} \tag{26}
$$

ϕ_{max} defined in Corollary 21, and

$$\frac{1}{n+r}\left(\sum_{i=1}^{n}\frac{(n\pi_0^*+r)\delta}{(n+r)\psi_\delta(x_i,\theta^*)}+r\right)<\pi_{max}, \tag{27}$$

then $B(\theta_{nG},\underline{x_n})>\frac{r}{n+r}$.

Proof For $\underline{x_{n+r}}=(x_1,\dots x_{n+r})$, let $\theta^+=\theta_{(n+r)G}(\underline{x_{n+r}})$. Let $H<G$. Then,

$$l^o_{(n+r)G}\leq\sum_{i=1}^{n}\log\left(\sum_{j=1}^{H}\pi_j^+\phi_j^+(x_i)+\sum_{j=H+1}^{G}\pi_j^+\phi_j^+(x_i)+\pi_0^+\delta\right)+r\log\phi_{max}.$$

Assume w.l.o.g. that the parameter estimators of the mixture components $H+1,\dots,G$ leave a compact set D of the form $D=[\pi_{min},1]\times C,\ C\subset\mathbb{R}^p\times\mathcal{S}_p$ compact, $\pi_{min}>0$. Then there exists ϕ_{min} bounding $\phi_j^+(x_i)$ from below for $j=1,\dots,H$ and $i=1,\dots,n$, so $\sum_{j=1}^{H}\pi_j^+\phi_j^+(x_i)\geq H\pi_{min}\phi_{min}$.

Consider sequences $(\theta_m)_{m\in\mathbb{N}}\in\Theta$ with $l_{(n+r)G}(\underline{x_{n+r}},\theta_m)\to l^o_{(n+r)G}$ and leaving any D for $j=H+1\dots,G$, i.e., $\|\mu_{mj}\|\to\infty$ or $\lambda_{k,j,m}\to\infty$ or $\pi_{mj}\to 0$, but with all $\lambda_{k,j,m}\geq\lambda_0$ as established in Corollary 21. Observe that for such sequences $\sum_{j=H+1}^{G}\pi_{mj}\phi_{mj}(x_i)$ becomes arbitrarily small for $i=1,\dots,n$. Thus, for arbitrary $\epsilon>0$ and D large enough:

$$\begin{aligned}l^o_{(n+r)G}&\leq\sum_{i=1}^{n}\log\left(\sum_{j=1}^{H}\pi_j^+\phi_j^+(x_i)+\pi_0^+\delta\right)+r\log\phi_{max}+\epsilon\\&\leq\max_{H<G}l^o_{nH}+r\log\phi_{max}+\epsilon\leq l^o_{n(G-1)}+r\log\phi_{max}+\epsilon.\end{aligned}$$

But a potential estimator $\hat\theta$ could be defined by $\hat\pi_0=\frac{n\pi_0^*+r}{n+r},\ \hat\pi_j=\frac{n}{n+r}\pi_j^*,\ \hat\mu_j=\mu_j^*,\ \hat\Sigma_j=\Sigma_j^*,\ j=1,\dots,G$. Note that $\hat\theta\in\Theta$ because of (27). Therefore,

$$\begin{aligned}l^o_{(n+r)G}&\geq\sum_{i=1}^{n}\log\left(\sum_{j=1}^{G}\pi_j^*\phi_j^*(x_i)+\left(\pi_0^*+\frac{r}{n}\right)\delta\right)\\&\quad+r\log\left[\left(\pi_0^*+\frac{r}{n}\right)\delta\right]+(n+r)\log\frac{n}{n+r}\\\Rightarrow l^o_{n(G-1)}&\geq\sum_{i=1}^{n}\log\left(\sum_{j=1}^{G}\pi_j^*\phi_j^*(x_i)+\left(\pi_0^*+\frac{r}{n}\right)\delta\right)\\&\quad+r\log\left[\left(\pi_0^*+\frac{r}{n}\right)\delta\right]+(n+r)\log\frac{n}{n+r}-r\log\phi_{max}-\epsilon.\end{aligned}$$

This contradicts (26) by $\epsilon\to 0$. ■

Table 1: Parameters of the AsyNoise sampling design. Let π and ν be the expected proportion and the degrees of freedom. m_1,v_1 and m_2,v_2 are the mean parameters (m) and variance parameters (v) along dimensions 1 and 2 respectively. $c_{1,2}$ denotes the covariance between marginals 1 and 2. All remaining variances are set equal to 1, while all remaining mean and covariance parameters are set equal to 0.

Parameter	Cluster				
	1	2	3	4	5

c_{12}	0.5	-1.5	1.3	0	0

7. Numerical experiments

In this section, we perform Monte Carlo experiments to compare robust clustering methods on the two sampling designs introduced in Section 2. There is already a comprehensive simulation study involving OTRIMLE and competitors in Coretto and Hennig (2016), so here we use different setups. Below, apart from involving competing methods from the literature, the two OTRIMLE algorithms are compared (see Remark 18).

The AsyNoise design of Figure 1 generates $G=5$ clusters in $p=20$ dimensions and an expected noise proportion of 33%. The five clusters are generated from a mixture of t-distributions with parameters given in Table 1. The five clusters show a combination of structures that are often difficult to handle together. Some of them are not well separated, they are of different size, and although they are all elliptically shaped, there are strong differences in cluster scatters, and deviations from normality. The noise originates from a distribution obtained as the product of two independent one-dimensional uniform distributions with support on the interval $[-25,25]$, and 18 independent one-dimensional χ^2-distributions with 1 degree of freedom. The first and the third marginal are distributed uniformly, producing background noise on both clustered and non-clustered dimensions, and the χ^2-distribution adds a strong dose of asymmetry.

The second sampling design is called GEM (see Figure 3). In this case, the sampling design is a mixture of two Gaussian distributions in $p=20$ dimensions, with the addition of a few potential outliers. In this design, the first cluster has strongly correlated marginals, whereas the second one is spherical, and this produces a large discrepancy between the clusters' shapes. Define the $p\times p$ correlation matrix $C(\rho):=(\rho^{|l-k|})_{l,k}$ for $l,k=1,\dots,p$ (also called AR(1) correlation model). The parameters of the GEM design are specified in Table 2. An expected 2% of points are generated from a 20-dimensional t-distribution with 3 degrees of freedom, centered at $(0,0,-7,\dots,-7)'$, with unit variances and correlation matrix $C(0.9999)$. This produces a few points far from both clusters, although these outliers

Table 2: Parameters of the GEM sampling design. Let π be the expected proportion. m is the mean parameter constant across all marginals for the same cluster. Each clusters has unit variance across all marginals and correlation matrix given by $C(\rho)$.

Parameter	Cluster

ρ	0.99	0

are not extremely separated from the regular data. While non-robust methods can cope with weakly separated outliers at the expense of large estimation bias, some robust methods capable of handling extreme outliers might get in trouble if the separation gap between regular and nonregular points is modest.

In this experiment, ML for Gaussian mixtures with uniform noise and TCLUST are compared with the RIMLE optimally tuned according to the OTRIMLE method introduced in Coretto and Hennig (2016). Methods under comparison are set up as follow:

OtrimleECM: RIMLE is computed based on the ECM algorithm 2 on a grid of 50 $\log(\delta))$ values as described in Section 5.2. The OTRIMLE criterion proposed in Coretto and Hennig (2016) selects the best solution. The input parameter $\pi_{\max}$ is always set to the conventional 50%. The eigenratio constraint is varied between the strongest restriction ($\gamma = 0$), and no restriction at all ($\gamma = +\infty$). In particular, $\log_{10}(\gamma) = \{0, 0.5, 1, 2, 3, 6, +\infty\}$. The initial partition is computed as described in Section 5.2. OtrimleECM is computed using the otrimle package of Coretto and Hennig (2017).

OtrimleAEM: RIMLE is computed using the approximate EM-algorithm introduced in Coretto and Hennig (2016). Both $\pi_{\max}$ and γ are set for OtrimleECM as well as initial values. Software for OtrimleAEM is available as part of the supplementary materials in Coretto and Hennig (2016).

TclustOracle: TCLUST with trimming rate set to the true underlying noise proportion. The eigenratio constraint is treated as for OtrimleECM. TclustOracle is computed using the tclust package of Fritz et al. (2012) which does not allow the user to choose an initial partition. TCLUST initialization is random, and we increased the default number of random starts to the sample size. The default maximum number of iterations is also increased to 500 because several convergence problems were recorded.

TclustFix: same as TclustOracle but with trimming rate fixed to a low 5% for the GEM design, and a high 50% for the AsyNoise design. The package tclust also includes the "ctlcurves"-tool for guiding the user toward the choice of a suitable trimming rate. Unfortunately, this graphical tool does not give any clear indication for the data sets generated in this experiment.

MCLUSTn: ML for Gaussian mixtures with uniform noise as implemented in the mclust package of Fraley et al. (2012). Regularization of the covariance matrices is done by choosing an appropriate covariance parameterization based on the BIC (Bayesian Information Criterion). Mclust requires noise initialization, and this is initialized as for the OtrimleECM. Note that the otrimle package uses mclust initialization for the regular points, hence OtrimleECM and MCLUSTn both start from the same partition.

There exist other methods capable of handling noise not considered here. The true clusters can be characterized by having a considerably higher density than the noise region, so density based clustering would seem to be another promising approach, but it suffers from the high dimensionality of the data, too. The DBSCAN algorithm of Ester et al. (1996) can handle noise, however its performance strongly depends on a pair of tunings that need to be carefully selected based on the dataset, and this makes it hardly comparable in a Monte Carlo experiment like the present one. ML based on t-mixtures of Peel and McLachlan (2000) would also be appropriate, however it requires discretionary decisions on how to define noise in terms of the tails of the estimated student-t distributions.

The sample size is set to $n = 500$ for AsyNoise, and $n = 100$ for GEM. With these relatively low sample sizes, the regularization of the covariance matrices becomes crucial because often small clusters are found compared to the dimensionality p. For both data sets 1000 Monte Carlo replicates have been considered. The true cluster label of a point is defined based on the component of the sampling distribution that generates it. Misclassification rates are computed with respect to the minimizing permutation of clusters' indexes not involving the estimated noise, which is always matched to the true noise. The underlying eigenratio behavior of these designs is largely varying. The true γ is 7 for AsyNoise, and it is 3704.7 for GEM. However, if one computes the eigenratio of sample clusters' covariances based on true labels the figure can be completely different. In fact, we computed the (5%, 95%)-quantiles of the Monte Carlo distribution of these quantities, and we obtained (44.5, 273.4) for AsyNoise, and (19899.3, 246826.8) for GEM. In the examples given in Section 2 we fixed $\gamma = 100$, because in real world applications one typically does not have information on it, and we used the central value adopted in these experiments.

Results are summarized in Tables 3 and 4, and Figures 5 and 6. Since MCLUSTn does not enforce an eigenratio constraint, results are recorded at $\gamma = +\infty$, although MCLUSTn has its own covariance regularization. MCLUSTn is seriously affected by contamination in both designs. Its performance is better for the AsyNoise design for which the boxplot of Figure 5 shows that in some replica it can produce misclassification rates below 10%. Regarding the Otrimle and Tclust versions, the performance depends on the setting of the eigenratio constraint. However, OtrimleECM offers the most stable performance in both designs. OtrimleECM achieves the best misclassification performance in all situations except for few cases where TclustOracle does better, but in fact, TclustOracle is run with the assumption that one knows the expected amount of noise exactly, which is never true in reality. Note that TclustOracle seems to not tolerate large values of γ in both designs. This is counterintuitive at least for GEM, where the true $\log_{10}(\gamma)$ is between 3 and 6, but in this range both TclustOracle and TclustFix have serious problems. OtrimleAEM is the second best overall, although it shows a large positive skewness in the distribution of the misclassification rates for AsyNoise, and in both designs it is not able to enforce low γ values appropriately. This is because in OtrimleAEM an approximate eigenratio constraint

Table 3: Monte Carlo averages, with standard errors in parenthesis, of misclassification rates (%) for the AsyNoise sampling design. "na" is reported if the software did not produce a valid answer in more than 50% of the replicates.

$\log_{10}(\gamma)$	OtrimleECM	OtrimleAEM	TclustOracle	TclustFix	MCLUSTn
0	15.31(0.00)	31.96(0.03)	4.33(0.00)	18.63(0.00)	—

is applied at the end of the EM iteration (see Remark 18). These results show a remarkable improvement of the ECM algorithm 2 over the approximate solution proposed in Coretto and Hennig (2016).

In practice the user has to specify γ. According to the results shown here, OtrimleECM is not very sensitive to this choice. Also the results show that good misclassification rates can be achieved in GEM, with a true $\gamma > 3000$, using a much lower γ for OTRIMLE; actually for TCLUST a much lower γ is even required to achieve good results. Choosing a lower γ in such situations may provide some welcome regularization. $\gamma = 100$ often seems to be a sensible choice. However, the user needs to have in mind that a straight interpretation of γ requires that a variance of 1 (say) along a one-dimensional projection has the same meaning in all directions in data space, which is particularly doubtful if variables have different measurement units or variable-wise variations are not meaningfully comparable. In such cases sphering or at least variable standardization may be advisable.

8. Concluding Remarks

The RIMLE robustifies the MLE in the Gaussian mixture model by adding an improper constant mixture component to catch outliers and points that cannot appropriately assigned to any cluster. Characteristics of the method compared to other robust clustering methods aiming for approximately Gaussian clusters are a smooth mixture-type transition between clusters and noise, and the fact that noise and outliers are not modelled by a specific and usually misspecified distribution, but rather as anything where the estimated mixture density is so low that the observation is rather classified to the constant noise than to any mixture component. If needed, the density value of the improper constant noise component can be chosen in a data-adaptive based on the OTRIMLE criterion developed in (Coretto and Hennig, 2016). The RIMLE/OTRIMLE has shown competitive performance when compared with state of the art methods for robust model-based clustering methods. In this paper we investigated theoretical properties of the RIMLE, and it is shown existence, consistency, breakdown behaviour, and convergence of algorithms. Since the RIMLE coincides with the MLE for Gaussian finite mixture models (when $\delta = 0$), the present paper also gives a comprehensive treatment for it which was missing in the literature.

Editor: Michael Mahoney

Abstract

We derive computationally tractable methods to select a small subset of experiment settings from a large pool of given design points. The primary focus is on linear regression models, while the technique extends to generalized linear models and Delta's method (estimating functions of linear regression models) as well. The algorithms are based on a continuous relaxation of an otherwise intractable combinatorial optimization problem, with sampling or greedy procedures as post-processing steps. Formal approximation guarantees are established for both algorithms, and numerical results on both synthetic and real-world data confirm the effectiveness of the proposed methods.

Keywords: optimal selection of experiments, A-optimality, computationally tractable methods, minimax analysis

1. Introduction

Despite the availability of large datasets, in many applications, collecting labels for all data points is not possible due to measurement constraints. We consider the problem of measurement-constrained regression where we are given a large pool of n data points but can only observe a small set of $k \ll n$ labels. Classical *experimental design* approaches in statistical literature Pukelsheim (1993) have investigated this problem, but the proposed solutions tend to be often combinatorial. In this work, we investigate computationally tractable methods for selecting data points to label from a given pool of design points in measurement-constrained regression.

Despite the simplicity and wide applicability of OLS, in practice it may not be possible to obtain the full n-dimensional response vector y due to measurement constraints. It is then a common practice to select a small subset of rows (e.g., $k \ll n$ rows) in X so that the statistical efficiency of regression on the selected subset of design points is maximized. Compared to the classical *experimental design* problem (Pukelsheim, 1993) where X can be freely designed, in this work we consider the setting where the selected design points must come from an existing (finite) design pool X.

Below we list three example applications where such measurement constraints are relevant:

Example 1 (Material synthesis) Material synthesis experiments are time-consuming and expensive, whose results are sensitive to experimental setting features such as temperature, duration and reactant ratio. Given hundreds, or even thousands of possible experimental settings, it is important to select a handful of representative settings such that a model can be built with maximized statistical efficiency to predict quality of the outcome material from experimental features. In this paper we consider such an application of low-temperature microwave-assisted thin film crystallization (Reeja-Jayan et al., 2012; Nakamura et al., 2017) and demonstrate the effectiveness of our proposed algorithms.

Example 2 (CPU benchmarking) Central processing units (CPU) are vital to the performance of a computer system. It is an interesting statistical question to understand how known manufacturing parameters (clock period, cache size, etc.) of a CPU affect its execution time (performance) on benchmark computing tasks (Ein-Dor and Feldmesser, 1987). As the evaluation of real benchmark execution time is time-consuming and costly, it is desirable to select a subset of CPUs available in the market with diverse range of manufacturing parameters so that the statistical efficiency is maximized by benchmarking for the selected CPUs.

Example 3 (Wind speed prediction) In Chen et al. (2015) a data set is created to record wind speed across a year at established measurement locations on highways in Minnesota, US. Due to instrumentation constraints, wind speed can only be measured at intersections of high ways, and a small subset of such intersections is selected for wind speed measurement in order to reduce data gathering costs.

In this work, we primarily focus on the linear regression model (though extensions to generalized linear models and functions of linear models are also considered later)

$$y = X\beta_0 + \varepsilon,$$

where $X \in \mathbb{R}^{n\times p}$ is the design matrix, $y \in \mathbb{R}^n$ is the response and $\varepsilon \sim \mathcal{N}_n(0, \sigma^2 I_n)$ are homoscedastic Gaussian noise with variance σ^2. β_0 is a p-dimensional regression model that one wishes to estimate. We consider the "large-scale, low-dimensional" setting where both $n, p \to \infty$ and $p < n$, and X has full column rank. A common estimator is the *Ordinary Least Squares* (OLS) estimator:

$$\widehat{\beta}^{\text{ols}} = \text{argmin}_{\beta\in\mathbb{R}^p} \|y - X\beta\|_2^2 = (X^\top X)^{-1}X^\top y.$$

The mean square error of the estimated regression coefficients $\mathbb{E}\|\widehat{\beta}^{\text{ols}} - \beta_0\|_2^2 = \sigma^2 \text{tr}\left[\left(X^\top X\right)^{-1}\right]$. Under measurement constraints, it is well-known that the statistically optimal subset S^* for estimating the regression coefficients is given by the *A-optimality* criterion (Pukelsheim, 1993):

$$S^* = \text{argmin}_{S\subseteq[n],|S|\le k} \text{tr}\left[\left(X_S^\top X_S\right)^{-1}\right]. \tag{1}$$

Despite the statistical optimality of Eq. (1), the optimization problem is combinatorial in nature and the optimal subset S^* is difficult to compute. A brute-force search over all possible subsets of size k requires $O(n^k k^3)$ operations, which is infeasible for even moderately sized designs X.

In this work, we focus on **computationally tractable** methods for experiment selection that achieve near-optimal statistical efficiency in linear regression models. We consider two experiment selection models: the *with replacement* model where each design point (row of X) can be selected more than once with independent noise involved for each selection, and the *without replacement* model where distinct row subsets are required. We propose two computationally tractable algorithms: one sampling based algorithm that achieves $O(1)$ approximation of the statistically optimal solution for the with replacement model and, when Σ^* is well-conditioned, the algorithm also works for the without replacement model. In the "soft budget" setting $|S| = O_{\mathbb{P}}(k)$, the approximation ratio can be further improved to $1+O(\epsilon)$. We also propose a greedy method that achieves $O(p^2/k)$ approximation for the without replacement model regardless of the conditioning of the design pool X.

2. Problem formulation and backgrounds

We first give a formal definition of the experiment selection problem in linear regression models:

Definition 1 (experiment selection problem in linear regression models) *Let X be a known $n\times p$ design matrix with full column rank and k be the subset budget, with $p \le k \le n$. An experiment selection problem aims to find a subset $S \subseteq [n]$ of size k, either deterministically or randomly, then observes $y_S = X_S\beta_0+\widetilde{\varepsilon}$, where each coordinate of $\widetilde{\varepsilon}$ is i.i.d. Gaussian random variable with zero mean and equal covariance, and then generates an estimate $\widehat{\beta}$ of the regression coefficients based on (X_S, y_S). Two types of experiment selection algorithms are considered:*

1. With replacement*: S is a multi-set which allows duplicates of indices. Note that fresh (independent) noise is imposed after, and independent of, experiment selection, and hence duplicate design points have independent noise. We use $\mathcal{A}_1(k)$ to denote the class of all with replacement experiment selection algorithms.*

2. Without replacement*: S is a standard set that may not have duplicate indices. We use $\mathcal{A}_2(k)$ to denote the class of all without replacement experiment selection algorithms.*

As evaluation criterion, we consider the mean square error $\mathbb{E}\|\widehat{\beta}-\beta_0\|_2^2$, where $\widehat{\beta}$ is an estimator of β_0 with X_S and y_S as inputs. We study *computationally tractable* algorithms that approximately achieves the *minimax* rate of convergence over $\mathcal{A}_1(k)$ or $\mathcal{A}_2(k)$:

$$\inf_{A'\in\mathcal{A}_b(k)} \sup_{\beta_0\in\mathbb{R}^p} \mathbb{E}\left[\|\widehat{\beta}_{A'}-\beta_0\|_2^2\right]. \tag{2}$$

Formally, we give the following definition:

1. "Additive" means that the statistical error of the resulting estimator cannot be bounded by a multiplicative factor of the minimax optimal error.
2. The leverage score sampling method in Ma et al. (2015) does not have rigorous approximation guarantees in terms of $\|\widehat{\beta}-\beta_0\|_2^2$ or $\|X\widehat{\beta}-X\beta_0\|_2^2$. However, the bounds in that paper establish that leverage score sampling can be worse or better than uniform sampling under different settings.

Table 1: Summary of approximation results. $\Sigma_* = X^\top \mathrm{diag}(\pi^*)X$, where π^* is the optimal solution of Eq. (4). Sampling based algorithms can be with or without replacement and are randomized, which succeed with at least 0.8 probability.

Algorithm	Model	Constraint	$C(n,p,k)$	Assumptions
Ma et al. (2015)	with rep.	additive[1]	-[2]	asymptotic
Avron and Boutsidis (2013)	with rep.	additive	$O(n/k)$	$k=\Omega(p)$
sampling	with rep.	$\|S\|=O_{\mathbb{P}}(k)$	$1+O(\epsilon)$	$p\log k/k = O(\epsilon^2)$
sampling	without rep.	$\|S\|=O_{\mathbb{P}}(k)$	$1+O(\epsilon)$	$\|\Sigma_*^{-1}\|_2\kappa(\Sigma_*)\|X\|_\infty \log p = O(\epsilon^2)$
sampling	with rep.	$\|S\|\le k$	$O(1)$	$p\log k/k = O(1)$
sampling	without rep.	$\|S\|\le k$	$O(1)$	$\|\Sigma_*^{-1}\|_2\kappa(\Sigma_*)\|X\|_\infty \log p = O(1)$ $k>p$, or $k=\Omega(p^2/\epsilon)$
greedy	without rep.	$\|S\|\le k$	**Rigorous**: $1+\frac{p(p+1)}{2(k-p+1)}$ **Conjecture**: $1+O(\frac{p}{k-p})$	if $(1+\epsilon)$-approximation desired

Definition 2 ($C(n,p,k)$-approximate algorithm) *Fix $n \ge k \ge p$ and $b \in \{1,2\}$. We say an algorithm (either deterministic or randomized) $A \in \mathcal{A}_b(k)$ is a $C(n,p,k)$-approximate algorithm if for any $X \in \mathbb{R}^{n\times p}$ with full column rank, A produces a subset $S \subseteq [n]$ with size k and an estimate $\widehat{\beta}_A$ in polynomial time such that, with probability at least 0.8,*

$$\sup_{\beta_0\in\mathbb{R}^p} \mathbb{E}\left[\|\widehat{\beta}_A-\beta_0\|_2^2 \middle| X_S\right] \le C(n,p,k)\cdot \inf_{A'\in\mathcal{A}_b(k)} \sup_{\beta_0\in\mathbb{R}^p} \mathbb{E}\left[\|\widehat{\beta}_{A'}-\beta_0\|_2^2\right]. \tag{3}$$

Here both expectations are taken over the randomness in the noise variables $\widetilde{\varepsilon}$ and the inherent randomness in A.

Table 1 gives an overview of approximation ratio $C(n,p,k)$ for algorithms proposed in this paper. We remark that the combinatorial A-optimality solution of Eq. (1) upper bounds the minimax risk (since minimaxity is defined over deterministic algorithms as well), hence the approximation guarantees also hold with respect to the combinatorial A-optimality objective.

2.1 Related work

There has been an increasing amount of work on fast solvers for the general least-square problem $\min_\beta \|y-X\beta\|_2^2$. Most of existing work along this direction (Woodruff, 2014; Dhillon et al., 2013; Drineas et al., 2011; Raskutti and Mahoney, 2015) focuses solely on the computational aspects and do not consider statistical constraints such as limited measurements of y. A convex optimization formulation was proposed in Davenport et al. (2015) for a constrained adaptive sensing problem, which is a special case of our setting, but without finite sample guarantees with respect to the combinatorial problem. In Horel et al. (2014) a computationally tractable approximation algorithm was proposed for the D-optimality criterion of the experimental design problem. However, the core idea in Horel et al. (2014) of pipage rounding an SDP solution (Ageev and Sviridenko, 2004) is not applicable in our problem because the objective function we consider in Eq. (4) is not submodular.

Popular subsampling techniques such as leverage score sampling (Drineas et al., 2008) were studied in least square and linear regression problems (Zhu et al., 2015; Ma et al., 2015; Chen et al., 2015). While computation remains the primary subject, measurement

constraints and statistical properties were also analyzed within the linear regression model (Zhu et al., 2015). However, none of the above-mentioned (computationally efficient) methods achieve near minimax optimal statistical efficiency in terms of estimating the underlying linear model β_0, since the methods can be worse than uniform sampling which has a fairly large approximation constant for general X. One exception is Avron and Boutsidis (2013), which proposed a greedy algorithm that achieves an error bound of estimation of β_0 that is within a multiplicative factor of the minimax optimal statistical efficiency. The multiplicative factor is however large and depends on the size of the full sample pool X, as we remark in Table 1 and also in Sec. 3.4.

Another related area is *active learning* (Chaudhuri et al., 2015; Hazan and Karnin, 2015; Sabato and Munos, 2014), which is a stronger setting where feedback from prior measurements can be used to guide subsequent data selection. Chaudhuri et al. (2015) analyzes an SDP relaxation in the context of active maximum likelihood estimation. However, the analysis in Chaudhuri et al. (2015) only works for the with replacement model and the two-stage feedback-driven strategy proposed in Chaudhuri et al. (2015) is not available under the experiment selection model defined in Definition 1 where no feedback is assumed.

2.2 Notations

For a matrix $A \in \mathbb{R}^{n\times m}$, we use $\|A\|_p = \sup_{x\neq 0} \frac{\|Ax\|_p}{\|x\|_p}$ to denote the induced p-norm of A. In particular, $\|A\|_1 = \max_{1\leq j\leq m} \sum_{i=1}^n |A_{ij}|$ and $\|A\|_\infty = \max_{1\leq i\leq n} \sum_{j=1}^m |A_{ij}|$. $\|A\|_F = \sqrt{\sum_{i,j} A_{ij}^2}$ denotes the Frobenius norm of A. Let $\sigma_1(A) \geq \sigma_2(A) \geq \cdots \geq \sigma_{\min(n,m)}(A) \geq 0$ be the singular values of A, sorted in descending order. The condition number $\kappa_2(A)$ is defined as $\kappa(A) = \sigma_1(A)/\sigma_{\min(n,m)}(A)$. For sequences of random variables X_n and Y_n, we use $X_n \xrightarrow{p} Y_n$ to denote X_n converges in probability to Y_n. We say $a_n \lesssim b_n$ if $\lim_{n\to\infty} |a_n/b_n| \leq 1$ and $a_n \gtrsim b_n$ if $\lim_{n\to\infty} |b_n/a_n| \leq 1$. For two d-dimensional symmetric matrices A and B, we write $A \preceq B$ if $u^\top(A-B)u \leq 0$ for all $u \in \mathbb{R}^d$, and $A \succeq B$ if $u^\top(A-B)u \geq 0$ for all $u \in \mathbb{R}^d$.

3. Methods and main results

We describe two computationally feasible algorithms for the experiment selection problem, both based on a continuous convex optimization problem. Statistical efficiency bounds are presented for both algorithms, with detailed proofs given in Sec. 7.

3.1 Continuous optimization and minimax lower bounds

We consider the following continuous optimization problem, which is a convex relaxation of the combinatorial A-optimality criterion of Eq. (1):

$$\pi^* = \operatorname{argmin}_{\pi\in\mathbb{R}^n} f(\pi; X) = \operatorname{argmin}_{\pi\in\mathbb{R}^p} \operatorname{tr}\left[\left(X^\top \operatorname{diag}(\pi) X\right)^{-1}\right], \tag{4}$$
$$s.t.\quad \pi \geq 0,\ \ \|\pi\|_1 \leq k,$$
$$\|\pi\|_\infty \leq 1 \quad \text{(only for the without replacement model)}.$$

Note that the $\|\pi\|_\infty \leq 1$ constraint is only relevant for the without replacement model and for the with replacement model we drop this constraint in the optimization problem. It is easy to verify that both the objective $f(\pi; X)$ and the feasible set in Eq. (4) are convex, and hence the global optimal solution π^* of Eq. (4) can be obtained using computationally tractable algorithms. In particular, we describe an SDP formulation and a practical projected gradient descent algorithm in Appendix B and D, both provably converge to the global optimal solution of Eq. (4) with running time scaling polynomially in n, p and k.

We first present two facts, which are proved in Sec. 7.

Fact 3.1 *Let π and π' be feasible solutions of Eq. (4) such that $\pi_i \leq \pi'_i$ for all $i = 1, \cdots, n$. Then $f(\pi; X) \geq f(\pi'; X)$, with equality if and only if $\pi = \pi'$.*

Fact 3.2 *$\|\pi^*\|_1 = k$.*

We remark that the inverse monotonicity of f in π implies second fact, which can potentially be used to understand sparsity of π^* in later sections.

The following theorem shows that the optimal solution of Eq. (4) lower bounds the minimax risk defined in Eq. (2). Its proof is placed in Sec. 7.

Theorem 3 *Let $f_1^*(k; X)$ and $f_2^*(k; X)$ be the optimal objective values of Eq. (4) for with replacement and without replacement, respectively. Then for $b \in \{1, 2\}$,*

$$\inf_{A\in\mathcal{A}_b(k)} \sup_{\beta_0\in\mathbb{R}^p} \mathbb{E}\left[\|\widehat{\beta}_A - \beta_0\|_2^2\right] \geq \sigma^2 \cdot f_b^*(k; X). \tag{5}$$

Despite the fact that Eq. (4) is computationally tractable, its solution π^* is *not* a valid experiment selection algorithm under a measurement budget of k because there can be much more than k components in π^* that are not zero. In the following sections, we discuss strategies for choosing a subset $\widehat{S}$ of rows with $|\widehat{S}| = O_{\mathbb{P}}(k)$ (i.e., soft constraint) or $|\widehat{S}| \leq k$ (i.e., hard constraint), using the solution π^* to the above.

3.2 Sampling based experiment selection: soft size constraint

We first consider a weaker setting where *soft* constraint is imposed on the size of the selected subset $\widehat{S}$; in particular, it is allowed that $|\widehat{S}| = O(k)$ with high probability, meaning that a constant fraction of over-selection is allowed. The more restrictive setting of hard constraint is treated in the next section.

A natural idea of obtaining a valid subset S of size k is by *sampling* from a weighted row distribution specified by π^*. Let $\Sigma_* = X^\top \operatorname{diag}(\pi^*) X$ and define distributions $p_j^{(1)}$ and $p_j^{(2)}$ for $j = 1, \cdots, n$ as

$$P^{(1)}:\ \ p_j^{(1)} = \pi_j^* x_j^\top \Sigma_*^{-1} x_j / p, \qquad \text{with replacement;}$$
$$P^{(2)}:\ \ p_j^{(2)} = \pi_j^* / k, \qquad \text{without replacement.}$$

Note that both $\{p_j^{(1)}\}_{j=1}^n$ and $\{p_j^{(2)}\}_{j=1}^n$ sum to one because $\sum_{j=1}^n \pi_j^* = k$ and $\sum_{j=1}^n \pi_j^* x_j^\top \Sigma_*^{-1} x_j = \operatorname{tr}((\sum_{j=1}^n \pi_j^* x_j x_j^\top)\Sigma_*^{-1}) = \operatorname{tr}(\Sigma_* \Sigma_*^{-1}) = p$.

input : $X \in \mathbb{R}^{n\times p}$, optimal solution π^*, target subset size k.
output: $\widehat{S} \subseteq [n]$, a selected subset of size at most $O_{\mathbb{P}}(k)$.
Initialization: $t = 0$, $S_0 = \emptyset$.
With replacement: for $t = 1, \cdots, k$ do:
- sample $i_t \sim P^{(1)}$ and set $w_t = \lceil \pi^*_{i_t}/(kp^{(1)}_{i_t})\rceil$;
- update: $S_{t+1} = S_t \cup \{w_t \text{ repetitions of } x_{i_t}\}$.

Without replacement: for $i = 1, \cdots, n$ do:
- sample $w_i \sim \text{Bernoulli}(kp^{(2)}_j)$;
- update: $S_{i+1} = S_i \cup \{w_i \text{ repetitions of } x_i\}$.

Finally, output $\widehat{S} = S_k$ for with replacement and $\widehat{S} = S_n$ for without replacement.

Figure 1: Sampling based experiment selection (expected size constraint).

Under the without replacement setting the distribution $P^{(2)}$ is straightforward: $p^{(2)}_j$ is proportional to the optimal continuous weights π^*_j; under the with replacement setting, the sampling distribution takes into account leverage scores (effective resistance) of each data point in the conditioned covariance as well. Later analysis (Theorem 5) shows that it helps with the finite-sample condition on k. Figure 1 gives details of the sampling based algorithms for both with and without replacement settings.

The following proposition bounds the size of $\widehat{S}$ in high probability:

Proposition 4 *For any $\delta \in (0, 1/2)$ with probability at least $1 - \delta$ it holds that $|\widehat{S}| \le 2(1 + 1/\delta)k$. That is, $|\widehat{S}| \le O_{\mathbb{P}}(k)$.*

Proof Apply Markov's inequality and note that an additional k samples need to be added due to the ceiling operator in with replacement sampling. ■

The sampling procedure is easy to understand in an asymptotic sense: it is easy to verify that $\mathbb{E}X^\top_{i_t} X_{i_t} = X^\top \text{diag}(\pi^*/k)X$ and $\mathbb{E}[w_{i_t}] = 1$, for both with and without replacement settings. Note that $\|p^{(2)}_{i_t}\|_\infty \le 1/k$ by feasibility constraints and hence $\text{Bernoulli}(kp^{(2)}_{i_t})$ is a valid distribution for all $i_t \in [n]$. For the with replacement setting, by weak law of large numbers, $X^\top_{\widehat{S}} X_{\widehat{S}} \xrightarrow{p} X^\top \text{diag}(\pi^*)X$ as $k \to \infty$ and hence $\text{tr}[(X^\top_S X_S)^{-1}] \xrightarrow{p} f(\pi^*; X)$ by continuous mapping theorem. A more refined analysis is presented in Theorem 5 to provide explicit conditions under which the asymptotic approximations are valid and on the statistical efficiency of $\widehat{S}$ as well as analysis under the more restrictive without replacement regime.

Theorem 5 *Fix $\epsilon > 0$ as an arbitrarily small accuracy parameter. Suppose the following conditions hold:*

$$\textit{With replacement}: \quad p \log k/k = O(\epsilon^2);$$
$$\textit{Without replacement}: \quad \|\Sigma_*^{-1}\|_2 \kappa(\Sigma_*) \|X\|^2_\infty \log p = O(\epsilon^2).$$

Here $\Sigma_* = X^\top \text{diag}(\pi^*)X$ and $\kappa(\Sigma_*)$ denotes the conditional number of Σ_*. Then with probability at least 0.9 the subset OLS estimator $\widehat{\beta} = (X^\top_{\widehat{S}} X_{\widehat{S}})^{-1} X^\top_{\widehat{S}} y_{\widehat{S}}$ satisfies

$$\mathbb{E}\left[\|\widehat{\beta} - \beta_0\|_2^2 \Big| X_{\widehat{S}}\right] = \sigma^2 \text{tr}\left[(X^\top_{\widehat{S}} X_{\widehat{S}})^{-1}\right] \le (1 + O(\epsilon)) \cdot \sigma^2 f^*_b(X; k), \qquad b \in \{1, 2\}.$$

We adapt the proof technique of Spielman and Srivastava in their seminal work on spectral sparsification of graphs (Spielman and Srivastava, 2011). More specifically, we prove the following stronger "two-sided" result which shows that $X^\top_{\widehat{S}} X_{\widehat{S}}$ is a *spectral approximation* of Σ_* with high probability, under suitable conditions.

Lemma 6 *Under the same conditions in Theorem 5, it holds that with probability at least 0.9 that*

$$(1 - \epsilon) z^\top \Sigma_* z \le z^\top \widehat{\Sigma}_{\widehat{S}} z \le (1 + \epsilon) z^\top \Sigma_* z, \quad \forall z \in \mathbb{R}^p,$$

where $\Sigma_* = X^\top \text{diag}(\pi^*)X$ and $\Sigma_{\widehat{S}} = X^\top_{\widehat{S}} X_{\widehat{S}}$.

Lemma 6 implies that with high probability $\sigma_j(\widehat{\Sigma}_{\widehat{S}}) \ge (1 - \epsilon)\sigma_j(\Sigma_*)$ for all $j = 1, \cdots, p$. Recall that $\text{tr}[(X^\top_S X_S)^{-1}] = \sum_{j=1}^p \sigma_j(\widehat{\Sigma}_{\widehat{S}})^{-1}$ and $f(\pi^*; X) = \sum_{j=1}^p \sigma_j(\Sigma_*)$. Subsequently, for $\epsilon \in (0, 1 - c]$ for some constant $c > 0$, $\text{tr}[(X^\top_{\widehat{S}} X_{\widehat{S}})^{-1}] \le (1 + O(\epsilon)) f(\pi^*; X)$. Theorem 5 is thus proved.

3.3 Sampling based experiment selection: hard size constraint

In some applications it is mandatory to respect a hard subset size constraint; that is, a randomized algorithm is expected to output $\widehat{S}$ that satisfies $|\widehat{S}| \le k$ almost surely, and no over-sampling is allowed. To handle such hard constraints, we revise the algorithm in Figure 1 as follows:

input : $X \in \mathbb{R}^{n\times p}$, optimal solution π^*, target subset size k.
output: $\widehat{S} \subseteq [n]$, a selected subset of size at most k.
Initialization: $t = 0$, $S_0 = \emptyset$, $R_0 = \emptyset$.
1. *With replacement*: sample $i_t \sim P^{(1)}$; set $w_t = \lceil \pi^*_{i_t}/(kp^{(1)}_{i_t})\rceil$;
   Without replacement: pick random $i_t \notin R_{t-1}$; sample $w_t \sim \text{Bernoulli}(kp^{(2)}_{i_t})$.
2. *Update*: $S_t = S_{t-1} \cup \{w_t \text{ repetitions of } i_t\}$, $R_t = R_{t-1} \cup \{i_t\}$.
3. Repeat steps 1 and 2 until at some $t = T$, $|S_{T+1}| > k$ or $R_{T+1} = [n]$. Output $\widehat{S} = S_T$.

Figure 2: Sampling based experiment selection (deterministic size constraint).

We have the following theorem, which mimics Theorem 5 but with weaker approximation bounds:

Theorem 7 *Suppose the following conditions hold:*

$$\textit{with replacement}: \quad p \log k/k = O(1);$$
$$\textit{without replacement}: \quad \|\Sigma_*^{-1}\|_2 \kappa(\Sigma_*) \|X\|^2_\infty \log p = O(1).$$

Then with probability at least 0.8 the subset estimator $\widehat{\beta} = (X_{\widehat{S}}^\top X_{\widehat{S}})^{-1} X_{\widehat{S}}^\top y_S$ *satisfies*

$$\mathbb{E}\left[\|\widehat{\beta} - \beta_0\|_2^2 \Big| X_{\widehat{S}}\right] = \sigma^2 \mathrm{tr}\left[(X_{\widehat{S}}^\top X_{\widehat{S}})^{-1}\right] \le O(1) \cdot \sigma^2 f_b^*(X;k), \qquad b \in \{1,2\}.$$

The following lemma is key to the proof of Theorem 7. Unlike Lemma 6, in Lemma 8 we only prove one side of the spectral approximation relation, which suffices for our purposes. To handle without replacement, we cite matrix Bernstein for combinatorial matrix sums in (Mackey et al., 2014).

Lemma 8 *Define* $\widehat{\Sigma}_{\widehat{S}} = X_{\widehat{S}}^\top X_{\widehat{S}}$. *Suppose the following conditions hold:*

$$\begin{aligned} &\textit{With replacement}: \quad p \log T/T = O(1); \\ &\textit{Without replacement}: \quad \|\Sigma_*^{-1}\|_2 \kappa(\Sigma_*) \|X\|_\infty^2 \log p = O(T/n). \end{aligned}$$

Then with probability at least 0.9 *the following holds:*

$$z^\top \widehat{\Sigma}_{\widehat{S}} z \ge K_T z^\top \Sigma_* z, \qquad \forall z \in \mathbb{R}^p, \tag{6}$$

where $K_T = \Omega(T/k)$ *for with replacement and* $K_T = \Omega(T/n)$ *for without replacement.*

Finally, we need to relate conditions on T in Lemma 8 to interpretable conditions on subset budget k:

Lemma 9 *Let* $\delta > 0$ *be an arbitrarily small fixed failure probability. The with probability at least* $1 - \delta$ *we have that* $T \ge \delta k$ *for with replacement and* $T \ge \delta n$ *for without replacement.*

Proof For with replacement we have $\mathbb{E}[\sum_{t=1}^T w_t] = T$ and for without replacement we have $\mathbb{E}[\sum_{t=1}^T w_t] = Tk/n$. Applying Markov's inequality on $\Pr[\sum_{t=1}^T w_t > k]$ for $T = \delta k$ and/or $T = \delta n$ we complete the proof of Lemma 9. ■

Combining Lemmas 8 and 9 with $\delta = 0.1$ and note that $T \le k$ almost surely (because $w_t \ge 1$), we prove Theorem 7.

3.4 Greedy experiment selection

input : $X \in \mathbb{R}^{n \times p}$, Initial subset $S_0 \subseteq [n]$, target size $k \le |S_0|$.
output: $\widehat{S} \subseteq [n]$, a selected subset of size k.
Initialization: $t = 0$.
1. Find $j^* \in S_t$ such that $\mathrm{tr}[(X_{S_t \backslash \{j^*\}}^\top X_{S_t \backslash \{j^*\}})^{-1}]$ is minimized.
2. Remove j^* from S_t: $S_{t+1} = S_t \backslash \{j^*\}$.
3. Repeat steps 1 and 2 until $|S_t| = k$. Output $\widehat{S} = S_t$.

Figure 3: Greedy experiment selection.

Avron and Boutsidis (2013) proposed an interesting greedy removal algorithm (outlined in Figure 3) and established the following result:

Lemma 10 *Suppose* $\widehat{S} \subseteq [n]$ *of size* k *is obtained by running algorithm in Figure 3 with an initial subset* $S_0 \subseteq [n]$, $|S_0| \ge k$. *Both* $\widehat{S}$ *and* S_0 *are standard sets (i.e., without replacement). Then*

$$\mathrm{tr}\left[(X_{\widehat{S}}^\top X_{\widehat{S}})^{-1}\right] \le \frac{|S_0| - p + 1}{k - p + 1} \mathrm{tr}\left[(X_{S_0}^\top X_{S_0})^{-1}\right].$$

In Avron and Boutsidis (2013) the greedy removal procedure in Figure 3 is applied to the entire design set $S_0 = [n]$, which gives approximation guarantee $\mathrm{tr}[(X_{\widehat{S}}^\top X_{\widehat{S}})^{-1}] \le \frac{n-p+1}{k-p+1} \mathrm{tr}[(X^\top X)^{-1}]$. This results in an approximation ratio of $C(n,p,k) = \frac{n-p+1}{k-p+1}$ as defined in Eq. (2), by applying the trivial bound $\mathrm{tr}[(X^\top X)^{-1}] \le f_2^*(k;X)$, which is tight for a design that has exactly k non-zero rows.

To further improve the approximation ratio, we consider applying the greedy removal procedure with S_0 equal to the support of π^*; that is, $S_0 = \{j \in [n] : \pi_j^* > 0\}$. Because $\|\pi^*\|_\infty \le 1$ under the without replacement setting, we have the following corollary:

Corollary 11 *Let* S_0 *be the support of* π^* *and suppose* $\|\pi^*\|_\infty \le 1$. *Then*

$$\mathrm{tr}[(X_{\widehat{S}}^\top X_{\widehat{S}})^{-1}] \le \frac{\|\pi^*\|_0 - p + 1}{k - p + 1} f(\pi^*; X) = \frac{\|\pi^*\|_0 - p + 1}{k - p + 1} f_2^*(k; X).$$

It is thus important to upper bound the support size $\|\pi^*\|_0$. With the trivial bound of $\|\pi^*\|_0 \le n$ we recover the $\frac{n-p+1}{k-p+1}$ approximation ratio by applying Figure 3 to $S_0 = [n]$. In order to bound $\|\pi^*\|_0$ away from n, we consider the following assumption imposed on X:

Assumption 3.1 *Define mapping* $\phi : \mathbb{R}^p \to \mathbb{R}^{\frac{p(p+1)}{2}}$ *as* $\phi(x) = (\xi_{ij} x(i) x(j))_{1 \le i \le j \le p}$, *where* $x(i)$ *denotes the* i*th coordinate of a* p*-dimensional vector* x *and* $\xi_{ij} = 1$ *if* $i = j$ *and* $\xi_{ij} = 2$ *otherwise. Denote* $\widetilde{\phi}(x) = (\phi(x), 1) \in \mathbb{R}^{\frac{p(p+1)}{2}+1}$ *as the affine version of* $\phi(x)$. *For any* $\frac{p(p+1)}{2} + 1$ *distinct rows of* X, *their mappings under* $\widetilde{\phi}$ *are linear independent.*

Assumption 3.1 is essentially a general-position assumption, which assumes that no $\frac{p(p+1)}{2} + 1$ design points in X lie on a degenerate affine subspace after a specific quadratic mapping. Like other similar assumptions in the literature (Tibshirani, 2013), Assumption 3.1 is very mild and almost always satisfied in practice, for example, if each row of X is independently sampled from absolutely continuous distributions.

We are now ready to state the main lemma bounding the support size of π^*.

Lemma 12 $\|\pi^*\|_0 \le k + \frac{p(p+1)}{2}$ *if Assumption 3.1 holds.*

Lemma 12 is established by an interesting observation into the properties of Karush-Kuhn-Tucker (KKT) conditions of the optimization problem Eq. (4), which involves a linear system with $\frac{p(p+1)}{2} + 1$ variables. The complete proof of Lemma 12 is given in Sec. 7.5. To contrast the results in Lemma 12 with classical rank/support bounds in SDP and/or linear programming (e.g. the Pataki's bound (Pataki, 1998)), note that the number of constraints in the SDP formulation of Eq. (4) (see also Appendix B) is linear in n, and hence analysis similar to (Pataki, 1998) would result in an upper bound of $\|\pi^*\|_0$ that scales with n, which is less useful for our analytical purpose.

Combining results from both Lemma 12 and Corollary 11 we arrive at the following theorem, which upper bounds the approximation ratio of the greedy removal procedure in Figure 3 initialized by the support of π^*.

Theorem 13 *Let π^* be the optimal solution of the without replacement version of Eq. (4) and $\widehat{S}$ be the output of the greedy removal procedure in Figure 3 initialized with $S_0 = \{i \in [n] : \pi_i^* > 0\}$. If $k > p$ and Assumption 3.1 holds then the subset OLS estimator $\widehat{\beta} = (X_{\widehat{S}}^\top X_{\widehat{S}})^{-1} X_{\widehat{S}}^\top y_{\widehat{S}}$ satisfies*

$$\mathbb{E}\left[\|\widehat{\beta} - \beta_0\| \big| X_{\widehat{S}}\right] = \sigma^2 \mathrm{tr}\left[(X_{\widehat{S}}^\top X_{\widehat{S}})^{-1}\right] \le \left(1 + \frac{p(p+1)}{2(k-p+1)}\right) f_2^*(k; X).$$

Under a slightly stronger condition that $k > 2p$, the approximation ratio $C(n,k,p) = 1 + \frac{p(p+1)}{2(k-p+1)}$ can be simplified to $C(n,k,p) = 1 + O(p^2/k)$. In addition, $C(n,k,p) = 1 + o(1)$ if $p^2/k \to 0$, meaning that near-optimal experiment selection is achievable with computationally tractable methods if $O(p^2)$ design points are allowed in the selected subset.

3.5 Interpretable subsampling example: anisotropic Gaussian design

Even though we consider a fixed pool of design points so far, here we use an anisotropic Gaussian design example to demonstrate that a non-uniform sampling can outperform uniform sampling even under random designs, and to interpret the conditions required in previous analysis. Let $x_1, \cdots, x_n$ be i.i.d. distributed according to an isotropic Gaussian distribution $\mathcal{N}_p(0, \Sigma_0)$.

We first show that non-uniform weights $\pi_i \neq k/n$ could improve the objective $f(\pi; X)$. Let π^{unif} be the uniformly weighted solution of $\pi_i^{\mathrm{unif}} = k/n$, corresponding to selecting each row of X uniformly at random. We then have

$$f(\pi^{\mathrm{unif}}; X) = \frac{1}{k}\mathrm{tr}\left[\left(\frac{1}{n}X^\top X\right)^{-1}\right] \xrightarrow{p} \frac{1}{k}\mathrm{tr}(\Sigma_0^{-1}).$$

On the other hand, let $B^2 = \gamma \mathrm{tr}(\Sigma_0)$ for some universal constant $\gamma > 1$ and $\mathbb{B} = \{x \in \mathbb{R}^p : \|x\|_2^2 \le B^2\}$, $\mathbb{X} = \{x_1, \cdots, x_n\}$. By Markov inequality, $|\mathbb{X} \cap \mathbb{B}| \gtrsim \frac{\gamma n}{1-\gamma}$. Define weighted solution π^w as $\pi_i^w \propto 1/p(x_i|\mathbb{B}) \cdot I[x_i \in \mathbb{B}]$ normalized such that $\|\pi_i^w\|_1 = k$. [1] Then

$$f(\pi^w; X) = \frac{1}{k} \frac{\mathrm{tr}\left[\left(\frac{1}{n}\sum_{x_i \in \mathbb{X}\cap\mathbb{B}} \frac{x_i x_i^\top}{p(x_i|\mathbb{B})}\right)^{-1}\right]}{\frac{1}{n}\sum_{x_i \in \mathbb{X}\cap\mathbb{B}} 1/p(x_i|\mathbb{B})} \xrightarrow{p} \frac{1}{k}\frac{n}{|\mathbb{X}\cap\mathbb{B}|} \frac{\mathrm{tr}\left[\left(\int_{\mathbb{B}} x x^\top \mathrm{d}x\right)^{-1}\right]}{\int_{\mathbb{B}} 1 \mathrm{d}x} \lesssim \frac{p^2}{(1-\gamma)\mathrm{tr}(\Sigma_0)}.$$

1. Note that π^* may *not* be the optimal solution of Eq. (4); however, it suffices for the purpose of the demonstration of improvement resulting from non-uniform weights.

Here in the last inequality we apply Lemma 17. Because $\frac{\mathrm{tr}(\Sigma_0^{-1})}{p} = \frac{1}{p}\sum_{i=1}^p \frac{1}{\sigma_i(\Sigma_0)} \ge \left(\frac{1}{p}\sum_{i=1}^p \sigma_i(\Sigma_0)\right)^{-1} = \frac{p}{\mathrm{tr}(\Sigma_0)}$ by Jensen's inequality, we conclude that in general $f(\pi^w; X) < f(\pi^{\mathrm{unif}}; X)$, and the gap is larger for ill-conditioned covariance Σ_0. This example shows that uneven weights in π helps reducing the trace of inverse of the weighted covariance $X^\top \mathrm{diag}(\pi) X$.

Under this model, we also simplify the conditions for the without replacement model in theorem 5 and 7. Because $x_1, \cdots, x_n \overset{i.i.d.}{\sim} \mathcal{N}_p(0, \Sigma_0)$, it holds that $\|X\|_\infty^2 \le O_{\mathbb{P}}(\|\Sigma_0\|_2^2 p \log n)$. In addition, by simple algebra $\|\Sigma_*^{-1}\|_2 \le p^{-1}\kappa(\Sigma_*)\mathrm{tr}(\Sigma_*^{-1}) \le p^{-1}\kappa(\Sigma_*) f_1^*(k; X)$. Using a very conservative upper bound of $f_1^*(k; X)$ by sampling rows in X uniformly at random and apply weak law of large numbers and the continuous mapping theorem, we have that $f_1^*(k; X) \lesssim \frac{1}{k}\mathrm{tr}(\Sigma_0^{-1})$. In addition, $\mathrm{tr}(\Sigma_0^{-1})\|\Sigma_0\|_2 \le p\|\Sigma_0^{-1}\|_2\|\Sigma_0\|_2 = p\kappa(\Sigma_0)$. Subsequently, the condition $\|\Sigma_*^{-1}\|_2\kappa(\Sigma_*)\|X\|_\infty^2 \log p = O(\epsilon^2)$ is implied by

$$\frac{p\kappa(\Sigma_*)^2\kappa(\Sigma_0)\log p \log n}{k} = O(\epsilon^2). \tag{7}$$

Essentially, the condition is reduced to $k \gtrsim \kappa(\Sigma_0)\kappa(\Sigma_*) \cdot p \log n \log p$. The linear dependency on p is necessary, as we consider the low-dimensional linear regression problem and $k < p$ would imply an infinite mean-square error in estimation of β_0. We also remark that the condition is scale-invariant, as $X' = \xi X$ and X share the same quantity $\|\Sigma_*^{-1}\|_2\kappa(\Sigma_*)\|X\|_\infty^2 \log k$.

3.6 Extensions

We discuss possible extension of our results beyond estimation of β_0 in the linear regression model.

3.6.1 Generalized linear models

In a generalized linear model $\mu(x) = \mathbb{E}[Y|x]$ satisfies $g(\mu(x)) = \eta = x^\top \beta_0$ for some known link function $g : \mathbb{R} \to \mathbb{R}$. Under regularity conditions (Van der Vaart, 2000), the maximum-likelihood estimator $\widehat{\beta}_n \in \mathrm{argmax}_\beta\{\sum_{i=1}^n \log p(y_i|x_i;\beta)\}$ satisfies $\mathbb{E}\|\widehat{\beta}_n - \beta_0\|_2^2 = (1+o(1))\mathrm{tr}(I(X,\beta_0)^{-1})$, where $I(X,\beta_0)$ is the Fisher's information matrix:

$$I(X,\beta_0) = -\sum_{i=1}^n \mathbb{E}\frac{\partial^2 \log p(y_i|x_i;\beta_0)}{\partial\beta\partial\beta^\top} = -\sum_{i=1}^n \left(\mathbb{E}\frac{\partial^2 \log p(y_i;\eta_i)}{\partial\eta_i^2}\right) x_i x_i^\top. \tag{8}$$

Here both expectations are taken over y conditioned on X and the last equality is due to the sufficiency of $\eta_i = x_i^\top \beta_0$. The experiment selection problem is then formulated to select a subset $S \subseteq [n]$ of size k, either with or without duplicates, that minimizes $\mathrm{tr}(I(X_S, \beta_0)^{-1})$.

It is clear from Eq. (8) that the optimal subset S^* depends on the unknown parameter β_0, which itself is to be estimated. This issue is known as the *design dependence* problem for generalized linear models (Khuri et al., 2006). One approach is to consider *locally optimal designs* (Khuri et al., 2006; Chernoff, 1953), where a consistent estimate $\check{\beta}$ of β_0 is first obtained on an initial design subset [2] and then $\check{\eta}_i = x_i^\top \check{\beta}$ is supplied to compute a more

2. Notice that a consistent estimate can be obtained using much fewer points than an estimate with finite approximation guarantee.

refined design subset to get the final estimate $\widehat{\beta}$. With the initial estimate $\check{\beta}$ available, one may apply transform $x_i \mapsto \widetilde{x}_i$ defined as

$$\widetilde{x}_i = \sqrt{-\mathbb{E}\frac{\partial^2 \log p(y_i;\check{\eta}_i)}{\partial \eta^2}} x_i.$$

Note that under regularity conditions $-\mathbb{E}\frac{\partial^2 \log p(y_i;\check{\eta}_i)}{\partial \eta_i^2} = \mathbb{E}\left(\frac{\partial \log(y_i;\check{x}_i)}{\partial \eta_i}\right)^2$ is non-negative and hence the square-root is well-defined. All results in Theorems 5, 7 and 13 are valid with $X = [x_1, \cdots, x_n]^\top$ replaced by $\widetilde{X} = [\widetilde{x}_1, \cdots, \widetilde{x}_n]^\top$ for generalized linear models. Below we consider two generalized linear model examples and derive explicit forms of $\widetilde{X}$.

Example 1: Logistic regression In a logistic regression model responses $y_i \in \{0, 1\}$ are binary and the likelihood model is

$$p(y_i; \eta_i) = \psi(\eta_i)^{y_i}(1 - \psi(\eta_i))^{1-y_i}, \qquad \text{where} \quad \psi(\eta_i) = \frac{e^{\eta_i}}{1 + e^{\eta_i}}.$$

Simple algebra yields

$$\widetilde{x}_i = \sqrt{\frac{e^{\check{\eta}_i}}{(1 + e^{\check{\eta}_i})^2}} x_i,$$

where $\check{\eta}_i = x_i^\top \check{\beta}$.

Example 2: Poisson count model In a Poisson count model the response variable y_i takes values of non-negative integers and follows a Poisson distribution with parameter $\lambda = e^{\eta_i} = e^{x_i^\top \beta_0}$. The likelihood model is formally defined as

$$p(y_i = r; \eta_i) = \frac{e^{\eta_i r} e^{-e^{\eta_i}}}{r!}, \qquad r = 0, 1, 2, \cdots.$$

Simple algebra yields

$$\widetilde{x}_i = \sqrt{e^{\check{\eta}_i}} x_i,$$

where $\check{\eta}_i = x_i^\top \check{\beta}$.

3.6.2 Delta's method

Suppose $g(\beta_0)$ is the quantity of interest, where $\beta_0 \in \mathbb{R}^p$ is the parameter in a linear regression model and $g : \mathbb{R}^p \to \mathbb{R}^m$ is some known function. Let $\widehat{\beta}_n = (X^\top X)^{-1} X^\top y$ be the OLS estimate of β_0. If ∇g is continuously differentiable and $\widehat{\beta}_n$ is consistent, then by the classical delta's method (Van der Vaart, 2000) $\mathbb{E}\|g(\widehat{\beta}_n) - g(\beta_0)\|_2^2 = (1 + o(1))\sigma^2 \mathrm{tr}(\nabla g(\beta_0)(X^\top X)^{-1} \nabla g(\beta_0)^\top) = (1 + o(1))\sigma^2 \mathrm{tr}(G_0 (X^\top X)^{-1})$, where $G_0 = \nabla g(\beta_0)^\top \nabla g(\beta_0)$. If G_0 depends on the unknown parameter β_0 then the design dependence problem again exists, and a locally optimal solution can be obtained by replacing G_0 in the objective function with $\check{G} = \nabla g(\check{\beta})^\top \nabla g(\check{\beta})$ for some initial estimate $\check{\beta}$ of β_0.

If $\check{G}$ is invertible, then there exists invertible $p \times p$ matrix $\check{P}$ such that $\check{G} = \check{P}\check{P}^\top$ because $\check{G}$ is positive definite. Applying the linear transform

$$x_i \mapsto \widetilde{x}_i = \check{P}^{-1} x_i$$

we have that $\mathrm{tr}[G_0 (X^\top X)^{-1}] = \mathrm{tr}[(\widetilde{X}^\top \widetilde{X})^{-1}]$, where $\widetilde{X} = [\widetilde{x}_1, \cdots, \widetilde{x}_n]^\top$. Our results in Theorems 5, 7 and 13 remain valid by operating on the transformed matrix $\widetilde{X} = X\check{P}^{-\top}$.

Table 2: Running time (seconds) / no. of iterations for L_5^* and $L_6^\dagger$.

Isotropic design (t distribution), df = 1.					
$k =$	$2p$	$4p$	$6p$	$8p$	$10p$
L_5^*	1.8/31	0.8/19	1.7/26	0.9/14	0.3/9
$L_6^\dagger$	140.1/90	425.9/156	767.5/216	993.7/245	1077/253
Isotropic design (t distribution), df = 3.					
$k =$	$2p$	$4p$	$6p$	$8p$	$10p$
L_5^*	0.6/14	0.4/8	0.3/7	0.2/5	0.2/5
$L_6^\dagger$	158.3/104	438.0/161	802.5/223	985.2/242	1105/252
Skewed design (multivariate Gaussian), $\alpha = 3$.					
$k =$	$2p$	$4p$	$6p$	$8p$	$10p$
L_5^*	0.8/16	0.7/12	0.5/9	0.4/8	0.4/8
$L_6^\dagger$	182.9/120	487.1/180	753.4/212	935.8/230	1057/250

Example: prediction error. In some application scenarios the *prediction error* $\|Z\widehat{\beta} - Z\beta_0\|_2^2$ rather than the estimation error $\|\widehat{\beta} - \beta_0\|_2^2$ is of interesting, either because the linear model is used mostly for prediction or component of the underlying model β_0 lack physical interpretations. Another interesting application is the *transfer learning* (Pan and Yang, 2010), in which the training and testing data have different designs (e.g., Z instead of X) but share the same conditional distribution of labels, parameterized by the linear model β_0.

Suppose $Z \in \mathbb{R}^{m \times p}$ is a known full-rank data matrix upon which predictions are seeked, and define $\widehat{\Sigma}_Z = \frac{1}{m} Z^\top Z \succ 0$ to be the sample covariance of Z. Our algorithmic framework as well as its corresponding analysis remain valid for such prediction problems with transform $x_i \mapsto \widehat{\Sigma}_Z^{-1/2} x_i$. In particular, the guarantees for the greedy algorithm and the with replacement sampling algorithm remain unchanged, and the guarantee for the without replacement sampling algorithm is valid as well, except that the $\|\Sigma_*^{-1}\|_2$ and $\kappa(\Sigma_*)$ terms have to be replaced by the (relaxed) optimal sample covariance after the linear transform $x_i \mapsto \widehat{\Sigma}_Z^{-1/2} x_i$.

4. Numerical results on synthetic data

We report selection performance (measured in terms of $F(S; X) := \mathrm{tr}[(X_S^\top X_S)^{-1}]$ which is the mean squared error of the ordinary least squares estimator based on (X_S, y_S) in estimating the regression coefficients) on synthetic data. Only the without replacement setting is considered, and results for the with replacement setting are similar. In all simulations, the experimental pool (number of given design points) n is set to 1000, number of variables p is set to 50, number of selected design points k ranges from $2p$ to $10p$. For randomized methods, we run them for 20 independent trials under each setting and report the median. Though Fedorov's exchange algorithm is randomized in nature (outcome depending on the initialization), we only run it once for each setting because of its expensive computational requirement. It is observed that in practice, the algorithm's outcome is not sensitive to initializations.

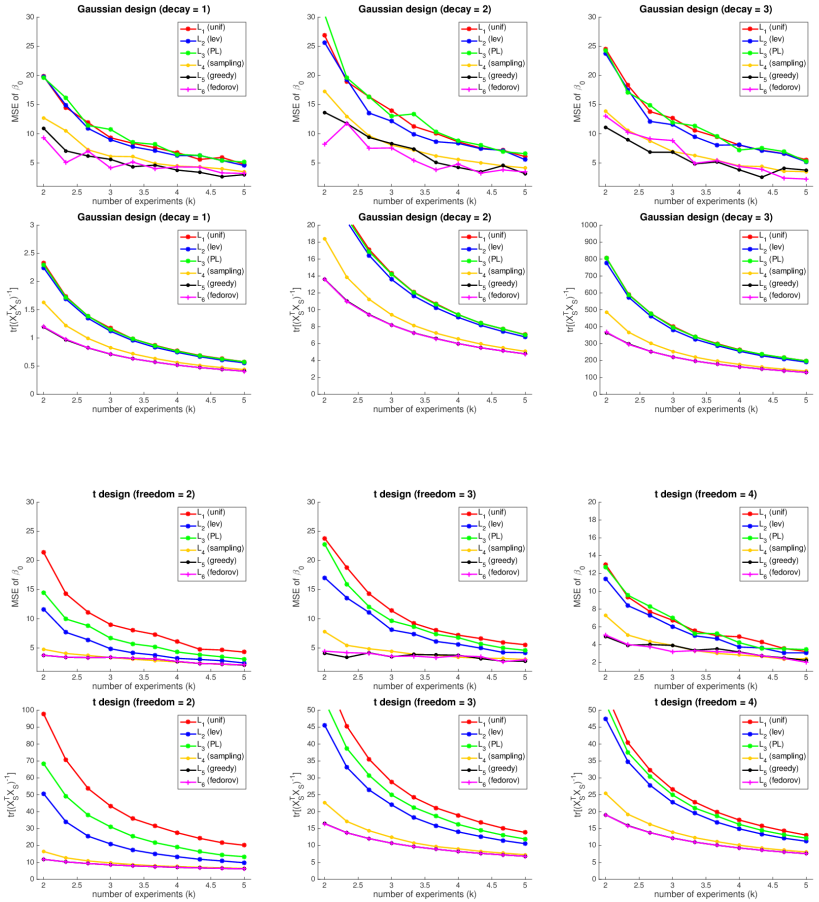

Figure 1: The ratio of MSE $\|\widehat{\beta} - \beta_0\|_2^2$ compared against the MSE of the OLS estimator on the full data pool $\|\widehat{\beta}^{\mathrm{ols}} - \beta_0\|_2^2$, $\widehat{\beta}^{\mathrm{ols}} = (X^\top X)^{-1} X^\top y$, and objective values $F(\widehat{S}; X) = \mathrm{tr}[(X_{\widehat{S}}^\top X_{\widehat{S}})^{-1}]$ on synthetic data sets. Note that the L_5 (greedy) curve is under the L_6 (federov) curve when not visible. See Sec. 4 for details of experimental settings.

4.1 Data generation

The design pool X is generated so that each row of X is sampled from some underlying distribution. We consider two distributional settings for generating X. Similar settings were considered in (Ma et al., 2015) for subsampling purposes.

1. *Distributions with skewed covariance*: each row of X is sampled i.i.d. from a multivariate Gaussian distribution $\mathcal{N}_p(0, \Sigma_0)$ with $\Sigma_0 = U \Lambda U^\top$, where U is a random orthogonal matrix and $\Lambda = \mathrm{diag}(\lambda_1, \cdots, \lambda_p)$ controls the skewness or conditioning of X. A power-law decay of λ, $\lambda_j = j^{-\alpha}$, is imposed, with small α corresponding to "flat" distribution and large α corresponding to "skewed" distribution. Rows 1-2 in Figure 1 correspond to this setting.

2. *Distributions with heavy tails*: We use t distribution as the underlying distribution for generating each entry in X, with degrees of freedom ranging from 2 to 4. These distributions are heavy tailed and high-order moments of X typically do not exist. They test the robustness of experiment selection methods. Rows 3-4 in Figure 1 correspond to this setting.

4.2 Methods

The methods that we compare are listed below:

- L_1 (uniform sampling): each row of X is sampled uniformly at random, without replacement.

- L_2 (leverage score sampling): each row of X, x_i, is sampled without replacement, with probability proportional to its leverage score $x_i^\top (X^\top X)^{-1} x_i$. This strategy is considered in Ma et al. (2015) for subsampling in linear regression models.

- L_3 (predictive length sampling): each row of X, x_i, is sampled without replacement, with probability proportional to its ℓ_2 norm $\|x_i\|_2$. This strategy is derived in Zhu et al. (2015).

- L_4^* (sampling based selection with π^*): the sampling based method that is described in Sec. 3.3, based on π^*, the optimal solution of Eq. (4). We consider the hard size constraint algorithm only.

- L_5^* (greedy based selection with π^*): the greedy based method that is described in Sec. 3.4.

- $L_6^\dagger$ (Fedorov's exchange algorithm): the Fedorov's exchange algorithm (Miller and Nguyen, 1994) with the A-optimality objective. Note that this method does not have guarantees, nor does it provably terminate in polynomial number of exchanges. Description of the algorithm is placed in Appendix C.

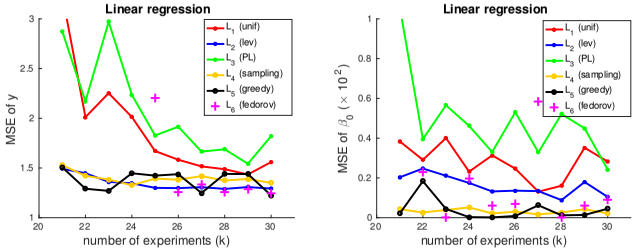

Figure 2: Results on real material synthesis data ($n = 133, p = 9, 20 < k \leq 30$). Left: prediction error $\|y - X\widehat{\beta}\|_2^2$, normalized by dividing by the prediction error $\|y - X\widehat{\beta}^{\text{ols}}\|_2^2$ of the OLS estimator on the full data set; right: estimation error $\|\widehat{\beta} - \widehat{\beta}^{\text{ols}}\|_2^2$. All randomized algorithms ($L_1, L_2, L_3, L_4^*, L_6^\dagger$) are run for 50 times and the median performance is reported.

4.3 Performance

The ratio of the mean square error $\|\widehat{\beta} - \beta_0\|_2^2$ compared to the OLS estimator on the full data set $\|\widehat{\beta}^{\text{ols}} - \beta_0\|_2^2$, $\widehat{\beta}^{\text{ols}} = (X^\top X)^{-1} X^\top y$, and objective values $F(\widehat{S}; X) = \text{tr}((X_{\widehat{S}}^\top X_{\widehat{S}})^{-1})$ are reported in Figure 1.

Table 2 reports the running time and number of iterations of L_5^* (greedy based selection) and $L_6^\dagger$ (Fedorov's exchange algorithm). In general, the greedy method is 100 to 1000 times faster than the exchange algorithm, and also converges in much fewer iterations.

For both synthetic settings, our proposed methods (L_4^* and L_5^*) significantly outperform existing approaches (L_1, L_2, L_3), and their performance is on par with the Fedorov's exchange algorithm, which is much more computationally expensive (cf. Table 2).

5. Numerical results on real data

5.1 The material synthesis dataset

We apply our proposed methods to an experimental design problem of low-temperature microwave-assisted crystallization of ceramic thin films (Reeja-Jayan et al., 2012; Nakamura et al., 2017). The microwave-assisted experiments were controlled by four experimental parameters: temperature T ($120°C$ to $170°C$), hold time H (0 to 60 minutes), ramp power P ($0W$ to $60W$) and tri-ethyl-gallium (TEG) volume ratio R (from 0 to 0.93). A generalized quadratic regression model was employed in (Nakamura et al., 2017) to estimate the coverage percentage of the crystallization CP:

$$CP = \beta_1 + \beta_2 T + \beta_3 H + \beta_4 P + \beta_5 R + \beta_6 T^2 + \beta_7 H^2 + \beta_8 P^2 + \beta_9 R^2. \quad (9)$$

As a proof of concept, we test our proposed algorithms and compare with baseline methods on a data set consisting of 133 experiments, with the coverage percentage fully collected and measured. We consider selection of subsets of k experiments, with k ranging

Table 3: Selected subsets of uniform sampling (Uniform), leverage score sampling (Levscore) and greedy method (Greedy) on the material synthesis dataset.

from 21 to 30, and report in Figure 2 the mean-square error (MSE) of both the prediction error $\|y - X\widehat{\beta}\|_2^2$, normalized by dividing by the prediction error $\|y - X\widehat{\beta}_{\text{ols}}\|_2^2$ of the OLS estimator on the full data set, on the full 133 experiments and the estimation error $\|\widehat{\beta} - \widehat{\beta}^{\text{ols}}\|_2^2$. Figure 2 shows that our proposed methods consistently achieve the best performance and are more stable compared to uniform sampling and Fedorov's exchange methods, even though the linear model assumption may not hold.

We also report the actual subset ($k = 30$) design points selected by uniform sampling (L_1), leverage score sampling (L_3) and our greedy method (L_5^*) in Table 3. Table 3 shows that the greedy algorithm (L_5^*) picked very diverse experimental settings, including several settings of very lower temperature ($120°C$) and very short hold time (0). In contrast, the experiments picked by both uniform sampling (L_1) and leverage score sampling (L_3) are less diverse.

5.2 The CPU performance dataset

CPU relative performance refers to the relative performance of a particular CPU model in terms of a base machine - the IBM 370/158 model. Comprehensive benchmark tests are required to accurately measure the relative performance of a particular CPU, which might be time-consuming or even impossible if the actual CPU has not been on the market yet. Ein-Dor and Feldmesser (1987) considered a linear regression model to characterize the relationship between CPU relative performance and several CPU capacity parameters such as main memory size, cache size, channel units and machine clock cycle time. These parameters are fixed for any specific CPU model and could be known even before the manufacturing process. The learned model can also be used to predict the relative performance of a new CPU model based on its model parameters, without running extensive benchmark tests.

Using domain knowledge, Ein-Dor and Feldmesser (1987) narrow down to three parameters of interest: *average memory size* (X_1), *cache size* (X_2) and *channel capacity* (X_3), all being explicitly computable functions from CPU model parameters. An offset parameter is also involved in the linear regression model, making the number of variables $p = 4$. A total of $n = 209$ CPU models are considered, with all of the model parameters and relative performance collected and no missing data. Stepwise linear regression was applied to obtain the following linear model:

$$0.49X_1 + 0.30X_2 + 0.19X_3 + 3.78. \tag{10}$$

To use this data set as a benchmark for evaluating the experiment selection methods, we synthesize labels Y using model Eq. (10) with standard Gaussian noise and measure the difference between fit $\widehat{\beta}$ and the true model $\beta_0 = [0.49; 0.30; 0.19; 3.78]$. Table 4 shows that under various measurement budget (k) constraints, the proposed methods L_4^* and L_5^* consistently achieve small estimation error, and is comparable to the Fedorov's exchange algorithm ($L_6^\dagger$). As the data set is small (209×4), all algorithms are computationally efficient.

5.3 The Minnesota Wind Dataset

The Minnesota wind dataset collects wind speed information across $n = 2642$ locations in Minnesota, USA for a period of 24 months (for the purpose of this experiment, we only use wind speed data for one month). The 2642 locations are connected with 3304 bi-directional roads, which form an $n \times n$ sparse unweighted undirected graph G. Let $L = \text{diag}(d) - G$ be the $n \times n$ Laplacian of G, where d is a vector of node degrees and let $V \in \mathbb{R}^{n \times p}$ be an orthonormal eigenbasis corresponding to the smallest p eigenvalues of L. As the wind speed signal $y \in \mathbb{R}^n$ is relatively smooth, it can be well-approximated as $y = V\theta + \varepsilon$, where $\theta \in \mathbb{R}^p$ corresponds to the coefficients of the graph Laplacian basis. The speed signal y has a fast decay on the Laplacian basis V; in particular, OLS on the first $p = 50$ basis accounts for over 99% of the variation in y. (That is, $\|V\widehat{\theta}^{\text{ols}} - y\|_2^2 \le 0.01\|y\|_2^2$, where $\widehat{\theta}^{\text{ols}} = (V^\top V)^{-1}V^\top y$.)

In our experiments we compare the 6 algorithms (L_1 through L_6) when a very small portion of the full samples is selected. The ratio of the mean-square prediction error $\frac{1}{n}\|V\widehat{\theta} - y\|_2^2$ compared to the MLE of the full-sample OLS estimator $\frac{1}{n}\|V\widehat{\theta}^{\text{ols}} - y\|_2^2$ is reported. Apart from the real speed data, we also report results under a "semi-synthetic" setting similar to Sec. 5.2, where the full OLS estimate $\widehat{\theta}^{\text{ols}}$ is first computed and then y is synthesized as $y = V\widehat{\theta}^{\text{ols}} + \varepsilon$ where ε are i.i.d. standard Normal random variables.

From Figure 3, greedy methods ($L_5^*, L_6^\dagger$) achieve consistently the lowest MSE and are robust to subset size k. However, the Fedorov's exchange algorithm is very slow and requires more than 10 times the running time than our proposed methods (L_4^*, L_5^*). On the other hand, sampling based methods (L_1 through L_4^*) behave quite badly when subset size k is small and close to the problem dimension p. This is because when k is close to p, even very small changes resulted from randomization could lead to highly singular designs and hence significantly increases the mean-square prediction error. We also observe that for

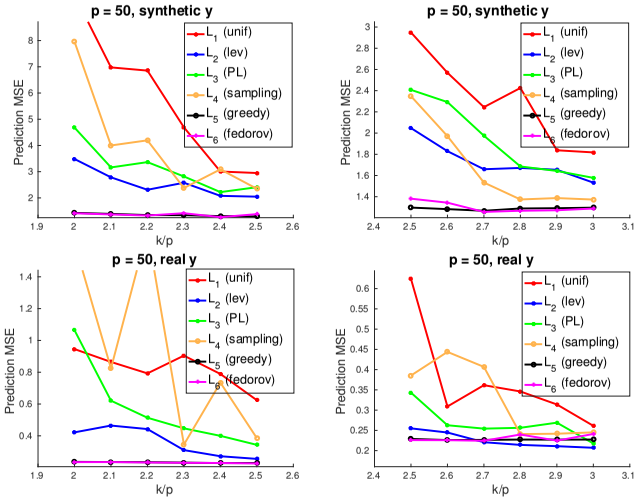

Figure 3: Plots of the ratio of mean square prediction error $\frac{1}{n}\|V\widehat{\theta} - y\|_2^2$ compared against the MSE of the full-sample OLS estimator $\frac{1}{n}\|V\widehat{\theta}^{\text{ols}} - y\|_2^2$ on the Minnesota wind dataset. In the top panel response variables y are synthesized as $y = V\widehat{\theta}^{\text{ols}} + \varepsilon$, where $\widehat{\theta}^{\text{ols}}$ is the full-sample OLS estimator and ε are i.i.d. standard Normal random variables. In the bottom panel the real wind speed response y is used. For randomized algorithms (L_1 to L_4) the experiments are repeated for 50 times and the median MSE ratio is reported.

sufficiently large subset size (e.g., $k = 3p$), the performance gap between all methods is smaller on real signal compared to the synthetic signals. We conjecture that this is because the linear model $y = V\theta + \varepsilon$ only approximately holds in real data.

6. Discussion

We discuss potential improvements in the analysis presented in this paper.

6.1 Sampling based method

To fully understand the finite-sample behavior of the sampling method introduced in Secs. 3.2 and 3.3, it is instructive to relate it to the *graph spectral sparsification* problem (Spielman and Srivastava, 2011) in theoretical computer science: Given a directed weighted graph $G = (V, E, W)$, find a subset $\widetilde{E} \subseteq E$ and new weights $\widetilde{W}$ such that $\widetilde{G} = (V, \widetilde{E}, \widetilde{W})$ is a *spectral sparsification* of G, which means there exists $\epsilon \in (0, 1)$ such that for any vector

$z \in \mathbb{R}^{|V|}$:

$$(1-\epsilon)\sum_{(u,v)\in E} w_{uv}(z_u - z_v)^2 \le \sum_{(u,v)\in \widetilde{E}} \widetilde{w}_{uv}(z_u - z_v)^2 \le (1+\epsilon)\sum_{u,v\in E} w_{uv}(z_u - z_v)^2.$$

Define $B_G \in \mathbb{R}^{|E|\times|V|}$ to be the *signed edge-vertex incidence matrix*, where each row of B_G corresponds to an edge in E, each column of B_G corresponds to a vertex in G, and $[B_G]_{ij} = 1$ if vertex j is the head of edge i, $[B_G]_{ij} = -1$ if vertex j is the tail of edge i, and $[B_G]_{ij} = 0$ otherwise. The spectral sparsification requirement can then be equivalently written as

$$(1-\epsilon)z^\top(B_G^\top W B_G)z \le z^\top(B_{\widetilde{G}}^\top \widetilde{W} B_{\widetilde{G}})z \le (1+\epsilon)z^\top(B_G^\top W B_G)z.$$

The similarity of graph sparsification and the experimental selection problem is clear: $B_G \in \mathbb{R}^{n\times p}$ would be the known pool of design points and $W = \text{diag}(\pi^*)$ is a diagonal matrix with the optimal weights π^* obtained by solving Eq. (4). The objective is to seek a small subset of rows in B_G (i.e., the sparsified edge set $\widetilde{E}$) which is a spectral approximation of the original $B_G^\top \text{diag}(\pi^*) B_G$. Approximation of the A-optimality criterion or any other eigen-related quantity immediately follows. One difference is that in linear regression each row of B_G is no longer a $\{\pm 1, 0\}$ vector. Also, the subsampled weight matrix $\widetilde{W}$ needs to correspond to an unweighted graph for linear regression, i.e. diagonal entries of $\widetilde{W}$ must be in $\{0, 1\}$. However, we consider this to be a minor difference as it does not interfere with the spectral properties of B_G.

The spectral sparsification problem where $\widetilde{W}$ can be arbitrarily designed (i.e. not restricted to have $\{0, 1\}$ diagonal entries) is completely solved (Spielman and Srivastava, 2011; Batson et al., 2012), where the size of the selected edge subset is allowed to be *linear* to the number of vertices, or in the terminology of our problem, $k \asymp p$. Unfortunately, both methods require the power of arbitrary designing the weights in $\widetilde{W}$, which is generally not available in experiment selection problems (i.e., cannot set noise variance or signal strength arbitrarily for individual design points). Recently, it was proved that when the original graph is unweighted ($W = I$), it is also possible to find unweighted linear-sized edge sparsifiers ($\widetilde{W} \propto I$) (Marcus et al., 2015a,b; Anderson et al., 2014). This remarkable result leads to the solution of the long-standing Kardison-Singer problem. However, the condition that the *original* weights W are uniform is not satisfied in the linear regression problem, where the optimal solution π^* may be far from uniform. The experiment selection problem somehow falls in between, where an *unweighted* sparsifier is desired for a *weighted* graph. This leads us to the following question:

Question 6.1 *Given a* weighted *graph $G = (V, E, W)$, under what conditions are there small edge subset $\widetilde{E} \subseteq E$ with* uniform *weights $\widetilde{W} \propto I$ such that $\widetilde{G} = (V, \widetilde{E}, \widetilde{W})$ is a (one-sided) spectral approximation of G?*

The answer to the above question, especially the smallest possible edge size $|\widetilde{E}|$, would have immediate consequences on finite-sample conditions of k and p in the experiment selection problem.

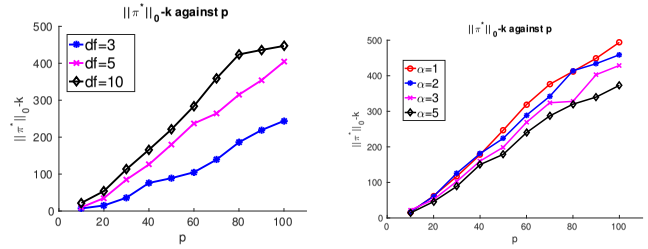

Figure 4: Empirical verification of the rate of $\|\pi^*\|_0$. Left: isotropic design (t distribution); Right: skewed design (transformed multivariate Gaussian) with spectral decay $\lambda_j \propto j^{-\alpha}$.

6.2 Greedy method

Corollary 11 shows that the approximation quality of the greedy based method depends crucially upon $\|\pi^*\|_0$, the support size of the optimal solution π^*. In Lemma 12 we formally established that $\|\pi^*\|_0 \le k + p(p+1)/2$ under mild conditions; however, we conjecture the $p(p+1)/2$ term is loose and could be improved to $O(p)$ in general cases.

In Fig 4 we plot $\|\pi^*\|_0 - k$ against number of variables p, where p ranges from 10 to 100 and k is set to $3p$. The other simulation settings are kept unchanged. We observe that in all settings $\|\pi^*\|_0 - k$ scales linearly with p, suggesting that $\|\pi^*\|_0 \le k + O(p)$. Furthermore, the slope of the scalings does not seem to depend on the conditioning of X, as shown in the right panel of Fig 4 where the conditioning of X is controlled by the spectral decay rate α. This is in contrast to the analysis of the sampling based method (Theorem 5), in which the finite sample bound depends crucially upon the conditioning of X for the without replacement setting.

6.3 High-dimensional settings

This paper focuses solely on the so-called *large-sample, low-dimensional* regression setting, where the number of variables p is assumed to be much smaller than both design pool size n and subsampling size k. It is an interesting open question to extend our results to the *high-dimensional* setting, where p is much larger than both n and k, and an assumption like sparsity of β_0 is made to make the problem feasible, meaning that very few components in β_0 are non-zero. In particular, it is desirable to find a sub-sampling algorithm that attains the following minimax estimation rate over high-dimensional sparse models:

$$\inf_{A \in \mathcal{A}_b(k)} \sup_{\|\beta_0\|_0 \le s} \mathbb{E}_{A,\beta_0} \left[\|\widehat{\beta} - \beta_0\|_2^2 \right].$$

One major obstacle of designing subsampling algorithms for high-dimensional regression is the difficulty of evaluating and optimizing the *restricted eigenvalue* (or other similar criteria) of the subsampled covariance matrix. Unlike the ordinary spectrum, the restricted eigenvalue of a matrix is NP-hard to compute (Dobriban and Fan, 2016) and heavily influences the statistical efficiency of a Lasso-type estimator (Bickel et al., 2009). The question

of optimizing such restricted eigenvalues could be even harder and remains largely open. We also mention that Davenport et al. (2015) suggests a two-step approach where half the budget is used to identify the sparse locations from randomly sampled points and the remaining budget is used to generate a better estimate of regression coefficients using the same convex programming formulation proposed in our paper. Their paper provides some experimental support for this idea, however, no theoretical guarantees are established for the (sub)optimality of such a procedure. Analyzing such a two-step approach could be an interesting future direction.

6.4 Approximate linear models

In cases when the linear model $y = X\beta_0 + \varepsilon$ only approximately holds, we describe here a method that takes into consideration both bias and variance of OLS estimates on subsampled data in order to find good sub-samples. Suppose $y = f_0(X) + \varepsilon$ for some unknown underlying function f_0 that might not be linear, and let $\beta^* = (X^\top X)^{-1} X^\top f_0(X)$ be the optimal linear predictor on the full sample X. Suppose $X_S = \Psi X$ is the subsampled data, where $\Psi \in \mathbb{R}^{|S| \times n}$ is the subsampling matrix where each row of Ψ is $e_i = (0, \cdots, 0, 1, 0, \cdots, 0) \in \mathbb{R}^n$, with $i \in [n]$ being the subsampled rows in X. Let $\widehat{\beta} = (X_S^\top X_S)^{-1} X_S^\top y_S$ be the OLS on the subsampled data. The error of $\widehat{\beta}$ can then be decomposed and upper bounded as

$$\mathbb{E}\|\widehat{\beta} - \beta^*\|_2^2 = f_0(X)^\top \left[(X^\top \Psi^\top \Psi X)^{-1} X^\top \Psi^\top \Psi - (X^\top X)^{-1} X^\top \right] f_0(X) + \sigma^2 \mathrm{tr}\left[(X^\top \Psi^\top \Psi X)^{-1} \right] \tag{11}$$

$$\le \left\| (X^\top \Psi^\top \Psi X)^{-1} X^\top \Psi^\top \Psi - (X^\top X)^{-1} X^\top \right\|_{\mathrm{op}} \cdot \|f_0(X)\|_2^2 + \sigma^2 \mathrm{tr}\left[(X^\top \Psi^\top \Psi X)^{-1} \right]. \tag{12}$$

In the high noise setting, the first term can be ignored and the solution is close to the one considered in this paper. In the low-noise setting, the second term can be ignored and a relaxation similar to Eq. (4) can be derived; however a linear approximation may be undesirable in this case. In general, when $\|f_0(X)\|_2^2 \approx \lambda$ is known or can be estimated, the following continuous optimization problem serves as an approximate objective of subsampled linear regression with approximate linear models:

$$\min_{\pi \in \mathbb{R}^n} \quad \lambda \left\| \left(\sum_{i=1}^n \pi_i x_i x_i^\top \right)^{-1} X^\top \mathrm{diag}(\pi) - (X^\top X)^{-1} X^\top \right\|_{\mathrm{op}} + \sigma^2 \mathrm{tr}\left[\left(\sum_{i=1}^n \pi_i x_i x_i^\top \right)^{-1} \right]$$

$$s.t. \quad \sum_{i=1}^n \pi_i \le k, \quad 0 \le \pi_i \le 1.$$

Unfortunately, the relaxation in Eq. (12) may be loose and hence the optimization problem above fails to serve as a good objective for the optimal subsampling problem with approximate linear models. Exact characterization of the bias term in Eq. (11) without strong assumptions on f_0 is an interesting open question.

7. Proofs

7.1 Proof of facts in Sec. 3.1

Proof [Proof of Fact 3.1] Let $A = X^\top \mathrm{diag}(\pi) X$ and $B = X^\top \mathrm{diag}(\pi') X$. By definition, $B = A + \Delta$ where $\Delta = X^\top \mathrm{diag}(\pi' - \pi) X$ is positive semi-definite. Subsequently, $\sigma_\ell(B) \geq \sigma_\ell(A)$ for all $\ell = 1, \cdots, p$. We then have that

$$f(\pi'; X) = \mathrm{tr}(B^{-1}) = \sum_{\ell=1}^{p} \sigma_\ell(B)^{-1} \leq \sum_{\ell=1}^{p} \sigma_\ell(A)^{-1} = \mathrm{tr}(A^{-1}) = f(\pi; X).$$

Note also that if $\pi' \neq \pi$ then $\Delta \neq 0$ and hence there exists at least one ℓ with $\sigma_\ell(B) < \sigma_\ell(A)$. Therefore, the equality holds if and only if $\pi = \pi'$. ■

Proof [Proof of Fact 3.2] Suppose $\|\pi^*\|_1 < k$. Then there exists some coordinate $j \in \{1, \cdots, n\}$ such that $\pi^*_j < 1$. Define π' as $\pi'_i = \pi^*_i$ for $i \neq j$ and $\pi'_j = \min\{1, \pi^*_j + k - \|\pi^*\|_1\}$. Then π' is also a feasible solution. On the other hand, By Fact 3.1 we have that $f(\pi'; X) < f(\pi^*; X)$, contradicting the optimality of π^*. Therefore, $\|\pi^*\|_1 = k$. ■

7.2 Proof of Theorem 3

We only prove Theorem 3 for the with replacement setting ($b = 1$). The proof for the without replacement setting is almost identical.

Define $\widetilde{\mathcal{A}}_1(k)$ as the class of *deterministic* algorithms that proceed as follows:

1. The algorithm deterministically outputs pairs $\{(w_i, x_i)\}_{i=1}^M$, where x_i is one of the rows in X and $\{w_i\}_{i=1}^n$ satisfies $w_i \geq 0$, $\sum_{i=1}^M w_i \leq k$. Here M is an arbitrary finite integer.
2. The algorithm observes $\{y_i\}_{i=1}^M$ with $y_i = \sqrt{w_i} x_i^\top \beta + \varepsilon_i$. Here β is a fixed but unknown regression model and $\varepsilon_i \overset{i.i.d.}{\sim} \mathcal{N}(0, \sigma^2)$ is the noise.
3. The algorithm outputs $\widehat{\beta}$ as an estimation of β, based on the observations $\{y_i\}_{i=1}^M$.

Because all algorithms in $\widetilde{\mathcal{A}}_1(k)$ are deterministic and the design matrix still has full column rank, the optimal estimator of $\widehat{\beta}$ *given* $\{(w_i, x_i)\}_{i=1}^M$ is the OLS estimator. For a specific data set weighted through $\sqrt{w_1}, \cdots, \sqrt{w_M}$, the minimax estimation error (which is achieved by OLS) is given by

$$\inf_{\widehat{\beta}} \sup_{\beta} \mathbb{E}\left[\|\widehat{\beta} - \beta\|_2^2\right] = \sup_{\beta} \mathbb{E}\left[\|\widehat{\beta}^{\mathrm{ols}} - \beta\|_2^2\right] = \sigma^2 \mathrm{tr}\left[(\widetilde{X}^\top \widetilde{X})^{-1}\right] = \sigma^2 \mathrm{tr}\left[\left(\sum_{i=1}^n \widetilde{w}_i x_i x_i^\top\right)^{-1}\right],$$

where $\widetilde{w}_i$ is the aggregated weight of data point x_i in all the M weighted pairs. Subsequently,

$$\inf_{\widetilde{A} \in \widetilde{\mathcal{A}}_1(k)} \sup_{\beta} \mathbb{E}\left[\|\widehat{\beta}_{\widetilde{A}} - \beta\|_2^2\right] = \inf_{w_1 + \cdots + w_M \leq k} \sigma^2 \mathrm{tr}\left[\left(\sum_{i=1}^M w_i x_i x_i^\top\right)^{-1}\right] = \sigma^2 f_1^*(k; X).$$

It remains to prove that

$$\inf_{\widetilde{A} \in \widetilde{\mathcal{A}}_1(k)} \sup_{\beta} \mathbb{E}\left[\|\widehat{\beta}_{\widetilde{A}} - \beta\|_2^2\right] \leq \inf_{A \in \mathcal{A}_1(k)} \sup_{\beta} \mathbb{E}\left[\|\widehat{\beta}_A - \beta\|_2^2\right].$$

We prove this inequality by showing that for every (possibly random) algorithm $A \in \mathcal{A}_1(k)$, there exists $\widetilde{A} \in \widetilde{\mathcal{A}}_1(k)$ such that $\sup_\beta \mathbb{E}[\|\widehat{\beta}_A - \beta\|_2^2] \geq \sup_\beta \mathbb{E}[\|\widehat{\beta}_{\widetilde{A}} - \beta\|_2^2]$. To see this, we construct $\widetilde{A}$ based on A as follows:

1. For every k-subset (duplicates allowed) of all possible outputs of A (which by definition are all subsets of X) and its corresponding weight vector w, add $(w'_i, \widetilde{x}_i)$ to the design set of $\widetilde{A}$, where $w'_i = w_i \Pr_A(\widetilde{X})$.
2. The algorithm $\widetilde{A}$ observes all responses $\{y_i\}$ for $\{(w'_i, \widetilde{x}_i)\}$.
3. $\widetilde{A}$ outputs the *expected* estimation of A; that is, $\widetilde{A}(X, y) = \mathbb{E}_{\widetilde{X}}[\mathbb{E}_y[\widehat{\beta}_A | \widetilde{X}]]$. Note that by definition of the estimator class $\mathcal{A}_1(k)$, all estimators $\widehat{\beta}_A$ *conditioned on subsampled data points* $\widetilde{X}$ are deterministic.

We claim that $\widetilde{A} \in \widetilde{\mathcal{A}}_1(k)$ because

$$\sum_i w'_i = \sum_{\widetilde{X}} \Pr(\widetilde{X}) \sum_{i=1}^k w_i \leq k.$$

Furthermore, by Jensen's inequality we have

$$\mathbb{E}_{\widetilde{X}, y}\left[\|\widehat{\beta}_A - \beta\|_2^2\right] \geq \mathbb{E}_y\left[\|\mathbb{E}_{\widetilde{X}}[\widehat{\beta}_A] - \beta\|_2^2\right] = \mathbb{E}_y\left[\|\widehat{\beta}_{\widetilde{A}} - \beta\|_2^2\right].$$

Taking supreme over β we complete the proof.

7.3 Proof of Lemma 6

With replacement setting Define $\Phi = \mathrm{diag}(\pi^*)$ and $\Pi = \Phi^{1/2} X \Sigma_*^{-1} X^\top \Phi^{1/2} \in \mathbb{R}^{n \times n}$. The following proposition lists properties of Π:

Proposition 14 (Properties of projection matrix) *The following properties for* Π *hold:*

1. Π *is a projection matrix. That is,* $\Pi^2 = \Pi$.
2. $\mathrm{Range}(\Pi) = \mathrm{Range}(\Phi^{1/2} X)$.
3. *The eigenvalues of* Π *are 1 with multiplicity* p *and 0 with multiplicity* $n - p$.
4. $\Pi_{ii} = \|\Pi_{i,\cdot}\|_2^2 = \pi_i^* x_i^\top \Sigma_*^{-1} x_i$.

Proof Proof of 1: By definition, $\Sigma_* = X^\top \Phi X$ and subsequently

$$\begin{aligned} \Pi^2 &= \Phi^{1/2} X \Sigma_*^{-1} X^\top \Phi^{1/2} \Phi^{1/2} X \Sigma_*^{-1} X^\top \Phi^{1/2} \\ &= \Phi^{1/2} X (X^\top \Phi X)^{-1} X^\top \Phi X (X^\top \Phi X)^{-1} \Phi^{1/2} \\ &= \Phi^{1/2} X (X^\top \Phi X)^{-1} X^\top \Phi^{1/2} = \Pi. \end{aligned}$$

Proof of 2: First note that $\text{Range}(\Pi) = \text{Range}(\Phi^{1/2}X\Sigma_*^{-1}X^\top\Phi^{1/2}) \subseteq \text{Range}(\Phi^{1/2}X)$. For the other direction, take arbirary $u \in \text{Range}(\Phi^{1/2}X)$ and express u as $u = \Phi^{1/2}Xv$ for some $v \in \mathbb{R}^p$. We then have

$$\begin{aligned}\Pi u &= \Phi^{1/2}X\Sigma_*^{-1}X^\top\Phi^{1/2}u \\ &= \Phi^{1/2}X(X^\top\Phi X)^{-1}X^\top\Phi^{1/2}\Phi^{1/2}Xv \\ &= \Phi^{1/2}Xv = u\end{aligned}$$

and hence $u \in \text{Range}(\Pi)$.

Proof of 3: Because $\Sigma_* = X^\top\Phi X$ is invertible, the $n\times p$ matrix $\Phi^{1/2}X$ must have full column rank and hence $\ker(\Phi^{1/2}X) = \{0\}$. Consequently, $\dim(\text{Range}(\Pi)) = \dim(\text{Range}(\Phi^{1/2}X)) = p - \dim(\ker(\Phi^{1/2}X)) = p$. On the other hand, the eigenvalues of Π must be either 0 or 1 because Π is a projection matrix. So the eigenvalues of Π are 1 with multiplicity p and 0 with multiplicity $n-p$.

Proof of 4: By definition,

$$\Pi_{ii} = \sqrt{\pi_i^*}x_i^\top\Sigma_*^{-1}x_i\sqrt{\pi_i^*} = \pi_i^* x_i^\top\Sigma_*^{-1}x_i.$$

In addition, Π is a symmetric projection matrix. Therefore,

$$\Pi_{ii} = [\Pi^2]_{ii} = \Pi_{i,\cdot}^\top\Pi_{i,\cdot} = \|\Pi_{i,\cdot}\|_2^2.$$

■

The following lemma shows that a spectral norm bound over deviation of the projection matrix implies spectral approximation of the underlying (weighted) covariance matrix.

Lemma 15 (Spielman and Srivastava (2011), Lemma 4) *Let $\Pi = \Phi^{1/2}X\Sigma_*^{-1}X^\top\Phi^{1/2}$ and W be an $n\times n$ non-negative diagonal matrix. If $\|\Pi W\Pi - \Pi\|_2 \le \epsilon$ for some $\epsilon \in (0, 1/2)$ then*

$$(1-\epsilon)u^\top\Sigma_* u \le u^\top\widetilde{\Sigma}_* u \le (1+\epsilon)u^\top\Sigma_* u, \quad \forall u \in \mathbb{R}^p,$$

where $\Sigma_* = X^\top\Phi X$ and $\widetilde{\Sigma}_* = X^\top W^{1/2}\Phi W^{1/2}X$.

We next proceed to find an appropriate diagonal matrix W and validate Lemma 15. Define $w_j^* = \pi_j^*/(kp_j^{(2)})$ and $\widehat{\Sigma}_{\widehat{W}} = \sum_{t=1}^k w_{i_t}^* x_{i_t}x_{i_t}^\top$. It is obvious that $\widehat{\Sigma}_{\widehat{W}} \preceq \widehat{\Sigma}_{\widehat{S}}$ because $w_i = \lceil w_i^* \rceil \ge w_i^*$. It then suffices to lower bound the spectrum of $\widehat{\Sigma}_{\widehat{W}}$ by the spectrum of $\widehat{\Sigma}_*$. Define random diagonal matrix $W^{(1)}$ as ($\mathbb{I}[\cdot]$ is the indicator function)

$$W_{jj}^{(1)} = \frac{\sum_{t=1}^k w_{i_t}^*\mathbb{I}[i_t = j]}{\pi_j^*}, \quad j = 1, \cdots, n.$$

Then by definition, $\widetilde{\Sigma}_* = X^\top W^{1/2}\Phi W^{1/2}X = \sum_{t=1}^k w_{i_t}^* x_{i_t}x_{i_t}^\top = \widehat{\Sigma}_{\widehat{R}}$. The following lemma bounds the perturbation $\|\Pi W\Pi - \Pi\|_2$ for this particular choice of W.

Lemma 16 *For any $\epsilon > 0$,*

$$\Pr\left[\|\Pi W^{(1)}\Pi - \Pi\|_2 > \epsilon\right] \le 2\exp\left\{-C\cdot\frac{k\epsilon^2}{p\log k}\right\},$$

where $C > 0$ is an absolute constant.

Proof Define n-dimensional random vector v as [3]

$$\Pr\left[v = \sqrt{\frac{kw_j^*}{\pi_j^*}}\Pi_{j\cdot}\right] = p_j^{(2)}, \quad j = 1, \cdots, n.$$

Let $v_1, \cdots, v_k$ be i.i.d. copies of v and define $A_t = v_t v_t^\top$. By definition, $\Pi W^{(1)}\Pi$ is equally distributed with $\frac{1}{k}\sum_{t=1}^k A_t$. In addition,

$$\mathbb{E}A_t = \sum_{j=1}^n \frac{kw_j^*}{\pi_j^*}p_j^{(2)}\Pi_{j\cdot}\Pi_{j\cdot}^\top = \Pi^2 = \Pi,$$

which satisfies $\|\mathbb{E}A_t\|_2 = 1$, and

$$\|A_t\|_2 = \|v_t\|_2^2 \le \sum_{1\le j\le n}\frac{kw_j^*}{\pi_j^*}\|\Pi_{j\cdot}\|_2^2 \le \sup_{1\le j\le n}\frac{p}{x_j^\top\Sigma_*^{-1}x_j}\cdot x_j^\top\Sigma_*^{-1}x_j = p.$$

Applying Lemma 18 we have that

$$\Pr\left[\|\Pi W^{(1)}\Pi - \Pi\|_2 > \epsilon\right] \le 2\exp\left\{-C\cdot\frac{k\epsilon^2}{p\log k}\right\}.$$

■

With Lemma 16, we know that $\|\Pi W\Pi - \Pi\|_2 \le \epsilon$ holds with probability at least 0.9 if $\frac{p\log k}{k} = O(\epsilon^2)$. Eq. (6) then holds with high probability by Lemma 15.

Without replacement setting Define independently distributed random matrices $A_1, \cdots, A_n$ as

$$A_j = (w_j - \pi_j^*)x_j x_j^\top, \quad j = 1, \cdots, n.$$

Note that w_j is a random Bernoulli variable with $\Pr[w_j = 1] = kp_j^{(2)} = \pi_j^*$. Therefore, $\mathbb{E}A_j = 0$. In addition,

$$\sup_{1\le j\le n}\|A_j\|_2 \le \sup_{1\le j\le n}\|x_j\|_2^2 \le \|X\|_\infty^2 \quad a.s.$$

and

$$\left\|\sum_{j=1}^n \mathbb{E}A_j^2\right\|_2 = \left\|\sum_{j=1}^n \pi_j^*(1-\pi_j^*)\|x_j\|_2^2 x_j x_j^\top\right\|_2 \le \|X\|_\infty^2\|\Sigma_*\|_2.$$

Noting that $\sum_{j=1}^n A_j = X_{\widehat{S}}^\top X_{\widehat{S}} - X^\top\text{diag}(\pi^*)X = \widehat{\Sigma}_{\widehat{S}} - \Sigma_*$ and invoking Lemma 19 with $t = \epsilon\lambda_{\min}(\Sigma_*)$ we have that

$$\Pr\left[\|\widehat{\Sigma}_{\widehat{S}} - \Sigma_*\|_2 > \epsilon\lambda_{\min}(\Sigma_*)\right] \le 2p\exp\left\{-\frac{\epsilon^2\lambda_{\min}(\Sigma_*)^2}{3\|\Sigma_*\|_2\|X\|_\infty^2 + 2\|X\|_\infty^2\cdot\epsilon\lambda_{\min}(\Sigma_*)}\right\}.$$

3. For those j with $\pi_j^* = 0$, we have by definition that $p_j^{(2)} = 0$.

Equating the right-hand side with $O(1)$ we have that

$$\|\Sigma_*^{-1}\|_2\kappa(\Sigma_*)\|X\|_\infty^2 \log p = O(\epsilon^2).$$

Finally, by Weyl's theorem we have that

$$\left|\lambda_\ell(\widehat{\Sigma}_{\widehat{S}}) - \lambda_\ell(\Sigma_*)\right| \le \|\widehat{\Sigma}_{\widehat{S}} - \Sigma_*\|_2 \le \epsilon\lambda_{\min}(\Sigma_*) \le \epsilon\lambda_\ell(\Sigma_*),$$

and hence the proof of Lemma 6.

7.4 Proof of Lemma 8

With replacement setting Define $\widetilde{w}_j^* = k/T \cdot w_j^* = \pi_j^*/(Tp_j^{(1)})$ and let $\widehat{\Sigma}_T = \sum_{t=1}^T \widetilde{w}_{i_t}^* x_{i_t} x_{i_t}^\top$. Because $\widehat{\Sigma}_T = \frac{k}{T}\widehat{\Sigma}_{\widehat{\Sigma}_W} \preceq \widehat{\Sigma}_{\widehat{S}}$, we have that $\widehat{\Sigma}_{\widehat{S}} \succeq \frac{T}{k}\widehat{\Sigma}_T$ and hence $z^\top\widehat{\Sigma}_{\widehat{S}}z \ge \frac{T}{k}z^\top\widehat{\Sigma}_T z$ for all $z \in \mathbb{R}^p$. Therefore, to lower bound the spectrum of $\widehat{\Sigma}_{\widehat{S}}$ it suffices to lower bound the spectrum of $\widehat{\Sigma}_T$.

Define diagonal matrix $W^{(2)}$ as

$$W_{jj}^{(2)} = \frac{\sum_{t=1}^T \widetilde{w}_{i_t}^* \mathbb{I}[i_t = j]}{\pi_j^*}, \qquad j = 1, \cdots, n.$$

We have that $\widetilde{\Sigma}_* = \widehat{\Sigma}_T$ for this particular choice of W. Following the same analysis in the proof of Lemma 16, we have that for every $t > 0$

$$\Pr\left[\|\Pi W^{(2)}\Pi - \Pi\|_2 > t\right] \le 2\exp\left\{-C \cdot \frac{T\epsilon^2}{p\log T}\right\}.$$

Set $t = O(1)$ and equate the right-hand side of the above inequality with $O(1)$. We then have

$$\Pr\left[\widehat{\Sigma}_T \succeq \Omega(1) \cdot \widehat{\Sigma}_*\right] = \Omega(1) \qquad \text{if } p\log T/T = O(1).$$

Subsequently, under the condition that $p\log T/T = O(1)$, with probability at least 0.9 it holds that

$$\widehat{\Sigma}_{\widehat{S}} \succeq \Omega(T/k) \cdot \Sigma_*,$$

which completes the proof of Lemma 8 for the without replacement setting.

Without replacement setting Define $\widehat{\Sigma}_{\widehat{R}} = X_{R_T}^\top X_{R_T} = \sum_{t=1}^T \pi_{i_t} x_{i_t} x_{i_t}^\top$. Conditioned on R_T, the subset $\widehat{S} = S_T$ is selected using the same procedure of the soft-constraint algorithm Figure 1 on $X_{R_T} = \{x_i\}_{i\in R_T}$. Subsequently, following analysis in the proof of Lemma 6 we have

$$\Pr\left[\|\widehat{\Sigma}_{\widehat{S}} - \widehat{\Sigma}_T\|_2 > t \middle| R_T\right] \le 2p \cdot \exp\left\{-\frac{t^2}{3\|\widehat{\Sigma}_T\|_2\|X\|_\infty^2 + 2\|X\|_\infty^2 t}\right\}.$$

Setting $t = O(1) \cdot \lambda_{\min}(\Sigma_T)$ we have that, if $\|\widehat{\Sigma}_T^{-1}\|_2\kappa(\widehat{\Sigma}_T)\|X\|_\infty^2 \log p = O(1)$, then with probability at least 0.95 conditioned on $\widehat{\Sigma}_T$

$$\Omega(1) \cdot \widehat{\Sigma}_T \preceq \widehat{\Sigma}_{\widehat{S}} \preceq O(1) \cdot \widehat{\Sigma}_T. \tag{13}$$

It remains to establish spectral similarity between $\widehat{\Sigma}_T$ and $\frac{T}{n}\Sigma_*$, a scaled version of Σ_*. Define deterministic matrices $A_1, \cdots, A_n$ as

$$A_j = \pi_j^* x_j x_j^\top - \frac{1}{n}\Sigma_*, \qquad j = 1, \cdots, n.$$

By definition, $\sum_{j=1}^n A_j = 0$ and $\sum_{t=1}^T A_{\sigma(t)} = \widehat{\Sigma}_T - \frac{T}{n}\Sigma_*$, where σ is a random permutation from $[n]$ to $[n]$. In addition,

$$\sup_{1\le j\le n} \|A_j\|_2 \le \frac{1}{n}\|\Sigma_*\|_2 + \sup_{1\le j\le n}\|x_j\|_2^2 \le 2\|X\|_\infty^2$$

and

$$\begin{aligned}
\frac{T}{n}\left\|\sum_{j=1}^n A_j^2\right\|_2 &\le \frac{2T}{n}\left(\left\|\sum_{j=1}^n (\pi_j^*)^2\|x_i\|_2^2 x_i x_i^\top\right\|_2 + \frac{1}{n^2}\|\Sigma_*\|_2^2\right) \\
&\le \frac{2T}{n}\left(\|X\|_\infty^2\left\|\sum_{j=1}^n \pi_j^* x_i x_i^\top\right\|_2 + \frac{1}{n^2}\|\Sigma_*\|_2^2\right) \\
&\le \frac{2T}{n}\left(\|X\|_\infty^2\|\Sigma_*\|_2 + \frac{1}{n^2}\|\Sigma_*\|_2^2\right) \\
&\le \frac{4T}{n}\|X\|_\infty^2\|\Sigma_*\|_2.
\end{aligned}$$

Invoking Lemma 20, we have that

$$\Pr\left[\left\|\widehat{\Sigma}_T - \frac{T}{n}\Sigma_*\right\|_2 > t\right] \le p\exp\left\{-t^2\left[\frac{48T}{n}\|X\|_\infty^2\|\Sigma_*\|_2 + 8\sqrt{2}\|X\|_\infty^2 t\right]^{-1}\right\}.$$

Set $t = O(T/n) \cdot \lambda_{\min}(\Sigma_*)$. We then have that, if $\|\Sigma_*^{-1}\kappa(\Sigma_*)\|X\|_\infty^2 \log p = O(T/n)$ holds, then with probability at least 0.95

$$\Omega(T/n) \cdot \Sigma_* \preceq \widehat{\Sigma}_T \preceq O(T/n) \cdot \Sigma_*. \tag{14}$$

Combining Eqs. (13,14) and noting that $\|\widehat{\Sigma}_T^{-1}\|_2 \le O(\frac{n}{T})\|\Sigma_*^{-1}\|_2$, $\kappa(\Sigma_T) \le O(1)\kappa(\Sigma_*)$, we complete the proof of Lemma 8 under the without replacement setting.

7.5 Proof of Lemma 12

Let $f(\pi; \lambda, \widetilde{\lambda}, \mu)$ be the Lagrangian muliplier function of the without replacement formulation of Eq. (4):

$$f(\pi;\lambda,\widetilde{\lambda},\mu) = f(\pi;X) - \sum_{i=1}^n \lambda_i\pi_i + \sum_{i=1}^n \widetilde{\lambda}_i\left(\pi_i - \frac{1}{k}\right) + \mu\left(\sum_{i=1}^n \pi_i - 1\right).$$

Here $\{\lambda_i\}_{i=1}^n \ge 0$, $\{\widetilde{\lambda}_i\}_{i=1}^n \ge 0$ and $\mu \ge 0$ are Lagrangian multipliers for constraints $\pi_i \ge 0$, $\pi_i \le 1$ and $\sum_i \pi_i \le k$, respectively. By KKT condition, $\frac{\partial f}{\partial \pi_i}\big|_{\pi^*} = 0$ and hence

$$-\left.\frac{\partial f}{\partial \pi_i}\right|_{\pi^*} = x_i^\top\Sigma_*^{-2}x_i = \widetilde{\lambda}_i - \lambda_i + \mu, \qquad i = 1, \cdots, n,$$

where $\Sigma_* = X^\top \mathrm{diag}(\pi^*) X$ is a $p \times p$ positive definite matrix.

Split the index set $[n]$ into three disjoint sets defined as $A = \{i \in [n] : \pi_i^* = 1\}$, $B = \{i \in [n] : 0 < \pi_i^* < 1\}$ and $C = \{i \in [n] : \pi_i^* = 0\}$. Note that $\|\pi^*\|_0 = |A| + |B|$ and $|A| \le k$. Therefore, to upper bound $\|\pi^*\|_0$ it suffices to upper bound $|B|$. By complementary slackness, for all $i \in B$ we have that $\widetilde{\lambda}_i = \lambda_i = 0$; that is,

$$x_i^\top \Sigma_*^{-2} x_i = \langle \phi(x_i), \psi(\Sigma_*^{-2}) \rangle = \mu, \qquad \forall i \in B, \tag{15}$$

where $\phi : \mathbb{R}^p \to \mathbb{R}^{p(p+1)/2}$ is the mapping defined in Assumption 3.1 and $\psi(\cdot)$ takes the upper triangle of a symmetric matrix and vectorizes it into a $\frac{p(p-1)}{2}$-dimensional vector. Assume by way of contradiction that $|B| > p(p+1)/2$ and let $x_1, \cdots, x_{p(p+1)/2+1}$ be arbitrary distinct $\frac{p(p+1)}{2} + 1$ rows whose indices belong to B. Eq. (15) can then be cast as a homogenous linear system with $\frac{p(p+1)}{2} + 1$ variables and equations as follows:

$$\begin{bmatrix} \widetilde{\phi}(x_1) \\ \widetilde{\phi}(x_2) \\ \vdots \\ \widetilde{\phi}(x_{p(p+1)/2+1}) \end{bmatrix} \begin{bmatrix} \psi(\Sigma_*^{-2}) \\ -\mu \end{bmatrix} = 0.$$

Under Assumption 3.1, $\widetilde{\Phi} = [\widetilde{\phi}(x_1); \cdots; \widetilde{\phi}(x_{p(p+1)/2+1})]^\top$ is invertible and hence both $\psi(\Sigma_*^{-2})$ and μ must be zero. This contradicts the fact that Σ_*^{-2} is positive definite.

Appendix A. Technical lemmas

Lemma 17 *Let $\mathbb{B} = \{x \in \mathbb{R}^p : \|x\|_2^2 \le B^2\}$ and $\mathrm{vol}(\mathbb{B}) = \int_{\mathbb{B}} 1 \mathrm{d}x$ be the volume of $\mathbb{B}$. Then $\int_{\mathbb{B}} x x^\top \mathrm{d}x = \frac{B^2}{p+2} \mathrm{vol}(\mathbb{B}) I_{p\times p}$.*

Proof Let U be the uniform distribution in the p-dimensional ball of radius B. By definition, $\int_{\mathbb{B}} x x^\top \mathrm{d}x = \mathrm{vol}(\mathbb{B}) \mathbb{E}_{x\sim U}[x x^\top]$. By symmetry, $\mathbb{E}_{x\sim U}[x x^\top] = c \cdot I_{p\times p}$ for some constant c that depends on p and B. To determine the constant c, note that

$$c = \mathbb{E}[x_1^2] = \frac{1}{p}\mathbb{E}\|x\|_2^2 = \frac{1}{p} \frac{\int_0^B r^{p-1} \cdot r^2 \mathrm{d}r}{\int_0^B r^{p-1} \mathrm{d}r} = \frac{B^2}{p+2}.$$

■

Lemma 18 (Rudelson and Vershynin (2007)) *Let x be a p-dimensional random vector such that $\|x\|_2 \le M$ almost surely and $\|\mathbb{E}x x^\top\|_2 \le 1$. Let $x_1, \cdots, x_n$ be i.i.d. copies of x. Then for every $t \in (0,1)$*

$$\Pr\left[\left\|\frac{1}{n}\sum_{i=1}^n x_i x_i^\top - \mathbb{E}x x^\top\right\|_2 > t\right] \le 2\exp\left\{-C \cdot \frac{nt^2}{M^2 \log n}\right\},$$

where $C > 0$ is some universal constant.

Lemma 19 (Corollary 5.2 of (Mackey et al., 2014), Matrix Bernstein) *Let $(Y_k)_{k\ge1}$ be a sequence of random d-dimensional Hermitian matrices that satisfy*

$$\mathbb{E}Y_k = 0 \quad \text{and} \quad \|Y_k\|_2 \le R \quad a.s.$$

Define $X = \sum_{k\ge1} Y_k$. The for any $t > 0$,

$$\Pr\left[\|X\|_2 \ge t\right] \le d \cdot \exp\left\{-\frac{t^2}{3\sigma^2 + 2Rt}\right\} \quad \text{for } \sigma^2 = \left\|\sum_{k\ge1} \mathbb{E}Y_k^2\right\|_2.$$

Lemma 20 (Corollary 10.3 of (Mackey et al., 2014)) *Let $A_1, \cdots, A_n$ be a sequence of deterministic d-dimensional Hermitian matrices that satisfy*

$$\sum_{k=1}^n A_k = 0 \quad \text{and} \quad \sup_{1\le k\le n} \|A_k\|_2 \le R.$$

Define random matrix $X = \sum_{j=1}^m A_{\sigma(j)}$ for $m \le n$, where σ is a random permutation from $[n]$ to $[n]$. Then for all $t > 0$,

$$\Pr\left[\|X\|_2 \ge t\right] \le d\exp\left\{-\frac{t^2}{12\sigma^2 + 4\sqrt{2}Rt}\right\} \quad \text{for } \sigma^2 = \frac{m}{n}\left\|\sum_{k=1}^n A_k^2\right\|_2.$$

Appendix B. Optimization methods

Two algorithms for optimizing Eq. (4) are described. The SDP formulation is of theoretical interest only and the projected gradient descent algorithm is practical, which also enjoys theoretical convergence guarantees.

SDP formulation For $\pi \in \mathbb{R}^n$ define $A(\pi) = \sum_{i=1}^n \pi_i x_i x_i^\top$, which is a $p \times p$ positive semidefinite matrix. By definition, $f(\pi; X) = \sum_{j=1}^p e_j^\top A(\pi)^{-1} e_j$, where e_j is the p-dimensional vector with only pth coordinate being 1. Subsequently, Eq. (4) is equivalent to the following SDP problem:

$$\min_{\pi,t} \sum_{j=1}^p t_j \quad \text{subject to} \quad 0 \le \pi_i \le 1, \ \sum_{i=1}^n \pi_i \le k, \ \ \mathrm{diag}(B_1, \cdots, B_p) \succeq 0,$$

where

$$B_j = \begin{bmatrix} A(\pi) & e_j \\ e_j^\top & t_j \end{bmatrix}, \qquad j = 1, \cdots, p.$$

Global optimal solution of an SDP can be computed in polynomial time (Vandenberghe and Boyd, 1996). However, this formulation is not intended for practical computation because of the large number of variables in the SDP system. First-order methods such as projected gradient descent is a more appropriate choice for practical computation.

Projected gradient descent For any convex set S and point x let $\mathcal{P}_S(x) = \text{argmin}_{y\in S}\|x-y\|_2$ denote the ℓ_2 projection of x onto S. The projected gradient descent algorithm is a general purpose method to solve convex constrained smooth convex optimization problems of the form

$$\min_x f(x) \quad \text{subject to} \quad x \in S.$$

The algorithm (with step size selected via backtracking line search) iterates until desired optimization accuracy is reached:

input : backtracking parameters $\alpha \in (0, 1/2]$, $\beta \in (0, 1)$.
output: $\widehat{x}$, approximate solution of the optimization problem.
Initialization: x_0, $t = 0$.
1. Compute gradient $g_t = \nabla f(x_t)$.
2. Find the smallest integer $s \geq 0$ such that $f(x') - f(x_t) \leq \alpha g_t^\top (x' - x_t)$, where $x' = \mathcal{P}_S(x_t - \beta^s g_t)$.
3. Set $x_{t+1} = \mathcal{P}_S(x_t - \beta^s g_t)$, $t \leftarrow t + 1$ and repeat steps 1 and 2, until the desired accuracy is achieved. Output $\widehat{x} = x_t$.

Figure 4: The projected gradient descent algorithm.

The gradient $\nabla_\pi f(\pi; X)$ in Eq. (4) is easy to compute:

$$\frac{\partial f(\pi; X)}{\partial \pi_i} = -x_i^\top (X^\top \text{diag}(\pi) X)^{-1} x_i, \quad i = 1, \cdots, n.$$

Because $X^\top \text{diag}(\pi) X$ is a shared term, computing $\nabla_\pi f(\pi; X)$ takes $O(np^2 + p^3)$ operations. The projection step onto the intersection of ℓ_1 and ℓ_∞ balls is complicated and non-trivial, which we describe in details in Appendix D. In general, the projection step can be done in $O(n \log \|\pi\|_\infty)$ time, where π is the point to be projected.

The following proposition establishes convergence guarantee for the projected gradient descent algorithm. Its proof is given in the appendix.

Proposition 21 *Let $\pi^{(0)}$ be the "flat" initialization (i.e., $\pi_i^{(0)} = k/n$) and $\pi^{(t)}$ be the solution after t projected gradient iterations. Then*

$$f(\pi^{(t)}; X) - f(\pi^*; X) \leq \frac{\|X\|_2^4 [\text{tr}(\widehat{\Sigma}^{-1})]^3 \|\pi^{(0)} - \pi^*\|_2^2}{\beta t},$$

where $\widehat{\Sigma} = \frac{1}{n} X^\top X$.

We also remark that the provided convergence speed is very conservative, especially in the cases when k is large where practical evidence suggests that the algorithm converges in very few iterations (cf. Sec. 4).

Appendix C. Fedorov's exchange algorithm

The algorithm starts with a initial subset $S \subseteq [n]$, $|S| \leq k$, usually initialized with random indices. A "best" pair of exchanging indices are computed as

$$i^*, j^* = \text{argmin}_{i\in S, j\notin S} \ell(S\backslash\{i\} \cup \{j\}),$$

where $\ell(S)$ is the objective function to be minimized. In our case it would be the A-optimality objective $\ell(S) = F(S; X) = \text{tr}((X_S^\top X_S)^{-1})$. The algorithm then "exchanges" i^* and j^* by setting $S' \leftarrow S\backslash\{i^*\} \cup \{j^*\}$ and continues such exchanges until no exchange can lower the objective value. Under without replacement settings, special care needs to be taken to ensure that S consists of distinct indices.

Computing the objective function $F(S; X) = \text{tr}((X_S^\top X_S)^{-1})$ requires inverting a $p \times p$ matrix, which could be computationally slow. A more computationally efficient approach is to perform rank-1 update of the inverse of $X_S^\top X_S$ after each iteration, via the Sherman-Morrison formula:

$$(A + uv^\top)^{-1} = A^{-1} - \frac{A^{-1} u v^\top A^{-1}}{1 + u^\top A^{-1} v}.$$

Each exchange would then take $O(nkp^2)$ operations. The total number of exchanges, however, is unbounded and could be as large as $\binom{n}{k}$ in theory. In practice we do observe that a large number of exchanges are required in order to find a local optimal solution.

Appendix D. Projection onto the intersection of ℓ_1 and ℓ_∞ norm balls

Similar to (Yu et al., 2012), we only need to consider the case that π lies in the first quadrant, i.e., $\pi_i \geq 0, i = 1, 2, ..., n$. Then the projection x also lies in the first quadrant. Furthermore, we assume the point to be project lies in the area which is out of both norm balls and projection purely onto either ℓ_1 or ℓ_∞ ball is not the intersection of both. Otherwise, it is trivial to conduct the projection. The projection problem is formulated as follows:

$$\begin{aligned} \min_x \quad & \frac{1}{2}\|\pi - x\|_2^2 \\ \text{s.t.} \quad & \|x\|_1 \leq c_1, \quad \|x\|_\infty \leq c_2. \end{aligned}$$

By introducing an auxiliary variable d, the problem above has the following equivalent form:

$$\begin{aligned} \min_{x,d} \quad & \frac{1}{2}\|\pi - x\|_2^2 \\ \text{s.t.} \quad & \|x\|_1 \leq c_1, \\ & x_i \leq d, \ i = 1, 2, ...n, \\ & d \leq c_2. \end{aligned} \tag{16}$$

The Lagrangian of problem (16) is

$$\mathcal{L}(x, d, \lambda_1, \lambda_2) = \frac{1}{2}||\pi - x||_2^2 + \sum_i \omega_i (x_i - d) + \lambda_1 (\|x\|_1 - c_1) + \lambda_2 (d - c_2) \tag{17}$$

input : π, c_1, c_2 and precision parameter δ.
output: x, the projection of π onto $\{x : \|x\|_1 \le c_1\} \cap \{x : \|x\|_\infty \le c_2\}$.
Initialization: $\lambda_1 = \|\pi\|_\infty$.
while $|h(\lambda_1)| > \delta$ **do**
  if $h(\lambda_1) > \delta$ **then**
    $l = \lambda_1$;
  else
    $r = \lambda_1$;
  end
  $\lambda_1 = (l + r)/2$;
  for each i **do** $x_i = \min(\max(\pi_i - \lambda_1, 0), c_2)$;
end

Algorithm 5: Projecting π onto $\{x : \|x\|_1 \le c_1\} \cap \{x : \|x\|_\infty \le c_2\}$.

Let x^*, d^* and λ_1^*, λ_2^* respectively be the primal and dual solution of (16), then its KKT condition is:

$$0 \in \partial \mathcal{L}_x(x^*, d^*, \lambda_1^*, \lambda_2^*), \tag{18}$$
$$0 \in \partial \mathcal{L}_d(x^*, d^*, \lambda_1^*, \lambda_2^*), \tag{19}$$
$$w_i^*(x_i^* - d^*) = 0, \quad i = 1, 2, ..., n \tag{20}$$
$$\lambda_2^*(d^* - c_2) = 0, \tag{21}$$
$$\lambda_1^*(\|x^*\|_1 - c_1) = 0, \tag{22}$$
$$x_i^* \le d^*, \quad i = 1, 2, ..., n \tag{23}$$
$$d^* \le c_2, \tag{24}$$
$$\|x^*\|_1 \le c_1, \tag{25}$$
$$x_i^*, d^*, \lambda_1^*, \lambda_2^*, w_i^* \ge 0. \tag{26}$$

The following lemmas illustrate the relation between the primal and dual solution of problem (16):

Lemma 22 *Either one of the following holds: 1) $d^* > 0$ and $\sum_i (\max(\pi_i - \lambda_1^*, 0) - x_i^*) = \lambda_2^*$; 2) $d^* = 0$ and $\sum_i \max(\pi_i - \lambda_1^*, 0) \le \lambda_2^*$.*

Lemma 23 *For $i = 1, 2, ..., n$, the optimal x_i^* satisfies*

$$x_i^* = \min(\max(\pi_i - \lambda_1^*, 0), d^*). \tag{27}$$

Proof Lemma 22 and Lemma 23 can be both viewed as the special cases of Lemma 6 and 7 in Yu et al. (2012). ■

Now the KKT conditions can be reduced to finding $\lambda_1^*, \lambda_2^*, d^*$ that satisfy the following equations:

$$\sum_i \min(\max(\pi_i - \lambda_1^*, 0), d^*) - c_1 = 0, \tag{28}$$
$$d^* - c_2 = 0, \tag{29}$$
$$\sum_i \max(\max(\pi_i - \lambda_1^*, 0) - d^*, 0) = \lambda_2^* \text{ iff } d^* > 0, \tag{30}$$
$$\sum_i \max(\pi_i - \lambda_1^*, 0) \le \lambda_2^* \text{ iff } d^* = 0, \tag{31}$$
$$d^* \ge 0, \lambda_2^* \ge 0, \lambda_1^* \ge 0. \tag{32}$$

Further simplification induces the following result:

Lemma 24 *Suppose d^* and λ_1^* are the primal and dual solution respectively, then*

$$d^* = c_2, \tag{33}$$
$$x_i^* = \min(\max(\pi_i - \lambda_1^*, 0), c_2). \tag{34}$$

Proof Direct result of (27) and (29). ■

(34) shows that the solution x^* is determined once the optimal λ_1^* is found. Given a $\lambda_1 \in [0, \max_i(\pi_i)]$, we only need to check whether (28) holds by looking into the function

$$h(\lambda_1) = \sum_i \min(\max(\pi_i - \lambda_1, 0), c_2) - c_1, \tag{35}$$

and λ_1^* is simply the zero point of $h(\cdot)$. The following theorem shows that $h(\cdot)$ is a strictly monotonically decreasing function, so a binary search is sufficient to find λ_1^*, and x_i^* can be determined accordingly.

Theorem 25 *1) $h(\lambda_1)$ is a continuous piecewise linear function in $[0, \max_i\{\pi_i\}]$; 2) $h(\lambda_1)$ is strictly monotonically decreasing and it has a unique root in $[0, \max_i\{\pi_i\}]$.*

Proof 1) is obviously true. It is easy to check that $h'(\lambda_1) < 0$ in each piece, $h(\max_i\{\pi_i\}) < 0$ and $h(0) > 0$, so 2) also holds. ■

Complexity Analysis: Algorithm 5 is proposed based on the observation above to solve the projection problem, which is essentially a bisection to search λ_1. Given a precision δ, the iteration complexity of bisection is $O(\log(\max_i(\pi_i)/\delta))$. Besides, the time complexity of evaluating $h(\cdot)$ is $O(n)$, so the total complexity of Algorithm 5 is $O(n \log(\max_i(\pi_i)/\delta))$.

Appendix E. Convergence analysis of PGD

We provide a convergence analysis of the projected gradient descent algorithm used in optimizing Eq. (4). The analysis shows that the PGD algorithm approximately computes the global optimum of Eq. (4) in polynomial time. In simulation studies, much fewer iterations are required for convergence than predicted by the theoretical results.

Because we're using exact projected gradient descent algorithms, the objective function shall decay monotonically and hence convergence of such algorithms can be established by showing Lipschitz continuity of ∇f on a specific *level set*; that is, for some Lipschitz constant $L > 0$ the following holds for all π, π' such that $f(\pi), f(\pi') \leq f(\pi^{(0)})$:

$$\|\nabla f(\pi) - \nabla f(\pi')\|_2 \leq L\|\pi - \pi'\|_2, \tag{36}$$

where $\pi^{(0)} = (1/n, 1/n, \cdots, 1/n)$ is the initialization point. Once Eq. (36) holds, linear convergence (i.e., $f(\pi^{(t)}) - f(\pi^*) = O(1/t)$) can be established via standard projected gradient analysis.

The main idea of establishing Eq. (36) is to upper bound the spectral norm of the Hessian matrix $H = \nabla^2 f(\pi)$ *uniformly* over all points π that satisfies $f(\pi) \leq f(\pi^{(0)})$. As a first step, we derive analytic forms of H in the following proposition:

Proposition 26 *Let $\widetilde{\Sigma} = X^\top \mathrm{diag}(\pi) X$. We then have that*

$$H = 2(X^\top \widetilde{\Sigma}^{-2} X) \circ (X^\top \widetilde{\Sigma}^{-1} X),$$

where $\circ$ denotes the element-wise Hadamard product between two matrices of same dimensions.

Proof We first derive the gradient of f. Fix arbitrary $i \in [n]$. The partial derivative can be computed as

$$\frac{\partial f}{\partial \pi_i} = \frac{\partial \mathrm{tr}(\widetilde{\Sigma}^{-1})}{\partial \pi_i} = \left\langle \frac{\partial \mathrm{tr}(\widetilde{\Sigma}^{-1})}{\partial \widetilde{\Sigma}}, \frac{\partial \widetilde{\Sigma}}{\partial \pi_i} \right\rangle = \left\langle -\widetilde{\Sigma}^{-2}, x_i x_i^\top \right\rangle = -x_i^\top \widetilde{\Sigma}^{-2} x_i.$$

Here $\langle A, B \rangle = \mathrm{tr}(B^\top A)$ is the element-wise multiplication inner product between two matrices. The second-order partial derivatives can then be computed as

$$\begin{aligned}\frac{\partial^2 f}{\partial \pi_i \partial \pi_j} = -\frac{\partial (x_i^\top \widetilde{\Sigma}^{-2} x_i)}{\partial \pi_j} &= -x_i^\top \frac{\partial \widetilde{\Sigma}^{-2}}{\partial \pi_j} x_i = x_i^\top \widetilde{\Sigma}^{-2} \frac{\partial \widetilde{\Sigma}^2}{\partial \pi_j} \widetilde{\Sigma}^{-2} x_i \\ &= x_i^\top \widetilde{\Sigma}^{-2} (x_j x_j^\top \widetilde{\Sigma} + \widetilde{\Sigma} x_j x_j^\top) \widetilde{\Sigma}^{-2} x_i = 2(x_i^\top \widetilde{\Sigma}^{-2} x_j) \cdot (x_i^\top \widetilde{\Sigma}^{-1} x_j).\end{aligned}$$

Subsequently,

$$H = \nabla^2 f = \left[\frac{\partial^2 f}{\partial \pi_i \partial \pi_j} \right]_{i,j=1}^n = 2(X^\top \widetilde{\Sigma}^{-2} X) \circ (X^\top \widetilde{\Sigma}^{-1} X).$$

■

Corollary 27 *Suppose π satisfies $f(\pi) \leq f(\pi^{(0)}) = \mathrm{tr}(\Sigma_0^{-1})$, where $\Sigma_0 = \frac{1}{n} X^\top X$. We then have*

$$\|H\|_2 = \|\nabla^2 f(\pi)\|_2 \leq 2\|X\|_2^4 \cdot [\mathrm{tr}(\Sigma_0^{-1})]^3.$$

Proof Let $\rho(A) = \max_i |\sigma_i(A)|$ denote the *spectral range* of matrix A. Clearly, $\|A\|_2 \leq \rho(A)$ and $\|A\|_2 = \rho(A)$ for positive semi-definite matrices. In (Hom and Johnson, 1991) it is established that $\rho(A \circ B) \leq \rho(A)\rho(B)$. Subsequently,

$$\|H\|_2 \leq 2\|X\|_2^4 \|\widetilde{\Sigma}^{-1}\|_2^3 \leq 2\|X\|_2^4 \cdot [\mathrm{tr}(\widetilde{\Sigma}^{-1})]^3 \leq 2\|X\|_2^4 \cdot [\mathrm{tr}(\Sigma_0^{-1})]^3,$$

where the last inequality is due to the condition that $\mathrm{tr}(\widetilde{\Sigma}^{-1}) = f(\pi) \leq f(\pi^{(0)}) = \mathrm{tr}(\Sigma_0^{-1})$. ■

From Corollary 27, we can prove the convergence of the optimization procedures outlined in Appendix. B following standard analysis of projected gradient descent on objective functions with Lipschitz continuous gradient:

Theorem 28 *Suppose $\pi^{(t)}$ is the solution at the tth iteration of the projected gradient descent algorithm and π^* is the optimal solution. We then have*

$$f(\pi^{(t)}) - f(\pi^*) \leq \frac{\|X\|_2^4 \cdot [\mathrm{tr}(\Sigma_0^{-1})]^3 \cdot \|\pi^{(0)} - \pi^*\|_2^2}{\beta t},$$

where $\beta \in (0, 1)$ is the backtracking parameter in backtracking line search.

Abstract

Sparsity is an important modeling tool that expands the applicability of convex formulations for data analysis, however it also creates significant challenges for efficient algorithm design. In this paper we investigate the generalized conditional gradient (GCG) algorithm for solving sparse optimization problems—demonstrating that, with some enhancements, it can provide a more efficient alternative to current state of the art approaches. After studying the convergence properties of GCG for general convex composite problems, we develop efficient methods for evaluating polar operators, a subroutine that is required in each GCG iteration. In particular, we show how the polar operator can be efficiently evaluated in learning low-rank matrices, instantiated with detailed examples on matrix completion and dictionary learning. A further improvement is achieved by interleaving GCG with fixed-rank local subspace optimization. A series of experiments on matrix completion, multi-class classification, and multi-view dictionary learning shows that the proposed method can significantly reduce the training cost of current alternatives.

Keywords: generalized conditional gradient, frank-wolfe, dictionary learning, matrix completion, multi-view learning, sparse estimation

1. Introduction

Sparsity is an important concept in high-dimensional statistics (Bühlmann and van de Geer, 2011) and signal processing (Eldar and Kutyniok, 2012), which has led to important application successes by reducing model complexity and improving interpretability of the results. Although it is common to promote sparsity by adding appropriate regularizers, such as the ℓ_1 norm, sparsity can also present itself in more sophisticated forms, such as group sparsity (Yuan and Lin, 2006), graph sparsity (Kim and Xing, 2009; Jacob et al., 2009), matrix rank sparsity (Candès and Recht, 2009), and other combinatorial sparsity patterns (Obozinski and Bach, 2012). These recent notions of *structured* sparsity (Bach et al., 2012; Micchelli et al., 2013) have greatly enhanced the ability to model structural relationships in data; however, they also create significant computational challenges.

A currently popular optimization scheme for training sparse models is *accelerated proximal gradient* (APG) (Beck and Teboulle, 2009; Nesterov, 2013), which enjoys an optimal rate of convergence among black-box first-order procedures (Nesterov, 2013). An advantage of APG is that each iteration consists solely of computing a *proximal update* (PU), which for simple regularizers can have a very low complexity. For example, under ℓ_1 norm regularization each iterate of APG reduces to a soft-shrinkage operator that can be computed in linear time, which partly explains its popularity for such problems. Unfortunately, for matrix low-rank regularizers the PU soon becomes a computational bottleneck. For example, the trace norm is often used to promote low rank solutions in matrix variable problems such as matrix completion (Candès and Recht, 2009); but here the associated PU requires a *full* singular value decomposition (SVD) of the gradient matrix on each iteration, which prevents APG from being applied to large problems. Not only does the PU require nontrivial computation for matrix regularizers, it also yields *dense* intermediate iterates.

To address the primary shortcomings with APG, we investigate the *generalized conditional gradient* (GCG) strategy for sparse optimization, which has been motivated by the promise of recent sparse approximation methods (Hazan, 2008; Clarkson, 2010). A special case of GCG, known as the conditional gradient (CG), was originally proposed by Frank and Wolfe (1956) and has received significant renewed interest (Bach, 2015; Clarkson, 2010; Freund and Grigas, 2016; Hazan, 2008; Jaggi and Sulovsky, 2010; Jaggi, 2013; Shalev-Shwartz et al., 2010; Tewari et al., 2011; Yuan and Yan, 2013). The key advantage of GCG for sparse estimation is that it need only compute the *polar* of the regularizer in each iteration, which sometimes admits a much more efficient update than the PU in APG. For example, under trace norm regularization, GCG only requires the *spectral norm* of the gradient to be computed in each iteration, which is an order of magnitude cheaper than evaluating the full SVD as required by APG. Furthermore, the greedy nature of GCG affords explicit control over the sparsity of intermediate iterates, which is not available in APG. Although existing work on GCG has generally been restricted to *constrained* optimization (i.e. enforcing an upper bound on the sparsity-inducing regularizer), in this paper we consider the more general *regularized* version of the problem. Despite their theoretical equivalence, the regularized form allows more efficient local optimization to be interleaved with the primary update, which provides a significant acceleration in practice.

This paper is divided into two major parts: first we present a general treatment of GCG and establish its convergence properties for convex optimization in Section 3, with a special focus on convex gauge regularizers; then we apply the method to important case studies to demonstrate its effectiveness on large-scale, sparse estimation problems in Section 4, with experiments presented in Section 5.

In particular, in the first part, after establishing notation and briefly discussing relevant optimization schemes (Section 2), we present our first main contribution (Section 3): the convergence properties of GCG for general convex composite optimization. The algorithm is then specialized to convex gauge regularizers with refined analysis (Section 3.2). Indeed we prove that, under standard assumptions, GCG converges to the global optimum at the rate of $O(1/t)$—which is a significant improvement over previous bounds (Dudik et al., 2012). Although the convergence rate for GCG remains inferior to that of APG, these two

algorithms demonstrate alternative trade-offs between the number of iterations required and the per-step complexity. As shown in our experiments, GCG can be significantly faster than APG in terms of *overall* computation time for large problems. The results in Section 3 are new.

Equipped with the technical results of GCG on convex optimization, the second part of the paper then applies the algorithm to the important application of low rank learning (Section 4). Since imposing a hard bound on matrix rank generally leads to an intractable problem, in Section 4.2 we first present a generic relaxation strategy based on convex gauges (Chandrasekaran et al., 2012; Tewari et al., 2011) that yields a convex program (Bach et al., 2008; Bradley and Bagnell, 2009; Zhang et al., 2012). Conveniently, the resulting problem can be easily optimized using the GCG algorithm from Section 3.2. To further reduce computation time, we introduce in Section 4.3 an auxiliary fixed rank subspace optimization within each iteration of GCG. Although similar hybrid approaches have been previously suggested (Burer and Monteiro, 2005; Laue, 2012; Mishra et al., 2013), we propose an efficient new alternative that, instead of locally optimizing a *constrained* fixed rank problem, optimizes an *unconstrained* surrogate objective based on a variational representation of matrix norms. This alternative strategy allows a far more efficient local optimization without compromising GCG's convergence properties. In Section 4.4 we show that the approach can be applied to dictionary learning and matrix completion problems, as well as a non-trivial multi-view form of dictionary learning (White et al., 2012).

Finally, in Section 5 we provide an extensive experimental evaluation that compares the performance of GCG (augmented with interleaved local search) to state-of-the-art optimization strategies, across a range of problems, including matrix completion, multi-class classification, and multi-view dictionary learning.

1.1 Extensions over Previously Published Work

Some of the results in this article have appeared in a preliminary form in two conference papers (Zhang et al., 2012; White et al., 2012); however, several specific extensions have been added in this paper, including:

- A more extensive and unified treatment of GCG in general Banach spaces.
- A more refined analysis of the convergence properties of GCG.
- A new application of GCG to multi-view dictionary learning.
- New experimental evaluations on larger data sets, including new results for matrix completion and image multi-class classification.
- Open source Matlab code released at `https://www.cs.uic.edu/~zhangx/GCG`.

2. Preliminaries

We first establish some of the definitions and notation that will be used throughout the paper, before providing a brief background on the relevant optimization methods that establish a context for discussing GCG.

2.1 Notation and Definitions

Throughout this paper we assume that the underlying space, unless otherwise stated, is a real Banach space $\mathcal{B}$ with norm $\|\cdot\|$; for example, $\mathcal{B}$ could be the Euclidean space $\mathbb{R}^d$ with any norm. The dual space (the set of all real-valued continuous linear functions on $\mathcal{B}$) is denoted $\mathcal{B}^*$ and is equipped with the dual norm $\|\mathbf{g}\|^\circ = \sup\{\mathbf{g}(\mathbf{w}) : \|\mathbf{w}\| \leq 1\}$. Note that for a differentiable function $f : \mathcal{B} \to \overline{\mathbb{R}} := \mathbb{R} \cup \{\infty\}$, its (Frechét) derivative ∇f is in the dual space $\mathcal{B}^*$.

We use bold lowercase letters to denote vectors, where the i-th component of a vector $\mathbf{w}$ is denoted w_i, while $\mathbf{w}_t$ denotes some other vector. We use the shorthand $\langle \mathbf{w}, \mathbf{g} \rangle := \mathbf{g}(\mathbf{w})$ for any $\mathbf{g} \in \mathcal{B}^*$ and $\mathbf{w} \in \mathcal{B}$. We call a function $f : \mathcal{B} \to \overline{\mathbb{R}}$ σ-strongly convex (w.r.t. the norm $\|\cdot\|$) if there exists some $\sigma \geq 0$ such that for all $0 \leq \lambda \leq 1$ and $\mathbf{w}, \mathbf{z} \in \mathcal{B}$,

$$f(\lambda \mathbf{w} + (1-\lambda)\mathbf{z}) + \tfrac{1}{2}\sigma\lambda(1-\lambda)\|\mathbf{w}-\mathbf{z}\|^2 \leq \lambda f(\mathbf{w}) + (1-\lambda) f(\mathbf{z}). \tag{1}$$

In the case where $\sigma = 0$ we simply say f is convex. A set $C \subseteq \mathcal{B}$ is called convex if for all $\mathbf{w}, \mathbf{z} \in C \implies \lambda \mathbf{w} + (1-\lambda)\mathbf{z} \in C$ for all $0 \leq \lambda \leq 1$. It follows from the definition that the domain of a convex function f, denoted as $\operatorname{dom} f := \{\mathbf{w} : f(\mathbf{w}) < \infty\}$, is a convex set. The function f is called proper if $\operatorname{dom} f \neq \emptyset$, and closed if all sublevel sets $\{\mathbf{w} : f(\mathbf{w}) \leq \alpha\}$ are closed for all $\alpha \in \mathbb{R}$. The subdifferential of a convex function $f : \mathcal{B} \to \overline{\mathbb{R}}$ at $\mathbf{w}$ is defined as the set $\partial f(\mathbf{w}) = \{\mathbf{g} \in \mathcal{B}^* : f(\mathbf{z}) \geq f(\mathbf{w}) + \langle \mathbf{z} - \mathbf{w}, \mathbf{g} \rangle, \forall \mathbf{z} \in \mathcal{B}\}$.

Key to our subsequent development is two particular functions associated with a nonempty set in $\mathcal{B}$: the indicator function

$$\iota_C(\mathbf{w}) = \begin{cases} 0, & \text{if } \mathbf{w} \in C \\ \infty, & \text{otherwise} \end{cases}, \tag{2}$$

and the gauge function

$$\kappa(\mathbf{w}) = \kappa_A(\mathbf{w}) := \inf\{\rho \geq 0 : \mathbf{w} \in \rho A\}, \tag{3}$$

where $\rho A := \{\rho \mathbf{w} : \mathbf{w} \in A\}$, and the infimum is taken to be infinity over an empty set (i.e. when the condition $\mathbf{w} \in \rho A$ is not satisfied for any $\rho \geq 0$). Intuitively, $\kappa(\mathbf{w})$ is the smallest rescaling of the set A to "barely" contain $\mathbf{w}$; see Figure 1. Note that we always have $\kappa(\mathbf{0}) = 0$, and the gauge function is always positive homogeneous (i.e., $\kappa(t\mathbf{w}) = t\kappa(\mathbf{w})$ for all $t \geq 0$). Let $\mathsf{B} = \mathsf{B}_\kappa := \{\mathbf{w} : \kappa(\mathbf{w}) \leq 1\}$ denote the "unit ball" of κ, and then $\kappa_{\mathsf{B}} = \kappa_A$. B_κ is obviously intrinsic to κ, while different choices of A may yield the same gauge κ_A. Clearly, the indicator function ι_C is convex iff C is convex, while the gauge function κ is convex iff its unit ball is convex. Moreover, the gauge κ is a semi-norm iff its unit ball B is convex and symmetric (i.e. $\mathsf{B} = -\mathsf{B}$). Specifically, all semi-norms are convex gauge functions.

In practice, it is natural to engineer κ_A from a general "atomic set" A, which does not have to be convex (and can even be discrete) or contain the origin. Examples include the set of permutation matrices (Chandrasekaran et al., 2012), and the set of $\mathbf{x}\mathbf{x}^\top$ with $\|\mathbf{x}\|_2 = 1$ and $x_i \geq 0$ for low-rank nonnegative matrix factorization ($\mathbf{x}^\top$ is the transpose of $\mathbf{x}$). In this paper, we will work only with *convex closed* gauge functions, for which a sufficient *but not necessary* condition is that A is convex, closed, and containing the origin (an assumption

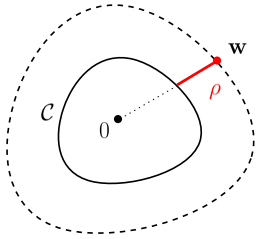

Figure 1: Defining a convex gauge via the Minkowski functional of a convex set $\mathcal{C}$.

made by many textbooks). For practical flexibility, we intentionally avoid making the latter assumptions in the first place, and the resulting technical complication is minimal.

A related function that underpins our algorithm is the *polar* of a gauge function κ_A, defined for all $\mathbf{g} \in \mathcal{B}^*$ as

$$\kappa^\circ(\mathbf{g}) = \kappa_A^\circ(\mathbf{g}) := \inf\{\mu \geq 0 : \langle \mathbf{w}, \mathbf{g} \rangle \leq \mu\kappa(\mathbf{w}),\ \forall \mathbf{w} \in \mathcal{B}\} \tag{4}$$

$$= \sup_{\mathbf{w} \in \mathsf{B}_\kappa} \langle \mathbf{w}, \mathbf{g} \rangle = \sup_{\mathbf{w} \in A \cup \{\mathbf{0}\}} \langle \mathbf{w}, \mathbf{g} \rangle . \tag{5}$$

As the notation suggests, the polar of a norm (a *bona fide* convex gauge) is its dual norm.

Lastly, a differential function $\ell : \mathcal{B} \to \mathbb{R}$ is said to be L-smooth (w.r.t. the norm $\|\cdot\|$) if for all $\mathbf{w}, \mathbf{z} \in \mathcal{B}$,

$$\ell(\mathbf{w}) \leq \tilde{\ell}_L(\mathbf{w}; \mathbf{z}) := \ell(\mathbf{z}) + \langle \mathbf{w} - \mathbf{z}, \nabla\ell(\mathbf{z}) \rangle + \tfrac{L}{2} \|\mathbf{w} - \mathbf{z}\|^2 , \tag{6}$$

i.e., ℓ is upper bounded by the quadratic approximation around $\mathbf{z}$. It is well-known that if the gradient $\nabla\ell$ is L-Lipschitz continuous, i.e., $\|\nabla\ell(\mathbf{w}) - \nabla\ell(\mathbf{z})\|^\circ \leq L\|\mathbf{w} - \mathbf{z}\|$ for all $\mathbf{w}, \mathbf{z}$, then ℓ is L-smooth. The converse is also true if ℓ is additionally convex. We will make repeated use of this quadratic upper bound in our analysis below.

2.2 Composite Minimization Problem

Many machine learning problems, particularly those formulated in terms of regularized risk minimization, can be formulated as:

$$\inf_{\mathbf{w} \in \mathcal{B}} F(\mathbf{w}),\ \text{such that}\ F(\mathbf{w}) := \ell(\mathbf{w}) + f(\mathbf{w}), \tag{7}$$

where f is convex and ℓ is convex and continuously differentiable. Typically, ℓ is a loss function and f is a regularizer although their roles can be reversed in some common examples, such as support vector machines and Lasso.

Due to the importance of this problem in machine learning, significant effort has been devoted to designing efficient algorithms for solving (7). Standard methods are generally based on computing an update sequence $\{\mathbf{w}_t\}$ that converges to a global minimizer of F when F is convex, or converges to a stationary point otherwise. For example, a popular

example is the mirror descent (MD) algorithm (Beck and Teboulle, 2003), which takes an arbitrary subgradient $\mathbf{g}_t \in \partial F(\mathbf{w}_t)$ and successively updates by

$$\mathbf{w}_{t+1} = \arg\min_{\mathbf{w}} \left\{ \langle \mathbf{w}, \mathbf{g}_t \rangle + \frac{1}{2\eta_t} \mathsf{D}(\mathbf{w}, \mathbf{w}_t) \right\} \tag{8}$$

with a suitable step size $\eta_t \geq 0$; here $\mathsf{D}(\mathbf{w}, \mathbf{z}) := \mathsf{d}(\mathbf{w}) - \mathsf{d}(\mathbf{z}) - \langle \mathbf{w} - \mathbf{z}, \nabla\mathsf{d}(\mathbf{z}) \rangle$ denotes a Bregman divergence induced by some differentiable 1-strongly convex function $\mathsf{d} : \mathcal{B} \to \overline{\mathbb{R}}$. Under mild assumptions, MD converges (in terms of the function value) at a rate of $O(1/\sqrt{t})$ (Beck and Teboulle, 2003). However, this algorithm ignores the composite structure in (7) and can be impractically slow for many applications.

Another widely used algorithm is the proximal gradient (PG) (e.g. Fukushima and Mine, 1981), also known as the forward-backward splitting procedure, which iteratively performs the proximal update (PU)

$$\mathbf{w}_{t+1} = \arg\min_{\mathbf{w}} \left\{ \langle \mathbf{w}, \nabla\ell(\mathbf{w}_t) \rangle + f(\mathbf{w}) + \frac{1}{2\eta_t} \mathsf{D}(\mathbf{w}, \mathbf{w}_t) \right\}. \tag{9}$$

PU differs from MD updates in that it does not linearize the regularizer f. The downside is that (9) is usually harder to solve than (8) for each iteration, with an upside that a faster $O(1/t)$ rate of convergence can be achieved (Tseng, 2010). This rate can be further improved to $O(1/t^2)$ with the extrapolation variant known as accelerated proximal gradient (APG) (Beck and Teboulle, 2009; Nesterov, 2013). In particular, suppose $\mathcal{B} = \mathbb{R}^d$, $\mathsf{D}(\mathbf{w}, \mathbf{z}) = \frac{1}{2}\|\mathbf{w} - \mathbf{z}\|_2^2$, and $f(\mathbf{w}) = \|\mathbf{w}\|_1$, where the ℓ_p norm is defined as $\|\mathbf{w}\|_\mathsf{p} := (\sum_{i=1}^d |w_i|^\mathsf{p})^{1/\mathsf{p}}$ for $\mathsf{p} \geq 1$. Then PU recovers the soft-shrinkage operator, which plays an important role in sparse estimation:

$$\mathbf{z}_t = \mathbf{w}_t - \eta_t \nabla\ell(\mathbf{w}_t), \qquad \text{and} \qquad \mathbf{w}_{t+1} = (1 - \eta_t / |\mathbf{z}_t|)_+ \, \mathbf{z}_t. \tag{10}$$

Here the algebraic operations in the latter formula are performed componentwise. Similarly, when $\mathcal{B} = \mathbb{R}^{m \times n}$, $\mathsf{D}(W, Z) = \frac{1}{2}\|W - Z\|_\mathrm{F}^2$ (Frobenius norm) and $f(W) = \|W\|_\mathrm{tr}$ (trace norm, i.e. sum of singular values), one recovers the matrix analogue of soft-shrinkage used for matrix completion (Candès and Recht, 2009): here the same gradient update of $\mathbf{z}_t$ in (10) is applied, but the shrinkage operator on $\mathbf{w}_{t+1}$ in (10) is applied to the singular values of Z_t while keeping the singular vectors intact. Unfortunately, such a PU can become prohibitively expensive for large matrices, since it requires a *full* singular value decomposition (SVD) at each iteration, at a cubic time cost. We will see in Section 3.2 that an alternative algorithm only requires computing the dual of the trace norm (namely the spectral norm $\|\cdot\|_\mathrm{sp}$, i.e. the greatest singular value), which requires only quadratic time per iteration.

3. Generalized Conditional Gradient for Convex Optimization

In this section we present the generalized conditional gradient (GCG) algorithm, which has recently been receiving renewed attention (Bredies and Lorenz, 2008; Hazan, 2008; Jaggi, 2013; Shalev-Shwartz et al., 2010; Yuan and Yan, 2013; Zhang et al., 2012). Our goal in this section will be to develop efficient solution methods for (7), where f is convex and ℓ

is convex and L-smooth (cf. (6)). In particular, we will refine our algorithms to convex gauge regularized problems where special computational savings can be achieved through its polar. These are clearly among the most important settings in practice, and after some enhancements the algorithm and convergence guarantees we establish in this section will be applied to dictionary learning in Section 4.

3.1 General Setting with Convex and Smooth ℓ

We first develop the framework of the GCG algorithm and its analysis by focusing on general convex functions f. Formally, we make the following assumption throughout this Section 3.

Assumption 1 *ℓ is convex and L-smooth, and f is convex.*

Protocol: To avoid unnecessary pathologies, we tacitly assume all functions considered in this work are proper and closed.

To derive the optimization algorithm, first observe that given the above assumption, $F = \ell + f$ is convex and so any $\mathbf{w} \in \mathcal{B}$ is globally optimal for (7) if, and only if,

$$\mathbf{0} \in \partial F(\mathbf{w}) = \nabla \ell(\mathbf{w}) + \partial f(\mathbf{w}). \tag{11}$$

Let $f^*(\mathbf{g}) := \sup_{\mathbf{w}} \langle \mathbf{w}, \mathbf{g} \rangle - f(\mathbf{w})$ denote the Fenchel conjugate of f, and using the fact that $\mathbf{g} \in \partial f(\mathbf{w})$ iff $\mathbf{w} \in \partial f^*(\mathbf{g})$ when f is closed (Borwein and Vanderwerff, 2010), one can observe that the necessary and sufficient condition for $\mathbf{w}$ to be globally optimal can also be expressed as

$$(11) \quad \Longleftrightarrow \quad \mathbf{w} \in \partial f^*(-\nabla \ell(\mathbf{w})) \quad \Longleftrightarrow \quad \mathbf{w} \in (1-\eta)\mathbf{w} + \eta \partial f^*(-\nabla \ell(\mathbf{w})), \tag{12}$$

where $\eta \in (0, 1)$. Then, by the definition of f^*, we have

$$\mathbf{d} \in \partial f^*(-\nabla \ell(\mathbf{w})) \quad \Longleftrightarrow \quad \mathbf{d} \in \arg\min_{\mathbf{d}} \left\{ \langle \mathbf{d}, \nabla \ell(\mathbf{w}) \rangle + f(\mathbf{d}) \right\}. \tag{13}$$

Thus, the condition for a global minimum can be characterized by the fixed-point inclusion

$$\mathbf{w} \in (1-\eta)\mathbf{w} + \eta \mathbf{d} \quad \text{ for some } \quad \mathbf{d} \in \arg\min_{\mathbf{d}} \left\{ \langle \mathbf{d}, \nabla \ell(\mathbf{w}) \rangle + f(\mathbf{d}) \right\}. \tag{14}$$

This particular fixed-point condition immediately suggests an update that provides the foundation for the generalized conditional gradient algorithm (GCG) outlined in Algorithm 1. Each iteration of this procedure involves linearizing the smooth loss ℓ, solving the subproblem (13), selecting a step size, taking a convex combination, then conducting some form of local improvement. The GCG update based on (14) naturally generalizes the original conditional gradient update, which was first studied by (Frank and Wolfe, 1956) for the case when $f = \iota_C$ for a polyhedral set C.

Note that the subproblem (13) shares some similarity with the proximal update (9): both choose to leave the potentially nonsmooth function f intact, but here the smooth loss ℓ is replaced by its plain linearization rather than its linearization *plus* a (strictly convex) proximal regularizer such as the quadratic upper bound $\tilde{\ell}_L(\cdot)$ in (6). Consequently, there might be *multiple* solutions, in which case we simply adopt any one, or no solution (e.g.

Algorithm 1 Generalized Conditional Gradient (GCG).

1: Initialize: $\mathbf{w}_0 \in \operatorname{dom} f$.
2: **for** $t = 0, 1, \ldots$ **do**
3: Compute $\mathbf{d}_t \in \arg\min_{\mathbf{d}} \{\langle \mathbf{d}, \mathbf{g}_t \rangle + f(\mathbf{d})\}$, where $\mathbf{g}_t = \nabla \ell(\mathbf{w}_t)$.
4: Choose step size $\eta_t \in [0, 1]$ and perform update $\tilde{\mathbf{w}}_{t+1} = (1 - \eta_t)\mathbf{w}_t + \eta_t \mathbf{d}_t$.
5: $\mathbf{w}_{t+1} = \texttt{Improve}(\tilde{\mathbf{w}}_{t+1}, \ell, f)$ ▷ Subroutine, see Definition 1
6: **end for**

divergence), in which case we will impose extra assumptions to ensure boundedness (details below, especially Assumption 2 and Theorem 2).

An important component of Algorithm 1 is the final step, `Improve`, in Line 5, which is particularly important in practice: it allows for heuristic local improvement to be conducted on the iterates without sacrificing any theoretical convergence properties of the overall procedure (see Section 4.3). A precursor of `Improve` appeared in (Meyer, 1974, Algorithm 2). Since `Improve` has access to both ℓ and f it can be very powerful in principle—we will consider the following variants that have respective consequences for practice and subsequent analysis.

Definition 1 *The subroutine `Improve` in Algorithm 1 is called `Null` if for all t, $\mathbf{w}_{t+1} = \tilde{\mathbf{w}}_{t+1}$; `Descent` if $F(\mathbf{w}_{t+1}) \leq F(\tilde{\mathbf{w}}_{t+1})$; `Monotone` if $F(\mathbf{w}_{t+1}) \leq F(\mathbf{w}_t)$; and `Relaxed` if*

$$F(\mathbf{w}_{t+1}) \leq \tilde{\ell}_L(\tilde{\mathbf{w}}_{t+1}; \mathbf{w}_t) + (1 - \eta_t) f(\mathbf{w}_t) + \eta_t f(\mathbf{d}_t). \tag{15}$$

Obviously, `Relaxed` can be easily morphed to further satisfy `Descent` and/or `Monotone` by comparing $F(\mathbf{w}_{t+1})$ with $F(\tilde{\mathbf{w}}_{t+1})$ and/or $F(\mathbf{w}_t)$, whereas `Null` and `Descent` must be `Relaxed` (since ℓ is L-smooth).

Our main goal remains to establish that Algorithm 1 indeed converges to a global optimum under general conditions given in Assumption 1. In order to address the aforementioned issue of bounding $\mathbf{d}_t$, we next introduce one more assumption.

Assumption 2 *The sequences $\{\mathbf{d}_t\}$ and $\{\mathbf{w}_t\}$ generated by the algorithm are bounded for any choice of $\eta_t \in [0, 1]$.*

Although this assumption is more stringent, it can fortunately be achieved under various conditions, which we summarize as follows. The proof is given in Appendix A.1.

Proposition 2 *Let Assumption 1 hold. Then Assumption 2 is satisfied if any of the following holds.*

(a) The subroutine `Improve` is `Monotone`; the sublevel set $\{\mathbf{w} \in \operatorname{dom} f : F(\mathbf{w}) \leq F(\mathbf{w}_0)\}$ is compact; and f is cofinite, i.e., its Fenchel conjugate f^* has full domain.

(b) The subroutine `Improve` is `Monotone`; the sublevel set $\{\mathbf{w} \in \operatorname{dom} f : F(\mathbf{w}) \leq F(\mathbf{w}_0)\}$ is bounded; and f is super-coercive, i.e., $\lim_{\|\mathbf{w}\| \to \infty} f(\mathbf{w}) / \|\mathbf{w}\| \to \infty$.

(c) $\operatorname{dom} f$ is bounded.

In particular, under any of the conditions in Theorem 2, Line 3 of Algorithm 1 is well-defined. Note that if $\mathcal{B} = \mathbb{R}^d$, then condition (a) is in fact equivalent to condition (b). On the other hand, if f is a convex gauge, then none of the three conditions above holds, and we will deal with this in Section 3.2.

Finally, for each $\mathbf{w} \in \mathcal{B}$ we define a quantity, referred to as the *duality gap*, that will be useful in understanding the convergence properties of GCG:

$$\begin{aligned}\mathsf{G}(\mathbf{w}) &:= F(\mathbf{w}) - \inf_{\mathbf{d}} \{\ell(\mathbf{w}) + \langle \mathbf{d} - \mathbf{w}, \nabla \ell(\mathbf{w})\rangle + f(\mathbf{d})\} \quad \text{(linearizing } \ell \text{ at } \mathbf{w}) \qquad (16)\\ &= \langle \mathbf{w}, \nabla \ell(\mathbf{w})\rangle + f(\mathbf{w}) - \inf_{\mathbf{d}} \{\langle \mathbf{d}, \nabla \ell(\mathbf{w})\rangle + f(\mathbf{d})\}\\ &= \langle \mathbf{w}, \nabla \ell(\mathbf{w})\rangle + f(\mathbf{w}) + f^*(-\nabla \ell(\mathbf{w})). \qquad \text{(definition of Fenchel dual)} \qquad (17)\end{aligned}$$

Since f and ℓ are convex in Assumption 1, the duality gap provides an upper bound on the suboptimality of any search point, as established in the following proposition.

Proposition 3 *Let Assumption 1 hold. Then* $\mathsf{G}(\mathbf{w}) \geq F(\mathbf{w}) - \inf_{\mathbf{d}} F(\mathbf{d}) \geq 0$ *for all* $\mathbf{w} \in \mathcal{B}$. *Furthermore,* $\mathsf{G}(\mathbf{w}) = 0$ *iff* $\mathbf{w}$ *is globally optimal, i.e.* $\mathbf{w}$ *satisfies the condition* (11).

Proof As ℓ is convex, (16) implies $\mathsf{G}(\mathbf{w}) \geq F(\mathbf{w}) - \inf_{\mathbf{d}}\{\ell(\mathbf{d}) + f(\mathbf{d})\} = F(\mathbf{w}) - \inf_{\mathbf{d}} F(\mathbf{d}) \geq 0$. By the Fenchel-Young inequality, (17) implies $\mathsf{G}(\mathbf{w}) = 0$ iff $\mathbf{w} \in \partial f^*(-\nabla \ell(\mathbf{w}))$, i.e. (11) holds. ■

Since $\mathsf{G}(\mathbf{w}_t)$ is an upper bound on the suboptimality of $\mathbf{w}_t$, the duality gap gives a natural stopping criterion for (7) that can be easily computed in each iteration of Algorithm 1.

We are now ready for the first convergence result regarding Algorithm 1.

Theorem 4 *Let Assumptions 1 and 2 hold. Also assume the subroutine is* `Relaxed`*, and the subproblem* (13) *is solved up to some additive error* $\varepsilon_t \geq 0$. *Then, for any* $\mathbf{w} \in \operatorname{dom} F$ *and* $t \geq 0$, *Algorithm 1 yields*

$$F(\mathbf{w}_{t+1}) \leq F(\mathbf{w}) + \pi_t(1 - \eta_0)(F(\mathbf{w}_0) - F(\mathbf{w})) + \sum_{s=0}^{t} \frac{\pi_t}{\pi_s} \eta_s^2 (\varepsilon_s/\eta_s + \tfrac{L}{2} \|\mathbf{d}_s - \mathbf{w}_s\|^2), \quad (18)$$

where $\pi_t := \prod_{s=1}^{t}(1 - \eta_s)$ *with* $\pi_0 = 1$. *Furthermore, for all* $t \geq k \geq 0$, *the minimal duality gap* $\tilde{\mathsf{G}}_k^t := \min_{k \leq s \leq t} \mathsf{G}(\mathbf{w}_s)$ *satisfies*

$$\tilde{\mathsf{G}}_k^t \leq \frac{1}{\sum_{s=k}^{t} \eta_s} \left[F(\mathbf{w}_k) - F(\mathbf{w}_{t+1}) + \sum_{s=k}^{t} \eta_s^2 \left(\varepsilon_s/\eta_s + \tfrac{L}{2} \|\mathbf{d}_s - \mathbf{w}_s\|^2 \right) \right]. \quad (19)$$

From Theorem 4 we derive the following concrete rates of convergence.

Corollary 5 *Under the same assumptions as Theorem 4, also let* $\eta_t = 2/(t+2)$, $\varepsilon_t \leq \delta \eta_t / 2$ *for some* $\delta \geq 0$, *and* $L_F := \sup_t L \|\mathbf{d}_t - \mathbf{w}_t\|^2$. *Then, for all* $t \geq 1$ *and* $\mathbf{w}$, *Algorithm 1 yields*

$$F(\mathbf{w}_t) \leq F(\mathbf{w}) + \frac{2(\delta + L_F)}{t+3}, \qquad \text{and} \qquad \tilde{\mathsf{G}}_1^t \leq \frac{3(\delta + L_F)}{t \ln 2} \leq \frac{4.5(\delta + L_F)}{t}. \quad (20)$$

The proofs of Theorem 4 and Theorem 5 can be found in Appendix A.2 and Appendix A.3 respectively. Note that the simple step size rule $\eta_t = 2/(t+2)$ already leads to an $O(1/t)$ bound on the objective value attained. Of course, it is possible to use other step size rules. For instance, both $\eta_s = 1/(s+1)$ and the constant rule $\eta_s = 1 - (t+1)^{1/t}$ lead to an $O(\frac{1+\log t}{t+1})$ rate; see (Freund and Grigas, 2016) for detailed calculations.

We emphasize that GCG with the open-loop step size rule $\eta_t = 2/(t+2)$ requires neither the Lipschitz constant L nor the norm $\|\cdot\|$ to be known. We can therefore freely adopt the best choices for the problem at hand in the analysis. Note that, even though the rate does not depend on the initial point $\mathbf{w}_0$ provided $\eta_0 = 1$, by letting $\eta_0 \neq 1$ the bound can be slightly improved (Freund and Grigas, 2016).

Remark 6 *The observation that an* $O(1/t)$ *rate can be obtained by an open-loop step size rule such as* $\eta_t = O(1/t)$ *appears to have been first made by Dunn and Harshbarger (1978). The same rate can be achieved by the closed-loop step size rule where* η_t *is selected to minimize* $\ell((1-\eta_t)\mathbf{w}_t + \eta_t \mathbf{d}_t)$ *or its quadratic upper bound* $\tilde{\ell}((1-\eta_t)\mathbf{w}_t + \eta_t \mathbf{d}_t; \mathbf{w}_t)$ *(Frank and Wolfe, 1956; Levitin and Polyak, 1966; Dem'yanov and Rubinov, 1967). A similar rate on the minimal duality gap was also given in (Clarkson, 2010), and extended by (Jaggi, 2013). However, all these previous works focused on the special case where* $f = \iota_C$ *for some compact set* C. *Fukushima and Mine (1981) was the first to consider a general convex function* f *(and possibly a nonconvex* ℓ*), but they only established convergence for the algorithm. Bredies and Lorenz (2008) proved the* $O(1/t)$ *rate by using a closed-loop step size rule. More recently, Bach (2015) considered the special case where* f *is strongly convex, and identified the equivalence between GCG and MD, hence also establishing the* $O(1/t)$ *rate for this special case.*

3.2 Improved Algorithm and Refined Analysis when f is a Convex Gauge

Although the results in Theorem 4 and Theorem 5 hold for general convex functions f, they require $\{\mathbf{d}_t\}$ and $\{\mathbf{w}_t\}$ to be bounded as in Assumption 2. Some sufficient conditions were provided by Theorem 2. Unfortunately, these conditions cannot be satisfied by an important class of regularizers in machine learning: norms, semi-norms, and more generally convex *gauge* functions, cf. Section 2 for the detailed definition. Examples include the ℓ_p norms ($p \geq 1$), the total variation semi-norm, the trace norm for matrices, etc. Indeed, the subproblem (13) in Line 3 of Algorithm 1 might diverge to $-\infty$, leaving the update undefined. In this subsection, we develop a specialized form of GCG that circumvents this problem and exploits properties of convex gauges to significantly reduce computational overhead. The resulting GCG formulation, which is one of our main contributions, will be used to achieve efficient algorithms in important case studies in the second part of the paper, such as matrix completion under trace norm regularization (Section 4.2.1 below).

In the literature, two main approaches have been used to bypass the unboundedness in solving (13); unfortunately, both remain unsatisfactory in different ways. First, one obvious way to restore boundedness to (13) is to reformulate the regularized problem (7) in its equivalent constrained form

$$\inf_{\mathbf{w}} \ \ell(\mathbf{w}) \ \text{ s.t. } \ f(\mathbf{w}) \leq \zeta, \quad (21)$$

where it is well-known that a correspondence between (7) and (21) can be achieved if the constant ζ is chosen appropriately. In this case, Algorithm 1 can be directly applied as long as (21) has a bounded domain. Much recent work in machine learning has investigated this variant (Hazan, 2008; Jaggi and Sulovsky, 2010; Jaggi, 2013; Shalev-Shwartz et al., 2010; Tewari et al., 2011; Yuan and Yan, 2013). However, finding the appropriate value of ζ is costly in general, and often one cannot avoid considering the penalized formulation (e.g. when it is nested in another problem). Furthermore, the constraints in (21) preclude the application of many efficient local `Improve` techniques designed for *unconstrained* problems.

A second, alternative, approach is to square f, which ensures that it becomes super-coercive (Bradley and Bagnell, 2009). However, this modification is somewhat arbitrary, in the sense that super-coerciveness can be achieved by raising the norm to the pth power for any $p > 1$ (when $\mathcal{B} = \mathbb{R}^d$). Moreover, the insertion of a local `Improve` step in such an approach requires the regularizer f to be evaluated at all iterates, which is expensive for applications such as matrix completion.

3.2.1 Generalized Convex Gauge Regularization

To address the issue of ensuring well defined iterates, while also reducing their cost, we develop an alternative modification of GCG. The algorithm we develop also allows a mild generalization of convex gauge regularization by introducing a composition with an increasing convex function. In particular, let κ denote a convex gauge induced by a convex, closed set $\mathcal{C}$ containing the origin (cf. (3)) and let $h : \mathbb{R}_+ \to \overline{\mathbb{R}}$ denote an *increasing convex* function over $\mathbb{R}_+ := [0, \infty]$. Then regularizing by $f(\cdot) = h(\kappa(\cdot))$ yields the particular form of (7) that we will address with this modified approach:

$$\inf_{\mathbf{w}} \ \ell(\mathbf{w}) + h(\kappa(\mathbf{w})). \tag{22}$$

For the structured sparse regularizers typically considered in machine learning, the set $\mathcal{C}$ used to construct the gauge function κ via (3) has additional structure that admits efficient computation (Chandrasekaran et al., 2012). In particular, $\mathcal{C}$ is often constructed by taking the convex hull of some *compact* set of "atoms" $\mathcal{A}$ specific to the problem; i.e., $\mathcal{C} = \operatorname{conv}\mathcal{A}$. Such a structured formulation allows one to re-express the gauge as the "$\mathfrak{l}_1$ norm" over an appropriate "atomic decomposition." In details:

$$\kappa_{\mathcal{C}}(\mathbf{w}) = \inf\left\{\sum_{i=1}^{r} \lambda_i : \mathbf{w} = \sum_{i=1}^{r} \lambda_i \mathbf{a}_i, \mathbf{a}_i \in \mathcal{A}, \lambda_i \geq 0\right\} \tag{23}$$

$$\kappa^{\circ}_{\mathcal{C}}(\mathbf{g}) = \sup_{\mathbf{w} \in \mathcal{A} \cup \{\mathbf{0}\}} \langle \mathbf{w}, \mathbf{g} \rangle . \tag{24}$$

That is, if we decompose $\mathbf{w}$ as a conic combination of the "atoms" in $\mathcal{A}$, then $\kappa(\mathbf{w})$ is the least $\mathfrak{l}_1$ norm of the decomposition coefficients. Determining the convex gauge $\kappa_{\mathcal{C}}$ directly from the set $\mathcal{C}$ is not always easy, and the following duality result may come into aid (Rockafellar and Wets, 1998, p. 491):

$$\mathcal{C} \text{ is closed convex and } \mathbf{0} \in \mathcal{C} \implies \kappa_{\mathcal{C}} = (\kappa^{\circ}_{\mathcal{C}})^{\circ}. \tag{25}$$

Since $\mathcal{A}$ is compact, the polar $\kappa^{\circ}_{\mathcal{C}}$ has full domain. Intuitively, κ° has a much simpler form than κ if the structure of $\mathcal{A}$ is "simple." In such cases, it is advantageous to design

an optimization algorithm that circumvents evaluation of κ, by instead using κ° which is generally far less expensive to evaluate. This will be the underpinning motivation of our algorithm design.

3.2.2 Modified GCG Algorithm for Generalized Gauge Regularization

The key to the modified algorithm is to avoid the possibly unbounded solution to (13) while also avoiding explicit evaluation of the gauge κ. First, to avoid unboundedness, we adopt the technique of moving the regularizer to the constraint, as in (21), but rather than applying the modification directly to (22) we only use it in the subproblem (13) via:

$$\mathbf{d}_t \in \arg\min_{\mathbf{d}: h(\kappa(\mathbf{d})) \leq \zeta} \langle \mathbf{d}, \nabla \ell(\mathbf{w}_t) \rangle . \tag{26}$$

Then, to bypass the complication of dealing with h and the unknown bound ζ, we decompose $\mathbf{d}_t$ into its normalized direction $\mathbf{a}_t$ and scale θ_t (i.e., such that $\mathbf{d}_t = \mathbf{a}_t \theta_t / \eta_t$), determining each separately. In particular, from this decomposition, the update from Line 4 of Algorithm 1 can be equivalently expressed as

$$\mathbf{w}_{t+1} = (1 - \eta_t)\mathbf{w}_t + \eta_t \mathbf{d}_t = (1 - \eta_t)\mathbf{w}_t + \theta_t \mathbf{a}_t, \tag{27}$$

hence the modified algorithm need only work with $\mathbf{a}_t$ and θ_t directly.

Determining the direction. First, the normalized direction, $\mathbf{a}_t$, can be recovered via

$$\mathbf{a}_t \in \arg\min_{\mathbf{a}: \kappa(\mathbf{a}) \leq 1} \langle \mathbf{a}, \nabla \ell(\mathbf{w}_t) \rangle \iff \mathbf{a}_t \in \arg\min_{\mathbf{a} \in \mathcal{A} \cup \{\mathbf{0}\}} \langle \mathbf{a}, \nabla \ell(\mathbf{w}_t) \rangle \quad \text{(by (4))} \tag{28}$$

$$\iff \mathbf{a}_t \in \arg\max_{\mathbf{a} \in \mathcal{A} \cup \{\mathbf{0}\}} \langle \mathbf{a}, -\nabla \ell(\mathbf{w}_t) \rangle . \tag{29}$$

Observe that (29) effectively involves computation of the polar $\kappa^{\circ}(-\nabla \ell(\mathbf{w}))$ only, by (4). Since this optimization might still be challenging, we further allow it to be solved only *approximately* to within an additive error $\varepsilon_t \geq 0$ and a multiplicative factor $\alpha_t \in (0, 1]$; that is, by relaxing (28) the modified algorithm only requires an $\mathbf{a}_t \in \mathcal{A}$ to be found that satisfies

$$\langle \mathbf{a}_t, \nabla \ell(\mathbf{w}_t) \rangle \leq \alpha_t \left(\varepsilon_t + \min_{\mathbf{a} \in \mathcal{A} \cup \{\mathbf{0}\}} \langle \mathbf{a}, \nabla \ell(\mathbf{w}_t) \rangle \right) = \alpha_t \left(\varepsilon_t - \kappa^{\circ}(-\nabla \ell(\mathbf{w}_t)) \right). \tag{30}$$

Intuitively, this formulation computes the normalized direction that has (approximately) the greatest negative "correlation" with the gradient $\nabla \ell$, yielding the steepest local decrease in ℓ. Importantly, this formulation does *not* require evaluation of the gauge function κ.

Determining the scale. Next, to choose the scale θ_t, it is natural to consider minimizing a simple upper bound on the objective that is obtained by replacing $\ell(\cdot)$ with its quadratic upper approximation $\tilde{\ell}_L(\cdot; \mathbf{w}_t)$ given in (6):

$$\min_{\theta \geq 0} \tilde{\ell}_L((1 - \eta_t)\mathbf{w}_t + \theta \mathbf{a}_t; \mathbf{w}_t) + h(\kappa((1 - \eta_t)\mathbf{w}_t + \theta \mathbf{a}_t)). \tag{31}$$

Unfortunately, κ still participates in (31), so a further approximation is required. Here is where the decomposition of $\mathbf{d}_t$ into $\mathbf{a}_t$ and θ_t is particularly advantageous. Observe that

$$\begin{aligned} h(\kappa((1-\eta_t)\mathbf{w}_t + \theta \mathbf{a}_t)) &\leq h((1-\eta_t)\kappa(\mathbf{w}_t) + \eta_t \kappa(\theta \mathbf{a}_t / \eta_t)) \\ &\leq (1-\eta_t) h(\kappa(\mathbf{w}_t)) + \eta_t h(\kappa(\theta \mathbf{a}_t / \eta_t)) \qquad (32) \\ &\leq (1 - \eta_t) h(\kappa(\mathbf{w}_t)) + \eta_t h(\theta / \eta_t)), \qquad (33) \end{aligned}$$

Algorithm 2 GCG for positively homogeneous regularizers.

Require: The set $\mathcal{A}$ whose convex hull $\mathcal{C}$ defines the gauge κ.

Initialize $\mathbf{w}_0$ and $\rho_0 \geq \kappa(\mathbf{w}_0)$.
for $t = 0, 1, \ldots$ **do**
  Choose normalized direction $\mathbf{a}_t$ that satisfies (30).
  Choose step size $\eta_t \in [0, 1]$ and set the scaling $\theta_t \geq 0$ by (34)
  $\tilde{\mathbf{w}}_{t+1} = (1 - \eta_t)\mathbf{w}_t + \theta_t \mathbf{a}_t$, and $\tilde{\rho}_{t+1} = (1 - \eta_t)\rho_t + \theta_t$
  $(\mathbf{w}_{t+1}, \rho_{t+1}) = \texttt{Improve}(\tilde{\mathbf{w}}_{t+1}, \tilde{\rho}_{t+1}, \ell, f)$ ▷ Subroutine, see Theorem 8
end for

where the first inequality follows from the convexity of κ and the fact that h is increasing, the second inequality follows from the convexity of h, and (33) follows from the fact that $\kappa(\mathbf{a}_t) \leq 1$ by construction ($\mathbf{a}_t \in \mathcal{A}$ in (4)). Although κ still participates in (33) we can now bypass evaluation of κ by maintaining a simple upper bound $\rho_t \geq \kappa(\mathbf{w}_t)$, yielding the relaxed update

$$\theta_t = \arg\min_{\theta \geq 0} \left\{ \tilde{\ell}_L((1 - \eta_t)\mathbf{w}_t + \theta \mathbf{a}_t; \mathbf{w}_t) + (1 - \eta_t)h(\rho_t) + \eta_t h(\theta/\eta_t) \right\}. \tag{34}$$

Crucially, the upper bound $\rho_t \geq \kappa(\mathbf{w}_t)$ can be maintained by the simple update $\rho_{t+1} = (1 - \eta_t)\rho_t + \theta_t$, which is sufficient to ensure that ρ_{t+1} upper bounds $\kappa(\mathbf{w}_{t+1})$:

$$\rho_{t+1} = (1 - \eta_t)\rho_t + \theta_t \geq (1 - \eta_t)\kappa(\mathbf{w}_t) + \theta_t \kappa(\mathbf{a}_t) \geq \kappa((1 - \eta_t)\mathbf{w}_t + \theta_t \mathbf{a}_t) \geq \kappa(\mathbf{w}_{t+1}). \tag{35}$$

From these components we obtain the final modified procedure, Algorithm 2: a variant of GCG (Algorithm 1) that avoids the potential unboundedness of the subproblem (13) by replacing it with (30), while also completely avoiding explicit evaluation of the gauge κ. The `Improve` subroutine can be adapted by mirroring Theorem 1.

Definition 7 *The subroutine* `Improve` *in Algorithm 2 is called* `Null` *if for all* t, $\mathbf{w}_{t+1} = \tilde{\mathbf{w}}_{t+1}$ *and* $\rho_{t+1} = \tilde{\rho}_{t+1}$. *Provided that* $\rho_{t+1} \geq \kappa(\mathbf{w}_{t+1})$, `Improve` *is called* `Descent` *if* $\ell(\mathbf{w}_{t+1}) + h(\rho_{t+1}) \leq \ell(\tilde{\mathbf{w}}_{t+1}) + h(\tilde{\rho}_{t+1})$; `Monotone` *if* $\ell(\mathbf{w}_{t+1}) + h(\rho_{t+1}) \leq \ell(\mathbf{w}_t) + h(\rho_t)$; *and* `Relaxed` *if*

$$\ell(\mathbf{w}_{t+1}) + h(\rho_{t+1}) \leq \tilde{\ell}_L(\tilde{\mathbf{w}}_{t+1}; \mathbf{w}_t) + (1 - \eta_t)h(\rho_t) + \eta_t h(\theta_t/\eta_t). \tag{36}$$

Similar to Theorem 1, `Relaxed` can be easily morphed to further satisfy `Descent` and/or `Monotone` by comparing $(\mathbf{w}_{t+1}, \rho_{t+1})$ with $(\tilde{\mathbf{w}}_{t+1}, \tilde{\rho}_{t+1})$ and/or $(\mathbf{w}_t, \rho_t)$ over $\ell(\mathbf{w}) + h(\rho)$. As before `Null` and `Descent` are specializations of `Relaxed`.

For problems of the form (22), Algorithm 2 can provide significantly more efficient updates than Algorithm 1. Despite the relaxations introduced in Algorithm 2 to achieve faster iterates, the following theorem establishes that the procedure is still sound, preserving essentially the same convergence guarantees as the more expensive Algorithm 1.

Theorem 8 *Let* $h : \mathbb{R}_+ \to \overline{\mathbb{R}}$ *be an increasing convex function,* κ *be a convex gauge induced by the convex hull of a compact atomic set* $\mathcal{A} \cup \{\mathbf{0}\}$, *and* ℓ *be* L*-smooth and convex. Let* $F = \ell + h \circ \kappa$ *and assume Algorithm 2 generates a bounded sequence* $\{\mathbf{w}_t\}$. *Let* $\alpha_t > 0$, $0 \leq \eta_t \leq 1$, *and the subroutine* `Improve` *be* `Relaxed`. *Then for any* $\mathbf{w} \in \operatorname{dom} F$ *and* $t \geq 0$, *we have*

$$F(\mathbf{w}_{t+1}) \leq F(\mathbf{w}) + \pi_t(1 - \eta_0)\big(F(\mathbf{w}_0) - F(\mathbf{w})\big) + \sum_{s=0}^{t} \frac{\pi_t}{\pi_s} \eta_s^2 \Big(\big(\rho\varepsilon_s + h(\rho/\alpha_s) - h(\rho)\big)/\eta_s + \tfrac{L}{2} \left\| \tfrac{\rho}{\alpha_s}\mathbf{a}_s - \mathbf{w}_s \right\|^2 \Big), \tag{37}$$

where $\rho := \kappa(\mathbf{w})$ *and* $\pi_t := \prod_{s=1}^{t}(1 - \eta_s)$ *with* $\pi_0 = 1$.

The proof is given in Appendix A.4. From this theorem, we obtain the following rate of convergence by pursuing a similar argument as in the proof of Theorem 5.

Corollary 9 *Under the same setting as in Theorem 8, let* $\eta_t = 2/(t + 2)$, $\varepsilon_t \leq \delta\eta_t/2$ *for some absolute constant* $\delta > 0$, $\alpha_t = \alpha > 0$, $\rho = \kappa(\mathbf{w})$, *and* $L_F := L \sup_t \left\| \frac{\rho}{\alpha}\mathbf{a}_t - \mathbf{w}_t \right\|^2$. *Then for all* $t \geq 1$ *and* $\mathbf{w}$, *we have*

$$F(\mathbf{w}_t) \leq F(\mathbf{w}) + \frac{2(\rho\delta + L_F)}{t + 3} + h(\rho/\alpha) - h(\rho). \tag{38}$$

Moreover, if $\ell \geq 0$ *and* h *is the identity map, then*

$$F(\mathbf{w}_t) \leq \frac{1}{\alpha} F(\mathbf{w}) + \frac{2(\rho\delta + L_F)}{t + 3}. \tag{39}$$

Some remarks concerning this algorithm and its convergence properties are in order.

Remark 10 *When* $\alpha_t = 1$ *for all* t, *and* h *is the indicator* $\iota_{[0,\zeta]}$ *for some* $\zeta > 0$, *Theorem 9 implies the same convergence rate for the constrained problem* (21), *which immediately recovers (some of) the more specialized results discussed in (Clarkson, 2010; Hazan, 2008; Jaggi, 2013; Shalev-Shwartz et al., 2010; Tewari et al., 2011; Yuan and Yan, 2013). For the special case where* h *is the identity map, a similar* $O(1/t)$ *rate achieved by a similar algorithm appeared in Harchaoui et al. (2015), whose workshop version appeared around the same time as our conference version (Zhang et al., 2012). Harchaoui et al. (2015) considered the slightly more restrictive setting where the convex gauge* κ *is the restriction of a norm into a convex cone and they did not consider (multiplicative) approximate polar computations. Their algorithm also needs to evaluate* κ *explicitly, while the key advantage of our method is to avoid this expensive computation by an upper bound. On the other hand, Harchaoui et al. (2015) investigated the memory based acceleration in (Holloway, 1974; Meyer, 1974) while we develop in the next section a fixed-rank local improvement step.*

Remark 11 *The additional factor* ρ *in the above bounds is necessary because the approximation in* (30) *is not invariant to scaling, requiring some compensation. Note also that* $\alpha \leq 1$, *since the right-hand side of* (30) *must become negative as* $\varepsilon_t \to 0$. *The result in* (39) *states roughly that an* α*-approximate subroutine (for computing the polar of* κ*) leads to an* α*-approximate "minimum", also at the rate of* $O(1/t)$. *This observation was independently made in (Bach, 2013), where the multiplicative factor* ρ *is introduced to solve approximately some matrix factorization problems. In a similar vein, Cheng et al. (2016) leveraged the multiplicative guarantee to solve some tensor problems.*

Remark 12 *The assumption that $\{\mathbf{w}_t\}$ is bounded can be satisfied easily, which in turn ensures $L_F < \infty$. The simplest way is to postulate that the sublevel set $\{\mathbf{w} \in \operatorname{dom} F : F(\mathbf{w}) \leq \ell(\mathbf{w}_0) + h(\rho_0)\}$ is bounded. In this case $\{\mathbf{w}_t\}$ is trivially bounded if* `Monotone` *is used. When* `Relaxed` *is used instead (which includes* `Null` *and* `Descent`*), we can strengthen it into* `Monotone` *via the roll-back trick in Theorem 7. At first sight, the algorithm appears to be stuck, but in fact the diminishing step size η_t will eventually lead to progresses as guaranteed by Theorem 9. Computationally, keeping track of $\ell(\mathbf{w}_t)+h(\rho_t)$ does not incur any overhead. We will provide concrete values/bounds of L_F for the case studies in Section 4.2 and Section 4.4.*

Remark 13 *The convergence results in Theorem 8 and Theorem 9 obviously hold when* `Null` *or* `Descent` *is employed for* `Improve`*, because they are both specializations of* `Relaxed`*. The update for θ in (34) requires knowledge of the Lipschitz constant L and the norm $\|\cdot\|$. If the norm $\|\cdot\|$ is Hilbertian and h is the identity map, we have the formula*

$$\theta_t = \tfrac{1}{L\|\mathbf{a}_t\|^2} \max\{\langle \mathbf{a}_t, L\eta_t\mathbf{w}_t - \nabla\ell(\mathbf{w}_t)\rangle - 1, 0\}.$$

However, it is also easy to devise other scaling and step size updates that do not require the knowledge of L or the norm $\|\cdot\|$, such as

$$(\eta_t^*, \theta_t^*) \in \arg\min_{1\geq\eta\geq 0, \theta\geq 0} \ell((1-\eta)\mathbf{w}_t + \theta\mathbf{a}_t) + (1-\eta)h(\rho_t) + \eta h(\theta/\eta), \tag{40}$$

followed by the `Null` *step. Note that (40) is jointly convex in η and θ, since $\eta h(\theta/\eta)$ is a perspective function. Evidently this update can be treated as a* `Relaxed` *subroutine, since for any (η_t, θ_t) chosen in step 4 of Algorithm 2, it follows that*

$$\begin{aligned}
\ell(\mathbf{w}_{t+1}) + h(\rho_{t+1}) &\leq \ell((1-\eta_t^*)\mathbf{w}_t + \theta_t^*\mathbf{a}_t) + (1-\eta_t^*)h(\rho_t) + \eta_t^* h(\theta_t^*/\eta_t^*) \\
&\leq \ell((1-\eta_t)\mathbf{w}_t + \theta_t\mathbf{a}_t) + (1-\eta_t)h(\rho_t) + \eta_t h(\theta_t/\eta_t) \quad \text{(by (40))} \\
&\leq \tilde{\ell}_L(\tilde{\mathbf{w}}_{t+1}; \mathbf{w}_t) + (1-\eta_t)h(\rho_t) + \eta_t h(\theta_t/\eta_t).
\end{aligned}$$

The upper bound $\rho_{t+1} \geq \kappa(\mathbf{w}_{t+1})$ can be verified in the same way as for (35); hence the update (40) enjoys the same convergence guarantee as in Theorem 9.

Remark 14 *An alternative workaround for solving (7) with gauge regularization would be to impose an upper bound $\zeta \geq \kappa(\mathbf{w})$ and consider $\min_{\mathbf{w}:\kappa(\mathbf{w})\leq\zeta}\{\ell(\mathbf{w}) + \kappa(\mathbf{w})\}$, while dynamically adjusting ζ. A standard GCG approach, similar to (Harchaoui et al., 2015), would then require solving*

$$\mathbf{d}_t \in \arg\min_{\mathbf{d}:\kappa(\mathbf{d})\leq\zeta} \{\langle \mathbf{d}, \nabla\ell(\mathbf{w}_t)\rangle + \kappa(\mathbf{d})\} \tag{41}$$

as a subproblem, which can be as easy to solve as (30). If, however, one wished to include a local improvement step `Improve` *(which is essential in practice), it is not clear how to efficiently maintain the constraint $\kappa(\mathbf{w}) \leq \zeta$. Moreover, solving (41) up to some* multiplicative *factor might* not *be as easy as (30).*

3.3 Additional Discussions and Related Work

In this section we discuss some further properties and extensions of the GCG algorithm.

Smoothing: The convergence rates we have established require the convex loss ℓ to be L-smooth. Although this holds for a variety of losses such as the square and logistic loss, it does not hold for the hinge loss used in support vector machines. However, one can always approximate a nonsmooth (Lipschitz) loss by a smooth function (Nesterov, 2005) before applying GCG, at the expense of getting a slower $O(1/\sqrt{t})$ rate of convergence.

Totally Corrective: As given, Algorithm 2 adds a single atom in each iteration, with a conic combination between the new atom and the previous aggregate. We will refer to it as *vanilla* GCG if `Improve` is further set to `Null`. If $f = \iota_C$ for some compact and convex set C, we simply call it *vanilla* CG for disambiguation. An even more aggressive scheme is to re-optimize the coefficients of all (or a subset of) existing atoms in each iteration. Such a procedure was first studied in (Meyer, 1974; Holloway, 1974), which is often known as the "totally (or fully) corrective update" in the boosting literature and as the "restricted simplicial decomposition" in optimization. More generally, for the convex gauge κ, each iteration of a totally corrective procedure would involve solving

$$\min_{\boldsymbol{\sigma}\geq 0} \ell\left(\sum_{\tau\in A_t} \sigma_\tau \mathbf{b}_\tau\right) + \sum_{\tau\in A_t} \sigma_\tau, \tag{42}$$

where A_t is a set of atoms accumulated up to the t-th iteration. When $f = \iota_C$, the totally corrective CG solves $\min_{\boldsymbol{\sigma}} \ell\left(\sum_{\tau\in A_t} \sigma_\tau \mathbf{b}_\tau\right)$ over $\boldsymbol{\sigma} \geq 0$ and $\mathbf{1}'\boldsymbol{\sigma} = 1$. As pointed out by Holloway (1974), as long as $\{\mathbf{w}_t, \mathbf{a}_t\} \subseteq A_t$, the totally corrective CG will converge at least as fast as the vanilla CG. Much faster convergence is usually observed in practice, although this advantage must be countered by the extra effort spent in solving (42) and alike, which itself need not be trivial. In a finite dimensional setting, provided that the atoms are linearly independent and some restricted strong convexity is present, it is possible to prove that the totally corrective CG converges at a linear rate; see (Shalev-Shwartz et al., 2010; Yuan and Yan, 2013). Recent work of Lacoste-Julien and Jaggi (2015) has further relaxed the requirement of linear independence by making a weaker assumption that the number of atoms is finite (i.e. the feasible region is a polytope).

GCG v.s. PG: The convergence rate established for GCG is on par with PG. When $f = \iota_C$, Canon and Cullum (1968) showed that the rate of *vanilla* CG cannot be improved in general even when ℓ is strongly convex.[1] In this sense, *vanilla* GCG (which subsumes *vanilla* CG) is slower than an "optimal" algorithm like APG. GCG's advantage, however, is that it only needs to solve a linear subproblem (13) in each iteration (i.e., computing the polar κ°), whereas APG (or PG) needs to compute the proximal update, which is a quadratic problem for the least square prox-function. The two approaches are complementary in the sense that the polar can be easier to compute in some cases, whereas in other cases the proximal update can be computed analytically. An additional advantage GCG has over APG, however, is its greedy sparse nature: Each iteration of GCG amounts to a single atom, hence the number of atoms never exceeds the total number of iterations for GCG. By contrast, APG can produce a dense update in each iteration, although in later stages the

1. Improvements in specific cases are still possible; see the next paragraph. Indeed the counter-example of Canon and Cullum (1968) only applies when the solution lies at the boundary of a polyhedral set.

estimates may become sparser due to the shrinkage effect of the proximal update. Moreover, GCG is "robust" with respect to α-approximate atom selection (cf. (39) in Theorem 9), whereas similar results do not appear to be available for PG or APG when the proximal update is computed up to a multiplicative factor.

Faster Rates: Faster rates of convergence for CG (with a closed-loop step size rule), under the restriction $f = \iota_C$, have been considered by a number of works. Levitin and Polyak (1966) first showed that if C is strongly convex and the gradient $\nabla\ell$ is bounded away from $\mathbf{0}$, then a linear rate of convergence can be achieved by CG. Guélat and Marcotte (1986) showed that if there is a minimizer in the interior of C, then again a linear rate of convergence can be obtained. Wolfe (1970) proposed an away step modification of CG, and a variant of it designed by Guélat and Marcotte (1986) attained linear rate of convergence when C is polyhedral. The analysis was further improved into a global linear rate in (Lacoste-Julien and Jaggi, 2015; Beck and Shtern, 2015). Dunn (1979) proved $o(1/t)$ rate, linear rate and finite convergence for CG, depending on how "continuous" the polar operation is. Lastly, Garber and Hazan (2015) showed that for polytope C, a modification of CG achieves the linear rate if ℓ is of quadratic growth (in particular, strongly convex), and Garber and Hazan (2016) proved the $O(1/t^2)$ rate if ℓ is of quadratic growth and C is strongly convex. Note that these faster rates are possible by putting restrictive assumptions on the constraint set C (polyhedral or strongly convex). Interestingly, results on faster rates for *general convex* functions f are scarce, although establishing it for GCG is conceivably not hard. For example, in (Zhang et al., 2012) we proved a linear rate for the totally corrective GCG when ℓ is strongly convex (in a slightly stronger sense), f is a convex gauge, and $\mathcal{B} = \mathbb{R}^n$.

4. Application to Low Rank Learning

As a first application of GCG, we consider the problem of optimizing low rank matrices; a problem that forms the cornerstone of many machine learning tasks such as dictionary learning and matrix completion. Since imposing a bound on matrix rank generally leads to an intractable problem, much recent work has investigated approaches that relax the hard rank constraint with carefully designed regularization penalties that indirectly encourage low rank structure (Bach et al., 2008; Bradley and Bagnell, 2009). In Section 4.2 we first formulate a generic convex relaxation scheme for low rank problems arising in matrix approximation tasks, including dictionary learning and matrix completion. Conveniently, the modified GCG algorithm developed in Section 3.2, Algorithm 2, provides a general solution method for the resulting problems. Next, in Section 4.3 we show how the local improvement component of the modified GCG algorithm can be provided in this case by a procedure that optimizes an unconstrained surrogate (instead of a constrained problem) to obtain greater efficiency. This modification significantly improves the practical efficiency of GCG without affecting its convergence properties. We illustrate these contributions by highlighting the example of matrix completion under trace norm regularization, where the improved GCG algorithm demonstrates state of the art performance. Finally, we demonstrate how the convex relaxation can be generalized to handle latent multi-view models (White et al., 2012) in Section 4.4, showing how the improved GCG algorithm can still be applied once the major challenge of efficiently computing the polar κ° has been solved.

4.1 Low Rank Learning Problems

Many machine learning tasks, such as dictionary learning and matrix completion, can be formulated as seeking low rank matrix approximations of a given data matrix. In these problems, one is presented with an $n \times m$ matrix X (perhaps only partially observed) where each column corresponds to a training example and each row corresponds to a feature across examples; the goal is to recover a low rank matrix W that approximates (the observed entries of) X. To achieve this, we assume we are given a convex loss function $\ell(W) := L(W, X)$ that measures how well W approximates X.[2] If we impose a hard bound, t, on the rank of W, the core training problem can then be expressed as

$$\inf_{W:\mathrm{rank}(W)\leq t} \ell(W) = \inf_{U\in\mathbb{R}^{n\times t}} \inf_{V\in\mathbb{R}^{t\times m}} \ell(UV). \tag{43}$$

Unfortunately, this problem is not convex, and except for special cases (such as SVD) is believed to be intractable.

The two forms of this problem that we will explicitly illustrate in this paper are dictionary learning and matrix completion. First, for dictionary learning, the $n \times m$ data matrix X is fully observed, the $n \times t$ matrix U is interpreted as a "dictionary" consisting of t basis vectors, and the $t \times m$ matrix V is interpreted as the "coefficients" consisting of m code vectors. For this problem, the dictionary and coefficient matrices need to be inferred *simultaneously*, in contrast to traditional signal approximation schemes where the dictionary (e.g., the Fourier or a wavelet basis) is fixed *a priori*. Unfortunately, learning the dictionary with the coefficients creates significant computational challenge since the formulation is no longer *jointly* convex in the variables U and V, even when the loss ℓ is convex. Indeed, for a fixed dictionary size t, the problem is known to be NP-hard (Vavasis, 2010) except for very special cases (Yu and Schuurmans, 2011).

The second learning problem we illustrate is low rank matrix completion. Here, one observes a small number of entries in $X \in \mathbb{R}^{n\times m}$ and the task is to infer the remaining entries. In this case, the optimization objective can be expressed as $\ell(W) := L(\mathcal{P}(W - X))$, where L is a reconstruction loss (such as Frobenius norm squared) and $\mathcal{P} : \mathbb{R}^{n\times m} \to \mathbb{R}^{n\times m}$ is a "mask" operator that simply fills the entries corresponding to unobserved indices in X with zero. Various recommendation problems, such as the Netflix prize,[3] can be cast as matrix completion. Due to the ill-posed nature of the problem it is standard to assume that the matrix X can be well approximated by a low rank reconstruction W. Unfortunately, the rank function is not convex, hence hard to minimize in general. Conveniently, both the dictionary learning and matrix completion problems are subsumed by the general formulation we consider in (43).

4.2 General Convex Relaxation and Solution via GCG

To develop a convex relaxation of (43), we first consider the factored formulation expressed in terms of U and V on the right hand side. Although it only involves an unconstrained minimization which can be convenient, care is needed to handle the scale invariance introduced by the factored form: since U can always be scaled and V counter-scaled to preserve

2. Note that the matrix W need not reconstruct the entries of X directly: a nonlinear transfer could be interposed while maintaining convexity of ℓ; for example, by using an appropriate Bregman divergence.
3. `http://www.netflixprize.com//community/viewtopic.php?id=1537`

the product UV, some form of penalty or constraint is required to restore well-posedness. A standard strategy is to constrain U, for which a particularly common choice is to constrain its columns to have unit length; i.e. $\|U_{:i}\|_c \leq 1$ for all i, where $U_{:i}$ stands for the i-th column of U, and c simply denotes some norm on the columns. In dictionary learning, for example, this amounts to constraining the basis vectors in the dictionary U to lie within the unit ball of $\|\cdot\|_c$. Similar normalization can be used to represent the rows $V_{i:}$, with the magnitude encoded by $\sigma_i \geq 0$. In consequence, the unconstrained optimization over $\ell(UV)$ in (43) can be reformulated as

$$\min_{U\in\mathbb{R}^{n\times t}, V\in\mathbb{R}^{t\times m}, \boldsymbol{\sigma}\in\mathbb{R}^t} \ell(U\operatorname{diag}(\boldsymbol{\sigma})V), \quad s.t. \quad \|U_{:i}\|_c \leq 1,\ \|V_{i:}\|_r \leq 1, \text{ and } \sigma_i \geq 0. \tag{44}$$

Here $\boldsymbol{\sigma} := (\sigma_1, \sigma_2, \ldots, \sigma_t)^\top$, and $\operatorname{diag}(\boldsymbol{\sigma})$ is a diagonal matrix with the i-th diagonal entry being σ_i. The specific form of the row norm $\|\cdot\|_r$ provides additional flexibility in promoting different structures; for example, the ℓ_1 norm leads to sparse solutions, the ℓ_2 norm yields low rank solutions, and block structured norms generate group sparsity. The specific form of the column norm $\|\cdot\|_c$ also has an effect, as discussed in Section 4.4 below.

Of course the problem remains non-convex. However, it has recently been observed that a simple relaxation of the rank constraint in (43) allows a convex reformulation to be achieved (Argyriou et al., 2008; Bach et al., 2008; Bradley and Bagnell, 2009; Zhang et al., 2011). Observe that replacing the rank constraint with a regularization penalty on the magnitude σ_i of each basis pair $(U_{:i}, V_{i:})$ yields a relaxed form of (43):

$$\inf_{U:\|U_{:i}\|_c\leq 1} \inf_{V:\|V_{i:}\|_r\leq 1} \inf_{\boldsymbol{\sigma}:\sigma_i\geq 0} \ell(U\operatorname{diag}(\boldsymbol{\sigma})V) + \lambda\|\boldsymbol{\sigma}\|_1, \tag{45}$$

where the number of columns in U (and also the number of rows in V) is *not* restricted. Similar to Lasso, the ℓ_1 norm on the "singular values" (combination weights) $\boldsymbol{\sigma}$ is used as a penalty that serves as a convex proxy for rank. By the shrinkage effect of the ℓ_1 norm, many σ_i will become zero, implying that the corresponding columns of U (and rows of V) can be dropped. As a result, the rank of the solution—which is indeed unknown *a priori*—can be chosen adaptively with the trade-off parameter $\lambda \geq 0$.

Importantly, although the problem (45) is still not jointly convex in the factors U, V and $\boldsymbol{\sigma}$, it can be exactly reformulated as a convex optimization as long as ℓ is convex:

$$(45) = \min_W\ \ell(W) + \lambda\ \inf\left\{\sum_i \sigma_i : \boldsymbol{\sigma}\geq 0, W = \sum_i \sigma_i U_{:i}V_{i:}, \|U_{:i}\|_c \leq 1, \|V_{i:}\|_r \leq 1\right\} \tag{46}$$

$$= \min_W\ \ell(W) + \lambda\,\kappa(W), \tag{47}$$

where the gauge κ is defined by the following set $\mathcal{A}$ with uncountably many elements

$$\mathcal{A} := \{\mathbf{u}\mathbf{v}^\top : \mathbf{u}\in\mathbb{R}^n, \mathbf{v}\in\mathbb{R}^m, \|\mathbf{u}\|_c \leq 1, \|\mathbf{v}\|_r \leq 1\}. \tag{48}$$

The resulting convex formulation (47) has been observed, in various forms, by, e.g., Argyriou et al. (2008); Bach et al. (2008); Zhang et al. (2011); White et al. (2012). However our derivation, first presented in (Zhang et al., 2012), provides a much simpler and flexible view based on convex gauges, which also establishes a direct connection to the GCG method

outlined in Section 3.2, yielding an efficient solution method with no additional effort. The reformulation (47) reveals that the relaxed learning problem (45) is essentially considering a rank-one decomposition of W, which generalizes the singular value decomposition. Furthermore it provides a clearer understanding of the computational properties of the regularizer in (47) via its polar:

$$\kappa^\circ(G) = \sup_{A\in\mathcal{A}} \langle A, G\rangle = \sup_{\|\mathbf{u}\|_c\leq 1, \|\mathbf{v}\|_r\leq 1} \mathbf{u}^\top G\mathbf{v} \tag{49}$$

$$= \sup_{\|\mathbf{v}\|_r\leq 1} \|G\mathbf{v}\|_c^\circ = \sup_{\|\mathbf{u}\|_c\leq 1} \left\|G^\top\mathbf{u}\right\|_r^\circ. \tag{50}$$

Recall that for gauge regularized problems in the form (47), Algorithm 2 only requires approximate computation of the polar (30) in Line 3; hence an efficient method for (approximately) solving (49) immediately yields an efficient implementation. However, this simplicity must be countered by the fact that the polar is not always tractable, since it involves *maximizing* a norm subject to a different norm constraint.[4] Nevertheless, there exist important cases where the polar can be efficiently evaluated, which we illustrate below.

The polar also allows one to gain insight into the structure of the original gauge regularizer, since by duality $\kappa = (\kappa^\circ)^\circ$ yields an explicit formula for κ. For example, consider the important special case where $\|\cdot\|_r = \|\cdot\|_c = \|\cdot\|_2$. In this case, using (49) one can infer that the polar $\kappa^\circ(\cdot) = \|\cdot\|_{\text{sp}}$ is the spectral norm, and therefore the corresponding gauge regularizer $\kappa(\cdot) = \|\cdot\|_{\text{tr}}$ is the trace norm. In this way, the trace norm regularizer, which is known to provide a convex relaxation of the matrix rank (Chandrasekaran et al., 2012), can be viewed from the perspective of dictionary learning as an *induced* norm that arises from a simple 2-norm constraint on the magnitude of the dictionary entries $U_{:i}$ and a simple 2-norm penalty on the magnitudes of the code vectors $V_{i:}$.

This convex relaxation strategy based on convex gauges is quite flexible and has been recently studied for some structured sparse problems (Chandrasekaran et al., 2012; Tewari et al., 2011; Zhang et al., 2012; Bach, 2013). Importantly, the generality of the column and row norms in (45) proffer considerable flexibility to finely characterize the structures sought by low rank learning methods. We will exploit this flexibility in Section 4.4 below to achieve a novel extension of this framework to multi-view dictionary learning (White et al., 2012).

4.2.1 Application to Matrix Completion

We end this subsection with a brief illustration of how the framework can be applied to matrix completion. Recall that in this case one is given a partially observed data matrix X, and the goal is to find a low rank approximator W that minimizes the reconstruction error on observed entries. In particular, consider the following standard specialization of (47):

$$\min_{W\in\mathbb{R}^{n\times m}} \frac{1}{2\|\mathcal{P}\|_0}\|\mathcal{P}(X-W)\|_{\text{F}}^2 + \lambda\|W\|_{\text{tr}}, \tag{51}$$

where, as noted above, $\mathcal{P}: \mathbb{R}^{n\times m} \to \mathbb{R}^{n\times m}$ is the mask operator that fills entries where X is unobserved with zero. $\|\mathcal{P}\|_0$ is the number of observed entries. Surprisingly, Candès and

4. In this regard, the α-approximate polar oracle introduced in (30) and Theorem 9 might be useful, although we shall not develop this idea further here. See the work of Bach (2013) for some applications of this idea to matrix factorization and the work of Cheng et al. (2016) to tensor problems.

Recht (2009) have proved that, assuming X is (approximately) low-rank, the solution of the convex relaxation (51) will recover the true matrix X with high probability, even when only a small *random* portion of X is observed.

Note that, since (51) is a specialization of (47), the modified GCG algorithm, Algorithm 2, can be immediately applied. Interestingly, such an approach contrasts with the most popular algorithm favored in the current literature: PG (or its accelerated variant APG; cf. Section 2). The two strategies, GCG versus PG, exhibit an interesting trade-off. Each iteration of PG (or APG) involves solving the PU (9), which in this case requires a *full* singular value decomposition (SVD) of the current approximant W. The modified GCG method, Algorithm 2, by contrast, only requires the polar of the gradient matrix $\nabla\ell(W)$ to be (approximately) computed in each iteration (i.e. dual of the trace norm; namely, the spectral norm), which is an order of magnitude cheaper to evaluate than a full SVD (cubic versus squared worst case time).[5] On the other hand, GCG has a slower theoretical rate than APG, $O(1/t)$ versus $O(1/t^2)$, in terms of the number of iterations required to achieve a given accuracy. Once the enhancements in the next section have been incorporated, our experiments in Section 5.1 will demonstrate that GCG is far more efficient than APG for solving the matrix completion problem (51) to tolerances used in practice.

Given the specific objective (51), we may derive a concrete bound on L_F used in Theorem 9. Obviously, the smoothness constant is $L = 1/\left\|\mathcal{P}\right\|_0$. Suppose we use `Monotone` with $W_0 = \mathbf{0}$. So all W_t (and the optimal W) need to satisfy $\lambda \left\|W_t\right\|_{\text{tr}} \leq C$, where $C = \left\|\mathcal{P}X\right\|_{\text{F}}^2 / (2\left\|\mathcal{P}\right\|_0)$. Due to the normalization, C can be considered a universal constant. All matrices $A \in \mathcal{A}$ in (48) satisfy $\left\|A\right\|_{\text{F}} \leq 1$. Obviously $\frac{1}{n}\left\|W_t\right\|_{\text{tr}}^2 \leq \left\|W_t\right\|_{\text{F}}^2 \leq \left\|W_t\right\|_{\text{tr}}^2$. So

$$L_F \leq 2L \sup_t \left\{ \frac{\rho^2}{\alpha^2}\left\|A_t\right\|_{\text{F}}^2 + \left\|W_t\right\|_{\text{F}}^2 \right\} \leq 2L \sup_t \left\{ \frac{\rho^2}{\alpha^2} + \left\|W_t\right\|_{\text{tr}}^2 \right\} \leq \frac{2}{\left\|\mathcal{P}\right\|_0}\left(\frac{1}{\alpha^2}+1\right)\frac{C^2}{\lambda^2}. \quad (52)$$

If λ needs to be less than $\frac{1}{\left\|\mathcal{P}\right\|_0}$, then the upper bound on L_F will be $O(\left\|\mathcal{P}\right\|_0)$. Notice that under `Monotone`, the expression of L_F in Theorem 5 is on par with the condition number $L_f D_*^2$ in (Harchaoui et al., 2015, Theorem 3).

4.3 Fixed-rank Local Optimization

Although the modified GCG algorithm, Algorithm 2, can be readily applied to the reformulated low rank learning problem (47), the sublinear rate of convergence established in Theorem 9 is still too slow in practice. Nevertheless, an effective local improvement scheme can be developed that satisfies the properties of a `Relaxed` subroutine in Algorithm 2, which allows empirical convergence to be greatly accelerated. Recall that in Algorithm 2, the intermediate iterate $\tilde{W}_{t+1}$ is determined by a linear combination of the previous iterate W_t and the newly added atom A_t (we changed the notation from $\tilde{\mathbf{w}}_{t+1}$ to $\tilde{W}_{t+1}$ since

5. The per-iteration cost of computing the spectral norm can be further reduced for the sparse matrices occuring naturally in matrix completion, since the gradient matrix in (51) contains at most k nonzero elements for k equal to the number of observed entries in X. In such cases, an ϵ accurate estimate of the squared spectral norm can be obtained in $O\left(\frac{k\log(n+m)}{\sqrt{\epsilon}}\right)$ time (Jaggi, 2013; Kuczyński and Woźniakowski, 1992), offering a significant speed up over the general case. Although some speed ups might also be possible when computing the SVD for sparse matrices, the gap between the computational cost for evaluating the spectral norm versus the trace norm for sparse matrices remains significant.

the optimization variables are now matrices). We will next demonstrate that $\tilde{W}_{t+1}$ can be further improved by solving a reformulated local problem, and then show how this can still preserve the convergence guarantees of Algorithm 2.

The key reformulation relies on the following fact.

Proposition 15 *The convex gauge κ induced by the set $\mathcal{A}$ in (48) can be re-expressed as*

$$\kappa(W) = \min\left\{ \sum_{i=1}^{t} \left\|U_{:i}\right\|_c \left\|V_{i:}\right\|_r : UV = W \right\} = \min\left\{ \frac{1}{2}\sum_{i=1}^{t}\left(\left\|U_{:i}\right\|_c^2 + \left\|V_{i:}\right\|_r^2 \right) : UV = W \right\},$$

for $U \in \mathbb{R}^{n\times t}$ and $V \in \mathbb{R}^{t\times m}$, as long as $t \geq mn$.

In Appendix B.1 we provide a direct proof that allows us to bound the number of terms involved in the summation. The above lower bound mn on t may not be sharp. For example, if $\left\|\cdot\right\|_r = \left\|\cdot\right\|_c = \left\|\cdot\right\|_2$, then κ is the trace norm, where $\sum_{i=1}^{t}(\left\|U_{:i}\right\|_c^2 + \left\|V_{i:}\right\|_r^2)$ is simply $\left\|U\right\|_{\text{F}}^2 + \left\|V\right\|_{\text{F}}^2$, the sum of the squared Frobenius norms; that is, Proposition 15 yields the well-known variational form of the trace norm in this case (Srebro et al., 2005). Observe that t in this case can be as low as the rank of W. Theorem 15 also appeared in (Bach et al., 2008; Bach, 2013), although without the explicit bound $t \geq mn$.

Based on Theorem 15, the objective in (47) can then be *approximated* at iteration t as

$$\mathcal{F}_{t+1}(U,V) := \ell(UV) + \frac{\lambda}{2}\sum_{i=1}^{t+1}\left(\left\|U_{:i}\right\|_c^2 + \left\|V_{i:}\right\|_r^2 \right). \quad (53)$$

Our key intuition is to first factorize $\tilde{W}_{t+1}$ into $U_{\text{init}}V_{\text{init}}$, and then find improvement to (U,V) with respect to $\mathcal{F}_{t+1}$ (*not* the original F). This results in U_{t+1} and V_{t+1} satisfying $\mathcal{F}_{t+1}(U_{t+1},V_{t+1}) \leq \mathcal{F}_{t+1}(U_{\text{init}},V_{\text{init}})$. Finally we restore the iterates based on Theorem 15

$$W_{t+1} = U_{t+1}V_{t+1} \qquad \text{and} \qquad \rho_{t+1} = \frac{1}{2}\sum_{i=1}^{t+1}\left(\left\|(U_{t+1})_{:i}\right\|_c^2 + \left\|(V_{t+1})_{i:}\right\|_r^2 \right). \quad (54)$$

Using $\mathcal{F}_{t+1}$ as a surrogate objective for local improvement is particularly advantageous in computation, because the problem is now unconstrained and the gauge function has been replaced by much simpler forms such as $\left\|U_{:i}\right\|_c^2$ and $\left\|V_{i:}\right\|_r^2$. This allows efficient unconstrained minimization routines (e.g. L-BFGS) to be applied directly, improving the quality of the current iterate *without* increasing the size of the dictionary. Note however that (53) is not *jointly* convex in (U,V) since the size $t+1$ (the iteration counter) is fixed. When t is sufficiently large, any local minimizer of (53) *globally* solves the original problem (47) (Burer and Monteiro, 2005)[6], but we locally reduce (53) in each iteration even for small t.

Once this modification is added to Algorithm 2 we obtain the final variant, Algorithm 3. In this algorithm, Line 3 remains equivalent to before, and Line 4 adopts the slightly more sophisticated update rule in (40), although one can also use (34) with $\eta_t = \frac{2}{t+2}$. Lines 5 to 8 *collectively* implement the `Improve` subroutine: Line 5 splits the iterate into two parts

6. The catch here is that seeking a local minimizer can still be highly non-trivial, sometimes it is even hard to certify the local optimality.

Algorithm 3 GCG variant for low rank learning.

9: **end for**

U_{init} and V_{init}, while Line 6 further reduces the reformulated local objective (53) with the designated initialization (e.g. by finding a local minimum). We referred to it as `Reduce` in order to be distinct from `Improve`. The last two steps restore the GCG iterate by (54).

The only major challenge left for inserting a local optimization step in Algorithm 2 is that the `Relaxed` condition (36) in Theorem 7 must be maintained. This is the condition under which Algorithm 3 retains the $O(1/t)$ rate of convergence established in Theorem 9. Fortunately this holds true as stated in Theorem 16 and its proof is given in Appendix B.2.

Proposition 16 *(U_{init}, V_{init}) in Line 5 is a factorization of the intermediate iterate $\tilde{W}_{t+1} = (1-\eta_t)W_t + \theta_t \mathbf{u}_t\mathbf{v}_t^\top$. Let (U_{t+1}, V_{t+1}) improve upon it in the sense that $\mathcal{F}_{t+1}(U_{t+1}, V_{t+1}) \le \mathcal{F}_{t+1}(U_{init}, V_{init})$. Then the W_{t+1} and ρ_{t+1} recovered by (54) satisfy the `Relaxed` condition.*

Although the `Reduce` subroutine is not guaranteed to achieve *strict* improvement in every iteration, we observe in our experiments in Section 5 below that Algorithm 3 is almost always significantly faster than the `Null` version of Algorithm 2. In other words, local acceleration appears to make a big difference in practice.

Remark 17 *Interleaving local improvement with a globally convergent procedure has been considered by Mishra et al. (2013) and Laue (2012). In particular, Laue (2012) considered the constrained problem* (21)*, which unfortunately leads to considering a constrained minimization for local improvement that can be less efficient than the unconstrained approach considered in* (53)*. In addition, Laue (2012) used the original objective F directly in local optimization. This leads to significant challenge when the regularizer κ is complicated such as the trace norm, and we avoid this issue by using a smooth surrogate objective $\mathcal{F}_{t+1}$.*

Focusing on trace norm regularization only, Mishra et al. (2013) proposed a trust-region procedure that locally minimizes the original *objective on the Stiefel manifold and the positive semidefinite cone, which unfortunately also requires constrained minimization and dynamic maintenance of the singular value decomposition of a small matrix. The rate of convergence of this procedure has not been analyzed.*

Remark 18 *We remark that local minimization of* (53) *constitutes the primary bottleneck of Algorithm 3, consuming over 50% of the computation. Since* (54) *is the same objective considered by the standard fixed rank approach to matrix factorization, the overall performance of Algorithm 3 can be substantially improved by leveraging the techniques that have been developed for this specific objective. These improvements include system level optimizations such as stochastic solvers on distributed, parallel and asynchronous infrastructures (Zhuang et al., 2013; Yun et al., 2014). In the experiments conducted in Section 5 below, we merely solve* (54) *using a generic L-BFGS solver to highlight the efficiency of the GCG framework itself. Nevertheless, such a study leaves significant room for further straightforward acceleration.*

Remark 19 *Much of our development in this section was inspired by the work of Bach et al. (2008), who first demonstrated, although in a slightly less clear way, that the convex relaxation in* (47) *is possible, but did not observe the computational connection to GCG. Our contribution here is to present this result succinctly using the notion of convex gauges, connect it naturally to the GCG algorithm we developed in Section 3, and propose an efficient fixed-rank local improvement subroutine `Reduce` that does not affect theoretical convergence guarantees. After our conference version (Zhang et al., 2012), Bach (2013) also independently extended the previous work (Bach et al., 2008) using convex gauges, and discussed a multiplicative approximate GCG variant similar to our Algorithm 2. However, the possibility to intervene fixed-rank local subroutines based on Theorem 15 with GCG, and its practical computational consequences, were not observed in (Bach, 2013).*

4.4 Multi-view Dictionary Learning

Finally, in this section we show how low rank learning can be generalized to a multi-view setting where, once again, the modified GCG algorithm can efficiently provide optimal solutions. The key challenge in this case is to develop column and row norms that can capture the more complex problem structure.

Consider a two-view learning task where one is given m paired observations $\left\{\begin{bmatrix}\mathbf{x}_j \\ \mathbf{y}_j\end{bmatrix}\right\}$ consisting of an x-view and a y-view with lengths n_1 and n_2 respectively. The goal is to infer a set of latent representations, $\mathbf{h}_j$ (of dimension $t < \min(n_1, n_2)$), and reconstruction models parameterized by the matrices A and B, such that $A\mathbf{h}_j \approx \mathbf{x}_j$ and $B\mathbf{h}_j \approx \mathbf{y}_j$ for all j. In particular, let X denote the $n_1 \times m$ matrix of x-view observations, Y the $n_2 \times m$ matrix of y-view observations, and $Z = \begin{bmatrix}X \\ Y\end{bmatrix}$ the concatenated $(n_1 + n_2) \times m$ matrix. The problem can then be expressed as recovering an $(n_1 + n_2) \times t$ matrix of model parameters, $C = \begin{bmatrix}A \\ B\end{bmatrix}$, and a $t \times m$ matrix of latent representations, H, such that $Z \approx CH$.

The key assumption behind multi-view learning is that each of the two views, $\mathbf{x}_j$ and $\mathbf{y}_j$, is conditionally independent given the shared latent representation, $\mathbf{h}_j$. Although multi-view data can always be concatenated hence treated as a single view, explicitly representing multiple views enables more accurate identification of the latent representation (as we will see), when the conditional independence assumption holds. To better motivate this model, it is enlightening to first reinterpret the classical formulation of multi-view dictionary learning, which is given by *canonical correlation analysis* (CCA). Typically, it is expressed as the problem of projecting two views so that the correlation between them is maximized. Assuming the data is centered (i.e. $X\mathbf{1} = \mathbf{0}$ and $Y\mathbf{1} = \mathbf{0}$), the sample covariance of X and Y is given by $XX^\top/m$ and $YY^\top/m$ respectively. CCA can then be expressed as an

optimization over matrix variables

$$\max_{U,V} \operatorname{tr}(U^\top XY^\top V) \qquad \text{s.t.} \qquad U^\top XX^\top U = V^\top YY^\top V = I \tag{55}$$

for $U \in \mathbb{R}^{n_1 \times t}$, $V \in \mathbb{R}^{n_2 \times t}$ (De Bie et al., 2005). Here I is the identity matrix whose size is clear from the context. Although this classical formulation (55) does not make the shared latent representation explicit, CCA can be expressed by a generative model: given a latent representation, $\mathbf{h}_j$, the observations $\mathbf{x}_j = A\mathbf{h}_j + \boldsymbol{\epsilon}_j$ and $\mathbf{y}_j = B\mathbf{h}_j + \boldsymbol{\nu}_j$ are generated by a linear mapping plus independent zero mean Gaussian noise, $\boldsymbol{\epsilon} \sim \mathcal{N}(\mathbf{0}, \Sigma_x)$, $\boldsymbol{\nu} \sim \mathcal{N}(\mathbf{0}, \Sigma_y)$ (Bach and Jordan, 2006). Interestingly, one can show that the classical CCA problem (55) is equivalent to the following multi-view dictionary learning problem.

Proposition 20 (White et al. 2012, Proposition 1) *Fix t, let*

$$(A, B, H) = \arg \min_{A:\|A_{:i}\|_2 \le 1} \min_{B:\|B_{:i}\|_2 \le 1} \min_{H} \left\| \begin{bmatrix} (XX^\top)^{-1/2} X \\ (YY^\top)^{-1/2} Y \end{bmatrix} - \begin{bmatrix} A \\ B \end{bmatrix} H \right\|_{\mathrm{F}}^2 . \tag{56}$$

Then $U = (XX^\top)^{-\frac{1}{2}} A$ and $V = (YY^\top)^{-\frac{1}{2}} B$ provide an optimal solution to (55).

Proposition 20 demonstrates how formulation (56) respects the conditional independence of the separate views: given a latent representation $\mathbf{h}_j$, the reconstruction losses on the two views, $\mathbf{x}_j$ and $\mathbf{y}_j$, cannot influence each other, since the reconstruction models A and B are *individually* constrained. By contrast, in single-view dictionary learning (i.e. *principal component analysis*) A and B are concatenated in the larger variable $C = \left[\begin{smallmatrix} A \\ B \end{smallmatrix}\right]$, where C as a whole is constrained but A and B are not. A and B must then compete against each other to acquire magnitude to explain their respective "views" given $\mathbf{h}_j$ (i.e. conditional independence is not enforced). Such sharing can be detrimental if the two views really are conditionally independent given $\mathbf{h}_j$.

This matrix factorization viewpoint has recently allowed dictionary learning to be extended from the single-view setting to the multi-view setting (Jia et al., 2010). However, despite its elegance, the computational tractability of CCA hinges on its restriction to squared loss under a particular normalization, precluding other important losses. To combat these limitations, we apply the same convex relaxation principle as in Section 4.2. In particular, we reformulate (56) by first incorporating an arbitrary loss function ℓ that is convex in its first argument, and then relaxing the rank constraint by replacing it with the $\mathfrak{l}_1$ norm of the "singular values". This amounts to the following training problem that extends (Jia et al., 2010):

$$\min_{A,B,H,\boldsymbol{\sigma}} \ell\left(\begin{bmatrix} A \\ B \end{bmatrix} \operatorname{diag}(\boldsymbol{\sigma}) H; Z \right) + \lambda \|\boldsymbol{\sigma}\|_1 , \quad \text{s.t.} \quad \|H_{i:}\|_2 \le 1, \quad \sigma_i \ge 0, \quad \begin{bmatrix} A_{:i} \\ B_{:i} \end{bmatrix} \in \mathcal{D} \; \forall \, i,$$
$$\text{where} \quad \mathcal{D} := \left\{ \begin{bmatrix} \mathbf{a} \\ \mathbf{b} \end{bmatrix} : \|\mathbf{a}\|_2 \le \beta, \; \|\mathbf{b}\|_2 \le \gamma \right\}. \tag{57}$$

The $\mathfrak{l}_2$ norm on the *rows* of H is a regularizer that encourages the rows to become sparse, hence reducing the size of the learned representation (Argyriou et al., 2008). Since the size of the latent representation (the number of rows of H) is not fixed, our results in Section 4.2

immediately allows the problem to be solved globally and efficiently for A, B and H. This considerably improves the previous local solutions in (Jia et al., 2010) which fixed the latent dimension and approached the non-convex problem by alternating block coordinate descent between A, B and $\operatorname{diag}(\boldsymbol{\sigma})H$.

Indeed, (57) fits exactly in the framework of (45), with $\|\cdot\|_r$ being the $\mathfrak{l}_2$ norm and

$$\|\mathbf{c}\|_c = \max\left(\frac{1}{\beta} \|\mathbf{a}\|_2 , \frac{1}{\gamma} \|\mathbf{b}\|_2 \right) \quad \text{for} \quad \mathbf{c} = \begin{bmatrix} \mathbf{a} \\ \mathbf{b} \end{bmatrix}. \tag{58}$$

Next we will show how to efficiently compute the polar operator (50) that underpins Algorithm 3 in this multi-view model.

4.4.1 Efficient Polar Operator

The polar operator (50) for problem (57) turns out to admit an efficient but nontrivial solution. For simplicity, we assume $\beta = \gamma = 1$ while the more general case can be dealt with in exactly the same way. The proof of the following key theorem is in Appendix B.3.

Proposition 21 *Let $I_1 := \operatorname{diag}(\left[\begin{smallmatrix} 1 \\ 0 \end{smallmatrix}\right])$ and $I_2 := \operatorname{diag}(\left[\begin{smallmatrix} 0 \\ 1 \end{smallmatrix}\right])$ be the identity matrices on the subspaces spanned by x-view and y-view, respectively. For any $\mu > 0$, denote $D_\mu = \sqrt{1+\mu} I_1 + \sqrt{1+1/\mu} I_2$ as a diagonal scaling of the two identity matrices. Then, for the row norm $\|\cdot\|_r = \|\cdot\|_2$ and column norm $\|\cdot\|_c$ defined as in (58), the corresponding polar (49) is given by*

$$\kappa^\circ(G) = \min_{\mu \ge 0} \|D_\mu G\|_{\mathrm{sp}} . \tag{59}$$

Despite its variational form, the polar (59) can still be efficiently computed by considering its squared form and expanding:

$$\|D_\mu G\|_{\mathrm{sp}}^2 = \left\| G^\top D_\mu D_\mu G \right\|_{\mathrm{sp}} = \left\| G^\top \left[(1+\mu) I_1 + (1+1/\mu) I_2 \right] G \right\|_{\mathrm{sp}} .$$

Clearly, the term inside the spectral norm $\|\cdot\|_{\mathrm{sp}}$ is convex in μ on $\mathbb{R}_+$ while the spectral norm is convex and increasing on the cone of positive semidefinite matrices, hence by the usual rules of convex composition the left hand side above is a *convex* function of μ. Consequently we can use a subgradient algorithm, or even golden section search, to find the optimal μ in (59). Given an optimal μ, an optimal pair of "atoms" $\mathbf{a}$ and $\mathbf{b}$ can be recovered via the KKT conditions; see Appendix B.4 for details. Thus, by using (59) Algorithm 3 is able to solve the resulting optimization problem far more efficiently than the initial procedure offered by White et al. (2012).

Similar to the case of matrix completion for single view in Section 4.2.1, the L_F in Theorem 5 for this multi-view setting can be bounded in exactly the same way as in (52). The only difference is that instead of $\|W\|_{\mathrm{tr}} \ge \|W\|_{\mathrm{F}}$, we now have $\kappa(W) \ge \frac{1}{\sqrt{2}} \|W\|_{\mathrm{F}}$. To see it, just set $\mu = 1$ in (59), and we immediately obtain $\kappa^\circ(G) \le \sqrt{2} \|G\|_{\mathrm{sp}}$. Dualizing both sides leads to $\kappa(W) \ge \frac{1}{\sqrt{2}} \|W\|_{\mathrm{tr}} \ge \frac{1}{\sqrt{2}} \|W\|_{\mathrm{F}}$. Therefore we can proceed in analogy to (52):

$$L_F \le 2L \sup_t \left\{ \frac{\rho^2}{\alpha^2} \|A_t\|_{\mathrm{F}}^2 + \|W_t\|_{\mathrm{F}}^2 \right\} \le 2L \sup_t \left\{ \frac{2\rho^2}{\alpha^2} + 2\kappa(W_t)^2 \right\} \le \frac{4}{\|\mathcal{P}\|_0} \left(\frac{1}{\alpha^2} + 1 \right) \frac{C^2}{\lambda^2}. \tag{60}$$

4.4.2 A Modified Power Iteration

In practice, one can compute the polar (59) much more efficiently by deploying a heuristic variant of the power iteration method, whose motivation arises from the KKT conditions in the proof of Theorem 21 (see (76) in Appendix B.4). In particular, two normalized vectors $\mathbf{a}$ and $\mathbf{b}$ are optimal for the polar (50) if and only if there exist nonnegative scalars μ_1 and μ_2 such that

$$\begin{bmatrix} \mu_1 \mathbf{a} \\ \mu_2 \mathbf{b} \end{bmatrix} = GG^\top \begin{bmatrix} \mathbf{a} \\ \mathbf{b} \end{bmatrix}, \qquad \text{and} \qquad \mu_1 I_1 + \mu_2 I_2 \succeq GG^\top. \tag{61}$$

Here $A \succeq B$ asserts that $A - B$ is positive semidefinite. Therefore, after randomly initializing $\mathbf{a}$ and $\mathbf{b}$ with unit norm, it is natural to extend the power iteration method by repeating the update:

$$\begin{bmatrix} \mathbf{s} \\ \mathbf{t} \end{bmatrix} \leftarrow GG^\top \begin{bmatrix} \mathbf{a} \\ \mathbf{b} \end{bmatrix}, \quad \text{then} \quad \begin{bmatrix} \mathbf{a}^{\text{new}} \\ \mathbf{b}^{\text{new}} \end{bmatrix} \leftarrow \begin{bmatrix} \frac{1}{\|\mathbf{s}\|_2}\mathbf{s} \\ \frac{1}{\|\mathbf{t}\|_2}\mathbf{t} \end{bmatrix}.$$

This procedure usually converges to a solution where the Lagrange multipliers μ_1 and μ_2, recovered from (61), satisfy (61) hence confirming their optimality. While we leave the investigation of the theoretical guarantees of this power iteration heuristic for future work, let us mention that it works very well in practice (as in the single view case) and when the occasional failure occurs we revert to (59) and follow the recovery rule detailed in Appendix B.4.

5. Experimental Evaluation

We evaluate the extended GCG approach developed above in three sparse learning problems: matrix completion, multi-class classification, and multi-view dictionary learning. All algorithms were implemented in Matlab unless otherwise noted.[7] All experiments were run on a single core of a cluster housed at National ICT Australia with AMD 6-Core Opteron 4184 (2.8GHz, 3M L2/6M L3 Cache, 95W TDP, 64 GB memory).

5.1 Matrix Completion with Trace Norm Regularization

Our first set of experiments is on matrix completion (51), where the division by $\|\mathcal{P}\|_0$ is omitted to be consistent with existing solvers. Five data sets are used and their statistics are given in Table 1. The data sets `Yahoo252M` (Dror et al., 2012) and `Yahoo60M`[8] provide music ratings, and the data sets `Netflix` (Dror et al., 2012), `MovieLens1M`, and `MovieLens10M`[9] all provide movie ratings. For `MovieLens1M` and `Yahoo60M`, we randomly sampled 75% ratings as training data, using the rest for testing. The other three data sets came with training and testing partition.

We compared the extended GCG approach (Algorithm 3) with three state-of-the-art solvers for trace norm regularized objectives: MMBS[10] (Mishra et al., 2013), DHM (Dudik et al., 2012), and JS (Jaggi and Sulovsky, 2010). The local optimization in GCG was performed by L-BFGS with the maximum number of iteration set to 20.[11] Traditional solvers such as proximal methods (Toh and Yun, 2010; Pong et al., 2010) were not included in this comparison because they are much slower.

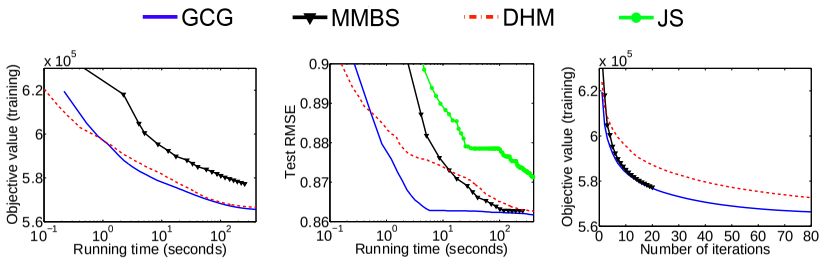
7. All code is available for download at `https://www.cs.uic.edu/~zhangx/GCG`.
8. `Yahoo60M` is the R1 data set at `http://webscope.sandbox.yahoo.com/catalog.php?datatype=r`.
9. Both MovieLens1M and MovieLens10M were downloaded from `http://www.grouplens.org/datasets/movielens`.
10. Downloaded from `http://www.montefiore.ulg.ac.be/~mishra/softwares/traceNorm.html`.

data set	n (#user)	m (#product)	#train	#test	λ
`MovieLens1M`	6,040	3,952	750,070	250,024	50
`MovieLens10M`	71,567	65,133	9,301,174	698,599	100
`Netflix`	2,549,429	17,770	99,072,112	1,408,395	1
`Yahoo60M`	98,130	1,738,442	60,021,577	20,872,219	300
`Yahoo252M`	1,000,990	624,961	252,800,275	4,003,960	100

Table 1: Summary of the data sets used in matrix completion experiments. Here n is the total number of users, m is the number of products (movies or music), #train and #test are the number of ratings used for training and testing respectively.

MMBS is confined to trace norm regularized problems. At each iteration t, they solve

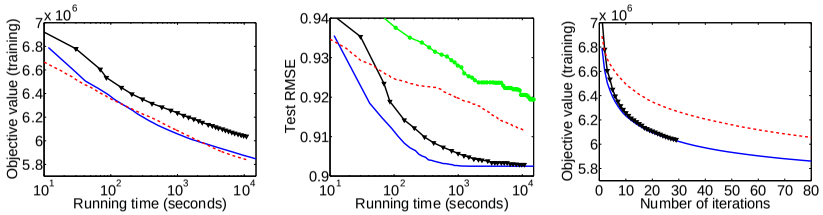
$$\min_{U \in \mathbb{R}^{n\times t},\ B \in \mathbb{R}^{t\times t},\ V \in \mathbb{R}^{t\times m}} \ell(UBV) + \lambda \operatorname{tr}(B), \quad \text{s.t. } U^\top U = VV^\top = I, \text{ and } B \succeq \mathbf{0}. \tag{62}$$



After obtaining a stationary point, the gradient of ℓ is computed, with its top left and right singular vectors appended to U and V respectively, and repeat. Unfortunately, the optimization in (62) is highly challenging on the Stiefel manifold, and their algorithm relies on the directional Hessian which becomes rather complicated in computation for general ℓ. By contrast, the local surrogate (53) used in our approach is substantially easier to optimize.

DHM is a special case of GCG, with `Improve` instantiated with a line search procedure (Dudik et al., 2012). The detail of line search is intricate, but in practice it is slower than totally corrective updates (42) solved by L-BFGS. To further streamline the optimization for (42), we buffered the quantities $\langle \mathcal{P}(\mathbf{u}_t\mathbf{v}_t'), \mathcal{P}(\mathbf{u}_s\mathbf{v}_s') \rangle$ and $\langle \mathcal{P}(\mathbf{u}_t\mathbf{v}_t'), \mathcal{P}(X) \rangle$, where $(\mathbf{u}_t, \mathbf{v}_t)$ is the result of polar operator at iteration t (Line 3 of Algorithm 3). This allowed the objective (42) to be evaluated efficiently without having to compute matrix inner product.

JS was proposed for solving the constrained problem: $\min_W \ell(W)$ s.t. $\|W\|_{\text{tr}} \leq \zeta$, which makes it hard to directly compare with solvers for the penalized problem (51). As a workaround, given λ we first found the optimal solution W^* for the penalized problem, and then we set $\zeta = \|W^*\|_{\text{tr}}$. To solve the constrained problem, JS lifts it to an SDP by observing that $\|W\|_{\text{tr}} \leq \frac{t}{2}$ iff there exist symmetric matrices A and B such that $Z := \begin{pmatrix} A & W \\ W^\top & B \end{pmatrix} \succeq \mathbf{0}$ and $\operatorname{tr}(A) + \operatorname{tr}(B) = t$. Then the objective $\ell(W)$ can be rewritten in terms of Z, solved by the conventional conditional gradient algorithm for constrained problems.



Figures 2 to 6 show how quickly the various algorithms drive the training objective down, while also providing the root mean square error (RMSE) on test data (i.e. comparing the reconstructed matrix each iteration to the ground truth). JS is comparable only on RMSE. The regularization constant λ, given in Table 1, was chosen from

11. Downloaded from `http://www.cs.ubc.ca/~pcarbo/lbfgsb-for-matlab.html`. Recall a suboptimal solution is sufficient for the fixed-rank local optimization in `Relaxed`.

Figure 3: Matrix completion on `MovieLens10M`

$\{1, 10, 50, 100, 200, 300, 400, 500, 1000\}$ to minimize the test RMSE. On the `MovieLens1M` and `MovieLens10M` data sets, GCG and DHM exhibit similar efficiency in reducing the objective value with respect to CPU time (see Figure 2(a) and 3(a)). However, GCG achieves comparable test RMSE an order of magnitude faster than DHM, as shown in Figure 2(b) and 3(b). Interestingly, this discrepancy can be explained by investigating the rank of the solution, i.e. the number of outer iterations taken. In Figure 2(c) and 3(c), DHM clearly converges much more slowly in terms of the number of iterations, which is expected because it does not re-optimize the basis at each iteration, unlike GCG and MMBS. Therefore, although the overall computational cost for DHM appears on par with that for GCG, its solution has a much higher rank, resulting in a much higher test RMSE in these cases.

MMBS takes nearly the same number of iterations as GCG to achieve the same objective value (see Figure 2(c) and 3(c)). However, its local search at each iteration is conducted on a *constrained* manifold, making it much more expensive than locally optimizing the unconstrained smooth surrogate (53). As a result, the overall computational complexity of MMBS is an order of magnitude greater than that of GCG, with respect to optimizing both the objective value and the test RMSE.

The observed discrepancies between the relative efficiency of optimizing the objective value and test RMSE becomes much smaller on the other three data sets, which are much larger in size. In Figure 4 to 6, it is clear that GCG takes significantly less CPU time to

optimize both criteria. The declining trend of the objective value has a similar shape to that of the test RMSE. Here we observe that DHM is substantially slower than GCG and MMBS, confirming the importance of optimizing the bases at the same time as optimizing their weights. JS, which does not exploit the penalized form of the objective, is considerably slower with respect to reducing the test RMSE.

5.2 Multi-class Classification with Trace Norm Regularization

Next we compared the four algorithms on multi-class classification problems also in the context of trace norm regularization. Here the task is to predict the class membership of input instances, $\mathbf{x}_i \in \mathbb{R}^n$, where each instance is associated with a unique label $y_i \in \{1, \ldots, C\}$. In particular, we consider a standard linear classification model where each class c is associated with a weight vector in $\mathbb{R}^n$, stacked in a model matrix $W \in \mathbb{R}^{n \times C}$. Then for each training example $(\mathbf{x}_i, y_i)$, the individual logistic loss $L(W; \mathbf{x}_i, y_i)$ is given by

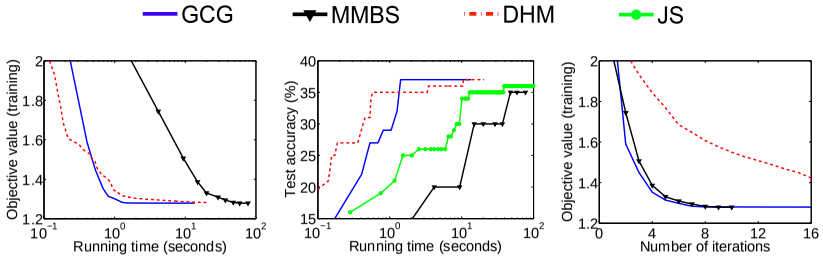
$$L(W; \mathbf{x}_i, y_i) = -\log \frac{\exp(\mathbf{x}_i' W_{:,y_i})}{\sum_{c=1}^{C} \exp(\mathbf{x}_i' W_{:c})},$$

data set	n	C	#train	#test	λ
Fungus10	4,096	10	10 per class	10 per class	10^{-2}
Fungus134	4,096	134	50 per class	50 per class	10^{-3}
k1024	131,072	50	50 per class	50 per class	10^{-3}

Table 2: Summary of the data sets used in multi-class classification experiments. Here n is the number of features, C is the number of classes, #train and #test are the number of training and test images respectively.

and the complete loss is given by averaging over the training set, $\ell(W) := \frac{1}{m}\sum_{i=1}^{m} L(W; \mathbf{x}_i, y_i)$. It is reasonable to assume that W has a low rank; i.e. the weight vector of all classes lie in a low dimensional subspace (Akata et al., 2014), which motivates the introduction of a trace norm regularizer on W, yielding a training problem in the form of (47).

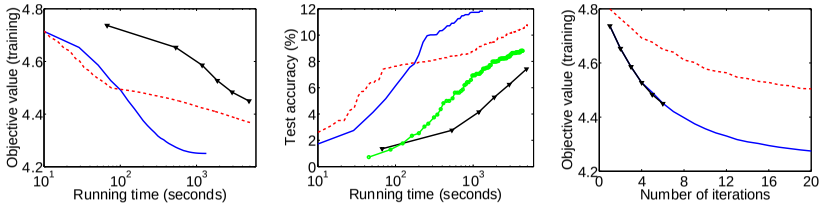
We conducted experiments on three data sets extracted from the ImageNet repository (Deng et al., 2009), with characteristics shown in Table 2 (Akata et al., 2014).[12] k1024 is from the ILSVRC2011 benchmark, and Fungus10 and Fungus134 are from the Fungus group. All images are represented by the Fisher descriptor.



As in the matrix completion case above, we again compared how fast the algorithms reduced the objective value and test accuracy. Here the value of λ was chosen from $\{10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}\}$ to maximize test accuracy. Figures 7 to 9 show that the models produced by GCG achieve comparable (or better) training objectives and test accuracies in far less time than MMBS, DHM and JS. Although DHM is often more efficient than GCG early on, it is soon overtaken. This observation could be related to the diminishing return of adding bases, as shown in Figure 7(c), 8(c), and 9(c), since the addition of the first few bases yields a much steeper decrease in objective value than that achieved by later bases. Hence, after the initial stage, the computational efficiency of a solver turns to be dominated by better exploitation of the bases. That is, using added bases as an initialization for local improvement (as in GCG) appears to be more effective than simply finding an optimal conic combination of added bases (as in DHM).

Also notice from Figures 7(c), 8(c) and 9(c) that MMBS and GCG are almost identical in terms of the number of iterations required to achieve a given objective value. However, the manifold based local optimization employed by MMBS at each iteration makes its overall computational time worse than that of DHM and JS. This is a different outcome from the matrix completion experiments we saw earlier, and seems to suggest that the manifold approach in MMBS is more effective for the least square loss than for the logistic loss.

5.3 Multi-view Dictionary Learning



Our third set of experiments focuses on optimizing the objective for the multi-view dictionary learning model (57) presented in Section 4.4. Here we compared the GCG approach outlined in Section 4.4 with a straightforward *local* solver that is based on block coordinate descent (BCD), which alternates between: (a) fixing H and optimizing A and B (with norm

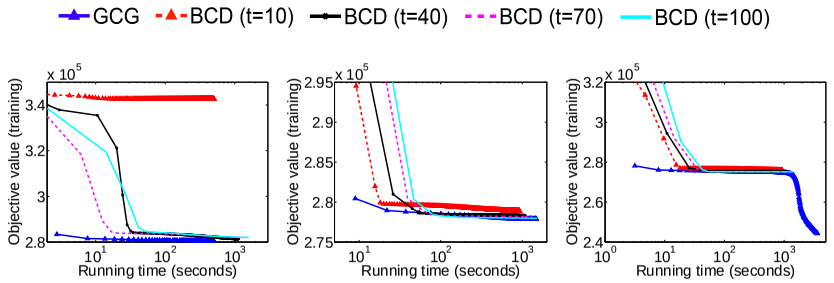
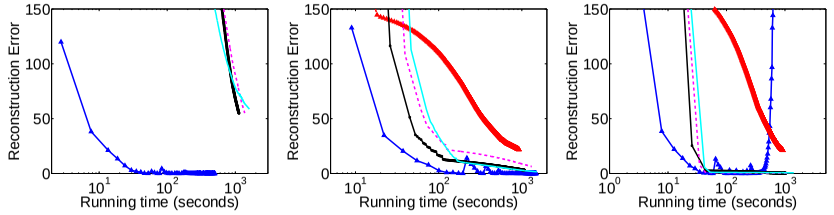
ball constraints), then (b) fixing A and B and optimizing H (with nonsmooth regularizer). Both steps were solved by FISTA (Beck and Teboulle, 2009), initialized with the solution from the previous iteration. We tested several values of t, the dimensionality of the latent subspace of the solution, in these experiments. The GCG approach used Algorithm 3 with the local objective (53) instantiated by the norm expression in (58) and solved by L-BFGS with max iteration set to 20. We initialized the U and V matrices with 20 columns and rows respectively, each drawn i.i.d. from a uniform distribution on the unit sphere. Based



on the noise model we consider in these experiments, we started with a base loss ℓ set to $\mathfrak{l}_1(Z, Z^*) = \sum_{ij} |Z_{ij} - Z^*_{ij}|$ where Z^* is the true underlying matrix; however, following (Becker et al., 2009, Eq 3.1), we smoothed this $\mathfrak{l}_1$ loss by adding a quadratic prox-function with strong convexity modulus 10^{-4}. Under the resulting loss, the optimization over A and B is decoupled given H. We terminated all algorithms after a maximum of running time (3,600 seconds) is reached.

5.3.1 Synthetic Data



We first constructed experiments on a synthetic data set that fulfills the conditional independence assumption (57) of the multi-view model (as discussed in Section 4.4). Here the x- and y-views have basis matrices $A^* \in \mathbb{R}^{n_1 \times t^*}$ and $B^* \in \mathbb{R}^{n_2 \times t^*}$ respectively, where all columns of A^* were drawn i.i.d. from the $\mathfrak{l}_2$ sphere of radius $\beta = 1$, and all columns of B^* were drawn i.i.d. from the $\mathfrak{l}_2$ sphere of radius $\gamma = 5$. We set $n_1 = 800$, $n_2 = 1000$, and $t^* = 10$ (so that the dictionary size is indeed small). The latent representation matrix $H^* \in \mathbb{R}^{t^* \times m}$ has all elements drawn i.i.d. from the zero-mean unit-variance Gaussian distribution. The number of training examples is set to $m = 200$, which is much lower than the number of features n_1 and n_2. Then the clean versions of x-view and y-view were generated by $X^* = A^*H^*$ and $Y^* = B^*H^*$ respectively, while the noisy versions were obtained by adding i.i.d. noise to 15% entries of X^* and Y^* that were selected uniformly at random, yielding $\hat{X}$ and $\hat{Y}$ respectively. The noise is uniformly distributed in $[0, 10]$. Given the noisy observations, the denoising task is to find reconstructions X and Y for the two views, such that the error $\|X - \hat{X}\|_{\mathrm{F}}^2 + \|Y - \hat{Y}\|_{\mathrm{F}}^2$ is small. The composite training problem is formulated in (57).

The results of comparing the modified GCG method with local optimization are presented in Figures 10 to 12, where the regularization parameter λ has been varied among $\{80, 60, 40\}$. In each case, GCG optimizes the objective value significantly faster than BCD for all values of t chosen for BCD. The differences between methods are even more evident when considering the reconstruction error. In particular, although the local optimization in GCG already achieves a low objective value in the first outer iteration (see Figure 10(a) and 11(a)), the reconstruction error remains high, thus requiring further effort to reduce it.

When $t = 10$ which equals the true rank $t^* = 10$, BCD is more likely to get stuck in a poor local minimum when λ is large, for example as shown in Figure 10(a) for $\lambda = 80$. This occurs because when optimizing H, the strong shrinkage in the proximal update stifles major changes in H (and in A and B consequently). This problem is exacerbated when the rank of the solution is overly restricted, leading to even worse local optima. On the other hand, under-regularization does indeed cause overfitting in this case; for example, as shown in Figure 12 for $\lambda = 40$. Interestingly, BCD gets trapped in local optima for all t, while GCG eventually escapes suboptimal solutions and eventually finds a way to considerably reduce the objective value. However, this simply creates a dramatic *increase* in the test reconstruction error, a typical phenomenon of overfitting.

5.3.2 Image Denoising

We then conducted multi-view dictionary learning experiments on natural image data. The data set we considered is based on the Extended Yale Face Database B[13] (Georghiades et al., 2001). In particular, the data set we used consists of grey level face images of 28 human subjects, each with 9 poses and 64 lighting conditions. To construct the data set, we set the x-view to a fixed lighting (+000E+00) and the y-view to a different fixed lighting (+000E+20). We obtained paired views by randomly drawing a subject and a pose under the two lighting conditions. The underlying assumption is that each lighting has its own set of bases (A and B) and each (person, pose) pair has the same latent representation for the two lighting conditions. All images were down-sampled to 50-by-50, meaning $n_1 = n_2 = 2500$, and we randomly selected $t = 50$ pairs of (person, pose) for training. The x-view was kept clean, while pixel errors were added to the y-view, randomly setting 10% of the pixel values to 1. This noise model mimics natural phenomena such as occlusion and loss of pixel information from image transfer. The goal is again to enable appropriate reconstruction of

Figure 15: Denoising on face data with $\lambda = 20$

a noisy image using other views. Naturally, we set $\beta = \gamma = 1$ since the data is in the $[0, 1]$ interval.

Figures 13 to 15 show the results comparing GCG with the local BCD for different choices of t for BCD. Clearly the value of λ that yields the lowest reconstruction error is 40. However, here BCD simply gets stuck at the trivial local minimum $H = \mathbf{0}$, as shown in Figure 13(a). This occurs because under the random initialization of A and B, the proximal update simply sets H to $\mathbf{0}$ when the regularization is too strong. When λ is decreased to 30, as shown in Figure 14(a), BCD can escape the trivial $H = \mathbf{0}$ solution for $t = 100$, but again it becomes trapped in another local minimum that remains much worse than the globally optimal solution found by GCG. When λ is further reduced to 20, the BCD algorithms finally escape the trivial $H = \mathbf{0}$ point for all t, but still fail to find an acceptable solution. Although GCG again converges to a much better global solution in terms of the objective value, overfitting can still occur: in Figure 15(b) the reconstruction error of GCG increases significantly after an initial decline.

6. Conclusion

We have presented a unified treatment of the generalized conditional gradient (GCG) algorithm that covers several useful extensions. After a thorough treatment of its convergence properties, we illustrated how an extended form of GCG can efficiently handle a convex gauge regularizer in particular. We illustrated the application of these GCG methods in learning low rank matrices, instantiated with examples on matrix completion, dictionary learning, and multi-view learning. In each case, we considered a generic convex relaxation procedure and focused on the efficient computation of the polar operator—one of the key steps to obtaining an efficient implementation of GCG. To further accelerate its convergence, we interleaved the standard GCG update with a fixed rank subspace optimization, which greatly improves performance in practice without affecting the theoretical convergence properties. Extensive experiments on matrix completion, multi-class classification, multi-view learning confirmed the superiority of the modified GCG approach in practice.

For future work, several interesting extensions are worth investigating. The current form of GCG is inherently framed as a batch method, where each iteration requires gradient of the loss to be computed over *all* training data. When the training data is large, it is preferable to only use a random subset, or distribute the training data across several processors. Another interesting direction is to interpolate between the polar operator and proximal updates; that is, one could incorporate a mini-batch of atoms at each iteration. For example, for trace norm regularization, one can consider adding k instead of just the 1 largest singular vectors. It remains an open question whether such a "mini-batch" of atoms can provably accelerate the overall optimization, but some recent work (Hsieh and Olsen, 2014) has demonstrated promise in practice.

Acknowledgments

X Zhang would like to thank the support of NICTA, where he worked as a researcher from Oct 2012 to Oct 2015 and conducted 50% of his work on this paper. We thank Csaba Szepesvári, the action editor, and the reviewers at various stages of this work for the many constructive comments.

Appendix A. Proofs for Section 3

A.1 Proof of Theorem 2

Since $\nabla \ell$ is Lipschitz continuous, it must be uniformly continuous on bounded set.

(a): Let C be the closure of the sequence $\{\mathbf{w}_t\}_t$. Due to the compactness assumption on the sublevel set and the monotonicity of $F(\mathbf{w}_t)$, C is compact. Moreover $C \subseteq \operatorname{dom} f$ since for all cluster points, say $\mathbf{w}$, of $\mathbf{w}_t$ we have from the closedness of F that $F(\mathbf{w}) \leq \liminf F(\mathbf{w}_{t_k}) \leq F(\mathbf{w}_0) < \infty$. Since $-\nabla \ell$ is continuous, $-\nabla \ell(C)$ is a compact subset of $\operatorname{int}(\operatorname{dom} f^*)$, the interior of $\operatorname{dom} f^*$. Note that f^* is continuous on the interior of its domain, therefore its subdifferential is locally bounded on $-\nabla \ell(C)$, see e.g. (Borwein and

Vanderwerff, 2010, Proposition 4.1.26). A standard compactness argument then establishes the boundedness of $(\partial f^*)(-\nabla \ell(C))$. Thus $\{\mathbf{d}_t\}_t$ is bounded.

(b): Note first that the boundedness of $\{\mathbf{w}_t\}_t$ follows immediately from the boundedness assumption on the sublevel set, thanks to the monotonic property of $F(\mathbf{w}_t)$. Since $\nabla \ell$ is uniformly continuous, the set $\{-\nabla \ell(\mathbf{w}_t)\}_t$ is again bounded. On the other hand, we know from (Borwein and Vanderwerff, 2010, Theorem 4.4.13, Proposition 4.1.25) that f is supercoercive iff ∂f^* maps bounded sets into bounded sets. Therefore $\{\mathbf{d}_t\}_t$ is again bounded.

(c): This is clear.

Note that the convexity of ℓ is not used in this proof.

A.2 Proof of Theorem 4

Since ℓ is L-smooth, for the sequences $\{\mathbf{w}_t\}$ and $\{\mathbf{d}_t\}$ generated by Algorithm 1, and for all $\eta \in [0,1]$, we have

$$\ell(\mathbf{w}_t + \eta(\mathbf{d}_t - \mathbf{w}_t)) \leq \ell(\mathbf{w}_t) + \eta \left\langle \mathbf{d}_t - \mathbf{w}_t, \nabla \ell(\mathbf{w}_t) \right\rangle + \tfrac{L\eta^2}{2} \left\| \mathbf{d}_t - \mathbf{w}_t \right\|^2. \tag{63}$$

Since the subroutine is `Relaxed` and the subproblem (13) is solved up to some $\varepsilon_t \geq 0$,

$$\begin{aligned} F(\mathbf{w}_{t+1}) &\leq \ell(\mathbf{w}_t) + \eta_t \left\langle \mathbf{d}_t - \mathbf{w}_t, \nabla \ell(\mathbf{w}_t) \right\rangle + \tfrac{L\eta_t^2}{2} \left\| \mathbf{d}_t - \mathbf{w}_t \right\|^2 + (1-\eta_t) f(\mathbf{w}_t) + \eta_t f(\mathbf{d}_t) \\ &\leq F(\mathbf{w}_t) - \eta_t \mathsf{G}(\mathbf{w}_t) + \tfrac{L\eta_t^2}{2} \left\| \mathbf{d}_t - \mathbf{w}_t \right\|^2 + \eta_t \varepsilon_t \\ &= F(\mathbf{w}_t) - \eta_t \mathsf{G}(\mathbf{w}_t) + \eta_t^2 (\varepsilon_t/\eta_t + \tfrac{L}{2} \left\| \mathbf{d}_t - \mathbf{w}_t \right\|^2). \end{aligned}$$

Define $\Delta_t := F(\mathbf{w}_t) - F(\mathbf{w})$ and $\mathsf{G}_t := \mathsf{G}(\mathbf{w}_t)$. Thus

$$\Delta_{t+1} \leq \Delta_t - \eta_t \mathsf{G}_t + \eta_t^2 (\varepsilon_t/\eta_t + \tfrac{L}{2} \left\| \mathbf{d}_t - \mathbf{w}_t \right\|^2), \qquad \text{and} \qquad \Delta_t \leq \mathsf{G}_t. \tag{64}$$

Plug the latter into the former and expand:

$$\Delta_{t+1} \leq \pi_t (1-\eta_0) \Delta_0 + \sum_{s=0}^{t} \frac{\pi_t}{\pi_s} \eta_s^2 (\varepsilon_s/\eta_s + \tfrac{L}{2} \left\| \mathbf{d}_s - \mathbf{w}_s \right\|^2). \tag{65}$$

To prove the second claim, we have from (64) $\eta_t \mathsf{G}_t \leq \Delta_t - \Delta_{t+1} + \eta_t^2 (\varepsilon_t/\eta_t + \tfrac{L}{2} \left\| \mathbf{d}_t - \mathbf{w}_t \right\|^2)$. Summing from k to t:

$$\left(\min_{k \leq s \leq t} \mathsf{G}_s \right) \sum_{s=k}^{t} \eta_s \leq \sum_{s=k}^{t} \eta_s \mathsf{G}_s \leq F(\mathbf{w}_k) - F(\mathbf{w}_{t+1}) + \sum_{s=k}^{t} \eta_s^2 (\varepsilon_s/\eta_s + \tfrac{L}{2} \left\| \mathbf{d}_s - \mathbf{w}_s \right\|^2).$$

Rearranging completes the proof.

A.3 Proof of Theorem 5

As $\eta_t = \frac{2}{t+2}$, we have $\eta_0 = 1$ and $\pi_t = \frac{2}{(t+1)(t+2)}$. For the first claim (upper bound on $F(\mathbf{w}_t)$) all we need to verify is that, by induction, $\frac{1}{(t+1)(t+2)} \sum_{s=0}^{t} \frac{s+1}{s+2} \leq \frac{1}{t+4}$. This is elementary.

We prove the second claim by a sequence of calculations similar to that in (Freund and Grigas, 2016). First, using (19) and the bound on $F(\mathbf{w}_t)$ in (20) with $t = 1$ and $\mathbf{w} = \mathbf{w}_2$:

$$\tilde{\mathsf{G}}_1^1 \leq \tfrac{1}{\eta_1} \left(F(\mathbf{w}_1) - F(\mathbf{w}_2) + \tfrac{\eta_1^2}{2} (\delta + L_F) \right) \leq \tfrac{3}{2} \left(\tfrac{1}{2} (\delta + L_F) + \tfrac{2}{9} (\delta + L_F) \right) = \tfrac{13}{12} (\delta + L_F),$$

proving the second claim on $\tilde{\mathsf{G}}_1^t$ for $t = 1, 2$ (note that $\tilde{\mathsf{G}}_1^2 \leq \tilde{\mathsf{G}}_1^1$ by definition). For $t \geq 3$, we consider $k = t/2 - 1$ if t is even and $k = (t+1)/2 - 1$ otherwise. Clearly $k \geq 1$, hence

$$\begin{aligned} \sum_{s=k}^{t} \eta_s &= 2 \sum_{s=k}^{t} \frac{1}{s+2} \geq 2 \int_{k-1}^{t} \frac{1}{s+2} \mathrm{d}s = 2 \ln \frac{t+2}{k+1} \geq 2 \ln 2, \\ \sum_{s=k}^{t} \eta_s^2/2 &= 2 \sum_{s=k}^{t} \frac{1}{(s+2)^2} \leq 2 \int_{k}^{t+1} \frac{1}{(s+2)^2} \mathrm{d}s = 2 \left(\frac{1}{k+2} - \frac{1}{t+3} \right). \end{aligned}$$

Using again (19), and the bound on $F(\mathbf{w}_t)$ in (20) with $t = k$ and $\mathbf{w} = \mathbf{w}_{t+1}$:

$$\tilde{\mathsf{G}}_1^t \leq \tilde{\mathsf{G}}_k^t \leq \frac{\delta + L_F}{2 \ln 2} \left(\frac{2}{k+3} + \frac{2}{k+2} - \frac{2}{t+3} \right) \leq \frac{\delta + L_F}{\ln 2} \left(\frac{2}{t+2} + \frac{1}{t+3} \right) \leq \frac{3(\delta + L_F)}{t \ln 2}.$$

A.4 Proof of Theorem 8

A proof can be based on the simple observation that the objective value $F^\star$ satisfies

$$F^\star := \inf_{\mathbf{w}} \{\ell(\mathbf{w}) + f(\mathbf{w})\} = \inf_{\mathbf{w}, \rho : \kappa(\mathbf{w}) \leq \rho} \ell(\mathbf{w}) + h(\rho). \tag{66}$$

Note that if ρ were known, the theorem could have been proved as before. The key idea behind the step size choice (34) is to ensure that Algorithm 2 performs almost the same as if it knew the *unknown* but fixed constant $\rho = \kappa(\mathbf{w})$ beforehand.

Consider an arbitrary $\mathbf{w}$ and let $\rho = \kappa(\mathbf{w})$. We also use the shorthand $\hat{F}_t := \ell(\mathbf{w}_t) + h(\rho_t) \geq \ell(\mathbf{w}_t) + f(\mathbf{w}_t) = F(\mathbf{w}_t)$. Then, the following chain of inequalities can be verified:

$$\begin{aligned} \hat{F}_{t+1} &:= \ell(\mathbf{w}_{t+1}) + h(\rho_{t+1}) \\ &\leq \hat{F}_t + \langle \theta_t \mathbf{a}_t - \eta_t \mathbf{w}_t, \nabla \ell(\mathbf{w}_t) \rangle + \tfrac{L}{2} \left\| \theta_t \mathbf{a}_t - \eta_t \mathbf{w}_t \right\|^2 - \eta_t h(\rho_t) + \eta_t h(\theta_t/\eta_t) \\ &\leq \hat{F}_t + \eta_t \left\langle \tfrac{\rho}{\alpha_t} \mathbf{a}_t - \mathbf{w}_t, \nabla \ell(\mathbf{w}_t) \right\rangle + \tfrac{L\eta_t^2}{2} \left\| \tfrac{\rho}{\alpha_t} \mathbf{a}_t - \mathbf{w}_t \right\|^2 - \eta_t h(\rho_t) + \eta_t h(\rho/\alpha_t) \\ &\leq \hat{F}_t + \min_{\mathbf{z} : \kappa(\mathbf{z}) \leq \rho} \eta_t \left\langle \mathbf{z} - \mathbf{w}_t, \nabla \ell(\mathbf{w}_t) \right\rangle + \eta_t \rho \varepsilon_t + \tfrac{L\eta_t^2}{2} \left\| \tfrac{\rho}{\alpha_t} \mathbf{a}_t - \mathbf{w}_t \right\|^2 - \eta_t h(\rho_t) + \eta_t h(\rho/\alpha_t) \\ &= \hat{F}_t + \min_{\mathbf{z} : \kappa(\mathbf{z}) \leq \rho} \eta_t \left\langle \mathbf{z} - \mathbf{w}_t, \nabla \ell(\mathbf{w}_t) \right\rangle - \eta_t h(\rho_t) + \eta_t h(\rho) \\ &\qquad + \eta_t^2 \Big(\underbrace{\tfrac{L}{2} \left\| \tfrac{\rho}{\alpha_t} \mathbf{a}_t - \mathbf{w}_t \right\|^2 + (\rho \varepsilon_t + h(\rho/\alpha_t) - h(\rho))/\eta_t}_{:= \delta_t} \Big) \\ &= \hat{F}_t + \eta_t^2 \delta_t - \eta_t \Big[\underbrace{\langle \mathbf{w}_t, \nabla \ell(\mathbf{w}_t) \rangle + h(\rho_t) - \min_{\mathbf{z} : \kappa(\mathbf{z}) \leq \rho} \langle \mathbf{z}, \nabla \ell(\mathbf{w}_t) \rangle + h(\rho)}_{:= \hat{\mathsf{G}}(\mathbf{w}_t)} \Big], \end{aligned}$$

where the first inequality is because the subroutine is `Relaxed`, the second inequality follows from the minimality of θ_t in (34), and the third inequality is due to the choice of $\mathbf{a}_t$ in Line 3 of Algorithm 2.

Recall that $\rho = \kappa(\mathbf{w})$. Moreover, due to the convexity of ℓ,

$$\begin{aligned}\hat{\mathsf{G}}(\mathbf{w}_t) &= \langle \mathbf{w}_t, \nabla \ell(\mathbf{w}_t)\rangle + h(\rho_t) - \min_{\mathbf{z}:\kappa(\mathbf{z})\le\rho} \big(\langle \mathbf{z}, \nabla \ell(\mathbf{w}_t)\rangle + h(\rho)\big) \\ &= h(\rho_t) - h(\kappa(\mathbf{w})) + \max_{\mathbf{z}:\kappa(\mathbf{z})\le\kappa(\mathbf{w})} \langle \mathbf{w}_t - \mathbf{z}, \nabla \ell(\mathbf{w}_t)\rangle \\ &\ge h(\rho_t) - h(\kappa(\mathbf{w})) + \max_{\mathbf{z}:\kappa(\mathbf{z})\le\kappa(\mathbf{w})} \ell(\mathbf{w}_t) - \ell(\mathbf{z}) \\ &\ge \hat{F}_t - F(\mathbf{w}).\end{aligned}$$

Thus we have retrieved the recursion:

$$\hat{F}_{t+1} - F(\mathbf{w}) \le \hat{F}_t - F(\mathbf{w}) - \eta_t \hat{\mathsf{G}}(\mathbf{w}_t) + \eta_t^2 \delta_t, \qquad \text{and} \qquad \hat{F}_t - F(\mathbf{w}) \le \hat{\mathsf{G}}(\mathbf{w}_t).$$

Summing the indices as in the proof of Theorem 4 and noting that $F(\mathbf{w}_t) \le \hat{F}_t$ for all t completes the proof.

Appendix B. Proofs for Section 4

B.1 Proof of Theorem 15

The first equivalence in Theorem 15 is well-known since Grothendieck's work on tensor products of Banach spaces (where it is usually called the projective tensor norm). The second equality follows directly from the arithmetic-geometric mean inequality.

We first note that the atomic set $\mathcal{A}$ in (48) is compact, so is its convex hull $\operatorname{conv}\mathcal{A}$. It is also easy to see that $\mathcal{A}$ is a connected set (by considering the continuous map $(\mathbf{u},\mathbf{v}) \mapsto \mathbf{u}\mathbf{v}^\top$).

$$\begin{aligned}\text{By (4), } \kappa(W) &= \inf\left\{\rho \ge 0 : W = \rho \sum\nolimits_i \sigma_i \mathbf{a}_i, \sigma_i \ge 0, \sum\nolimits_i \sigma_i = 1, \mathbf{a}_i \in \mathcal{A}\right\} \qquad (67)\\ &= \inf\left\{\rho \ge 0 : W \in \rho\ \operatorname{conv}\mathcal{A}\right\}.\end{aligned}$$

Since $\operatorname{conv}\mathcal{A}$ is compact with $\mathbf{0} \in \operatorname{int}(\operatorname{conv}\mathcal{A})$ we know the infimum above is attained. Thus there exist $\rho \ge 0$ and $C \in \operatorname{conv}\mathcal{A}$ so that $W = \rho C$ and $\kappa(W) = \rho$. Applying Caratheodory's theorem for connected sets (Rockafellar and Wets, 1998, Theorem 2.29) we know $C = \sum_{i=1}^t \sigma_i \mathbf{u}_i \mathbf{v}_i^\top$ for some $\sigma_i \ge 0$, $\sum_i \sigma_i = 1$, $\mathbf{u}_i\mathbf{v}_i^\top \in \mathcal{A}$ and $t \le mn$. Let $U = \sqrt{\rho}\,[\sqrt{\sigma_1}\mathbf{u}_1, \ldots, \sqrt{\sigma_t}\mathbf{u}_t]$, and $V = \sqrt{\rho}\,[\sqrt{\sigma_1}\mathbf{v}_1, \ldots, \sqrt{\sigma_t}\mathbf{v}_t]^\top$. We then have $W = UV$ and $\kappa(W) = \rho \ge \frac{1}{2}\sum_{i=1}^t \left(\|U_{:i}\|_c^2 + \|V_{i:}\|_r^2 \right)$, which proves one side of Theorem 15.

On the other hand, consider any U and V that satisfy

$$W = UV = \sum_{j=1}^t \|U_{:j}\|_c \|V_{j:}\|_r \sum_{i=1}^t \frac{\|U_{:i}\|_c \|V_{i:}\|_r}{\sum_{j=1}^t \|U_{:j}\|_c \|V_{j:}\|_r} \frac{U_{:i}}{\|U_{:i}\|_c} \frac{V_{i:}}{\|V_{i:}\|_r},$$

assuming w.l.o.g. that $\|U_{:i}\|_c \|V_{i:}\|_r \ne 0$ for all $1 \le i \le t$. This, together with the definition (67), gives the other half of the equality: $\kappa(W) \le \sum_{i=1}^t \|U_{:i}\|_c \|V_{i:}\|_r$. The proof is completed by making the elementary observation that $\sum_{i=1}^t \|U_{:i}\|_c \|V_{i:}\|_r \le \frac{1}{2}\sum_{i=1}^t \left(\|U_{:i}\|_c^2 + \|V_{i:}\|_r^2 \right)$.

B.2 Proof of Theorem 16

Since $U_{\text{init}} = (\sqrt{1-\eta_t}U_t, \sqrt{\theta_t}\mathbf{u}_t)$ and $V_{\text{init}} = (\sqrt{1-\eta_t}V_t^\top, \sqrt{\theta_t}\mathbf{v}_t)^\top$, it is obvious that $\tilde{W}_{t+1} = U_{\text{init}}V_{\text{init}}$. Note $\|\mathbf{u}_t\|_c \le 1$ and $\|\mathbf{v}_t\|_r \le 1$. By construction

$$\begin{aligned}\ell(W_{t+1}) + \lambda\rho_{t+1} &= \ell(U_{t+1}V_{t+1}) + \frac{\lambda}{2}\sum_{i=1}^{t+1}\left(\|(U_{t+1})_{:i}\|_c^2 + \|(V_{t+1})_{i:}\|_r^2\right) \\ &= \mathcal{F}_{t+1}(U_{t+1}, V_{t+1}) \ \le\ \mathcal{F}_{t+1}(U_{\text{init}}, V_{\text{init}}) \\ &\le \ell((1-\eta_t)U_tV_t + \theta_t\mathbf{u}_t\mathbf{v}_t^\top) + \lambda\theta_t + \lambda\frac{(1-\eta_t)}{2}\sum_{i=1}^{t}\left(\|(U_t)_{:i}\|_c^2 + \|(V_t)_{i:}\|_r^2\right) \\ &= \ell((1-\eta_t)W_t + \theta_t\mathbf{u}_t\mathbf{v}_t^\top) + \lambda(1-\eta_t)\rho_t + \lambda\theta_t, \qquad (68)\end{aligned}$$

where the inequality is by the definition of U_{init} and V_{init}, and the last equality is by the definition of ρ_t in (54). In addition, $\kappa(W_{t+1}) \le \rho_{t+1}$ follows from (54) and Theorem 15.

B.3 Proof of Theorem 21

By (50), the square of the polar is

$$(\kappa^\circ(G))^2 = \max\left\{\mathbf{c}^\top ZZ^\top \mathbf{c} : \|\mathbf{a}\|_2 \le 1, \|\mathbf{b}\|_2 \le 1\right\}, \quad \text{where} \quad \mathbf{c} = \begin{bmatrix}\mathbf{a}\\ \mathbf{b}\end{bmatrix}. \qquad (69)$$

Since it maximizes a convex quadratic function over a convex set, there must be a maximizer attained at an extreme point of the feasible region. Therefore the problem is equivalent to

$$\begin{aligned}(\kappa^\circ(G))^2 &= \max\left\{\mathbf{c}^\top ZZ^\top \mathbf{c} : \|\mathbf{a}\|_2 = 1, \|\mathbf{b}\|_2 = 1\right\} \qquad (70)\\ &= \max\left\{\operatorname{tr}(SZZ^\top) : \operatorname{tr}(SI_1) = 1, \operatorname{tr}(SI_2) = 1, S \succeq 0, \operatorname{rank}(S) = 1\right\}, \qquad (71)\end{aligned}$$

where $S = \mathbf{c}\mathbf{c}^\top$. Key to this proof is the fact that the rank one constraint can be dropped without breaking the equivalence. To see why, notice that without this rank constraint the feasible region is the intersection of the positive semidefinite cone with two hyperplanes, hence the rank of all its extreme points must be upper bounded by one (Pataki, 1998). Furthermore the linearity of the objective implies that there must be a maximizing solution attained at an extreme point of the feasible region. Therefore we can continue by

$$\begin{aligned}(\kappa^\circ(G))^2 &= \max\left\{\operatorname{tr}(SZZ^\top) : \operatorname{tr}(SI_1) = 1, \operatorname{tr}(SI_2) = 1, S \succeq 0\right\} \\ &= \max_{S\succeq 0}\min_{\mu_1,\mu_2\in\mathbb{R}} \operatorname{tr}(SGG^\top) - \mu_1(\operatorname{tr}(SI_1) - 1) - \mu_2(\operatorname{tr}(SI_2) - 1) \\ &= \min_{\mu_1,\mu_2\in\mathbb{R}}\max_{S\succeq 0} \operatorname{tr}(SGG^\top) - \mu_1(\operatorname{tr}(SI_1) - 1) - \mu_2(\operatorname{tr}(SI_2) - 1) \\ &= \min\left\{\mu_1 + \mu_2 : \mu_1, \mu_2 \in \mathbb{R}, GG^\top \preceq \mu_1 I_1 + \mu_2 I_2\right\} \qquad (72)\\ &= \min\left\{\mu_1 + \mu_2 : \mu_1 \ge 0, \mu_2 \ge 0, \left\|D_{\mu_2/\mu_1}G\right\|_{\text{sp}}^2 \le \mu_1 + \mu_2\right\} \qquad (73)\\ &= \min\left\{\|D_\mu G\|_{\text{sp}}^2 : \mu \ge 0\right\}, \qquad (74)\end{aligned}$$

where the third equality is due to the Lagrangian duality, the fifth equality follows from the equivalence $\left\|D_{\mu_2/\mu_1}G\right\|_{\text{sp}}^2 \leq \mu_1+\mu_2 \iff D_{\mu_2/\mu_1}GG^\top D_{\mu_2/\mu_1} \preceq (\mu_1+\mu_2)I \iff GG^\top \preceq (\mu_1+\mu_2)D_{\mu_2/\mu_1}^{-1}D_{\mu_2/\mu_1}^{-1} = \mu_1 I_1 + \mu_2 I_2$, and the last equality is obtained through the re-parameterization $\mu = \mu_2/\mu_1, \nu = \mu_1+\mu_2$ and the elimination of ν.

B.4 Solving the multi-view polar

Here we show how to efficiently compute the polar (dual norm) in the multi-view setting.

Let us first backtrack in (73), which produces the optimal μ_1 and μ_2 via

$$\mu_1+\mu_2 = \|D_\mu G\|_{\text{sp}}^2, \qquad \text{and} \qquad \frac{\mu_2}{\mu_1} = \mu. \tag{75}$$

Then the KKT condition for the step from (72) to (73) can be written as

$$M \succeq \mathbf{0}, \qquad M\mathbf{c} = \mathbf{0}, \qquad \|\mathbf{a}\|_2 = \|\mathbf{b}\|_2 = 1, \quad \text{where} \quad M := \mu_1 I_1 + \mu_2 I_2 - GG^\top. \tag{76}$$

By duality, this is a sufficient and necessary condition for $\mathbf{a}$ and $\mathbf{b}$ to be the solution of the polar operator. Given the optimal μ_1 and μ_2, the first condition $M \succeq \mathbf{0}$ must have been satisfied already. Let the null space of M be spanned by an orthonormal basis $\{\mathbf{q}_1, \ldots, \mathbf{q}_k\}$. Then we can parameterize $\mathbf{c}$ as $\mathbf{c} = Q\boldsymbol{\alpha}$ where $Q = [\mathbf{q}_1, \ldots, \mathbf{q}_k] =: \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix}$. By (76),

$$0 = \|\mathbf{a}\|_2^2 - \|\mathbf{b}\|_2^2 = \boldsymbol{\alpha}' \left(Q_1^\top Q_1 - Q_2^\top Q_2\right) \boldsymbol{\alpha}. \tag{77}$$

Let $P\Sigma P^\top$ be the eigen-decomposition of $Q_1^\top Q_1 - Q_2^\top Q_2$ with Σ being diagonal and P being unitary. Let $\mathbf{v} = P^\top \boldsymbol{\alpha}$. Then $\mathbf{c} = QP\mathbf{v}$ and (77) simply becomes $\mathbf{v}^\top \Sigma \mathbf{v} = 0$. In addition, (76) also implies $2 = \|\mathbf{c}\|_2^2 = \mathbf{v}^\top P^\top Q^\top QP\mathbf{v} = \mathbf{v}^\top \mathbf{v}$. So finally the optimal solution to the polar problem (70) can be completely characterized by

$$\left\{ \begin{bmatrix} \mathbf{a} \\ \mathbf{b} \end{bmatrix} = QP\mathbf{v} : \mathbf{v}^\top \Sigma \mathbf{v} = 0, \|\mathbf{v}\|_2^2 = 2 \right\}, \tag{78}$$

which is simply a linear system after a straightforward change of variable. The major computational cost for recovery is to find the null space of M, which can be achieved by QR decomposition. The complexity of eigen-decomposition for $Q_1^\top Q_1 - Q_2^\top Q_2$ depends on the dimension of the null space of M, which is usually low in practice.

Abstract

Follow the leader (FTL) is a simple online learning algorithm that is known to perform well when the loss functions are convex and positively curved. In this paper we ask whether there are other settings when FTL achieves low regret. In particular, we study the fundamental problem of linear prediction over a convex, compact domain with non-empty interior. Amongst other results, we prove that the curvature of the boundary of the domain can act as if the losses were curved: In this case, we prove that as long as the mean of the loss vectors have positive lengths bounded away from zero, FTL enjoys logarithmic regret, while for polytope domains and stochastic data it enjoys finite expected regret. The former result is also extended to strongly convex domains by establishing an equivalence between the strong convexity of sets and the minimum curvature of their boundary, which may be of independent interest. Building on a previously known meta-algorithm, we also get an algorithm that simultaneously enjoys the worst-case guarantees and the smaller regret of FTL when the data is 'easy'. Finally, we show that such guarantees are achievable directly (e.g., by the follow the regularized leader algorithm or by a shrinkage-based variant of FTL) when the constraint set is an ellipsoid.

Keywords: online linear optimization, follow the leader, logarithmic regret, strongly convex decision set, curvature

1. Introduction

Learning theory traditionally has been studied in a statistical framework, discussed at length, for example, by Shalev-Shwartz and Ben-David (2014). The issue with this approach is that the analysis of the performance of learning methods seems to critically depend on whether the data generating mechanism satisfies some probabilistic assumptions. Realizing that these assumptions are not necessarily critical, much work has been devoted recently to studying learning algorithms in the so-called online learning framework (Cesa-Bianchi and Lugosi, 2006). The online learning framework makes minimal assumptions about the data generating mechanism, while allowing one to replicate results of the statistical framework through online-to-batch conversions (Cesa-Bianchi et al., 2004). By following a minimax approach, however, results proven in the online learning setting, at least initially, led to rather conservative results and algorithm designs, failing to capture how more regular, "easier" data, may give rise to faster learning. This is problematic as it may suggest overly conservative learning strategies, missing opportunities to extract more information when the data is nicer. Also, it is hard to argue that data resulting from passive data collection, such as weather data, would ever be adversarially generated (though it is equally hard to defend that such data satisfies precise stochastic assumptions). Realizing this issue, during recent years much work has been devoted to understanding what regularities and how can lead to faster learning speed. For example, much work has been devoted to showing that faster learning speed (smaller "regret") can be achieved in the online convex optimization setting when the loss functions are "curved", such as when the loss functions are strongly convex or exp-concave, or when the losses show small variations, or the best prediction in hindsight has a small total loss, and that these properties can be exploited in an adaptive manner (e.g., Merhav and Feder 1992, Freund and Schapire 1997, Gaivoronski and Stella 2000, Cesa-Bianchi and Lugosi 2006, Hazan et al. 2007, Bartlett et al. 2007, Kakade and Shalev-Shwartz 2009, Orabona et al. 2012, Rakhlin and Sridharan 2013, van Erven et al. 2015, Foster et al. 2015).

In this paper we contribute to this growing literature by studying online linear prediction and the follow the leader (FTL) algorithm. Online linear prediction is arguably the simplest yet fundamental of all the learning settings, and lies at the heart of online convex optimization, while it also serves as an abstraction of core learning problems such as prediction with expert advice. FTL, the online analogue of empirical risk minimization of statistical learning, is the simplest learning strategy, one can think of. Although the linear setting removes the possibility of exploiting the curvature of losses, there are multiple ways online learning problems can present data that allows for small regret, even for FTL. As is well known, in the worst case, FTL suffers a linear regret (e.g., Example 2.2 of Shalev-Shwartz 2012). However, for "curved" losses (e.g., exp-concave losses), FTL was shown to achieve small (logarithmic) regret (see, e.g., Merhav and Feder 1992; Cesa-Bianchi and Lugosi 2006; Gaivoronski and Stella 2000; Hazan et al. 2007).

We take a thorough look at FTL in the case when the losses are linear, but the problem perhaps exhibits other regularities. The motivation comes from the simple observation that, for prediction over the simplex, when the loss vectors are selected independently of each other from a distribution with a bounded support with a nonzero mean, FTL quickly locks onto selecting the loss-minimizing vertex of the simplex, achieving finite expected regret. In this case, FTL is an excellent algorithm. In fact, FTL is shown to be the minimax optimizer for the binary losses in the stochastic expert setting in the paper of Kotłowski (2016). Thus, we ask the question of whether there are other regularities that allow FTL to achieve nontrivial performance guarantees. Our main result shows that when the decision set (or constraint set) has a sufficiently "curved" boundary (or equivalently, if it is strongly convex) and the linear loss is bounded away from 0, FTL is able to achieve logarithmic regret even in the adversarial setting, thus opening up a new way to prove fast rates not based on the curvature of losses, but on that of the boundary of the constraint set and non-singularity of the linear loss. In a matching lower bound we show that this regret bound is essentially unimprovable. We also show an alternate bound for polytope constraint sets, which allows us to prove that (under certain technical conditions) for stochastic problems the expected regret of FTL will be finite. To finish, we use $(\mathcal{A},\mathcal{B})$-prod of Sani et al. (2014) to design an algorithm that adaptively interpolates between the worst case $O(\sqrt{n \log n})$ regret and the smaller regret bounds, which we prove here for "easy data." We also show that if the constraint set is an ellipsoid, both the follow the regularized leader (FTRL) algorithm and a combination of FTL and shrinkage, which we call follow the shrunken leader

(FTSL), achieve logarithmic regret for easy data. Simulation results on artificial data complement the theoretical findings.

While we believe that we are the first to point out that the curvature of the constraint set $\mathcal{W}$ can help in speeding up learning, this effect is known in convex optimization since at least the work of Levitin and Polyak (1966), who showed that exponential rates are attainable for strongly convex constraint sets if the norm of the gradients of the objective function admit a uniform lower bound. More recently, Garber and Hazan (2015) proved an $O(1/n^2)$ optimization error bound (with problem-dependent constants) for the Frank-Wolfe algorithm for strongly convex and smooth objectives and strongly convex constraint sets. The effect of the shape of the constraint set was also discussed by Abbasi-Yadkori (2009) who demonstrated $O(\sqrt{n})$ regret in the linear bandit setting. Although at a high level these results are similar to ours, our proof technique is rather different.

2. Preliminaries, Online Learning and the Follow the Leader Algorithm

We consider the standard framework of online convex optimization, where a learner and an environment interact in a sequential manner over n rounds: In every round $t = 1, \dots, n$, first the learner predicts $w_t \in \mathcal{W}$. Then the environment picks a loss function $\ell_t \in \mathcal{L}$, and the learner suffers loss $\ell_t(w_t)$ and observes ℓ_t. Here, $\mathcal{W}$ is a compact and convex subset of the d-dimensional Euclidean space $\mathbb{R}^d$ with non-empty interior, and $\mathcal{L}$ is a set of convex functions mapping $\mathcal{W}$ to the reals. The elements of $\mathcal{L}$ are called loss functions. The performance of the learner is measured in terms of its regret,

$$R_n = \sum_{t=1}^{n} \ell_t(w_t) - \min_{w \in \mathcal{W}} \sum_{t=1}^{n} \ell_t(w)\,.$$

The simplest possible case, which will be the focus of this paper, is when the losses are linear, that is, when $\ell_t(w) = \langle f_t, w\rangle$ for some $f_t \in \mathcal{F} \subset \mathbb{R}^d$. In fact, the linear case is not only simple, but is also fundamental since the case of nonlinear loss functions can be reduced to it: Indeed, even if the losses are nonlinear, defining $f_t \in \partial\ell_t(w_t)$ to be a subgradient[1] of ℓ_t at w_t and letting $\tilde{\ell}_t(u) = \langle f_t, u\rangle$, by the definition of subgradients, $\ell_t(w_t) - \ell_t(u) \le \ell_t(w_t) - (\ell_t(w_t) + \langle f_t, u - w_t\rangle) = \tilde{\ell}_t(w_t) - \tilde{\ell}_t(u)$, hence for any $u \in \mathcal{W}$,

$$\sum_t \ell_t(w_t) - \sum_t \ell_t(u) \le \sum_t \tilde{\ell}_t(w_t) - \sum_t \tilde{\ell}_t(u)\,.$$

In particular, if an algorithm keeps the regret small no matter how the linear losses are selected (even when allowing the environment to pick losses based on the choices of the learner), the algorithm can also be used to keep the regret small in the nonlinear case.

Hence, in what follows we will study the linear case $\ell_t(w) = \langle f_t, w\rangle$ and, in particular, we will study the regret of the so-called "Follow The Leader" (FTL) learner, which in round $t \ge 2$ picks

$$w_t = \operatorname*{argmin}_{w \in \mathcal{W}} \sum_{i=1}^{t-1} \ell_i(w)\,.$$

For the first round, $w_1 \in \mathcal{W}$ is picked in an arbitrary manner. When $\mathcal{W}$ is compact, the optimal w of $\min_{w\in\mathcal{W}} \sum_{i=1}^{t-1}\langle w, f_t\rangle$ is attainable, which we will assume henceforth. If multiple minimizers exist, we simply fix one of them as w_t. We will also assume that $\mathcal{F}$ is non-empty, compact and convex.

One problem of the linearization technique is that if some algorithm's performance depends on some additional properties of the linear loss function, linearization may not preserve these and could lead to suboptimal performance. For example, if the loss functions are strongly convex and the optimum in hindsight (in fact, w_{n+1}) is an inner point of $\mathcal{W}$, FTL has no chance to do well, since

1. We let $\partial g(x)$ denote the subdifferential of a convex function $g : \mathrm{dom}(g) \to \mathbb{R}$ at x, that is, $\partial g(x) = \left\{\theta \in \mathbb{R}^d \,|\, g(x') \ge g(x) + \langle \theta, x' - x\rangle \ \forall x' \in \mathrm{dom}(g)\right\}$, where $\mathrm{dom}(g) \subset \mathbb{R}^d$ is the domain of g.

it will always predict points on the boundary. Thus, while our results extend from linear losses to arbitrary convex functions, some of the conditions of our regret bounds may be violated or the constants in the bounds might blow up, possibly leading to trivial or weak regret bounds. Thus, in practice, one should always check if the linearization step makes sense. On the positive side, no problem occurs if the optimum is outside of $\mathcal{W}$.

2.1 Support Functions

Let $\Theta_t = -\frac{1}{t}\sum_{i=1}^{t} f_i$ be the negative average of the first t vectors in $(f_t)_{t=1}^n$, $f_t \in \mathcal{F}$. For convenience, we define $\Theta_0 := 0$. Thus, for $t \ge 2$,

$$w_t = \operatorname*{argmin}_{w\in\mathcal{W}} \sum_{i=1}^{t-1}\langle w, f_i\rangle = \operatorname*{argmin}_{w\in\mathcal{W}}\langle w, -\Theta_{t-1}\rangle = \operatorname*{argmax}_{w\in\mathcal{W}}\langle w, \Theta_{t-1}\rangle\,.$$

Denote by $\Phi(\Theta) = \max_{w\in\mathcal{W}}\langle w, \Theta\rangle$ the so-called *support function* of $\mathcal{W}$. The support function, being the maximum of linear and hence convex functions, is itself convex. Further Φ is positive homogenous: for $a \ge 0$ and $\theta \in \mathbb{R}^d$, $\Phi(a\theta) = a\Phi(\theta)$. It follows then that the epigraph $\mathrm{epi}(\Phi) = \left\{(\theta, z) \,|\, z \ge \Phi(\theta), z \in \mathbb{R}, \theta \in \mathbb{R}^d\right\}$ of Φ is a cone, since for any $(\theta, z) \in \mathrm{epi}(\Phi)$ and $a \ge 0$, $az \ge a\Phi(\theta) = \Phi(a\theta)$, $(a\theta, az) \in \mathrm{epi}(\Phi)$ also holds.

The differentiability of the support function is closely tied to whether in the FTL algorithm the choice of w_t is uniquely determined:

Proposition 1 *Let $\mathcal{W} \ne \emptyset$ be convex and closed. Fix Θ and let $\mathcal{Z} := \{w \in \mathcal{W} \,|\, \langle w, \Theta\rangle = \Phi(\Theta)\}$. Then, $\partial\Phi(\Theta) = \mathcal{Z}$ and, in particular, $\Phi(\Theta)$ is differentiable at Θ if and only if $\max_{w\in\mathcal{W}}\langle w, \Theta\rangle$ has a unique optimizer. In this case, $\nabla\Phi(\Theta) = \operatorname{argmax}_{w\in\mathcal{W}}\langle w, \Theta\rangle$.*

The proposition follows from Danskin's theorem when $\mathcal{W}$ is compact (e.g., Proposition B.25 of Bertsekas 1999), but a simple direct argument, presented in Appendix A.1 for completeness, can also be used to show that it also remains true even when $\mathcal{W}$ is unbounded. By Proposition 1, when Φ is differentiable at Θ_{t-1}, $w_t = \nabla\Phi(\Theta_{t-1})$.

2.2 A Motivating Example

We close this section with an example demonstrating how fast rates can be achieved by the FTL algorithm. Consider the case when the losses are independent and identically distributed (i.i.d.), which means that (f_t) is an i.i.d. sequence with expectation $\mu \in \mathbb{R}^d$. Then $\mathbb{E}[\Theta_t] = -\mu$, and we have $\|\Theta_t + \mu\|_2 = O(1/\sqrt{t})$ with high probability. For $\mathcal{W}$ being the unit ball of $\mathbb{R}^d$ one has $w_t = \Theta_t/\|\Theta_t\|_2$ and therefore a crude bound suggests that $\|w_t - w^*\|_2 = O(1/\sqrt{t})$ where w^* is the optimal decision in hindsight, overall predicting that $\mathbb{E}[R_n] = O(\sqrt{n})$. On the other hand, in the rest of the paper we provide conditions when the expected regret can be much smaller than this. Below we give a simple geometric explanation how it can happen.

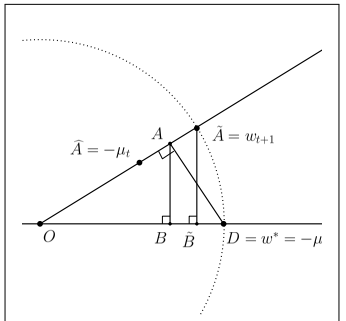

Figure 1: Illustration of how fast rates can be achieved by FTL.

Let $\mathcal{W} = \{w \,|\, \|w\|_2 \le 1\}$ and consider a stochastic setting where the f_t are i.i.d. samples with expectation $\mathbb{E}[f_t] = \mu = (-1, 0, \dots, 0)$ and $\|f_t\|_\infty \le M$ almost surely. It is straightforward to see that $w^* = (1, 0, \dots, 0)$, and thus $\langle w^*, \mu\rangle = -1$. Let $\mu_t = -\Theta_t$ denote our estimate of μ after t time steps; then $\|\mu_t - \mu\| = O(1/\sqrt{t})$ with high

probability. Now consider Fig. 1: The origin is denoted by O, the optimal prediction $w^* = -\mu$ by D, and $-\mu_t$ by $\hat{A}$. Then the prediction of FTL at time t is $\tilde{A}$, the intersection of the line connecting O and $\hat{A}$ with the unit sphere, and its instantaneous excess loss is $\langle \overrightarrow{OA}, \overrightarrow{OD} \rangle - 1 = |\overline{\tilde{B}D}|$ where $\tilde{B}$ is the orthogonal projection of $\tilde{A}$ to $\overline{OD}$. Next we give a simple geometric argument showing that if $|\overline{\hat{A}D}| \le \epsilon$ then $|\overline{\tilde{B}D}| \le \epsilon^2$. Since $|\overline{\hat{A}D}| = \|\mu_t - \mu\| = O(1/\sqrt{t})$ with high probability, this means that the excess error at time t is $O(1/t)$, making the regret $O(\log n)$ in n time steps, much smaller than the previously anticipated $O(\sqrt{n})$ regret. To finish, let A denote the orthogonal projection of D to the line connecting O and $\hat{A}$; then the Pythagorean theorem implies that $|\overline{OA}| \le |\overline{OD}| = |\overline{O\tilde{A}}|$, and so $A \in \overline{O\tilde{A}}$. Therefore, the orthogonal projection of A to $\overline{OD}$, denoted by B, belongs to the segment $\overline{O\tilde{B}}$, and so $|\overline{BD}| \ge |\overline{\tilde{B}D}|$. Since the triangles OAD and ABD are similar, we have $\frac{|\overline{BD}|}{|\overline{AD}|} = \frac{|\overline{AD}|}{|\overline{OD}|}$. Therefore, $|\overline{BD}| \le |\overline{AD}|^2 \le |\overline{\hat{A}D}|^2$ (by the definition of A), implying $|\overline{\tilde{B}D}| \le |\overline{\hat{A}D}|^2$, which we wanted to prove.

3. Non-Stochastic Analysis of FTL

We start by rewriting the regret of FTL in an equivalent form, which shows that we can expect FTL to enjoy a small regret when successive weight vectors move little.

Proposition 2 *The regret R_n of FTL satisfies the following identity:*

$$R_n = \sum_{t=1}^{n} t \, \langle w_{t+1} - w_t, \Theta_t \rangle \, .$$

The result is a direct corollary of Lemma 9 of McMahan (2010), which holds for any sequence of losses (even non-convex). It is also a tightening of the well-known inequality $R_n \le \sum_{t=1}^{n} \ell_t(w_t) - \ell_t(w_{t+1})$, which again holds for arbitrary loss sequences (e.g., Lemma 2.1 of Shalev-Shwartz, 2012). To keep the paper self-contained, we give a direct proof based on the summation by parts formula:

Proof The summation by parts formula states that for any $u_1, v_1, \ldots, u_{n+1}, v_{n+1}$ reals, $\sum_{t=1}^{n} u_t \, (v_{t+1} - v_t) = (u_{t+1} v_{t+1} - u_1 v_1) - \sum_{t=1}^{n} (u_{t+1} - u_t) \, v_{t+1}$. Applying this to the definition of regret with $u_t := w_{t,\cdot}$ and $v_{t+1} := t\Theta_t$, we get

$$\begin{aligned} R_n &= -\sum_{t=1}^{n} \langle w_t, t\Theta_t - (t-1)\Theta_{t-1} \rangle + \langle w_{n+1}, n\Theta_n \rangle \\ &= -\left\{ \cancel{\langle w_{n+1}, n\Theta_n \rangle} - 0 - \sum_{t=1}^{n} \langle w_{t+1} - w_t, t\Theta_t \rangle \right\} + \cancel{\langle w_{n+1}, n\Theta_n \rangle} . \end{aligned}$$

■

Our next proposition gives another identity for the regret. Although this formula is not directly needed for the rest of the paper, it provides interesting insights: as opposed to the previous result, it is independent of w_t, and directly connects the sequence $(\Theta_t)_t$ to the geometric properties of $\mathcal{W}$ through the support function Φ. A similar expression for a general "Follow the Regularized Leader" algorithm was also derived by Abernethy et al. (2014). For this proposition, we will momentarily assume that Φ is differentiable at $(\Theta_t)_{t \ge 1}$.

Proposition 3 *Assume Φ is differentiable at $\Theta_1, \ldots, \Theta_n$. Then*

$$R_n = \sum_{t=1}^{n} t \, D_\Phi(\Theta_t, \Theta_{t-1}) \, , \tag{1}$$

where $D_\Phi(\theta', \theta) = \Phi(\theta') - \Phi(\theta) - \langle \nabla\Phi(\theta), \theta' - \theta \rangle$ is the Bregman divergence of Φ and we use the convention that $\nabla\Phi(0) = w_1$.

Proof Let $v = \operatorname{argmax}_{w \in \mathcal{W}} \langle w, \theta \rangle$, $v' = \operatorname{argmax}_{w \in \mathcal{W}} \langle w, \theta' \rangle$. When Φ is differentiable at θ,

$$D_\Phi(\theta', \theta) = \Phi(\theta') - \Phi(\theta) - \langle \nabla\Phi(\theta), \theta' - \theta \rangle = \langle v', \theta' \rangle - \langle v, \theta \rangle - \langle v, \theta' - \theta \rangle = \langle v' - v, \theta' \rangle \, . \tag{2}$$

Therefore, by Proposition 2, $R_n = \sum_{t=1}^{n} t \langle w_{t+1} - w_t, \Theta_t \rangle = \sum_{t=1}^{n} t \, D_\Phi(\Theta_t, \Theta_{t-1})$. ■

When Φ is non-differentiable at some of the points $\Theta_1, \ldots, \Theta_n$, the equality in the above proposition can be replaced with inequalities. Defining the upper Bregman divergence $\overline{D}_\Phi(\theta', \theta) = \sup_{w \in \partial\Phi(\theta)} \Phi(\theta') - \Phi(\theta) - \langle w, \theta' - \theta \rangle$ and the lower Bregman divergence $\underline{D}_\Phi(\theta', \theta)$ similarly with inf instead of sup, we can easily obtain an analogue of Proposition 3:

$$\sum_{t=1}^{n} t \, \underline{D}_\Phi(\Theta_t, \Theta_{t-1}) \le R_n \le \sum_{t=1}^{n} t \, \overline{D}_\Phi(\Theta_t, \Theta_{t-1}) \, . \tag{3}$$

3.1 Constraint Sets with Positive Curvature

The previous results show in an implicit fashion that the curvature of $\mathcal{W}$ controls the regret. Before presenting our first main results, which make this connection explicit, we define some basic notions from differential geometry related to the curvature, while some extra details are presented in Appendix A.2 (all differential geometry concept and results that we need can be found in Section 2.5 of the book of Schneider, 2014).

3.1.1 Curvature and Strong Convexity

Given a twice continuously differentiable planar curve γ in $\mathbb{R}^2$, there exists a parametrization with respect to the curve length s, such that $\|\gamma'(s)\| = \| \, (x'(s), y'(s)) \, \| = \sqrt{x'(s)^2 + y'(s)^2} = 1$. Under the curve length parametrization, the curvature of γ at $\gamma(s)$ is $\|\gamma''(s)\|$. Define the unit normal vector $\mathbf{n}(s)$ as the unit vector that is perpendicular to $\gamma'(s)$.[2] Note that $\mathbf{n}(s) \cdot \gamma'(s) = 0$. Thus $0 = (\mathbf{n}(s) \cdot \gamma'(s))' = \mathbf{n}'(s) \cdot \gamma'(s) + \mathbf{n}(s) \cdot \gamma''(s)$, and $\|\gamma''(s)\| = \|\mathbf{n}(s) \cdot \gamma''(s)\| = \|\mathbf{n}'(s) \cdot \gamma'(s)\| = \|\mathbf{n}'(s)\|$. Therefore, the curvature of γ at point $\gamma(s)$ is the length of the differential of its unit normal vector.

Denote the boundary of $\mathcal{W}$ by $\mathrm{bd}(\mathcal{W})$ and a tangent plane of $\mathrm{bd}(\mathcal{W})$ at point w by $T_w\mathcal{W}$. We shall assume that $\mathcal{W}$ is twice continuously differentiable, that is, $\mathrm{bd}(\mathcal{W})$ is a twice continuously differentiable submanifold of $\mathbb{R}^d$. Then $T_w\mathcal{W}$ is unique, and there exists a unique unit vector at w that is perpendicular to $T_w\mathcal{W}$ and points outward of $\mathcal{W}$. In fact, one can define a continously differentiable normal unit vector field on $\mathrm{bd}(\mathcal{W})$, $u_\mathcal{W} : \mathrm{bd}(\mathcal{W}) \to \mathbb{S}^{d-1}$, the so-called Gauss map, which maps a boundary point $w \in \mathrm{bd}(\mathcal{W})$ to the unique outer normal vector to $\mathcal{W}$ at w, where $\mathbb{S}^{d-1} = \left\{ x \in \mathbb{R}^d \,|\, \|x\|_2 = 1 \right\}$ denotes the unit sphere in $\mathbb{R}^d$. Since $u_\mathcal{W}(w)$ maps $\mathrm{bd}(\mathcal{W})$ to unit vectors, the differential of the Gauss map, $\nabla u_\mathcal{W}(w)$, defines a linear endomorphism of $T_w\mathcal{W}$. Moreover, $\nabla u_\mathcal{W}(w)$ is a self-adjoint operator, with nonnegative eigenvalues. The differential of the Gauss map, $\nabla u_\mathcal{W}(w)$, describes the curvature of $\mathrm{bd}(\mathcal{W})$ via the second fundamental form. In particular, the *principal curvatures* of $\mathrm{bd}(\mathcal{W})$ at $w \in \mathrm{bd}(\mathcal{W})$ are defined as the eigenvalues of $\nabla u_\mathcal{W}(w)$. Perhaps a more intuitive, yet equivalent definition, is that the principal curvatures are the eigenvalues of the Hessian of $f = f_w$ in the parameterization $t \mapsto w + t - f_w(t) u_\mathcal{W}(w)$ of $\mathrm{bd}(\mathcal{W})$, which is valid in a small open neighborhood of w, where $f_w : T_w\mathcal{W} \to [0, \infty)$ is a suitable convex, nonnegative valued function that also satisfies $f_w(0) = 0$ (see Fig. 2). Thus, the principal curvatures at some point $w \in \mathrm{bd}(\mathcal{W})$ describe the local shape of $\mathrm{bd}(\mathcal{W})$ up to the second order. In this paper, we are interested in the minimum principal curvature at $w \in \mathrm{bd}(\mathcal{W})$, which can be interpreted as the minimum curvature at w over all the planar curves $\gamma \in \mathrm{bd}(\mathcal{W})$ that go through w.

2. There exist two unit vectors that are perpendicular to $\gamma'(s)$ for each point on γ. Pick the ones that are consistently oriented.

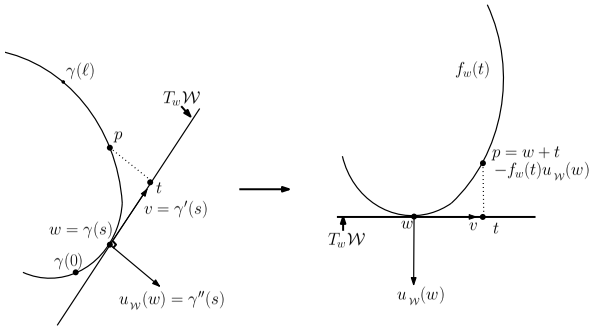

Figure 2: Some differential geometry notations.

A related concept that has been used in convex optimization to show fast rates is that of a strongly convex constraint set (Levitin and Polyak, 1966; Garber and Hazan, 2015): $\mathcal{W}$ is λ-strongly convex with respect to the norm $\|\cdot\|$ if, for any $x, y \in \mathcal{W}$ and $\gamma \in [0,1]$, the $\|\cdot\|$-ball with origin $\gamma x+(1-\gamma)y$ and radius $\gamma(1-\gamma)\lambda \|x-y\|^2/2$ is included in $\mathcal{W}$. That is, for any $z \in \mathbb{R}^d$ with $\|z\| = 1$, $\gamma x+(1-\gamma)y+\gamma(1-\gamma)\frac{\lambda}{2}\|x-y\|^2 z \in \mathcal{W}$. Next we show that a convex body $\mathcal{W}$ with twice continuously differentiable boundary is λ-strongly convex with respect to $\|\cdot\|_2$ if and only if the principal curvatures of the surface $\mathrm{bd}(\mathcal{W})$ are all at least λ.[3] In the rest of the paper, $B_r(x) = \{y \in \mathbb{R}^d \,|\, \|x-y\|_2 \le r\}$ will denote the Euclidean ball of radius r centered at x (in case x is the origin, it will often be omitted).

Proposition 4 *Let $\mathcal{W} \subset \mathbb{R}^d$ be a convex body with with twice continuously differentiable boundary and support function φ, and let λ be an arbitrary positive number. Then the following statements are equivalent:*

(i) The smallest principal curvature of $\mathcal{W}$ is at least λ.

(ii) $\mathcal{W} = \cap_{\theta \in \mathbb{S}^{d-1}} B_{1/\lambda}(w_\theta - \theta/\lambda)$ where $w_\theta \in \partial\varphi(\theta) \subset \mathrm{bd}(\mathcal{W})$.

(iii) $\mathcal{W}$ is λ-strongly convex.

Condition (ii), which is actually the definition of Polovinkin (1996) for strongly convex sets, means that $\mathcal{W}$ can be obtained as the intersection of closed balls of radius $1/\lambda$, such that there is one ball for every boundary point w and tangent hyperplane P where the ball touches P at w. Note that a ball with radius $1/\lambda$ satisfies all conditions: (i) and (ii) by definition, while (iii) holds, e.g., by Example 13 of Journée et al. (2010).

3.1.2 Regret Bounds

As promised, our next result connects the principal curvatures of $\mathrm{bd}(\mathcal{W})$ to the regret of FTL and shows that FTL enjoys logarithmic regret for highly curved surfaces, as long as $\|\Theta_t\|_2$ is bounded away from zero.

Theorem 5 *Assume $d \ge 2$ and let $\mathcal{W} \subset \mathbb{R}^d$ be a convex body with twice continuously differentiable boundary. Let $M = \max_{f \in \mathcal{F}} \|f\|_2$ and assume that Φ is differentiable at $(\Theta_t)_t$. Assume that the principal curvatures of the surface $\mathrm{bd}(\mathcal{W})$ are all at least λ_0 for some constant $\lambda_0 > 0$ (that is, $\mathcal{W}$ is λ_0 strongly convex) and $L_n := \min_{1 \le t \le n} \|\Theta_t\|_2 > 0$. Choose $w_1 \in \mathrm{bd}(\mathcal{W})$. Then*

$$R_n \le \frac{2M^2}{\lambda_0 L_n}(1+\log n)\,.$$

Before presenting the proof of the theorem, we discuss some of its implications and refinements. After the proof we will provide some examples of constraint sets with positive minimum principal curvature.

Remark 6 As we will show later in an essentially matching lower bound, this bound is tight, showing that the forte of FTL is when L_n is bounded away from zero and λ_0 is large. Note that the bound is vacuous as soon as $L_n = O(\log n/n)$ and is worse than the minimax bound of $O(\sqrt{n})$ when $L_n = o(\log n/\sqrt{n})$. One possibility to reduce the bound's sensitivity to L_n is to use the trivial bound $\langle w_{t+1} - w_t, \Theta_t\rangle \le LW = L \sup_{w,w' \in \mathcal{W}} \|w - w'\|_2$ for indices t when $\|\Theta_t\|_2 \le L$ (with an arbitrary $L > 0$). Then, by optimizing the bound over L, one gets a data-dependent bound of the form

$$R_n \le \inf_{L>0}\left(\frac{2M^2}{\lambda_0 L}(1+\log n) + LW\sum_{t=1}^n t\,\mathbb{I}\left(\|\Theta_t\|_2 \le L\right)\right), \tag{4}$$

which is more complex, but is free of L_n and thus reflects the nature of FTL better. Note that in the case of stochastic problems, where $f_1, \dots, f_n$ are independent and identically distributed (i.i.d.) with $\mu := -\mathbb{E}[\Theta_t] \ne 0$, the probability that $\|\Theta_t\|_2 < \|\mu\|_2/2$ is exponentially small in t. Thus, selecting $L = \|\mu\|_2/2$ in the previous bound, the contribution of the expectation of the second term is $O(\|\mu\|_2 W)$, giving an overall bound of the form $O(\frac{M^2}{\lambda_0\|\mu\|_2}\log n + \|\mu\|_2 W)$. On the other hand, if $\|\Theta_t\|_2 = 1$ if t is odd and $\|\Theta_t\| = 0$ otherwise (such an example is trivial to construct), the optimal choice of L in the above bound is $L = \Theta\left(\frac{M}{n}\sqrt{\frac{\log n}{\lambda_0 W}}\right)$ leads to a vacuous $O\left(Mn\sqrt{\frac{W\log n}{\lambda_0}}\right)$ regret bound.

Remark 7 Now consider the case of i.i.d. losses in a bit more detail. Assume that $\mathcal{W} = \mathcal{F} = B_1$, the Euclidean unit ball centered at the origin, and assume $\mathbb{E}[f_t] = \mu \ne 0$. Then it is straightforward to derive a high probability lower bound for $\|\Theta_t\|$: Using that $\mathbb{E}\|\Theta_t\|_2^2 = \|\mu\|_2^2 + \frac{\sigma^2}{t}$ where $\sigma^2 = \mathbb{E}\|f_i\|_2^2 - \|\mu\|_2^2$, we get

$$\mathbb{P}\left[\|\Theta_t\|_2 \le \frac{\|\mu\|_2}{2}\right] = \mathbb{P}\left[\|\Theta_t\|_2^2 - \mathbb{E}\|\Theta_t\|_2^2 \le -\frac{3\|\mu\|_2^2}{4} - \frac{\sigma^2}{t}\right] \le e^{-\frac{t}{18}\left(\frac{3\|\mu\|_2^2}{4} + \frac{\sigma^2}{t}\right)^2} \le e^{-t\frac{\|\mu\|_2^4}{32}}\,,$$

where the first inequality is due to McDiarmid's inequality (Boucheron et al., 2013) after noticing that changing a single f_i to some $f_i' \in \mathcal{F}$ may change the value of $\|\Theta_t\|_2^2$ by at most $6/t$. Combining this with (4) for $L = \|\mu\|_2/2$, we get

$$\mathbb{E}R_n \le \frac{4}{\|\mu\|_2}(1+\log n) + \frac{\|\mu\|_2}{4\sinh\left(\frac{\|\mu\|_2^4}{32}\right)} \le \frac{4}{\|\mu\|_2}(1+\log n) + O(1/\|\mu\|_2^7)\,. \tag{5}$$

Koolen et al. (2016) also proved an $O(\log n)$ bound on the expected regret of the sophisticated algorithm MetaGrad for the above case (Theorem 3 and Lemma 5 of their paper): in particular, they showed that MetaGrad achieves $O(Bd\log n)$ regret where $B = \frac{2\lambda_{\max}}{\|\mu\|}$ with $\lambda_{\max}$ being the maximum eigenvalue of $\mathbb{E}[f_t f_t^\top]$. Since $\lambda_{\max}$ can be as large as 1 (if $\|f_t\|_2 = 1$), (5) can improve (asymptotically) a factor of d over this regret bound. On the other hand, if f_t is uniformly distributed on the half unit sphere (e.g., the first coordinate of f_t is nonnegative with probability 1), Koolen et al. (2016) shows that $B \le \frac{24}{\sqrt{d}}$, which leads to an $O(\sqrt{d}\log n)$ regret, essentially matching (5), as one can show that $\frac{c}{\sqrt{d}} \le \|\mu\|_2 \le \frac{1}{\sqrt{d}}$ for some constant c.

3. Following Schneider (2014), a convex body in $\mathbb{R}^d$ is any compact, convex subset of $\mathbb{R}^d$ with non-empty interior.

Proof of Theorem 5 Fix $\theta_1, \theta_2 \in \mathbb{R}^d$ and let $w^{(1)} = \operatorname{argmax}_{w\in\mathcal{W}}\langle w, \theta_1\rangle$, $w^{(2)} = \operatorname{argmax}_{w\in\mathcal{W}}\langle w, \theta_2\rangle$. Note that if $\theta_1, \theta_2 \neq 0$ then $w^{(1)}, w^{(2)} \in \operatorname{bd}(\mathcal{W})$. Below we will show that

$$\langle w^{(1)} - w^{(2)}, \theta_1\rangle \le \frac{1}{2\lambda_0}\frac{\|\theta_2 - \theta_1\|_2^2}{\|\theta_2\|_2}\,. \tag{6}$$

Proposition 2 shows that bounding the regret is equivalent to bounding $\langle w_{t+1} - w_t, \Theta_t\rangle$. We then apply (6), which shows that the regret can be bounded by controlling the stability of Θ_t. A straightforward calculation shows that Θ_t cannot move much: for any norm $\|\cdot\|$ on $\mathcal{F}$, we have

$$\begin{aligned}
\|\Theta_t - \Theta_{t-1}\| &= \left\|\frac{1}{t-1}\sum_{i=1}^{t-1} f_i - \frac{1}{t}\sum_{i=1}^{t} f_i\right\| = \left\|\sum_{i=1}^{t-1}\left(\frac{1}{t-1} - \frac{1}{t}\right) f_i - \frac{1}{t} f_t\right\| \\
&\le \left\|\sum_{i=1}^{t-1}\left(\frac{1}{t-1} - \frac{1}{t}\right) f_i\right\| + \left\|\frac{1}{t} f_t\right\| = \left\|\sum_{i=1}^{t-1}\frac{1}{t(t-1)} f_i\right\| + \left\|\frac{1}{t} f_t\right\| \\
&= \frac{1}{t}\left\|\frac{1}{t-1}\sum_{i=1}^{t-1} f_i\right\| + \frac{1}{t}\|f_t\| \le \frac{2}{t} M\,.
\end{aligned} \tag{7}$$

where $M = \max_{f\in\mathcal{F}}\|f\|$ is a constant that depends on $\mathcal{F}$ and the norm $\|\cdot\|$.

Combining inequality (6) with Proposition 2 and (7), we get

$$\begin{aligned}
R_n &= \sum_{t=1}^{n} t\langle w_{t+1} - w_t, \Theta_t\rangle \le \sum_{t=1}^{n}\frac{t}{2\lambda_0}\frac{\|\Theta_t - \Theta_{t-1}\|_2^2}{\|\Theta_{t-1}\|_2} \\
&\le \frac{2M^2}{\lambda_0}\sum_{t=1}^{n}\frac{1}{t\|\Theta_{t-1}\|_2} \le \frac{2M^2}{\lambda_0 L_n}\sum_{t=1}^{n}\frac{1}{t} \le \frac{2M^2}{\lambda_0 L_n}(1 + \log n)\,.
\end{aligned}$$

To finish the proof we need to show (6). Below we provide a derivation based on the definition of principal curvature. Using the equivalence between the principal curvature and the modulus of strong convexity (cf., Proposition 4), we also provide an alternative proof in Appendix A.3 based on strong convexity, which leads to the slightly weaker result (24), loosing a constant factor of 4.

The following elementary lemma relates the cosine of the angle between two vectors θ_1 and θ_2 to the squared normalized distance between the two vectors, thereby reducing our problem to bounding the cosine of this angle. For brevity, we denote by $\cos(\theta_1, \theta_2)$ the cosine of the angle between θ_1 and θ_2.

Lemma 8 *For any non-zero vectors $\theta_1, \theta_2 \in \mathbb{R}^d$,*

$$1 - \cos(\theta_1, \theta_2) \le \frac{1}{2}\frac{\|\theta_1 - \theta_2\|_2^2}{\|\theta_1\|_2\|\theta_2\|_2}. \tag{8}$$

Proof Note that $\|\theta_1\|_2\|\theta_2\|_2\cos(\theta_1, \theta_2) = \langle\theta_1, \theta_2\rangle$. Therefore, (8) is equivalent to $2\|\theta_1\|_2\|\theta_2\|_2 - 2\langle\theta_1, \theta_2\rangle \le \|\theta_1 - \theta_2\|_2^2$, which, by algebraic manipulations, is itself equivalent to $0 \le (\|\theta_1\|_2 - \|\theta_2\|_2)^2$. ■

Given this result, it suffices to show that $\cos(\theta_1, \theta_2) \le 1 - \lambda_0\langle w^{(1)} - w^{(2)}, \frac{\theta_1}{\|\theta_1\|_2}\rangle$, which we prove using the tools from differential geometry introduced in Section 3.1.1. Let $\tilde{\theta}_i = \frac{\theta_i}{\|\theta_i\|_2}$ for $i = 1, 2$. The angle between θ_1 and θ_2 is the same as the angle between the normalized vectors $\tilde{\theta}_1$ and $\tilde{\theta}_2$. To calculate the cosine of the angle between $\tilde{\theta}_1$ and $\tilde{\theta}_2$, let P be a plane spanned by $\tilde{\theta}_1$ and $w^{(1)} - w^{(2)}$ and passing through $w^{(1)}$ (P is uniquely determined if $\tilde{\theta}_1$ is not parallel to $w^{(1)} - w^{(2)}$; if there are multiple planes, just pick any of them). Further, let $\hat{\theta}_2 \in \mathbb{S}^{d-1}$ be the unit vector along the projection of $\tilde{\theta}_2$ onto the plane P, as indicated in Fig. 3. Clearly, $\cos(\tilde{\theta}_1, \tilde{\theta}_2) \le \cos(\tilde{\theta}_1, \hat{\theta}_2)$.

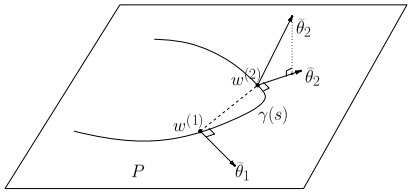

Figure 3: Illustration of the construction used in the proof of (6).

Consider a curve $\gamma(s)$ on $\operatorname{bd}(\mathcal{W})$ connecting $w^{(1)}$ and $w^{(2)}$ that is defined by the intersection of $\operatorname{bd}(\mathcal{W})$ and P and is parametrized by its curve length s so that $\gamma(0) = w^{(1)}$ and $\gamma(l) = w^{(2)}$, where l is the length of the curve γ between $w^{(1)}$ and $w^{(2)}$. Note that since γ is parametrized by its length, $\|\gamma'(s)\|_2 = 1$ for all $s \in [0, l]$. Let $u_{\mathcal{W}}(w)$ denote the outer normal vector to $\mathcal{W}$ at w as before, and let $u_\gamma : [0, l] \to \mathbb{S}^{d-1}$ denote the Gauss map of the planar curve γ, that is, $u_\gamma(s) = \hat{\theta}$ where $\hat{\theta}$ is the unit vector parallel to the projection of $u_{\mathcal{W}}(\gamma(s))$ on the plane P. Now, for any $\theta \in \mathbb{S}^{d-1}$, $w_\theta = \operatorname{argmax}_{w\in\mathcal{W}}\langle w, \theta\rangle$ is a point where a hyperplane with normal vector θ touches $\mathcal{W}$, thus, $u_{\mathcal{W}}(w_\theta) = \theta$. Therefore, $u_\gamma(0) = \tilde{\theta}_1$ and $u_\gamma(l) = \hat{\theta}_2$. In fact γ exists in two versions since $\mathcal{W}$ is a compact convex body, hence the intersection of P and $\operatorname{bd}(\mathcal{W})$ is a closed curve. Of these two versions we choose the one that satisfies that $\langle\gamma'(s), \tilde{\theta}_1\rangle \le 0$ for $s \in [0, l]$.[4] Given the above, we have

$$\cos(\tilde{\theta}_1, \hat{\theta}_2) = \langle\hat{\theta}_2, \tilde{\theta}_1\rangle = 1 + \langle\hat{\theta}_2 - \tilde{\theta}_1, \tilde{\theta}_1\rangle = 1 + \Big\langle\int_0^l u'_\gamma(s)\,\mathrm{d}s, \tilde{\theta}_1\Big\rangle = 1 + \int_0^l \langle u'_\gamma(s), \tilde{\theta}_1\rangle\,\mathrm{d}s. \tag{9}$$

Note that γ is a planar curve on $\operatorname{bd}(\mathcal{W})$, thus its curvature $\lambda(s)$ satisfies $\lambda(s) \ge \lambda_0$ for any $s \in [0, l]$. Also, for all $s \in [0, l]$, $\gamma'(s)$ is a unit vector parallel to P (since γ is parametrized by its curve length). Moreover, $u'_\gamma(s)$ is parallel to $\gamma'(s)$ since $u_\gamma(s)$ is the Gauss map, and $\lambda(s) = \|u'_\gamma(s)\|_2$. Therefore,

$$\langle u'_\gamma(s), \tilde{\theta}_1\rangle = \|u'_\gamma(s)\|_2\langle\gamma'(s), \tilde{\theta}_1\rangle \le \lambda_0\langle\gamma'(s), \tilde{\theta}_1\rangle,$$

where the last inequality holds because $\langle\gamma'(s), \tilde{\theta}_1\rangle \le 0$. Plugging this into (9), we get the desired

$$\cos(\tilde{\theta}_1, \hat{\theta}_2) \le 1 + \lambda_0\int_0^l \langle\gamma'(s), \tilde{\theta}_1\rangle\,\mathrm{d}s = 1 + \lambda_0\Big\langle\int_0^l \gamma'(s)\,\mathrm{d}s, \tilde{\theta}_1\Big\rangle = 1 - \lambda_0\langle w^{(1)} - w^{(2)}, \tilde{\theta}_1\rangle\,.$$

Reordering and combining with (8) we obtain

$$\langle w^{(1)} - w^{(2)}, \tilde{\theta}_1\rangle \le \frac{1}{\lambda_0}\Big(1 - \cos(\tilde{\theta}_1, \hat{\theta}_2)\Big) \le \frac{1}{\lambda_0}\left(1 - \cos(\theta_1, \theta_2)\right) \le \frac{1}{2\lambda_0}\frac{\|\theta_1 - \theta_2\|_2^2}{\|\theta_1\|_2\|\theta_2\|_2}\,.$$

Multiplying both sides by $\|\theta_1\|_2$ gives (6), thus, finishing the proof. ■

Next we present the smallest principal curvature of some common convex bodies (the proofs are relegated to the appendix), often used as constraint sets in machine learning.

Example 1 *(i) The smallest principal curvature λ_0 of the Euclidean ball $\mathcal{W} = \{w \,|\, \|w\|_2 \le r\}$ of radius r satisfies $\lambda_0 = \frac{1}{r}$.*

4. γ' and u'_γ denote the derivatives of γ and u_γ, respectively, which exist since $\operatorname{bd}(\mathcal{W})$ is twice continuously differentiable. When $s = 0$ or $s = l$, it suffices to take the corresponding one-sided derivatives or, equivalently, extend the definitions of γ and u_γ to an interval $[-\epsilon, l + \epsilon]$ for some $\epsilon > 0$.

(ii) Let Q be a positive definite matrix. If $\mathcal{W} = \left\{ w \,|\, w^\top Q w \le 1 \right\}$ then $\lambda_0 = \lambda_{\min}/\sqrt{\lambda_{\max}}$, where $\lambda_{\min}$ and $\lambda_{\max}$ are the minimal, respectively, maximal eigenvalues of Q.

(iii) Let $p > 1$ and $\mathcal{W} = \{w \,|\, \|w\|_p \le 1\}$. If $p > 2$, then $\lambda_0 = 0$. Otherwise, if $1 < p \le 2$, then

$$\lambda_0 = \min_{w \in \mathrm{bd}(\mathcal{W})} \min_{v \in \mathbb{S}^{d-1} : \langle w^{\odot(p-1)}, v \rangle = 0} (p-1) \frac{v^\top \operatorname{diag}\left(|w_1|^{p-2}, \cdots, |w_d|^{p-2} \right) v}{\|w^{\odot(p-1)}\|_2} \ge (p-1) d^{\frac{1}{2} - \frac{1}{p}} \,,$$

where $w^{\odot(p-1)} = (|w_1|^{p-1}, \ldots, |w_d|^{p-1})$ and $\operatorname{diag}(a_1, \ldots, a_k)$ denotes a $k \times k$ diagonal matrix with diagonal entries $a_1, \ldots, a_k$.

(iv) In general, let $\phi : \mathbb{R}^d \to \mathbb{R}$ be a twice continuously differentiable convex function. Then, for $\mathcal{W} = \{w \,|\, \phi(w) \le 1\}$, $\lambda_0 = \min_{w \in \mathrm{bd}(\mathcal{W})} \min_{v \in \mathbb{S}^{d-1} : \langle \phi'(w), v \rangle = 0} \frac{v^\top \nabla^2 \phi(w) v}{\|\phi'(w)\|_2}$.

Some of the results above have been derived in the literature based on seemingly different but equivalent assumptions explored in Proposition 4: (i) is a standard result in books on differential geometry; Polovinkin (1996) derived (ii) based on the strong convexity definition (ii) in Proposition 4, while (iii) was proved by Garber and Hazan (2015) based on the strong convexity definition (iii) in Proposition 4. Other examples of strongly sets convex sets, that is, sets with positive minimal principal curvature, can be found in the paper of Garber and Hazan (2015).

Our last result in this section is a lower bound for the linear game, showing that FTL achieves the optimal rate under the condition that $\min_t \|\Theta_t\|_2 \ge L > 0$.

Theorem 9 *Let $\lambda, L \in (0,1)$. Assume that $\{(1,-L),(-1,-L)\} \subset \mathcal{F}$ and let*

$$\mathcal{W} = \left\{ (x,y) \in \mathbb{R}^2 : x^2 + \frac{y^2}{\lambda^2} \le 1 \right\}$$

be an ellipsoid with principal curvature λ. Then, for any learning strategy, there exists a sequence of losses in $\mathcal{F}$ such that $\|\Theta_t\|_2 \ge L$ for all t and

$$R_n \ge \frac{1}{84\sqrt{2}} \frac{1}{\lambda L} \log n - \frac{1}{\lambda L} \left(\frac{2}{1 - e^{-\lambda^2 L^2}} + \frac{\pi^2}{108} \right) \,. \tag{10}$$

The theorem states that the regret of any learning strategy can be made at least as large as $\Omega(\log n/(L\lambda))$. Note that by Example 1, the minimal principal curvature of $\mathcal{W}$ in the above theorem is λ. In fact, it is not too hard to extend the above argument for any set $\mathcal{W}$ such that there is $w \in \mathrm{bd}(\mathcal{W})$ where the curvature is λ, and the curvature is a continuous function in a neighborhood of w over the boundary $\mathrm{bd}(\mathcal{W})$. The constants in the bound then depend on how fast the curvature changes within this neighborhood. In the case above, for small λL, the n-independent term in (10) is of order $1/(\lambda L)^3$.

Proof We define a random loss sequence, and we will show that no algorithm on this sequence can achieve an $o(\log n/(\lambda_0 L))$ regret. Let P be a random variable with $\mathrm{Beta}(K,K)$ distribution for some $K > 0$, and, given P, assume that $X_t, t \ge 1$ are i.i.d. Bernoulli random variables with parameter P. Let $f_t = X_t(1,-L) + (1-X_t)(-1,-L) = (2X_t - 1, -L)$. Thus, the second coordinate of f_t is always $-L$, and so $\|\Theta_t\|_2 = \left\| \frac{1}{t} \sum_{i=1}^t f_i \right\|_2 \ge L$. Furthermore, the conditional expectation of the loss vector is $f^p \triangleq \mathbb{E}[\, f_t |\, P = p] = (2p-1, -L)$.

Note that X_t is a function of f_t for all t; thus the conditional expectation of P, given $f_1, \ldots, f_{t-1}$, can be determined by the well-known formula $\hat{P}_{t-1} = \mathbb{E}[\, P | f_1 \ldots f_{t-1}] = \frac{K + \sum_{i=1}^{t-1} X_i}{2K + t - 1}$. Given p, denote the optimizer of f^p by w^p, that is, $w^p = \operatorname{argmin}_{w \in \mathcal{W}} \langle w, f^p \rangle$. Then the Bayesian optimal

choice in round t is

$$\begin{aligned}
\operatorname*{argmin}_{w \in \mathcal{W}} \mathbb{E}\left[\left[\langle w, f^P \rangle \right| f_1 \ldots f_{t-1} \right] &= \operatorname*{argmin}_{w \in \mathcal{W}} \left\langle w, \mathbb{E}\left[f^P \right| f_1 \ldots f_{t-1} \right] \right\rangle \\
&= \operatorname*{argmin}_{w \in \mathcal{W}} \left\langle w, f^{\hat{P}_{t-1}} \right\rangle \\
&= w^{\hat{P}_{t-1}} \,,
\end{aligned} \tag{11}$$

where the first equality follows by linearity of the inner product, the second since f^p is a linear function of p and the third by the definition of w^p.

Thus, denoting by W_t the prediction of an arbitrary algorithm in round t, the expected regret can be bounded from below as

$$\begin{aligned}
\mathbb{E}[R_n] &= \mathbb{E}\left[\max_{w \in \mathcal{W}} \sum_{t=1}^n \langle W_t - w, f_t \rangle \right] = \mathbb{E}\left[\mathbb{E}\left[\max_{w \in \mathcal{W}} \sum_{t=1}^n \langle W_t - w, f_t \rangle \middle| P \right] \right] \\
&\ge \mathbb{E}\left[\mathbb{E}\left[\sum_{t=1}^n \langle W_t - w^P, f_t \rangle \middle| P \right] \right] = \mathbb{E}\left[\sum_{t=1}^n \mathbb{E}\left[\langle W_t - w^P, f_t \rangle \right| P, f_1, \ldots, f_{t-1} \right] \right] \\
&= \mathbb{E}\left[\sum_{t=1}^n \mathbb{E}\left[\langle W_t - w^P, f^P \rangle \right| f_1, \ldots, f_{t-1} \right] \right] \qquad (12) \\
&\ge \mathbb{E}\left[\sum_{t=1}^n \min_{w \in \mathcal{W}} \mathbb{E}\left[\langle w - w^P, f^P \rangle \right| f_1, \ldots, f_{t-1} \right] \right] \\
&= \mathbb{E}\left[\sum_{t=1}^n \mathbb{E}\left[\left\langle w^{\hat{P}_{t-1}} - w^P, f^P \right\rangle \right| f_1, \ldots, f_{t-1} \right] \right] \qquad (13) \\
&= \sum_{t=1}^n \mathbb{E}\left[\left\langle w^{\hat{P}_{t-1}} - w^P, f^P \right\rangle \right] \,,
\end{aligned}$$

where (12) holds because of the independence of the f_s given P and since W_t is chosen based on $f_1, \ldots, f_{t-1}$ (but not on P), and (13) holds by (11).

By Lemma 17, given in Appendix A.4, we have

$$\begin{aligned}
\sum_{t=1}^n \mathbb{E}\left[\left\langle w^{\hat{P}_{t-1}} - w^P, f^P \right\rangle \right] &\ge \frac{\lambda L}{2} \sum_{t=1}^n \mathbb{E}\left[\frac{\left(\frac{2\hat{P}_{t-1} - 2P}{\lambda L} \right)^2}{\sqrt{1 + \left(\frac{1-2P}{\lambda L} \right)^2} \left(1 + \left(\frac{1 - 2\hat{P}_{t-1}}{\lambda L} \right)^2 \right)} \right] \qquad (14) \\
&= \frac{2}{\lambda L} \sum_{t=1}^n \mathbb{E}\left[\frac{1}{\sqrt{1 + \left(\frac{1-2P}{\lambda L} \right)^2}} \mathbb{E}\left[\frac{(\hat{P}_{t-1} - P)^2}{1 + \left(\frac{1 - 2\hat{P}_{t-1}}{\lambda L} \right)^2} \middle| P \right] \right] \\
&\ge \frac{2}{\lambda L} \sum_{t=1}^n \mathbb{E}\left[\frac{1}{\sqrt{1 + \left(\frac{1-2P}{\lambda L} \right)^2}} \mathbb{E}\left[\frac{(\hat{P}_{t-1} - P)^2}{1 + 2\left(\frac{1-2P}{\lambda L} \right)^2 + 2\left(\frac{2P - 2\hat{P}_{t-1}}{\lambda L} \right)^2} \middle| P \right] \right] , \qquad (15)
\end{aligned}$$

where in the last step we used $(a+b)^2 \le a^2 + b^2$. Let $\mathcal{G}_t$ be the event that $|\hat{P}_t - P| \le \frac{K|1-2P|}{2K+t} + \frac{t\lambda L}{2K+t}$; note that $\mathcal{G}_t$ holds with high probability by Lemma 18 in Appendix A.4. Then, lower bounding the

first term by 0, (15) can be lower bounded by

$$\begin{aligned}
&\frac{2}{\lambda L}\sum_{t=1}^{n-1}\mathbb{E}\left[\frac{1}{\sqrt{1+\left(\frac{1-2P}{\lambda L}\right)^2}}\mathbb{E}\left[\frac{(\hat{P}_t-P)^2}{1+2\left(\frac{1-2P}{\lambda L}\right)^2+2\left(\frac{2P-2\hat{P}_t}{\lambda L}\right)^2}\mathbb{I}(\mathcal{G}_t)\middle| P\right]\right]\\
&\geq \frac{2}{\lambda L}\sum_{t=1}^{n-1}\mathbb{E}\left[\frac{1}{\sqrt{1+\left(\frac{1-2P}{\lambda L}\right)^2}}\frac{\mathbb{E}\left[(\hat{P}_t-P)^2\mathbb{I}(\mathcal{G}_t)\middle| P\right]}{\left(1+2\left(\frac{1-2P}{\lambda L}\right)^2+2\left(\frac{2K}{2K+t}\frac{|1-2P|}{\lambda L}+\frac{2t}{2K+t}\right)^2\right)}\right]\\
&\geq \frac{2}{\lambda L}\sum_{t=1}^{n-1}\mathbb{E}\left[\frac{1}{\sqrt{1+\left(\frac{1-2P}{\lambda L}\right)^2}}\frac{\mathbb{E}\left[(\hat{P}_t-P)^2\mathbb{I}(\mathcal{G}_t)\middle| P\right]}{\left(9+4\left(\frac{1-2P}{\lambda L}\right)^2+8\frac{|1-2P|}{\lambda L}\right)}\right].
\end{aligned}$$

Combining the above, and using $(\hat{P}_t-P)^2\leq 1$ together with the upper bound on the probability of the event $\mathcal{G}_t^c$, the complement of $\mathcal{G}_t$, given in Lemma 18, we get

$$\begin{aligned}
\mathbb{E}[R_n] &\geq \frac{2}{\lambda L}\sum_{t=1}^{n-1}\mathbb{E}\left[\frac{1}{\sqrt{1+\left(\frac{1-2P}{\lambda L}\right)^2}}\frac{\mathbb{E}\left[(\hat{P}_t-P)^2\middle| P\right]-\mathbb{P}[\mathcal{G}_t^c]}{\left(9+4\left(\frac{1-2P}{\lambda L}\right)^2+8\frac{|1-2P|}{\lambda L}\right)}\right]\\
&\geq \frac{2}{\lambda L}\sum_{t=1}^{n-1}\left(\mathbb{E}\left[\frac{1}{\sqrt{1+\left(\frac{1-2P}{\lambda L}\right)^2}}\frac{\mathbb{E}\left[(\hat{P}_t-P)^2\middle| P\right]}{\left(9+4\left(\frac{1-2P}{\lambda L}\right)^2+8\frac{|1-2P|}{\lambda L}\right)}\right]-e^{-(t-1)\lambda^2L^2}\right)\\
&\geq \frac{2}{\lambda L}\left(\sum_{t=1}^{n-1}\mathbb{E}\left[\frac{1}{\sqrt{1+\left(\frac{1-2P}{\lambda L}\right)^2}}\frac{\mathbb{E}\left[(\hat{P}_t-P)^2\middle| P\right]}{\left(9+4\left(\frac{1-2P}{\lambda L}\right)^2+8\frac{|1-2P|}{\lambda L}\right)}\right]-\frac{1}{1-e^{-\lambda^2L^2}}\right). \qquad (16)
\end{aligned}$$

Now, by Lemma 19, given in Appendix A.4, we have

$$\mathbb{E}\left[(\hat{P}_t-P)^2\middle| P\right]=\frac{K^2(1-2P)^2}{(2K+t)^2}+\frac{tP(1-P)}{(2K+t)^2}\geq P(1-P)\left(\frac{1}{t}-\frac{2}{t(2K+t)}\right).$$

Combining this with (16) and introducing the constant

$$C=\mathbb{E}\left[\frac{1}{\sqrt{1+\left(\frac{1-2P}{\lambda L}\right)^2}}\frac{P(1-P)}{\left(9+4\left(\frac{1-2P}{\lambda L}\right)^2+8\frac{|1-2P|}{\lambda L}\right)}\right]$$

we obtain, for any $K>0$,

$$\begin{aligned}
\mathbb{E}[R_n] &\geq \frac{2}{\lambda L}\left[-\frac{1}{1-e^{-\lambda^2L^2}}+\sum_{t=1}^{n-1}C\left(\frac{1}{t}-\frac{2}{t(2K+t)}\right)\right] \qquad (17)\\
&\geq \frac{2C}{\lambda L}\log n-\frac{1}{\lambda L}\left(\frac{2}{1-e^{-\lambda^2L^2}}+\frac{C\pi^2}{3}\right). \qquad (18)
\end{aligned}$$

where we used $\sum_{t=1}^{n-1}\geq\int_1^n 1/t=\log n$ and $\sum_{t=1}^{n-1}1/(t(2K+t))\leq\sum_{t=1}^{\infty}1/t^2=\pi^2/6$. It remains to calculate a constant lower bound for C that is independent of λ and L. Denote $\frac{|1-2P|}{\lambda L}$ by Y; then $0\leq P(1-P)=\frac{1-Y^2\lambda^2L^2}{4}\leq 1/4$. Define $\widehat{\mathcal{G}}$ to be the event when $|Y|\leq 1$. Since P has Beta(K,K) distribution, $\mathbb{E}[P]=\frac{1}{2}$ and $\mathrm{Var}(P)=\frac{1}{8K}$. Therefore, by Chebyshev's inequality,

$$\mathbb{P}\left[\widehat{\mathcal{G}}^c\right]=\mathbb{P}\left[\left|P-\frac{1}{2}\right|>\frac{\lambda L}{2}\right]\leq\frac{1}{2K\lambda^2L^2}.$$

Therefore,

$$\begin{aligned}
C&=\mathbb{E}\left[\frac{1}{\sqrt{1+Y^2}}\frac{1-Y^2\lambda^2L^2}{4(9+4Y^2+8Y)}\right]\geq\mathbb{E}\left[\frac{1}{\sqrt{1+Y^2}}\frac{1-Y^2\lambda^2L^2}{4(9+4Y^2+8Y)}\mathbb{I}(\widehat{\mathcal{G}})\right]\\
&\geq\frac{1}{84\sqrt{2}}\mathbb{E}\left[(1-Y^2\lambda^2L^2)\mathbb{I}(\widehat{\mathcal{G}})\right]\geq\frac{1}{84\sqrt{2}}\left(\mathbb{E}\left[1-Y^2\lambda^2L^2\right]-\mathbb{P}\left[\widehat{\mathcal{G}}^c\right]\right)\\
&\geq\frac{1}{84\sqrt{2}}\left(1-\mathbb{E}\left[(1-2P)^2\right]-\frac{1}{2K\lambda^2L^2}\right)=\frac{1}{84\sqrt{2}}\left(1-\frac{1}{2K}-\frac{1}{2K\lambda^2L^2}\right)\\
&\geq\frac{1}{84\sqrt{2}}\cdot\frac{1}{2}
\end{aligned}$$

for any $K\geq 1+\frac{1}{\lambda^2L^2}$. Hence,

$$\mathbb{E}[R_n]\geq\frac{1}{84\sqrt{2}}\frac{1}{\lambda L}\log n-\frac{1}{\lambda L}\left(\frac{2}{1-e^{-\lambda^2L^2}}+\frac{\pi^2}{108}\right),$$

where we used the trivial upper bound $C\leq 1/36$ (obtained by maximizing the argument of the expectation in P in the definition of C by selecting $P=1/2$). The result is completed by noting that the worst-case regret is at least as big as the expected regret, thus, for every n, there exist a P and a sequence of loss vectors $f_1,\ldots,f_n$ such that the regret R_n satisfies (10). ■

3.2 Other Regularities

So far we have looked at the case when FTL achieves a low regret due to the curvature of $\mathrm{bd}(\mathcal{W})$. The next result characterizes the regret of FTL when $\mathcal{W}$ is a polytope, which has a flat, non-smooth boundary and thus Theorem 5 is not applicable. For this statement recall that given some norm $\|\cdot\|$, its dual norm is defined by $\|w\|_*=\sup_{\|v\|\leq 1}\langle v,w\rangle$.

Theorem 10 *Assume that $\mathcal{W}$ is a polytope and that Φ is differentiable at Θ_i, $i=1,\ldots,n$. Let $w_t=\mathrm{argmax}_{w\in\mathcal{W}}\langle w,\Theta_{t-1}\rangle$, $W=\sup_{w_1,w_2\in\mathcal{W}}\|w_1-w_2\|_*$ and $F=\sup_{f_1,f_2\in\mathcal{F}}\|f_1-f_2\|$. Then the regret of FTL is*

$$R_n\leq W\sum_{t=1}^{n}t\,\mathbb{I}(w_{t+1}\neq w_t)\|\Theta_t-\Theta_{t-1}\|\leq FW\sum_{t=1}^{n}\mathbb{I}(w_{t+1}\neq w_t).$$

Note that when $\mathcal{W}$ is a polytope, w_t is expected to "snap" to some vertex of $\mathcal{W}$. Hence, we expect the regret bound to be non-vacuous, if, e.g., Θ_t "stabilizes" around some value. Some examples after the proof will illustrate this.

Proof Let $v=\mathrm{argmax}_{w\in\mathcal{W}}\langle w,\theta\rangle$, $v'=\mathrm{argmax}_{w\in\mathcal{W}}\langle w,\theta'\rangle$. Similarly to the proof of Theorem 5,

$$\begin{aligned}
\langle v'-v,\theta'\rangle&=\langle v',\theta'\rangle-\langle v',\theta\rangle+\langle v',\theta\rangle-\langle v,\theta\rangle+\langle v,\theta\rangle-\langle v,\theta'\rangle\\
&\leq\langle v',\theta'\rangle-\langle v',\theta\rangle+\langle v,\theta\rangle-\langle v,\theta'\rangle=\langle v'-v,\theta'-\theta\rangle\leq W\,\mathbb{I}(v'\neq v)\|\theta'-\theta\|,
\end{aligned}$$

where the first inequality holds because $\langle v',\theta\rangle\leq\langle v,\theta\rangle$. Therefore, by (7),

$$R_n=\sum_{t=1}^{n}t\,\langle w_{t+1}-w_t,\Theta_t\rangle\leq W\sum_{t=1}^{n}t\,\mathbb{I}(w_{t+1}\neq w_t)\|\Theta_t-\Theta_{t-1}\|\leq FW\sum_{t=1}^{n}\mathbb{I}(w_{t+1}\neq w_t).$$

■

As noted before, since $\mathcal{W}$ is a polytope, w_t is (generally) attained at the vertices. In this case, the

epigraph of Φ is a polyhedral cone. Then, the event when $w_{t+1} \neq w_t$, that is, when the "leader" switches corresponds to when Θ_t and Θ_{t-1} belong to different linear regions corresponding to different linear pieces of the graph of Φ.

We now spell out a corollary for the stochastic setting. In particular, in this case FTL will often enjoy a constant regret:

Corollary 11 (Stochastic setting) *Assume that $\mathcal{W}$ is a polytope and that $(f_t)_{1\le t\le n}$ is an i.i.d. sequence of random variables such that $\mathbb{E}[f_i] = \mu$ and $\|f_i\|_\infty \le M$. Let $W = \sup_{w_1,w_2\in\mathcal{W}} \|w_1 - w_2\|_1$. Further assume that there exists a constant $r > 0$ such that Φ is differentiable for any ν such that $\|\nu - \mu\|_\infty \le r$. Then,*

$$\mathbb{E}[R_n] \le 2MW\left(3 + \frac{2M^2}{r^2}\log\left(\frac{2M^2 d}{r^2}\right)\right).$$

The existence of an r such that Φ is differentiable for any ν such that $\|\nu - \mu\|_\infty \le r$ is equivalent to that Φ is differentiable at μ. By Proposition 1, this condition requires that at μ, $\max_{w\in\mathcal{W}}\langle w, \theta\rangle$ has a unique optimizer (note that the volume of the set of vectors θ with multiple optimizers is zero). On the other hand, r should be selected to be the radius of the largest ball such that the optimal decisions for the expected losses μ and ν (i.e., the maximizers defining $\Phi(-\mu)$ and $\Phi(-\nu)$) belong to the same face of $\mathcal{W}$.

Proof Let $V = \{\nu \,|\, \|\nu - \mu\|_\infty \le r\}$. Note that the epigraph of the function Φ is a polyhedral cone. Since Φ is differentiable in the interior of V, $\{(\theta, \Phi(\theta)) \,|\, \theta \in V\}$ is a subset of a linear subspace. Therefore, for $-\Theta_t, -\Theta_{t-1} \in V$, $w_{t+1} = w_t$. Hence, by Theorem 10,

$$\mathbb{E}[R_n] \le 2MW\sum_{t=1}^{n}\mathbb{P}[-\Theta_t, -\Theta_{t-1} \notin V] \le 4MW\left(1 + \sum_{t=1}^{n}\mathbb{P}[-\Theta_t \notin V]\right). \tag{19}$$

On the other hand, note that $\|f_i\|_\infty \le M$. Then

$$\mathbb{P}[-\Theta_t \notin V] = \mathbb{P}\left[\left\|\frac{1}{t}\sum_{i=1}^{t} f_i - \mu\right\|_\infty \ge r\right] \le \sum_{j=1}^{d}\mathbb{P}\left[\left|\frac{1}{t}\sum_{i=1}^{t} f_{i,j} - \mu_j\right| \ge r\right] \le 2de^{-\frac{tr^2}{2M^2}},$$

where the last inequality is due to Hoeffding's inequality. Now, using that for any $\alpha > 0$ and $\tau > 0$, $\sum_{t=\tau+1}^{n}\exp(-\alpha t) \le \int_\tau^n \exp(-\alpha t)dt \le \frac{1}{\alpha}\exp(-\alpha\tau)$, from (19) we obtain

$$\mathbb{E}[R_n] \le 2MW\left(1 + \tau + \frac{2d}{\alpha}e^{-\alpha\tau}\right).$$

Setting $\alpha = \frac{r^2}{2M^2}$ and $\tau = \frac{1}{\alpha}\log(d/\alpha)$ in the above bound finishes the proof. ■

4. Adaptive Algorithms

While FTL can exploit the curvature of the surface of the constraint set to achieve $O(\log n)$ regret, it requires the curvature condition and $\min_t \|\Theta_t\|_2 \ge L$ being bounded away from zero, or it may suffer linear regret. On the other hand, many algorithms such as the follow the regularized leader (FTRL) are known to achieve a regret guarantee of $O(\sqrt{n})$ even for the worst-case data in the linear setting (see, e.g., Shalev-Shwartz, 2012). This raises the question of whether one can have an algorithm that can achieve constant or $O(\log n)$ regret in the respective settings of Corollary 11 or Theorem 5, while it still maintains $O(\sqrt{n})$ regret for worst-case data. One way to design an adaptive algorithm is to use the $(\mathcal{A}, \mathcal{B})$-prod algorithm of Sani et al. (2014), trivially leading to the following result:

Algorithm 1 Follow The Shrunken Leader (FTSL)

Predict $w_1 = 0$;
for $t = 2, ..., n-1$ **do**
  FTL: Compute $\tilde{w}_t = \operatorname{argmin}_{w\in\mathcal{W}}\langle w, F_{t-1}\rangle$.
  Shrinkage: Predict $w_t = \frac{\|F_{t-1}\|_2}{\sqrt{\|F_{t-1}\|_2^2 + t + 2}}\tilde{w}_t$.
end for
FTL: Compute $\tilde{w}_n = \operatorname{argmin}_{w\in\mathcal{W}}\langle w, F_{n-1}\rangle$.
Shrinkage: Predict $w_n = \frac{\|F_{n-1}\|_2}{\sqrt{\|F_{n-1}\|_2^2 + n}}\tilde{w}_n$.

Proposition 12 *Consider $(\mathcal{A}, \mathcal{B})$-prod of Sani et al. (2014), where algorithm $\mathcal{A}$ is chosen to be FTRL with an appropriate regularization term, while $\mathcal{B}$ is chosen to be FTL. Then the regret of the resulting hybrid algorithm $\mathcal{H}$ enjoys the following guarantees:*

- *If FTL achieves constant regret as in the setting of Corollary 11, then the regret of $\mathcal{H}$ is also constant.*
- *If FTL achieves a regret of $O(\log n)$ as in the setting of Theorem 5, then the regret of $\mathcal{H}$ is also $O(\log n)$.*
- *Otherwise, the regret of $\mathcal{H}$ is at most $O(\sqrt{n\log n})$.*

In the next section we show that if the constraint set is an ellipsoid, it is possible to design adaptive algorithms directly.

4.1 Adaptive Algorithms for Ellipsoid Constraint Sets

In this section we provide some interesting results about adaptive algorithms for the case when $\mathcal{W}$ is an ellipsoid in $\mathbb{R}^d$. First, we show that a variant of FTL using shrinkage as regularization has $O(\log n)$ regret when $\|\Theta_t\|_2 \ge L > 0$ for all t, but it also has $O(\sqrt{n})$ worst case guarantee. Furthermore, we show that the standard FTRL algorithm is adaptive if the constraint set is an ellipsoid and the loss vectors are stochastic. Throughout the section we will use the notation $F_t = -t\,\Theta_t = \sum_{i=1}^{t} f_i$.

4.1.1 Follow the Shrunken Leader

In this section we are going to analyze a combination of the FTL algorithm and the idea of shrinkage often used for regularization purposes in statistics. We assume that $\mathcal{W}$ is the d-dimensional unit ball and, without loss of generality, we further assume that $\|f\|_2 \le 1$ for all $f \in \mathcal{F}$. The Follow The Shrunken Leader (FTSL) algorithm is given in Algorithm 1. The main idea of the algorithm is to predict a shrunken version of the FTL prediction, in this way keeping it away from the boundary of $\mathcal{W}$. The next theorem shows that the right amount of shrinkage leads to a robust, adaptive algorithm.

Theorem 13 *Assume that $\mathcal{W} = \left\{x \in \mathbb{R}^d \,|\, \|x\|_2 \le 1\right\}$ and $\|f\|_2 \le 1$ for all $f \in \mathcal{F}$. Then the regret of FTSL is $O(\sqrt{n})$. If, in addition, there exists an $L > 0$ such that $\|\Theta_t\|_2 \ge L$ for $1 \le t \le n$, then the regret of is $O(\log n/L)$.*

Proof By the definition of F_t and $\mathcal{W}$, $\tilde{w}_t = -F_{t-1}/\|F_{t-1}\|_2$ for $t \ge 2$. Let $\sigma_n = \frac{\|F_{n-1}\|_2}{\sqrt{\|F_{n-1}\|_2^2 + n}}$. Our proof follows the idea of Abernethy et al. (2008). We compute the upper bound on the value of the game for each round backwards for $t = n, n-1, \ldots, 1$, by solving the optimal strategies for f_t. The

value of the game using FTSL is defined as

$$\begin{aligned} V_n &= \max_{f_1,\dots,f_n} \sum_{t=1}^{n} \langle w_t, f_t\rangle - \min_{w\in\mathcal{W}} \langle w, F_n\rangle \\ &= \max_{f_1,\dots,f_{n-1}} \sum_{t=1}^{n-1} \langle w_t, f_t\rangle + \underbrace{\max_{f_n} \|F_{n-1}+f_n\|_2 + \langle f_n, w_n\rangle}_{=:U_n} \end{aligned}$$

We first prove that U_n, the second term above, is bounded from above by $\sqrt{\|F_{n-1}\|_2^2+n}$. To see this, let $f_n = a_n\tilde{F}_{n-1} + b_n\Omega_{n-1}$ where $\tilde{F}_{n-1}$ is the unit vector parallel to F_{n-1} and Ω_{n-1} is a unit vector orthogonal to F_{n-1}. Furthermore, since $\|f_n\|_2 \le 1$, we have $a_n^2 + b_n^2 \le 1$. Thus,

$$\begin{aligned} U_n &= \max_{f_n} \sqrt{\|F_{n-1}\|_2^2 + 2a_n\|F_{n-1}\|_2 + a_n^2 + b_n^2} - a_n\sigma_n \\ &\le \max_{a} \sqrt{\|F_{n-1}\|_2^2 + 2a\|F_{n-1}\|_2 + n} - a\sigma_n \\ &= \sqrt{\|F_{n-1}\|_2^2 + n}, \end{aligned}$$

where the last equality follows since the maximum is attained at $a = 0$. A similar statement holds for the other time indices: for any $t \ge 1$,

$$\max_{f_t} \sqrt{\|F_{t-1}+f_t\|_2^2 + t + 1} + \langle f_t, w_t\rangle \le \sqrt{\|F_{t-1}\|_2^2 + t} + \frac{1}{\sqrt{t}}\,. \tag{20}$$

Before proving this inequality, we show how it implies the first statement of the theorem:

$$\begin{aligned} V_n &\le \max_{f_1,\dots,f_{n-1}} \sum_{t=1}^{n-1} \langle w_t, f_t\rangle + \sqrt{\|F_{n-1}\|_2^2 + n} \\ &\le \max_{f_1,\dots,f_{n-2}} \sum_{t=1}^{n-2} \langle w_t, f_t\rangle + \sqrt{\|F_{n-2}\|_2^2 + n - 1} + \frac{1}{\sqrt{n-1}} \\ &\le \dots \\ &\le 1 + \sum_{t=1}^{n-1} \frac{1}{\sqrt{t}} \le 2(1+\sqrt{n-1}). \end{aligned}$$

Moreover, if $\|\Theta_t\|_2 \ge L > 0$ for $1 \le t \le n$, a stronger version of (20) also holds:

$$\max_{f_t} \sqrt{\|F_{t-1}+f_t\|_2^2 + t + 1} + \langle f_t, w_t\rangle \le \sqrt{\|F_{t-1}\|_2^2 + t} + \frac{1}{(t-1)L}. \tag{21}$$

This implies the second statement of the theorem, since

$$\begin{aligned} V_n &\le \max_{f_1,\dots,f_{n-1}} \sum_{t=1}^{n-1} \langle w_t, f_t\rangle + \sqrt{\|F_{n-1}\|_2^2 + n} \\ &\le \max_{f_1,\dots,f_{n-2}} \sum_{t=1}^{n-2} \langle w_t, f_t\rangle + \sqrt{\|F_{n-2}\|_2^2 + n - 1} + \frac{1}{(n-1)L} \\ &\le \dots \\ &\le 1 + \sum_{t=1}^{n-1} \frac{1}{tL} \le 1 + \frac{1}{L} + \frac{\log(n-1)}{L}\,. \end{aligned}$$

To finish the proof, it remains to show (20) and (21). Let $f_t = a_t\tilde{F}_{t-1} + b_t\Omega_{t-1}$ where $\tilde{F}_{t-1}$ is the unit vector parallel to F_{t-1} and Ω_{t-1} is a unit vector orthogonal to F_{t-1}. Since $\|f_t\|_2 \le 1$, observe that $a_t^2 + b_t^2 = \|f_t\|_2 \le 1$. Furthermore, let $\sigma_t = \frac{\|F_{t-1}\|_2}{\sqrt{\|F_{t-1}\|_2^2+t+2}}$. Then, for any $t \ge 1$,

$$\begin{aligned} \Delta_t &= \max_{f_t} \sqrt{\|F_{t-1}\|_2^2 + 2a_t\|F_{t-1}\|_2 + a_t^2 + b_t^2 + t + 1} - a_t\sigma_t - \sqrt{\|F_{t-1}\|_2^2 + t} \\ &\le \max_{a_t} \sqrt{\|F_{t-1}\|_2^2 + 2a_t\|F_{t-1}\|_2 + t + 2} - a_t\sigma_t - \sqrt{\|F_{t-1}\|_2^2 + t} \\ &= \sqrt{\|F_{t-1}\|_2^2 + t + 2} - \sqrt{\|F_{t-1}\|_2^2 + t} \\ &= \frac{2}{\sqrt{\|F_{t-1}\|_2^2 + t + 2} + \sqrt{\|F_{t-1}\|_2^2 + t}} \\ &\le \frac{1}{\sqrt{t}}. \end{aligned} \tag{22}$$

This proves (20). Moreover, if $\|F_{t-1}\|_2 = \|(t-1)\Theta\|_2 \ge (t-1)L > 0$, by (22) we obtain

$$\Delta_t \le \frac{2}{\sqrt{\|F_{t-1}\|_2^2 + t + 2} + \sqrt{\|F_{t-1}\|_2^2 + t}} \le \frac{1}{\|F_{t-1}\|_2} \le \frac{1}{(t-1)L},$$

proving (21). ■

Remark 14 The above result can easily be extended to the case when $\mathcal{W}$ is an ellipsoid, that is, $\mathcal{W} = \{w \,|\, w^\top Q w \le 1\}$ for some positive-definite matrix Q. Transforming the predictions as $\hat{w}_t = Q^{1/2}w_t$ and the losses $\hat{f}_t = Q^{-1/2}f_t$, we see that, for all t, the new prediction $\hat{w}_t$ belongs to the unit ball (i.e., $\hat{w}_t \in B_1$) and $\langle w_t, f_t\rangle = \langle \hat{w}_t, \hat{f}_t\rangle$. Thus, the value of the game can be bounded as

$$\begin{aligned} V_n &= \max_{f_1,\dots,f_n\,:\,\|f_i\|_2\le 1} \sum_{t=1}^{n} \langle w_t, f_t\rangle - \min_{w\in\mathcal{W}} \langle w, F_n\rangle \\ &= \max_{f_1,\dots,f_n\,:\,\|f_i\|_2\le 1} \sum_{t=1}^{n} \langle \hat{w}_t, Q^{-1/2}f_t\rangle - \min_{\hat{w}\in B_1} \langle \hat{w}, Q^{-1/2}F_n\rangle \\ &= \max_{\hat{f}_1,\dots,\hat{f}_n\,:\,\|Q^{1/2}\hat{f}_i\|_2\le 1} \sum_{t=1}^{n} \langle \hat{w}_t, \hat{f}_t\rangle - \min_{\hat{w}\in B_1} \langle \hat{w}, \widehat{F}_n\rangle \\ &\le \max_{\hat{f}_1,\dots,\hat{f}_n\,:\,\|\hat{f}_i\|_2\le \frac{1}{\sqrt{\lambda_{\min}}}} \sum_{t=1}^{n} \langle \hat{w}_t, \hat{f}_t\rangle - \min_{\hat{w}\in B_1} \langle \hat{w}, \widehat{F}_n\rangle \\ &= \frac{1}{\sqrt{\lambda_{\min}}} \max_{\tilde{f}_1,\dots,\tilde{f}_n\,:\,\|\tilde{f}_i\|_2\le 1} \sum_{t=1}^{n} \langle \hat{w}_t, \tilde{f}_t\rangle - \min_{\hat{w}\in B_1} \langle \hat{w}, \tilde{F}_n\rangle\,, \end{aligned}$$

where $\lambda_{\min}$ is the minimal eigenvalue of the matrix Q, $\widehat{F}_n = \sum_{t=1}^n \hat{f}_t$, $\tilde{f}_t = \sqrt{\lambda_{\min}}\,\hat{f}_t$, and $\tilde{F}_n = \sqrt{\lambda_{\min}}\,\widehat{F}_n = \sum_{t=1}^n \tilde{f}_t$. Thus, playing over $\mathcal{W}$ with loss vectors from the unit ball is equivalent to playing over the unit ball B_1 against losses over $\mathcal{W}$ (note that $\|Q^{1/2}\hat{f}_i\|_2 \le 1$ is equivalent to $\hat{f}_i \in \mathcal{W}$), which can be reduced to playing against losses with maximum Euclidean norm 1. Thus, an algorithm for the ellipsoid constraint set $\mathcal{W}$ is to run FTSL over the unit ball B_1 with the transformed losses $\tilde{f}_t$, and predict $w_t = Q^{-1/2}\hat{w}_t$ where $\hat{w}_t$ is the prediction of FTSL. Assuming that $\|\Theta_t\|_2 \ge L$ for all t in the original problem, in the transformed problem we have $\|\sqrt{\lambda_{\min}}\,Q^{-1/2}\Theta_t\|_2 \ge L\sqrt{\lambda_{\min}/\lambda_{\max}}$ where $\lambda_{\max}$ is the largest eigenvalue of Q. Hence, the regret of the algorithm (in both the original

and the transformed problems) is at most $O\big(\frac{\sqrt{\lambda_{\max}}}{L\lambda_{\min}}\log n\big)$. Note that this is exactly the same rate as we can obtain from Theorem 5 and Example 1 (ii) for the (non-adaptive) FTL algorithm for the ellipsoid constraint set $\mathcal{W}$ (a closer inspection of the constants shows that the leading constant for FTSL is actually a factor of 2 better).

4.1.2 FTRL for Stochastic Losses

This section shows that when $\mathcal{W}$ is the unit ball B_1, FTRL with regularizer $R(w)=\frac{1}{2}\|w\|^2$ is an adaptive algorithm achieving logarithmic regret for stochastic losses. To fix the notation, in round t, FTLR predicts

$$w_t = \operatorname*{argmin}_{w\in\mathcal{W}} \eta_t\langle F_{t-1}, w\rangle + R(w),$$

if $t>1$ and $w_1=0$. It has been well known that FTRL with $\eta_t = 1/\sqrt{t-1}$ is guaranteed to achieve $O(\sqrt{n})$ regret in the adversarial setting (see, e.g., Shalev-Shwartz, 2012). It remains to prove that FTRL indeed achieves a fast rate in the stochastic setting.

Theorem 15 *Assume that the sequence of loss vectors, $f_1,\dots,f_n\in\mathbb{R}^d$ satisfies $\|f_t\|_2\le 1$ almost surely and $\mathbb{E}[f_t]=\mu$ for all t with some $\|\mu\|_2>0$. Then FTRL with $\eta_t=1/\sqrt{t-1}$ suffers $O(\log n)$ regret .*

Proof Using $R(w)=\frac{1}{2}\|w\|^2$ as its regularization, in round $t>1$ FTRL predicts

$$w_t = \operatorname*{argmin}_{w\in\mathcal{W}} \eta_t\langle F_{t-1}, w\rangle + R(w) = \begin{cases} \frac{1}{\sqrt{t-1}}F_{t-1} & \text{if } \|F_{t-1}\|\le\sqrt{t-1}\,; \\ \frac{F_{t-1}}{\|F_{t-1}\|} & \text{otherwise.}\end{cases} \tag{23}$$

For any $1\le t\le n$, denote the event $\|F_t\|\ge\sqrt{t}$ by $\mathcal{E}_t$. Note that if $\|F_{t-1}\|\ge\sqrt{t-1}$, FTRL predicts exactly the same w_t as FTL. Denote the accumulated loss of FTL in n rounds by $\mathcal{L}_n^{FTL}$. Thus, the regret of FTRL is

$$\begin{aligned}\mathbb{E}[R_n] &= \mathbb{E}\left[\sum_{t=1}^n\langle f_t,w_t\rangle - \min_{w\in\mathcal{W}}\langle f_t,w\rangle\right] \\ &= \mathbb{E}\left[\sum_{t=1}^n\langle f_t,w_t\rangle - \mathcal{L}_n^{FTL}\right] + \mathbb{E}\left[\mathcal{L}_n^{FTL} - \min_{w\in\mathcal{W}}\langle f_t,w\rangle\right] \\ &\le 2\sum_{t=1}^n \mathbb{P}[\mathcal{E}_t^c] + O(\log n),\end{aligned}$$

where to obtain the last inequality we applied (23) for the first term, while the second term is $O(\log n)$ by Remark 7. It remains to bound the first term, $2\sum_{t=1}^n\mathbb{P}[\mathcal{E}_t^c]$ in the above. For any $t>\frac{4}{\|\mu\|_2^2}$,

$$\begin{aligned}\mathbb{P}\left[\|F_t\|_2\le\sqrt{t}\right] &\le \mathbb{P}\left[\|F_t\|_2<\frac{t}{2}\|\mu\|_2\right] \le \sum_{i=1}^d\mathbb{P}\left[|F_{t,i}|<\frac{t}{2}|\mu_i|\right] \\ &\le \sum_{i=1}^d\mathbb{P}\left[|F_{t,i}-t\mu_i|>\frac{t}{2}|\mu_i|\right] \le 2\sum_{i=1}^d e^{-\frac{\mu_i^2}{4}t}\end{aligned}$$

Thus,

$$\begin{aligned}\sum_{t=1}^n\mathbb{P}[\mathcal{E}_t^c] &= \sum_{t=1}^{4/\|\mu\|_2^2}\mathbb{P}[\mathcal{E}_t^c] + \sum_{t=4/\|\mu\|_2^2}^n\mathbb{P}[\mathcal{E}_t^c] \\ &\le \frac{4}{\|\mu\|_2^2} + 2\sum_{i=1}^d\sum_{t=0}^n e^{-\frac{\mu_i^2}{4}t} \\ &\le \frac{4}{\|\mu\|_2^2} + 2\sum_{i=1}^d\frac{1}{1-e^{-\frac{\mu_i^2}{4}}} \\ &\le \frac{4}{\|\mu\|_2^2} + 2\sum_{i=1}^d\frac{\mu_i^2}{4} = \frac{4}{\|\mu\|_2^2} + \frac{\|\mu\|_2^2}{2}\,.\end{aligned}$$

where in the last inequality we used $1/(1-e^{-a})\le a$. Therefore, if $\|\mu\|>0$, the regret of FTRL satisfies

$$\mathbb{E}[R_n]\le\frac{8}{\|\mu\|_2^2}+\|\mu\|_2^2+O(\log n)=O(\log n).$$

■

Remark 16 Similarly to FTSL, the above result can be extended to ellipsoid constraint sets with an adequate choice of the regularizer $R(w)$. Assume that $\mathcal{W}=\{w\,|\,w^\top Qw\le 1\}$ for some positive definite matrix Q, and let $R(w)=\frac{1}{2}w^\top Qw$. Then

$$w_t = \operatorname*{argmin}_{w\in\mathcal{W}}\eta_t\langle F_{t-1},w\rangle + R(w) = Q^{-1/2}\operatorname*{argmin}_{\tilde{w}\in B_1}\eta_t\langle Q^{-1/2}F_{t-1},\tilde{w}\rangle + \frac{1}{2}\|\tilde{w}\|_2^2,$$

and

$$R_n = \sum_{t=1}^n\langle f_t,w_t\rangle - \min_{w\in\mathcal{W}}\langle f_t,w\rangle = \sum_{t=1}^n\langle Q^{-1/2}f_t,\tilde{w}_t\rangle - \min_{w\in B_1}\langle Q^{-1/2}f_t,\tilde{w}\rangle.$$

Thus, the problem is equivalent to the case of a unit ball constraint set with the loss vector $Q^{-1/2}f_t$ for time t, and FTRL with the selected regularizer achieves $O(\sqrt{n})$ worst case regret and $O(\log n)$ regret in the case of an i.i.d. loss sequence. Whether FTRL with a constraint-set-independent regularizer $R(w)=\frac{1}{2}\|w\|_2^2$ achieves similar adaptivity, remains an open question.

5. Simulations

We performed three simulations to illustrate the differences between FTL, FTRL with the regularizer $R(w)=\frac{1}{2}\|w\|_2^2$ when $w_t=\operatorname{argmin}_{w\in\mathcal{W}}\sum_{i=1}^{t-1}\langle f_{i-1},w\rangle+R(w)$, and the adaptive algorithm $(\mathcal{A},\mathcal{B})$-prod (AB) using FTL and FTRL as its candidates, which we shall call AB(FTL,FTRL).

For the experiments the constraint set $\mathcal{W}$ was chosen to be a slightly elongated ellipsoid in the 4-dimensional Euclidean space, with volume matching that of the 4-dimensional unit ball. The actual ellipsoid is given by $\mathcal{W}=\{w\in\mathbb{R}^4\,|\,w^\top Qw\le 1\}$ where Q is randomly generated as

$$Q=\begin{pmatrix} 4.3367 & 3.6346 & -2.2250 & 3.5628 \\ 3.6346 & 3.9966 & -2.3613 & 3.2817 \\ -2.2250 & -2.3613 & 2.0589 & -2.1295 \\ 3.5628 & 3.2817 & -2.1295 & 3.4206 \end{pmatrix}.$$

We experimented with three types of data to illustrate the behavior of the different algorithms: stochastic, "half-adversarial", and "worst-case" data (worst-case for FTL), as will be explained below. The first two data sets are random, so the experiments were repeated 100 times, and we report the average regret with its standard deviation; the worst case data is deterministic, so there no repetition was needed. For each experiment, we set $n = 2500$. The regularization coefficient for the FTRL, and the learning rate for AB were chosen based on their theoretical bounds minimizing the worst-case regret.

5.1 Stochastic Data

In this setting we used the following model to generate f_t: Let $(\hat{f}_t)_t$ be an i.i.d. sequence drawn from the 4-dimensional standard normal distribution, and let $\tilde{f}_t = \hat{f}_t / \left\|\hat{f}_t\right\|_2$. Then, f_t is defined as $f_t = \tilde{f}_t + Le_1$ where $e_1 = (1, 0, \dots, 0)^\top$. Therefore, $\mathbb{E}\left[\left\|\frac{1}{t}\sum_{s=1}^{t} f_s\right\|_2\right] \to L$ as $t \to \infty$. In the experiments we picked $L \in \{0, 0.1\}$.

The results are shown in Fig. 4. On the left-hand side we plotted the regret against the logarithm of the number of rounds, while on the right-hand side we plotted the regret against the square root of the number of rounds, together with the standard deviation of the results over the 100 independent runs. As can be seen from the figures, when $L = 0.1$, the growth-rate of the regret of FTL is indeed logarithmic, while when $L = 0$, the growth-rate is $\Theta(\sqrt{n})$. In particular, when $L = 0.1$, FTL enjoys a major advantage compared to FTRL, while for $L = 0$, FTL and FTRL perform essentially the same (in this special case, the regret of FTL will indeed be $O(\sqrt{n})$ as w_t will stay bounded, but $\|\Theta_t\| = O(1/\sqrt{t})$). As expected, AB(FTL,FTRL), gets the better of the two regrets with little to no extra penalty.

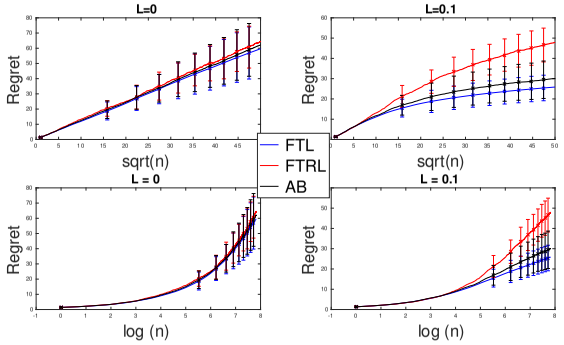

Figure 4: Regret of FTL, FTRL and AB(FTL,FTRL) against time for stochastic data.

5.2 "Half-Adversarial" Data

The half-adversarial data used in this experiment is the optimal solution for the adversary in the *linear game* when $\mathcal{W}$ is the unit ball (Abernethy et al., 2008). This data is generated as follows: The sequence $\hat{f}_t$ for $t = 1, \dots, n$ is generated randomly in the $(d-1)$-dimensional subspace $S = \text{span}\{e_2, \dots, e_d\}$ (here e_i is the ith unit vector in $\mathbb{R}^d$) as follows: $\hat{f}_1$ is drawn from the uniform distribution on the unit sphere of S (actually $\mathbb{S}^{d-1}$. For $t = 2, \dots, n$, $\hat{f}_t$ is drawn from the uniform distribution on the

unit sphere of the intersection of S and the hyperplane perpendicular to $\sum_{i=1}^{t-1} \hat{f}_i$ and going through the origin. Then, $f_t = Le_1 + \sqrt{1 - L^2}\hat{f}_t$ for some $L \geq 0$.

The results are reported in Fig. 5. When $L = 0$, the regret of both FTL and FTRL grows as $O(\sqrt{n})$. When $L = 0.1$, FTL achieves $O(\log n)$ regret, while the regret of FTRL appears to be $O(\sqrt{n})$. AB(FTL,FTRL) closely matches the regret of FTL.

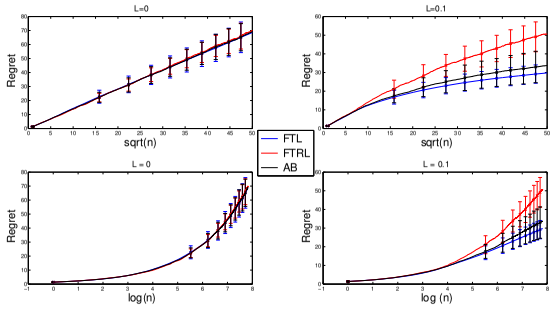

Figure 5: Experimental results for "half-adversarial" data.

5.3 Worst-Case Data

We also tested the algorithms on data where FTL is known to suffer linear regret, mainly to see how well AB(FTL,FTRL) is able to deal with this setting. In this case, we set $f_{t,i} = 0$ for all t and $i \geq 2$, while for the first coordinate, $f_{1,1} = 0.9$, and $f_{t,1} = 2(t \mod 2) - 1$ for $t \geq 2$.

The results are reported in Fig. 6. It can be seen that the regret of FTL is linear (as one can easily verify theoretically), and AB(FTL,FTRL) succeeds to adapt to FTRL, and they both achieve a much smaller $O(\sqrt{n})$ regret.

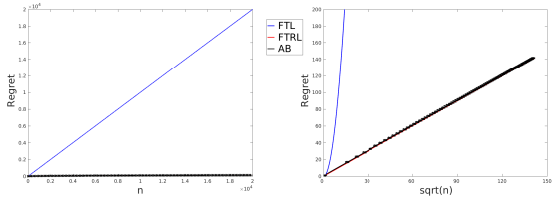

Figure 6: Experimental results for worst-case data.

5.4 The Unit Ball

We close this section by comparing the performance of our adaptive algorithms on the unit ball, namely, FTL, FTSL, FTLR, and AB(FTL,FTRL). All these algorithms are parametrized as above. The problem setup is similar to the stochastic data setting and the worst-case data setting. Again, we consider a 4-dimensional setting, that is, $\mathcal{W}$ is the unit ball in $\mathbb{R}^4$ centered at the origin. The

worst-case data is generated exactly as above, while the generation process of the stochastic data is slightly modified to increase the difference between FTLR and FTL: we sample the i.i.d. vectors $\hat{f}_t$ from a zero-mean normal distribution with independent components whose variance is $1/16$, and let $\tilde{f}_t = \hat{f}_t$ if $\|\hat{f}_t\|_2 \le 1$ and $\tilde{f}_t = \hat{f}_t / \left\|\hat{f}_t\right\|_2$ when $\left\|\hat{f}_t\right\|_2 > 1$ (i.e., we only normalize if $\hat{f}_t$ falls outside of the unit ball). The reason of this modification is to encourage the occurrence of the event $\|F_{t-1}\|_2 < \sqrt{t-1}$. Recall that when $\|F_{t-1}\|_2 \ge \sqrt{t-1}$, the prediction of FTRL matches that of FTL, so we are trying to create some data where their behavior is actually different. As a result, we will be able to observe that the predictions of FTL and FTRL are different in the early rounds. Finally, as before, we let $f_t = \tilde{f}_t + Le_1$, and set the time horizon to $n = 20,000$.

The results of the simulation of the stochastic data setting are shown in Figure 7. In the case of $L = 0.1$, FTRL suffers more regret at the beginning for some rounds, but then succeeds to match the performance of FTL. The results of the simulation of the worst-case data setting are shown in Figure 8, where FTSL has similar performance as FTRL.

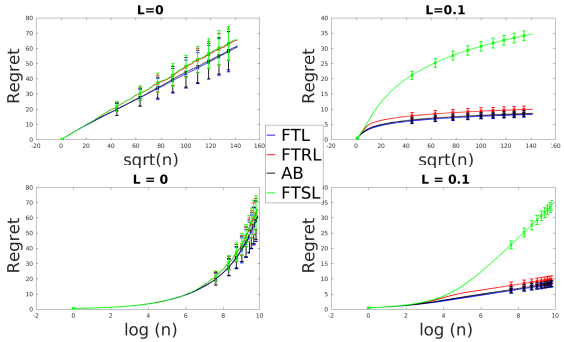

Figure 7: Experimental results for stochastic data when $\mathcal{W}$ is the unit ball.

6. Conclusion

FTL is a simple method that is known to perform well in many settings, while existing worst-case results fail to explain its good performance. While taking a thorough look at why and when FTL can be expected to achieve small regret, we discovered that the curvature of the boundary of the constraint and having average loss vectors bounded away from zero help keep the regret of FTL small. These conditions are significantly different from previous conditions on the curvature of the loss functions which have been considered extensively in the literature. It would be interesting to further investigate this phenomenon for other algorithms or in other learning settings.

Acknowledgments

The authors would like to thank the anonymous reviewers for their comments that helped improving the presentation of the paper, in particular, for the alternative proof of (6) based on strong convexity. This work was supported in part by the Alberta Innovates Technology Futures through the Alberta Ingenuity Centre for Machine Learning and by NSERC. During part of this work, T. Lattimore was

with the Department of Computing Science, University of Alberta and with the School of Informatics and Computing, Indiana University Bloomington.

Appendix A. Technical Results

A.1 Proof of Proposition 1

Under the extra condition that $\mathcal{W}$ is compact the result follows from Danskin's theorem (e.g., Proposition B.25 of Bertsekas 1999). However, compactness is not required. For completeness, we provide a short, direct proof. We need to show that $\mathcal{Z} = \partial\varphi(\Theta)$ where recall that

$$\partial\varphi(\Theta) = \left\{u \in \mathbb{R}^d \,|\, \varphi(\Theta) + \langle u, \cdot - \Theta\rangle \le \varphi(\cdot)\right\} = \left\{u \in \mathbb{R}^d \,|\, \varphi(\Theta) \le \langle u, \Theta\rangle + \varphi(\cdot) - \langle u, \cdot\rangle\right\} .$$

Since $\mathcal{Z} \subset \mathcal{W}$, if $w \in \mathcal{Z}$, $\varphi(\Theta') \ge \langle w, \Theta'\rangle$ for any Θ' by the definition of φ. Hence, $\varphi(\Theta) = \langle w, \Theta\rangle \le \langle w, \Theta\rangle + \varphi(\Theta') - \langle w, \Theta'\rangle$ for any Θ', implying that $w \in \partial\varphi(\Theta)$.

On the other hand, assume $w \in \partial\varphi(\Theta)$. Then $\varphi(\Theta) \le \langle w, \Theta\rangle$ since $\varphi(0) = \langle w, 0\rangle = 0$. Since $\mathcal{W}$ is closed, $\mathcal{Z}$ is also closed. Therefore, if $w \notin \mathcal{Z}$, the strict separation theorem (applied to $\{w\}$, a convex compact set, and $\mathcal{Z}$, a convex closed set) implies that there exists $\rho \in \mathbb{R}^d$ such that $\langle z, \rho\rangle < \langle w, \rho\rangle$ for all $z \in \mathcal{Z}$. Let $\Theta' = \Theta + \rho$. Then, $\varphi(\Theta') = \max_{u\in\mathcal{W}} \langle u, \Theta\rangle + \langle u, \rho\rangle < \varphi(\Theta) + \langle w, \Theta' - \Theta\rangle \le \langle w, \Theta'\rangle \le \varphi(\Theta')$, a contradiction. Hence, $w \in \mathcal{Z}$.

A.2 Preliminaries in Differential Geometry

In this section we present some extra details on the tools we use from differential geometry. We focus on providing the intuitive picture and foundational results used in the paper, omitting formal definitions that do not directly contribute to this goal. The interested reader can find a detailed formal treatment, for example, in Section 2.5 of the book of Schneider (2014).

A.2.1 Planar Curves

We only consider twice continuously differentiable curves in this paper, defined as injective twice continuously differentiable functions $\gamma : [a, b] \to X$ from an interval $[a, b] \subset \mathbb{R}$ to a differentiable manifold $X \subset \mathbb{R}^d$ such that $\gamma'(u) \ne 0$. Given a differentiable curve γ, we define its length between $\gamma(u)$ and $\gamma(v)$ as $\ell([u, v]) = \int_u^v \|\gamma'(s)\| ds$ for $u, v \in [a, b]$; throughout this section $\|\cdot\|$ denotes the

Euclidean norm, and—with a slight abuse of notation—we will also use ℓ to denote the length of a curve or an interval. Given a twice continuously differentiable bijective mapping $r : [a,b] \to J$ (where $J \subset \mathbb{R}$ is an interval), γ can be reparametrized as a twice continuously differentiable function from J to X, by $\tilde{\gamma}(\ell) = \gamma(r^{-1}(\ell))$. In particular, when the mapping is $r(u) = \ell([a,u])$, that is, the curve is reparametrized by the curve length, we have $r^{-1}(\ell([a,u])) = u$ and $r'(u) = \|\gamma'(u)\| > 0$. Moreover, since $\ell = r(r^{-1}(\ell))$, we also have $1 = \frac{d\, r(r^{-1}(\ell))}{d\,\ell} = r'(u)\frac{d\, r^{-1}(\ell)}{d\,\ell}$ where $r(u) = \ell$. Thus, $\frac{d\, r^{-1}(\ell)}{d\,\ell} = \frac{1}{r'(u)} = \frac{1}{\|\gamma'(u)\|}$, and so

$$\|\tilde{\gamma}'(\ell)\| = \left\| \frac{d\,\gamma(r^{-1}(\ell))}{d\,\ell} \right\| = \left| \frac{d\, r^{-1}(\ell)}{d\,\ell} \right| \|\gamma'(u)\| = 1.$$

Thus, if the curve is parametrized by the its length, its gradient is always a unit vector. For the rest of this section, we always assume this parametrization.

A planar curve is a curve in a 2-dimensional plane. Given a point $\gamma(u)$ on the curve, one can compute its tangent vector in the plane by $\gamma'(u)$. Note that since γ is parametrized by its curve length, $\gamma'(u)$ is a unit vector. To measure how *curved* a planar curve is at point $\gamma(u)$, we define its curvature as

$$\kappa(\gamma(u)) = \left\| \frac{d\,\gamma'(u)}{d\,u} \right\| = \|\gamma''(u)\|_2.$$

Furthermore, since $\gamma'(u)$ is a unit vector,

$$0 = \frac{d\,1}{d\,u} = \frac{d\,\|\gamma'(u)\|^2}{d\,u} = \frac{d\,\langle \gamma'(u),\, \gamma'(u)\rangle}{d\,u} = 2\langle \gamma'(u),\, \gamma''(u)\rangle,$$

thus $\gamma'(u)$ is perpendicular to $\gamma''(u)$.

A.2.2 Manifolds, Tangent Plane, and Principal Curvature

A manifold M of dimension d is a Hausdorff topological space that is locally homeomorphic to $\mathbb{R}^d$. Given a convex body (a convex body is a compact, convex subset of $\mathbb{R}^d$ with non-empty interior) $\mathcal{W} \subset \mathbb{R}^d$, its boundary is a manifold $M = \mathrm{bd}(\mathcal{W})$ of dimension $d-1$. Assume that M is twice continuously differentiable, and let ζ denote the standard embedding map from M to $\mathcal{W}$.[5] Now let $\gamma_1, \gamma_2 : [-1,1] \to M$ be two curves (not necessarily parametrized by curve length), such that $\gamma_1(0) = \gamma_2(0) = w$. The two curves are equivalent at the point w if and only if their derivatives are equal at the point u, that is, $(\zeta \circ \gamma_1)'(0) = (\zeta \circ \gamma_2)'(0)$ and the tangent vector embedded in $\mathbb{R}^d$ associated with this equivalence class is $(\zeta \circ \gamma_1)'(0)$. The set of all the tangent vectors form the tangent space, denoted by $T_w M$ or $T_w \mathcal{W}$. One can verify that $T_w M$ is a $d-1$ dimensional hyperplane in $\mathbb{R}^d$. Note that this definition of tangent space is consistent with the 'natural' tangent plane in the Euclidean space $\mathbb{R}^3$.[6]

Since $T_w M$ is a $d-1$ dimensional hyperplane in $\mathbb{R}^d$, there exists a unique vector that is perpendicular to $T_w M$, is of length 1 and points outward of $\mathcal{W}$ (note that in this sense $M = \mathrm{bd}(\mathcal{W})$ is oriented): this vector is called the Gauss vector at point w for $\mathcal{W}$. The mapping $u_{\mathcal{W}} : \mathrm{bd}(\mathcal{W}) \to \mathbb{S}^{d-1}$ that maps every $w \in \mathrm{bd}(\mathcal{W})$ to the corresponding Gauss vector is called the Gauss map. Since M is twice continuously differentiable, the Gauss map $u_{\mathcal{W}}$ is continuously differentiable. One can actually show that $\nabla u_{\mathcal{W}}(w)$, the so-called Weingarten map, is a self-adjoint operator with nonnegative eigenvalues, which can be represented as a $(d-1)\times(d-1)$ positive semidefinite matrix. The eigenvalues of this matrix (or the self-adjoint operator) are called the principal curvatures of M at

5. A detailed discussion of manifolds including local charts and atlases can be found in Section 2.5 of the book of Schneider (2014), together with a formal definition of differentiability. To build the intuition required to follow the arguments in the paper it is sufficient to think of a manifold as the boundary of a convex body.
6. More generally, one can define the tangent space without embedding it to $\mathbb{R}^d$, but, for simplicity, we only consider here the definitions through the embedding ζ, which is always possible and allows to perform calculations in $\mathbb{R}^d$.

point w. Intuitively, how fast the Gauss map $u_{\mathcal{W}}$ changes characterizes the curvature of the manifold M. An interesting property of the operator $\nabla u_{\mathcal{W}}(w)$ is that it maps $T_w M$ to itself: for any unit vector $v \in T_w M$, $0 = \lim_{\epsilon\to 0} \frac{\partial 1}{\partial \epsilon} = \lim_{\epsilon\to 0} \frac{\partial \|u_{\mathcal{W}}(w+\epsilon v)\|_2^2}{\partial \epsilon} = 2\lim_{\epsilon\to 0}\langle \nabla u_{\mathcal{W}}(w+\epsilon v)v,\, u_{\mathcal{W}}(w+\epsilon v)\rangle = 2\langle \nabla u_{\mathcal{W}}(w)v,\, u_{\mathcal{W}}(w)\rangle$, thus $\nabla u_{\mathcal{W}}(w)v$ is perpendicular to $u_{\mathcal{W}}(w)$, thus belongs to $T_w M$.

A.3 Technical Proofs Related to Strongly Convex Sets and Principal Curvatures

Proof of Proposition 4 We show that (i) implies (ii), (ii) implies (iii), and (iii) implies (i). We start with showing that (i) implies (ii). First note that all principal curvatures of the d-dimensional ball $B = B_{1/\lambda}$ with radius $1/\lambda$ (centered at the origin) are λ. Therefore, (i) and Theorem 3.2.9 of Schneider (2014) implies that there is a convex body $\mathcal{M}$ such that $\mathcal{W} + \mathcal{M} = B$, where for two sets, $S_1, S_2 \subset \mathbb{R}^d$, $S_1 + S_2$ is defined as $\{s_1 + s_2 \,|\, s_1 \in S_1, s_2 \in S_2\}$. For any $\theta \in \mathbb{S}^{d-1}$, let $m_\theta \in \mathrm{argmax}_{m\in\mathcal{M}}\langle m, \theta\rangle$. Then clearly $w_\theta + m_\theta$ maximizes $\langle b, \theta\rangle$ for $b \in \mathcal{W} + \mathcal{M}$. Therefore, $\mathcal{W} + m_\theta$ is a subset of B and touches it at $w_\theta + m_\theta$, or equivalently $\mathcal{W} \subset B - m_\theta$ and they touch each other, and a tangent hyperplane with normal vector θ, in w_θ. This proves that (i) implies (ii).

Next we prove that (ii) implies (iii). Assuming (ii) holds, let $w \in \mathcal{W}$ be any point in the interior of $\mathcal{W}$, and let $p \in \mathrm{bd}(\mathcal{W})$ be the closest boundary point to w, and recall that $T_p\mathcal{W}$ is the tangent space of $\mathcal{W}$ at p. By construction, $B_{\|w-p\|_2}(w)$ touches the boundary of $\mathcal{W}$ at p (in the sense that they do not intersect, but they can have multiple common points), and so $w - p$ is orthogonal to $T_p\mathcal{W}$. Therefore, $B_{\|w-p\|_2}(w)$ also touches the boundary of the ball $B = B_{1/\lambda}(p + \frac{w-p}{\lambda\|w-p\|_2})$, which contains $\mathcal{W}$ by assumption (ii). Now consider any two points $x, y \in \mathcal{W}$ and $\gamma \in [0,1]$ such that $w = \gamma x + (1-\gamma)y$. Then the ball with radius $\lambda\gamma(1-\gamma)\|x-y\|_2^2/2$ centered at w is contained in B, since B is λ-strongly convex. But then its radius is at most $\|p - w\|_2$, and so it is also contained in $\mathcal{W}$. This shows that $\mathcal{W}$ is λ-strongly convex, thus (iii) holds.

To finish the proof of the proposition, assume (iii). To prove that (i) holds, we have to show that for any point w on $\mathrm{bd}(\mathcal{W})$ and for any unit vector $v \in T_w\mathcal{W}$, the curvature of the boundary along v is at least λ. Using the same notations as in Fig. 2 in Section 3.1, let P be the hyperplane spanned by v and the outer normal vector $u_{\mathcal{W}}(w)$ of $\mathcal{W}$ at point w, and consider the planar curve γ defined by $\mathrm{bd}(\mathcal{W}) \cap P$. Using v as the axis of a local 2-dimensional coordinate system, a point $\gamma(s)$ on the curve γ in the neighborhood of w can be expressed as $\gamma(s) = w + sv - f(s)u_{\mathcal{W}}(w)$, where w serves as the origin in the local coordinate system, f is the restriction of the function $f_w(sv)$ (see Section 3.1) to P (to simplify the notation, we denote it by $f(s)$, omitting v and w), and the curve γ is the epigraph of the function f, as in Fig. 9.

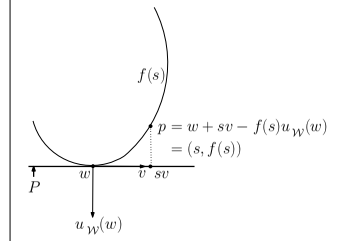

Figure 9: The local coordinate system at w.

Note that $f'(0) = 0$, and by Proposition 2.1 of Pressley (2010), the curvature of γ at p can be obtained as

$$\left.\frac{f''(s)}{\sqrt{1+f'(s)^2}^3}\right|_{s=0} = f''(0)\ .$$

Now since $w(s), w(-s) \in \mathcal{W}$ for a sufficiently small s, the strong convexity of $\mathcal{W}$ applied to $w(s)$ and $w(-s)$ with $\gamma = 1/2$ implies that $q = \frac{w(s)+w(-s)}{2} + \frac{\lambda}{8}\|w(s) - w(-s)\|_2^2 u \in \mathcal{W}$. Substituting the definition of $w(s)$ and $w(-s)$, we get

$$q = p - u\left[\frac{f(s)+f(-s)}{2} - \frac{\lambda}{8}\Big(4s^2 + (f(s)-f(-s))^2\Big)\right].$$

Therefore, $q \in \mathcal{W}$ implies $f(s) + f(-s) \geq \lambda s^2$, and so

$$f''(0) = \lim_{s \to 0} \frac{\frac{f(s)-f(0)}{s} - \frac{f(0)-f(-s)}{s}}{s} = \frac{f(s)+f(-s)}{s^2} \geq \lambda.$$

Thus (i) holds, finishing the proof of the proposition. ∎

Proof of a weakened variant of (6) based on strong convexity
Given θ_1 and θ_2, for any $0 < \gamma < 1$, define $\theta_\gamma = \gamma\theta_1 + (1-\gamma)\theta_2$ and

$$w_\gamma = \gamma w^{(1)} + (1-\gamma)w^{(2)} + \frac{\lambda_0}{2}\gamma(1-\gamma)\|w^{(1)} - w^{(2)}\|_2^2 \frac{\theta_\gamma}{\|\theta_\gamma\|_2} .$$

By the strong convexity of $\mathcal{W}$, $w_\gamma \in \mathcal{W}$, and so by the definition and convexity of the support function Φ, we have

$$\langle w_\gamma, \theta_\gamma \rangle \leq \Phi(\theta_\gamma) \leq \gamma\Phi(\theta_1) + (1-\gamma)\Phi(\theta_2) = \gamma\langle w^{(1)}, \theta_1\rangle + (1-\gamma)\langle w^{(2)}, \theta_2\rangle.$$

Plugging in the definitions of w_γ and θ_γ, and applying the Cauchy-Schwarz inequality, we obtain

$$\frac{\lambda_0}{2}\gamma(1-\gamma)\|w^{(1)} - w^{(2)}\|_2^2\|\theta_\gamma\|_2 \leq \gamma(1-\gamma)\langle \theta_1 - \theta_2, w^{(1)} - w^{(2)}\rangle \leq \gamma(1-\gamma)\|\theta_1 - \theta_2\|_2\|w^{(1)} - w^{(2)}\|_2 .$$

Rearranging and letting $\gamma \to 0$ implies

$$\|w^{(1)} - w^{(2)}\|_2 \leq \frac{2}{\lambda_0}\frac{\|\theta_1 - \theta_2\|_2}{\|\theta_2\|_2} .$$

Finally, the definition of $w^{(2)}$ and the Cauchy-Schwarz inequality yields

$$\begin{aligned}\langle w^{(1)} - w^{(2)}, \theta_1\rangle &\leq \langle w^{(1)} - w^{(2)}, \theta_1\rangle + \underbrace{\langle w^{(2)} - w^{(1)}, \theta_2\rangle}_{\geq 0} = \langle w^{(1)} - w^{(2)}, \theta_1 - \theta_2\rangle \\ &\leq \|w^{(1)} - w^{(2)}\|_2\|\theta_1 - \theta_2\|_2 \leq \frac{2}{\lambda_0}\frac{\|\theta_1 - \theta_2\|_2^2}{\|\theta_2\|_2}, \end{aligned} \tag{24}$$

finishing the proof. ∎

Proof of Example 1 We start with proving the last statement, part (iv), which implies the rest. Fix $w \in \mathrm{bd}(\mathcal{W})$. Note that $\phi'(w)$ is a normal vector at w for $\mathrm{bd}(\mathcal{W})$, thus $T_w\mathcal{W} = \{v : \langle v, \phi'(w)\rangle\}$. Then the Gauss map $u_\mathcal{W}$ of $\mathcal{W}$ satisfies $u_\mathcal{W}(w) = \frac{\phi'(w)}{\|\phi'(w)\|_2}$ for $w \in \mathrm{bd}(\mathcal{W})$. According to Schneider (2014, page 105), the principal curvatures of $\mathcal{W}$ at w are the eigenvalues of the Weingarten map $W_w(v)$, which is a linear map from $T_w\mathcal{W}$ to itself defined through the derivative of $u_\mathcal{W}$: $W_w(v) = \langle \frac{du_\mathcal{W}}{dw}, v\rangle$. In our case,

$$W_w(v) = \left\langle \frac{du_\mathcal{W}}{dw}, v \right\rangle = \frac{\nabla^2\phi(w)v}{\|\phi'(w)\|_2} - \frac{\phi'(w)\nabla^2\phi(w)\phi'(w)^\top v}{\|\phi'(w)\|_2^3} = \frac{\nabla^2\phi(w)v}{\|\phi'(w)\|_2} ,$$

where in the last step we used that $\phi'(w)$ is orthogonal to the tangent space $T_w\mathcal{W}$ (since it is parallel to the normal vector $u_\mathcal{W}(w)$), and $v \in T_w\mathcal{W}$. Therefore, the smallest principal curvature at w is the smallest eigenvalue $\min_{v \in \mathbb{S}^{d-1}:\langle \phi'(w), v\rangle = 0} \frac{v^\top\nabla^2\phi(w)v}{\|\phi'(w)\|_2}$. Taking minimum over all $w \in \mathrm{bd}(\mathcal{W})$ finishes the proof.

Now part (ii) follows for $\phi(w) = w^\top Q w$, as we need to minimize $v^\top Q v/\|w^\top Q\|_2$. It is easy to see that the denominator is maximized when $w \in \mathrm{bd}(\mathcal{W})$ is an eigenvector of Q corresponding to

$\lambda_{\max}$ (with length $1/\sqrt{\lambda_{\max}}$), and the numerator is minimized (for arbitrary $v \in \mathbb{S}^{d-1}$) when v is an eigenvector of Q corresponding to $\lambda_{\min}$. Since the two eigenvectors, w and v are orthogonal (or can be chosen to be orthogonal if they are not unique), v is orthogonal to $\phi'(w) = Qw = \lambda_{\max}w$, and hence it is a valid minimizer. This completes the proof of part (ii), and part (i) follows as a special case.

Part (iii) follows similarly: Due to symmetry, it is enough to consider w in the nonnegative quadrant (i.e., $w_i \geq 0$ for all i). Calculating the first and second derivatives of $\phi(w) = \|w\|_p = \left(\sum_{i=1}^d w_i^p\right)^{1/p}$, for any $w \in \mathrm{bd}(\mathcal{W})$ (i.e., $\|w\|_p = 1$), we obtain

$$\phi'(w) = \left(\sum_{i=1}^d w_i^p\right)^{1/p-1} w^{\odot(p-1)} = w^{\odot(p-1)} \quad \text{and} \quad \nabla^2\phi(w) = (p-1)\,\mathrm{diag}\left(w_1^{p-2}, \cdots, w_d^{p-2}\right).$$

When $p > 2$, picking $w = (1, 0, 0, \cdots, 0)$, one can easily verify that $\lambda_0 = 0$. For $1 < p \leq 2$, $|w_i|^{p-2} \geq 1$ since $|w_i| \leq 1$ by the assumption that $\|w\|_p = 1$. Thus, the minimum eigenvalue of $\mathrm{diag}\left(w_1^{p-2}, \cdots, w_d^{p-2}\right)$ is at least 1, and so $\lambda_0 \geq (p-1)/\|w^{\odot(p-1)}\|_2$ since $v^\top\,\mathrm{diag}\left(w_1^{p-2}, \cdots, w_d^{p-2}\right)v \geq 1$. Defining q via $1/p + 1/q = 1$, for any $w \in \mathrm{bd}(\mathcal{W})$ (i.e., with $\|w_p\| = 1$), Hölder's inequality implies

$$\|w^{\odot(p-1)}\|_2 \leq d^{\frac{1}{2}-\frac{1}{q}}\|w^{\odot(p-1)}\|_q = d^{\frac{1}{2}-\frac{1}{q}}\left(\sum_{i=1}^d w_i^{(p-1)q}\right)^{\frac{1}{q}} = d^{\frac{1}{2}-\frac{1}{q}}\left(\sum_{i=1}^d w_i^p\right)^{\frac{1}{q}} = d^{\frac{1}{2}-\frac{1}{q}} = d^{\frac{1}{p}-\frac{1}{2}} .$$

Thus, $\lambda_0 \geq (p-1)d^{\frac{1}{2}-\frac{1}{p}}$, as desired. ∎

A.4 Technical Lemmas for the Lower Bound, Theorem 9

Lemma 17 *Under the assumptions of Theorem 9, for any $0 < P_1, P_2 < 1$,*

$$\left\langle w^{P_2} - w^{P_1}, f^{P_1}\right\rangle \geq \frac{\lambda L}{2}\frac{\left(\frac{2P_2-2P_1}{\lambda L}\right)^2}{\sqrt{1 + \left(\frac{1-2P_1}{\lambda L}\right)^2\left(1 + \left(\frac{1-2P_2}{\lambda L}\right)^2\right)}} .$$

Proof It is easy to see that for any p, w^p is on the boundary of $\mathcal{W}$, that is, $w^p = \mathrm{argmin}_{w\in\mathcal{W}}\langle w, f^p\rangle = (\cos(\varphi^p), \lambda\sin(\varphi^p))$ for some φ^p. Then $\langle w^p, f^p\rangle = (2p-1)\cos(\varphi^p) - \lambda L\sin(\varphi^p)$, and so taking the derivative it is easy to verify that $\tan(\varphi^p) = \frac{\lambda L}{1-2p}$ and $\sin(\varphi^p) = \frac{\lambda L}{\sqrt{(\lambda L)^2 + (1-2p)^2}} > 0$. Thus, $1 - 2P_1 = \frac{\lambda L\cos(\varphi^{P_1})}{\sin(\varphi^{P_1})}$. To simplify notation, let $\varphi_1 = \varphi^{P_1}$ and $\varphi_2 = \varphi^{P_2}$. Then,

$$\begin{aligned}\left\langle w^{P_2} - w^{P_1}, f^{P_1}\right\rangle &= \left\langle \begin{pmatrix} \cos\varphi_2 - \cos\varphi_1 \\ \lambda(\sin\varphi_2 - \sin\varphi_1)\end{pmatrix}, \begin{pmatrix} \frac{-\lambda L\cos\varphi_1}{\sin\varphi_1} \\ -L\end{pmatrix}\right\rangle \\ &= -\lambda L\left((\cos(\varphi_2) - \cos(\varphi_1))\frac{\cos(\varphi_1)}{\sin(\varphi_1)} + (\sin(\varphi_2) - \sin(\varphi_1))\right) \\ &= \frac{-\lambda L}{\sin(\varphi_1)}\left(\cos(\varphi_2)\cos(\varphi_1) - \cos^2(\varphi_1) + \sin(\varphi_1)\sin(\varphi_2) - \sin^2(\varphi_1)\right) \\ &= \frac{\lambda L}{\sin(\varphi_1)}\left(1 - \cos(\varphi_2)\cos(\varphi_1) - \sin(\varphi_1)\sin(\varphi_2)\right) \\ &= \frac{\lambda L}{\sin(\varphi_1)}\left(1 - \cos(\varphi_1 - \varphi_2)\right) \\ &= \frac{\lambda L}{\sin(\varphi_1)}\left(\frac{1}{2}\left(\cos(\varphi_1 - \varphi_2) - 1\right)^2 + \frac{1}{2}\sin^2(\varphi_1 - \varphi_2)\right)\end{aligned}$$

$$\geq \frac{\lambda L}{2\sin(\varphi_1)}\sin^2(\varphi_1-\varphi_2)$$
$$= \frac{\lambda L}{2}\sin(\varphi_1)\sin^2\varphi_2\left(\cot(\varphi_1)-\cot(\varphi_2)\right)^2 .$$

The proof is finished by substituting $\cot(\varphi_i) = \frac{1-2P_i}{\lambda L}$, $\sin(\varphi_1) = \frac{1}{\sqrt{1+\left(\frac{1-2P_1}{\lambda L}\right)^2}}$ and $\sin^2(\varphi_2) = \frac{1}{1+\left(\frac{1-2P_2}{\lambda L}\right)^2}$. ■

Lemma 18 (Concentration of $\hat{P}_t$) *For any $u > 0$,*

$$\mathbb{P}\left[|\hat{P}_t - P| > \frac{K}{2K+t}|1-2P| + \frac{t}{2K+t}u \,\middle|\, P\right] \leq 2\exp(-tu^2) .$$

Proof Recall that $\hat{P}_t = \frac{K+\sum_{i=1}^t X_i}{2K+t}$. Thus,

$$\begin{aligned}\mathbb{P}\left[|\hat{P}_t - P| > u \,\middle|\, P\right] &= \mathbb{P}\left[\left|\frac{K+\sum_{i=1}^t X_i}{2K+t} - P\right| > \frac{K}{2K+t}|1-2P| + \frac{t}{2K+t}u \,\middle|\, P\right] \\ &= \mathbb{P}\left[\left|\sum_{i=1}^t X_i - Pt + K(1-2P)\right| > K|1-2P| + tu \,\middle|\, P\right] \\ &\leq \mathbb{P}\left[\left|\sum_{i=1}^t X_i - Pt\right| > tu \,\middle|\, P\right], \end{aligned} \tag{25}$$

where the last inequality is due to $\mathbb{P}\left[|A+b| > c\right] \leq \mathbb{P}\left[|A| > c - |b|\right]$. Note that conditioned on P, $X_1, \ldots, X_t$ are independent Bernoulli random variables with expectation P, thus (25) holds by Hoeffding's inequality (see, e.g., (Cesa-Bianchi and Lugosi, 2006, Corollary A.1)). ■

Lemma 19

$$\mathbb{E}\left[(P-\hat{P}_t)^2 \,\middle|\, P\right] = \frac{K^2(1-2P)^2}{(2K+t)^2} + \frac{tP(1-P)}{(2K+t)^2} .$$

Proof Recall that $\hat{P}_t = \frac{K+\sum_{i=1}^t X_i}{2K+t}$.Thus,

$$\begin{aligned}\mathbb{E}\left[(P-\hat{P}_t)^2 \,\middle|\, P\right] &= \mathbb{E}\left[\left(\frac{K(1-2P)}{2K+t} + \frac{\sum_{i=1}^t X_i - Pt}{2K+t}\right)^2 \,\middle|\, P\right] \\ &= \frac{K^2(1-2P)^2}{(2K+t)^2} + \frac{1}{(2K+t)^2}\mathbb{E}\left[\left(\sum_{i=1}^t X_i - tP\right)^2 \,\middle|\, P\right] \\ &= \frac{K^2(1-2P)^2}{(2K+t)^2} + \frac{tP(1-P)}{(2K+t)^2} ,\end{aligned}$$

where the second equality is due to $\mathbb{E}\left[\sum_{i=1}^t X_i - Pt \,\middle|\, P\right] = 0$, and the last equality is due to that conditioned on P, $\sum_{i=1}^t X_i$ has a Binomial distribution with parameters t and P. ■

Abstract

We study estimation properties of regularized procedures of the form

$$\hat{f} \in \operatorname*{argmin}_{f \in F} \Big(\frac{1}{N} \sum_{i=1}^{N} \big(Y_i - f(X_i)\big)^2 + \lambda \Psi(f) \Big)$$

for a convex class of functions F, regularization function $\Psi(\cdot)$ and some well chosen regularization parameter λ, where the given data is an independent sample $(X_i, Y_i)_{i=1}^N$.

We obtain bounds on the L_2 estimation error rate that depend on the complexity of the true model $F^* := \{f \in F : \Psi(f) \leq \Psi(f^*)\}$, where $f^* \in \operatorname{argmin}_{f \in F} \mathbb{E}(Y - f(X))^2$ and the (X_i, Y_i)'s are independent and distributed as (X, Y). Our estimate holds under weak stochastic assumptions – one of which being a small-ball condition satisfied by F – and for rather flexible choices of regularization functions $\Psi(\cdot)$. Moreover, the result holds in the learning theory framework: we do not assume any a-priori connection between the output Y and the input X.

As a proof of concept, we apply our general estimation bound to various choices of Ψ, for example, the ℓ_p and S_p-norms (for $p \geq 1$), weak-ℓ_p, atomic norms, max-norm and SLOPE. In many cases, the estimation rate almost coincides with the minimax rate in the class F^*.

Keywords: Empirical processes theory, high-dimensional Statistics, regularization, learning theory, minimax rates.

1. Introduction

In the standard learning framework, one would like to approximate / predict an unknown random variable Y using functions from a given class F, and to do so using only random data. To be more accurate, let $(\mathcal{X}, \mu)$ be a probability space and consider a class of functions F on $(\mathcal{X}, \mu)$. Let X be distributed according to μ and set $X_1, \ldots, X_N \in \mathcal{X}$ to be N independent copies of X.

Given an unknown random variable Y, let $\mathcal{D} = (X_i, Y_i)_{i=1}^N$ be a sample selected according to the joint distribution of (X, Y). One would like to use the data $\mathcal{D}$ and construct a (random) function $\hat{f}(\cdot) = \hat{f}(\mathcal{D}, \cdot) \in F$, with $\hat{f}(X)$ serving as a good guess of Y.

While there are various interpretations of the meaning of 'a good guess', the notion we will focus on here is as follows.

In a typical problem, very little is assumed on the target Y or on the measure μ; on the other hand, the class F is known and a typical assumption is that F **is convex and closed** in $L_2(\mu)$. Therefore, the functional $f \to \mathbb{E}(f(X) - Y)^2$ has a unique minimizer in F,

$$f^* = \operatorname*{argmin}_{f \in F} \mathbb{E}(Y - f(X))^2. \tag{1.1}$$

The notion of 'a good guess' is that $\hat{f}$ is close to f^* in $L_2(\mu)$, and one would like to obtain a high probability bound on the $L_2(\mu)$ distance of the form

$$\left\| \hat{f} - f^* \right\|_{L_2}^2 = \mathbb{E}\left[\big(f^*(X) - \hat{f}(X)\big)^2 | \mathcal{D} \right] \leq \alpha_N^2. \tag{1.2}$$

In this case, α_N^2 is called a *rate of convergence*, the *error rate* or the $L_2(\mu)$-*estimation rate* of the problem.

Clearly, one has to pay a price for allowing a rather general target Y. Also, to have any hope that $f^*(X)$ is reasonably close to Y, one has to consider large classes, leading to an error α_N^2 that is often too large to be of any use.

A possible way of bypassing the fact that F may be very large, is the classical approach to *regularization*, where a certain property one believes f^* to possess is emphasized by penalizing functions that do not have that property. The penalty is endowed via a *regularization function* $\Psi(\cdot)$, defined on an appropriate subspace $E \subset L_2(\mu)$ that contains F, and for which $\Psi(f^*)$ is believed to be small (though one does not know that for certain). As a consequence, regularization procedures are designed to fit the data and to have a small Ψ value at the same time. One way of achieving that is to search for functions in F that realize a good tradeoff between fitting that data, which is measured via an empirical loss function $P_N \ell_f$, and the size of the regularization term $\lambda \Psi(f)$.

Definition 1.1 *The Regularized Empirical Risk Minimization procedure (RERM) is defined by*

$$\hat{f} \in \operatorname*{argmin}_{f \in F} \big(P_N \ell_f + \lambda \Psi(f) \big), \tag{1.3}$$

where here and throughout the article, $P_N h$ denotes the empirical mean of h, ℓ_f is the loss function associated with f and λ is the so-called regularization parameter.

We only consider the square loss $\ell_f(x, y) = (y - f(x))^2$, and thus,

$$P_N \ell_f = \frac{1}{N} \sum_{i=1}^{N} (Y_i - f(X_i))^2.$$

A well known example to this, the "classical approach" to regularization, is the cubic smoothing spline that can be obtained with the choice

$$\Psi(f) = \int \big(f''(t)\big)^2 \, dt.$$

Another well-studied example is of the form

$$\Psi(f) = \int_{\mathbb{R}^d} \frac{\left|\bar{f}(t)\right|^2}{\bar{G}(t)} dt$$

where the integration is with respect to the Lebesgue measure, $\bar{f}$ is the Fourier transform of f and $\bar{G}$ is some positive function tending to zero when $|t|$ goes to infinity (cf. Girosi et al. (1995)). In fact, this type of regularization methods dates back to Tikhonov (Tikhonov (1943)) and is sometimes called Tikhonov regularization; it is also known as L_2-regularization or Ridge regularization (Golub et al. (1979)).

These methods and others like them have been used to "smooth" estimators that have poor generalization capability because of their tendency to over-fit the data, and for the corresponding regularization functions, having a small Ψ value is a guarantee of smoothness. We refer to Hastie et al. (2009) for other examples of regularization functions that have been used to "smooth" estimators.

We said "classical approach to regularization" because in the more modern approach the aim is somewhat different. One uses a penalty that seemingly has little to do with the property one wishes to emphasize (usually, some notion of *sparsity*). Yet somehow, almost magically, the penalty enhances a hidden property and the resulting error rate does not depend on $\Psi(f^*)$ but on that hidden property of f^*. We call such error rates **sparsity-dependent error rates**.

The first part of this article (Lecué and Mendelson (to appear)) has dealt with the modern approach to regularization. Here we would like to complete the picture by exploring bounds that depend on $\Psi(f^*)$ rather than on some hidden sparsity structure of f^*. Such error rates will be called **complexity-dependent error rates**, since the aim is to obtain rates of convergence that depend on the complexity of the unknown true model $\{f \in F : \Psi(f) \leq \Psi(f^*)\}$. Of course, the two approaches may sometimes be combined advantageously (see some examples below).

In this context, we will consider regularization functions that satisfy the following properties, which are more general than the ones considered in Lecué and Mendelson (to appear).

Assumption 1.1 *A function $\Psi : E \to \mathbb{R}_+$ is a regularization function if*

- *It is nonnegative, even, convex and $\Psi(0) = 0$.*
- *There is a constant $\eta \geq 1$, for which, for every $f, h \in E$,*

$$\Psi(f + h) \leq \eta(\Psi(f) + \Psi(h)).$$

- *For every $0 \leq \alpha \leq 1$ and $h \in E$, $\Psi(\alpha h) \leq \alpha \Psi(h)$.*

Remark 1.2 *Classical Model Selection regularization functions, such as the cardinality of the support of a vector or the rank of a matrix, are usually not convex and do not satisfy Assumption 1.1. Such examples are therefore not considered in what follows.*

1.1 Classical vs. modern

As mentioned above, the direction we take here is closely related to the classical approach to regularization and is rather different from the modern approach. To explain the differences we shall use the celebrated LASSO estimator (cf. Tibshirani (1996); Donoho and Johnstone (1994)) as an example.

Let F be a class of linear functionals on $\mathbb{R}^d$ of the form $\langle t, \cdot \rangle$. Set $t^* \in \operatorname{argmin}_{t \in \mathbb{R}^d} \mathbb{E}(Y - \langle X, t \rangle)^2$, and consider the RERM (1.3) with the ℓ_1^d-norm, $\|t\|_1 = \sum_{i=1}^d |t_i|$, serving as a regularization function. Let

$$\hat{t} \in \operatorname*{argmin}_{t \in \mathbb{R}^d} \left(\frac{1}{N} \sum_{i=1}^N \left(Y_i - \langle X_i, t \rangle \right)^2 + \lambda \|t\|_1 \right),$$

and the resulting minimizer is the LASSO estimator.

Estimation, de-noising, prediction and support recovery results have been obtained for the LASSO in the last decades (see, for example, Tibshirani (1996), Bickel et al. (2009), and the books Giraud (2015); Bühlmann and van de Geer (2011) and Koltchinskii (2011) for additional references).

The LASSO has been used in high-dimensional problems, in which the aim was to enhance a low-dimensional structure. The hope was that if the signal t^* were sparse (that is, supported on relatively few coordinates), the regularization procedure $\hat{t}$ would estimate t^* with an error rate depending on the cardinality of the support of t^*, denoted by $\|t^*\|_0 = |\{j \in \{1, \ldots, d\} : t_j^* \neq 0\}|$.

However, if t^* happens to be 'well-spread' rather than sparse, though with a reasonable ℓ_1^d norm, the sparsity-dependent error rate is useless, while a complexity-dependent error rate, which yields bounds in terms of $\|t^*\|_1$, is sharper. The obvious example is $t_1^* = (1/d, ..., 1/d)$ and $t_2^* = (1, 0, ..., 0)$: although $\|t_1^*\|_1 = \|t_2^*\|_1 = 1$, the cardinalities of their supports are very different, and sparsity-dependent error rates when $t^* = t_1^*$ are likely to be bad.

Examples of that nature are the reason why error rates combining both sparsity and complexity have been obtained for the LASSO. A typical example is Corollary 9.1 in Koltchinskii (2011). To formulate it, Let $W_1, \cdots, W_N$ be N independent, centered subgaussian variables with variance σ^2 and set $x_1, \ldots, x_N$ to be N deterministic vectors in $\mathbb{R}^d$. Assume that the design matrix, $\Gamma = N^{-1/2} \sum_{i=1}^N \langle x_i, \cdot \rangle e_i$, whose rows are $x_i/\sqrt{N}$, satisfies some Restricted Isometry Property (cf. Candès et al. (2006)). If $Y_i = \langle x_i, t^* \rangle + W_i$, $i = 1, \ldots, N$, then for a well chosen regularization parameter λ, one has, with high probability,

$$\mathbb{E}\langle X, \hat{t} - t^* \rangle^2 \leq C \min \left\{ \frac{\sigma^2 \|t^*\|_0 \log d}{n}, \sigma \|t^*\|_1 \sqrt{\frac{\log d}{n}} \right\} \tag{1.4}$$

for a suitable absolute constant C.

The error rate from (1.4) consists of two components: the sparsity-dependent error term $\sigma^2(\|t^*\|_0 \log d)/n$, and the complexity-dependent error term $\sigma \|t^*\|_1 \sqrt{(\log d)/n}$, and in what follows we will present a few other examples that combine the two rates – because the procedure one uses to obtain both types of rate is the same.

The aim of this article is to address the "complexity-based" aspect of the problem: to study regularization problems in which one believes that the $\Psi(f^*)$ is relatively small, and obtain an error rate that depends on $\Psi(f^*)$ rather than on some sparsity property of f^*.

1.2 Attaining Minimax rates

A natural benchmark for measuring the success of a regularization method is the minimax error rate, assuming that $\Psi(f^*)$ is known: if one is given additional information on $\Psi(f^*)$, e.g., that $f^* \in \{f : \Psi(f) \leq R\}$, one may consider the estimation problem in $\{f : \Psi(f) \leq R\}$ using the given random data. Such a problem has an optimal error rate (called the minimax rate): it is the best rate any learning procedure may achieve in the class $\{f : \Psi(f) \leq R\}$ given the random data $(X_i, Y_i)_{i=1}^N$. This minimax rate will serve as our benchmark, and will be compared with the error rates that we obtain.

Of course, one *is not* given additional information on $\Psi(f^*)$ and it is reasonable to expect that the error rate of the regularization procedure will be significantly slower than this benchmark. The question we shall study here focuses on that gap. In fact, we will show that the price one has to pay for not knowing $\Psi(f^*)$ is surprisingly small, under rather weak assumptions.

From a technical perspective, all regularization-based procedures share one crucial aspect: the calibration of the regularization parameter λ. That choice is very important as λ is an essential component in ensuring that the error rate of the estimator $\hat{f}$ is well-behaved. Thus, to study the gap between the regularization error rate and the minimax rate, one has to identify the right choice of λ.

Question 1.3 *What is the 'correct choice' of the regularization parameter λ, and given that choice, what is the rate of convergence of RERM? Specifically, how far is the resulting rate from the one that could have been achieved had $\Psi(f^*)$ been given in advance?*

An answer to Question 1.3 requires one to identify λ; to find a high probability upper bound on $\|\hat{f} - f^*\|_{L_2(\mu)}^2$ where $\hat{f}$ is defined in Definition 1.1 for that choice of λ; and then to compare the error rate to the minimax rate of the estimation problem in the class $\{f \in F : \Psi(f) \leq \Psi(f^*)\}$ (the so-called true model).

The strategy we use below follows a similar path to Lecué and Mendelson (to appear) and is based on the small ball method, introduced in Mendelson (2015, 2014); Koltchinskii and Mendelson (2015); Mendelson (To appear).

1.3 The small-ball method

Given a closed and convex class F and an unknown target Y, recall that $f^* \in F$ is a minimizer in F of the functional $f \to \mathbb{E}(f(X) - Y)^2$.

The excess loss functional associated with $f \in L_2(\mu)$ is

$$\begin{aligned} f \to \mathcal{L}_f(X,Y) =& \ell_f(X,Y) - \ell_{f^*}(X,Y) = (f(X) - Y)^2 - (f^*(X) - Y)^2 \\ =& (f - f^*)^2(X) + 2(f^*(X) - Y)(f - f^*)(X). \end{aligned} \tag{1.5}$$

Moreover, since F is closed and convex, then by the characterization of the nearest point map in a Hilbert space,

$$\mathbb{E}(f^*(X) - Y)(f - f^*)(X) \geq 0 \quad \text{for every } f \in F;$$

thus

$$\frac{1}{N}\sum_{i=1}^N (f^*(X_i) - Y_i)(f - f^*)(X_i) \geq \frac{1}{N}\sum_{i=1}^N (f^*(X_i) - Y_i)(f - f^*)(X_i) - \mathbb{E}(f^*(X) - Y)(f - f^*)(X). \tag{1.6}$$

Let E be a subspace that contains F and set $\Psi(\cdot)$ to be a regularization function on E (i.e., a functional that satisfies Assumption 1.1). Set $\rho \geq 0$ and put

$$K_\rho(f^*) = \{h \in E : \Psi(h - f^*) \leq \rho\},$$

which, by the convexity of Ψ, is a convex set.

Definition 1.4 *For every $\lambda > 0$ and any $f \in L_2(\mu)$, define the regularized excess loss by*

$$\mathcal{L}_f^\lambda = (\ell_f + \lambda\Psi(f)) - (\ell_{f^*} + \lambda\Psi(f^*)) = \mathcal{L}_f + \lambda\left(\Psi(f) - \Psi(f^*)\right).$$

Note that for every sample $(X_i, Y_i)_{i=1}^N$, a minimizer $\hat{f}$ of the empirical regularized loss functional (1.3) also minimizes in F the empirical regularized excess loss $f \to P_N\mathcal{L}_f^\lambda$. Hence, since $\mathcal{L}_{f^*}^\lambda = 0$, it follows that for every $(X_i, Y_i)_{i=1}^N$, the empirical regularized excess loss in $\hat{f}$ is non-positive:

$$P_N\mathcal{L}_{\hat{f}}^\lambda \leq 0. \tag{1.7}$$

This observation is at the heart of our analysis, as it allows one to exclude functions f in F that satisfy $P_N\mathcal{L}_f^\lambda > 0$ as potential minimizers of the empirical regularized loss function. Our strategy is therefore to show that if $f \in F$ and $\|f - f^*\|_{L_2(\mu)}$ is not 'too small', then necessarily $P_N\mathcal{L}_f^\lambda > 0$ (for the right choice of λ); hence, functions cannot be minimizers of the empirical regularized (excess) loss function.

To simplify notation, set $\xi = Y - f^*(X)$,

$$\mathcal{M}_{f-f^*}(X,Y) = \xi(f - f^*)(X) - \mathbb{E}\xi(f - f^*)(X) \quad \text{and} \quad \mathcal{Q}_{f-f^*}(X) = (f - f^*)^2(X);$$

therefore, combining (1.5) and (1.6),

$$P_N\mathcal{L}_f \geq P_N\mathcal{Q}_{f-f^*} - 2\left|P_N\mathcal{M}_{f-f^*}\right|. \tag{1.8}$$

The main step in the small-ball method is to find a lower bound on the quadratic process $f \to P_N\mathcal{Q}_{f-f^*}$ and an upper bound on $f \to |P_N\mathcal{M}_{f-f^*}|$. The two estimates should hold with high probability on certain subsets of F. Then, they have to be compared with the behaviour of the regularization term $\lambda(\Psi(f) - \Psi(f^*))$ on those sets to ensure that $P_N\mathcal{L}_f^\lambda > 0$.

A uniform lower bound on the quadratic component $P_N\mathcal{Q}_{f-f^*}$ can be obtained under the following small-ball condition:

Assumption 1.2 *Assume that there are constants $\kappa > 0$ and $0 < \varepsilon \leq 1$, for which, for every $f, h \in F$,*

$$Pr\left(|f(X) - h(X)| \geq \kappa \|f - h\|_{L_2(\mu)}\right) \geq \varepsilon.$$

There are numerous examples in which Assumption 1.2 may be verified for κ and ε that are absolute constants and we refer the reader to Mendelson (2014, 2015); Lecué and Mendelson (2017); Mendelson (To appear); Koltchinskii and Mendelson (2015); Rudelson and Vershynin (2015) for some of them.

To put Assumption 1.2 in some perspective, recall that the class $F = \{f_t = \langle \cdot, t\rangle : t \in \mathbb{R}^d\}$ is *identifiable* if for every $t_1, t_2 \in \mathbb{R}^d$, $Pr(f_{t_1} \neq f_{t_2}) > 0$, (where the probability is taken with respect to the underlying measure μ). By linearity, this condition is equivalent to assuming that for every $t \in \mathbb{R}^d$, $Pr(|\langle X, t\rangle| > 0) > 0$. Thus, the small-ball condition (which in this case implies that for every $t \in \mathbb{R}^d$, $Pr(|\langle X, t\rangle| \geq \kappa \|\langle X, t\rangle\|_{L_2}) \geq \varepsilon$) is simply a uniform estimate on the degree of identifiability of class F and is therefore a rather weak assumption from a statistical point of view.

Now, let us introduce two complexity parameters that play a central role in our analysis. Let D be the unit ball in $L_2(\mu)$ and for $r > 0$ set

$$rD_{f^*} = \{f \in L_2(\mu) : \|f - f^*\|_{L_2(\mu)} \leq r\} = f^* + rD.$$

Definition 1.5 *Given a class F of functions and $\tau > 0$, let*

$$r_Q(F, \tau) = r_Q(F, f^*, \tau) = \inf\left\{r > 0 : \mathbb{E} \sup_{f \in F \cap rD_{f^*}} \left|\frac{1}{N}\sum_{i=1}^N \varepsilon_i (f - f^*)(X_i)\right| \leq \tau r\right\},$$

where $(\varepsilon_i)_{i=1}^N$ are independent, symmetric, $\{-1, 1\}$-valued random variables that are also independent of $(X_i, Y_i)_{i=1}^N$.

Set

$$\phi_N(F, f^*, s) = \sup_{f \in F \cap sD_{f^*}} \left|\frac{1}{\sqrt{N}}\sum_{i=1}^N \varepsilon_i \xi_i (f - f^*)(X_i)\right| \tag{1.9}$$

and put

$$r_M(F, \tau, \delta) = r_M(F, f^*, \tau, \delta) = \inf\left\{s > 0 : Pr\left(\phi_N(F, f^*, s) \leq \tau s^2 \sqrt{N}\right) \geq 1 - \delta\right\}.$$

One may show the following (see Theorem 3.1 in Mendelson (2015)):

Theorem 1.6 *Let F be a closed, convex class of functions that satisfies Assumption 1.2 with constants κ and ε, and set $\theta = \kappa^2\varepsilon/16$. For every $\delta \in (0, 1)$, with probability at least $1 - \delta - 2\exp(-N\varepsilon^2/2)$ one has both:*

- *for every $f \in F$,*

$$|P_N \mathcal{M}_{f - f^*}| \leq \frac{\theta}{4} \max\left\{\|f - f^*\|^2_{L_2(\mu)}, r_M^2\left(F, \theta/5, \delta/4\right)\right\},$$

- *for every $f \in F$ with $\|f - f^*\|_{L_2(\mu)} \geq r_Q\left(F, \kappa\varepsilon/32\right)$,*

$$P_N \mathcal{Q}_{f - f^*} \geq \theta \|f - f^*\|^2_{L_2(\mu)}.$$

In particular, with probability at least $1 - \delta - 2\exp(-N\varepsilon^2/2)$, $P_N \mathcal{L}_f \geq \frac{\theta}{2}\|f - f^*\|^2_{L_2(\mu)}$ for every $f \in F$ that satisfies

$$\|f - f^*\|_{L_2(\mu)} \geq \max\left\{r_M\left(F, \theta/5, \delta/4\right), r_Q\left(F, \kappa\varepsilon/32\right)\right\}.$$

Remark 1.7 *An immediate outcome of Theorem 1.6 is that with high probability, a minimizer in F of the empirical excess-loss functional $P_N \mathcal{L}_f$ must satisfy*

$$\|\tilde{f} - f^*\|_{L_2(\mu)} \leq \max\left\{r_M\left(F, \theta/5, \delta/4\right), r_Q\left(F, \kappa\varepsilon/32\right)\right\}. \tag{1.10}$$

In fact, results from Lecué and Mendelson show that (1.10) is optimal in the minimax sense under additional mild technical assumptions on F when the data is assumed to satisfy the Gaussian regression model, that is, when the targets are of the form $Y = f_0(X) + W$ for $f_0 \in F$ and W that is a centered Gaussian random variable, independent of X. *Empirical risk minimization* performed in the set

$$F^* = \{f \in F : \Psi(f) \leq \Psi(f^*)\}$$

yields

$$\|\tilde{f} - f^*\|_{L_2} \leq \max\left\{r_M\left(F^*, \theta/5, \delta/4\right), r_Q\left(F^*, \kappa\varepsilon/32\right)\right\}, \tag{1.11}$$

and the r.h.s. of (1.11) is the minimax rate of the estimation problem in F^* (up to some mild technical assumptions). This will serve as a benchmark for the performance of the regularization procedure (1.3).

1.4 The Main result

Let $F \cap K_\rho(f^*) = \{f \in F : \Psi(f - f^*) \leq \rho\}$ and observe that these are convex subsets of F. To simplify notation, set

$$r_M(\rho) = r_M\left(F \cap K_\rho(f^*), \frac{\kappa^2\varepsilon}{80}, \frac{\delta}{4}\right) \text{ and } r_Q(\rho) = r_Q\left(F \cap K_\rho(f^*), \frac{\kappa\varepsilon}{32}\right). \tag{1.12}$$

Let $r(\cdot)$ be a function that satisfies that for every $\rho \geq 0$, one has

$$r(\rho) \geq \max\{r_M(\rho), r_Q(\rho)\}. \tag{1.13}$$

It should be noted that $r(\rho)$ may depend on f^*, and that it also depends on other parameters – like δ, κ and ε. We will not specify the dependence on those parameters, but rather, only on the radius ρ.

When sharp estimates on $r_M(\rho)$ and $r_Q(\rho)$ can be obtained, one may set $r(\rho)$ to be of the order of $\max\{r_M(\rho), r_Q(\rho)\}$ for the class $F \cap K_\rho(f^*)$. This choice leads to the rate appearing in Theorem 1.6 and in (1.10). As we mentioned previously, the rate $\max\{r_M(\rho), r_Q(\rho)\}$ is optimal in the minimax sense under additional mild technical assumptions on $F \cap K_\rho(f^*)$.

More information on the $r(\rho)$ may be found in Section 1 of Lecué and Mendelson or in Mendelson (2015).

AS it happens, the geometry of the sets $F \cap K_\rho(f^*)$ (see Figure 1) determines both the error rate and the regularization parameter λ, while $r(\rho)$ measures the sets' 'sizes'.

The choice of λ is made as follows:

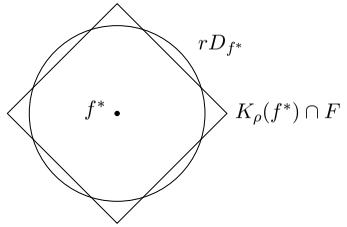

Figure 1: Localization of the set $F \cap K_\rho(f^*)$, i.e. its intersection with $L_2(\mu)$-balls of various radii r for the right choice of radius ρ, plays a central role in the analysis of the quadratic and multiplier processes.

Let

$$\mathcal{O}(\rho) = \sup\left(|P_N \mathcal{M}_{f-f^*}| : f \in F \cap K_\rho(f^*) \cap r(\rho) D_{f^*}\right)$$

and for $\tau > 0$ and $0 < \delta < 1$, set

$$\gamma_{\mathcal{O}}(\rho, \tau, \delta) = \inf\left\{x > 0 : Pr\left(\mathcal{O}(\rho) \leq \tau x\right) \geq 1 - \delta\right\}$$

and

$$\gamma_{\mathcal{O}}(\rho) = \gamma_{\mathcal{O}}(\rho, 3/(80\eta^3), \delta).$$

In other words, $\gamma_{\mathcal{O}}(\rho)$ is proportional to the smallest possible upper estimate on $\mathcal{O}(\rho)$ that still holds with probability at least $1 - \delta$.

Definition 1.8 *For any $\tau > 0$ and $0 < \delta < 1$, set*

$$\lambda_0(\delta, \tau) = \sup_{\rho > 0, f^* \in F} \frac{\gamma_{\mathcal{O}}(\rho, \tau, \delta)}{\rho}.$$

To compare $\lambda_0(\delta, \tau)$ with r_Q and r_M, first note that $r_M(\rho)$ and $\mathcal{O}(\rho)$ both depend on properties of the multiplier processes indexed by localizations of $F \cap K_\rho(f^*)$, and recall that symmetrized and centered processes are essentially equivalent. Second, if $r(\rho) = r_M(\rho)$ then $\gamma_{\mathcal{O}}(\rho) \sim r_M^2(\rho)$; moreover, $\gamma_{\mathcal{O}}(\rho)$ is trivially bounded by $\sim r^2(\rho)$ for the right choice of τ and δ. However, if $r_M(\rho) \leq r_Q(\rho)$, that is, when $r(\rho) = r_Q(\rho)$ – which is the case when ρ is very large – one may find that $\gamma_{\mathcal{O}}(\rho)$ is actually significantly smaller than $\sim r^2(\rho)$. This observation is of crucial importance because of the choice of the regularization parameter: for the right choice of τ, $\gamma_{\mathcal{O}}(\rho) \leq r^2(\rho)$ and

$$\lambda_0(\delta, \tau) \leq \sup_{\rho > 0, f^* \in F} r^2(\rho)/\rho;$$

thus, one may be tempted to select the latter as a regularization term. However, there are natural examples in which $\sup_{\rho>0} r^2(\rho)/\rho = \infty$, rendering that choice impossible, whereas $\sup_{\rho>0, f^* \in F} \gamma_{\mathcal{O}}(\rho)/\rho$ turns out to be finite. Of course, there are still cases in which $\sup_{\rho>0, f^* \in F} r^2(\rho)/\rho$ is finite, and $\lambda_0(\delta, \tau)$ is of the same order as $\sup_{\rho>0, f^* \in F} r_M^2(\rho)/\rho$, though that is not the generic situation.

We now come to the main result of the article.

Theorem 1.9 *Let F be a closed, convex class of functions that satisfies Assumption 1.2 with constants κ and ε. Set $\Psi(\cdot)$ to be a regularization function that satisfies Assumption 1.1 with constant η. Furthermore, assume that $\lim_{\rho \to 0} r(\rho) = 0$ and put $\lambda > \lambda_0(\delta, 3/(80\eta^3))$.*

If $\hat{f}$ is the RERM with a regularization parameter λ as in (1.3), then with probability at least $1 - 2\delta - 2\exp(-N\varepsilon^2/2)$,

$$\|\hat{f} - f^*\|_{L_2(\mu)}^2 \leq \max\left\{r^2\left(10\eta\Psi(f^*)\right), \left(\frac{32}{\kappa^2\varepsilon}\right)\lambda\Psi(f^*)\right\}. \tag{1.14}$$

Observe that λ_0 depends only on the oscillations of the multiplier process. Hence, if the problem is noise-free then $\lambda_0 = 0$, showing that any regularization parameter $\lambda > 0$ would do. Moreover, in that case $r_M(\rho) = 0$ and so one can choose $r(\rho) \geq r_Q(\rho)$ obtaining an error rate that depends only on $r_Q^2(10\eta\Psi(f^*))$.

As noted previously, if one considers empirical risk minimization performed in $F^* = \{f \in F : \Psi(f) \leq \Psi(f^*)\}$, the resulting error rate is $\|\tilde{f} - f^*\|_{L_2(\mu)}^2 \leq c_0 r^2(c\Psi(f^*))$ for a suitable absolute constant c_0 and a constant c that depends on κ, ε and δ; moreover, under some minor additional assumptions, that rate is optimal in the minimax sense (cf. Lecué and Mendelson) when one takes $r(\rho) \sim \max\left\{r_M(\rho), r_Q(\rho)\right\}$. Hence, up to constants involved, the first term in Theorem 1.9 is essentially the minimax rate that one can obtain if $\Psi(f^*)$ were known.

If one chooses $\lambda \sim \lambda_0(\delta, \tau)$ for $\tau = 3/(80\eta^3)$ then the second term in (1.14) is of the order of

$$\lambda\Psi(f^*) = \left(\sup_{\rho, f^*} \frac{\gamma_{\mathcal{O}}(\rho, \tau, \delta)}{\rho}\right) \cdot \Psi(f^*).$$

Note that for ρ that is of the order of $\Psi(f^*)$, one has

$$\frac{\gamma_{\mathcal{O}}(\rho, \tau, \delta)}{\rho} \cdot \Psi(f^*) \leq c_1 \gamma_{\mathcal{O}}(\rho, \tau, \delta) \leq c_2 r^2(c_3\Psi(f^*)),$$

which coincides with the first term, up to the constants involved. Thus, the price that one has to pay for not knowing $\Psi(f^*)$ is manifested in the need to take the supremum over all possible choices of ρ in the second term, rather than considering only the level $\rho \sim \Psi(f^*)$.

Thankfully, there are many natural cases in which that price is rather small, allowing for satisfactory outcomes of Theorem 1.9 that are close to the minimax rate.

2. Proof of Theorem 1.9

Before we present the proof, let us introduce some notation. Throughout, absolute constants or constants that depend on other parameters are denoted by c, C, c_1, c_2, etc., (and,

of course, we will specify when a constant is absolute and when it depends on other parameters). The values of these constants may change from line to line. The notation $x \sim y$ (resp. $x \lesssim y$) means that there exist absolute constants $0 < c < C$ for which $cy \leq x \leq Cy$ (resp. $x \leq Cy$). If $b > 0$ is a parameter, then $x \lesssim_b y$ means that $x \leq C(b)y$ for some constant $C(b)$ that depends only on b.

The normed space ℓ_p^d is $\mathbb{R}^d$ endowed with the norm $\|x\|_p = \left(\sum_j |x_j|^p\right)^{1/p}$; the corresponding unit ball is denoted by B_p^d and the unit Euclidean sphere in $\mathbb{R}^d$ is S^{d-1}.

Finally, from here on we write Pr and $\|\ \|_{L_2}$ without specifying the underlying measure.

The proof of Theorem 1.9 follows an almost identical path as the proof of Theorem 3.2 from Lecué and Mendelson (to appear). The differences between the two arguments are minor and their source is the fact that unlike Lecué and Mendelson (to appear), here we do not assume that Ψ is a norm. In Remark 2.2 we will outline how a version of Theorem 1.9 may be derived directly from Theorem 3.2 in Lecué and Mendelson (to appear) when Ψ is a norm.

Theorem 1.9 is an immediate outcome of the following lemma:

Lemma 2.1 *Let $\lambda_0 = \lambda_0(\delta, 3/(80\eta^3))$ and set $\lambda > \lambda_0$. If $\lim_{\rho\to 0} r(\rho) = 0$, $\rho \geq 5\eta\Psi(f^*)$ and $\rho > 0$, then with probability at least $1 - 2\delta - 2\exp(-N\varepsilon^2/2)$,*

$$\|\hat{f} - f^*\|_{L_2}^2 \leq \max\left\{r^2(\rho), (32/(\kappa^2\varepsilon))\lambda\Psi(f^*)\right\}.$$

To see how Lemma 2.1 can be used to conclude the proof of Theorem 1.9, observe that if $\Psi(f^*) > 0$, one may simply select $\rho = 5\eta\Psi(f^*)$ in the lemma. If, on the other hand, $\Psi(f^*) = 0$, let $(\gamma_n)_{n=1}^\infty$ be a positive sequence decreasing to 0 and set $\mathcal{A}_n = \{\|\hat{f} - f^*\|_{L_2} \leq \gamma_n\}$, which is a decreasing sequence of events. If $Pr(\mathcal{A}_n) \geq 1 - \nu$ for some $0 \leq \nu \leq 1$ and every n then $Pr(\{\hat{f} = f^*\}) \geq 1 - \nu$. Since $\lim_{\rho\to 0} r(\rho) = 0$, one may apply Lemma 2.1 to each member of a nonnegative sequence ρ_n that decreases to zero and for which $\gamma_n = r(\rho_n)$ decreases to zero. By Lemma 2.1, $Pr(\mathcal{A}_n) \geq 1 - 2\delta - 2\exp(-N\varepsilon^2/2)$ for every n and the proof of Theorem 1.9 follows.

Proof of Lemma 2.1. Fix f^* and set $\rho > 0$ that satisfies $\rho \geq 5\eta\Psi(f^*)$. Let

$$F_1 = \{f \in F : \Psi(f - f^*) \leq \rho\} = F \cap K_\rho(f^*),$$

and

$$F_2 = \{f \in F : \Psi(f - f^*) = \rho\}.$$

Clearly, F_1 is a convex set that contains f^*, and by the continuity of the real-valued function $t \to \Psi(f^* + t(f - f^*))$, every ray $[f^*, f)$ that originates in f^* and passes through some $f \in F\backslash F_1$ intersects F_2.

Let $\theta = \kappa^2\varepsilon/16$ and set

$$r_Q(\rho) = r_Q(F_1, \kappa\varepsilon/32) \quad \text{and} \quad r_M(\rho) = r_M(F_1, \theta/5, \delta/4).$$

There is an event $\mathcal{A}_0$ of probability at least $1-\delta-2\exp(-N\varepsilon^2/2)$, and for every $(X_i, Y_i)_{i=1}^N \in \mathcal{A}_0$ the following holds:

- If $f \in F_1$ and $\|f - f^*\|_{L_2} \geq r_Q(\rho)$ then

$$\frac{1}{N}\sum_{i=1}^N (f - f^*)^2(X_i) \geq \theta\|f - f^*\|_{L_2}^2.$$

- If $f \in F_1$ then

$$\left|\frac{1}{N}\sum_{i=1}^N \xi_i(f - f^*)(X_i) - \mathbb{E}\xi(f - f^*)(X)\right| \leq \frac{\theta}{4}\max\{\|f - f^*\|_{L_2}^2, r_M^2(\rho)\}.$$

In particular, if $f \in F_1$ and $\|f - f^*\|_{L_2} \geq r(\rho) \geq \max\{r_M(\rho), r_Q(\rho)\}$ then

$$P_N\mathcal{L}_f \geq \frac{\theta}{2}\|f - f^*\|_{L_2}^2.$$

By the choice of λ, there is an event $\mathcal{A}_1$ of probability at least $1 - \delta$ on which if $f \in F_1$ and $\|f - f^*\|_{L_2} \leq r(\rho)$, then

$$\left|\frac{2}{N}\sum_{i=1}^N \xi_i(f - f^*)(X_i) - \mathbb{E}\xi(f - f^*)(X)\right| < \frac{3}{80\eta^3}\lambda\rho < \frac{3}{5\eta}\lambda\rho. \tag{2.1}$$

Set $\mathcal{A} = \mathcal{A}_0 \cap \mathcal{A}_1$ and let $(X_i, Y_i)_{i=1}^N \in \mathcal{A}$. The proof now follows in three steps:

(1) Show that the functional $f \to P_N\mathcal{L}_f^\lambda$ is bounded from below – away from zero – in F_2.

(2) An outcome of (1) is that if $f \in F\backslash F_1$, $P_N\mathcal{L}_f^\lambda > 0$; hence, $\hat{f} \notin F\backslash F_1$.

(3) Finally, pin-point $\hat{f}$ within $F_1 = \{f \in F : \Psi(f - f^*) \leq \rho\}$.

Step 1. Fix $f \in F_2$ and note that by the 'triangle inequality' satisfied by Ψ,

$$\Psi(f) \geq \eta^{-1}\Psi(f - f^*) - \Psi(f^*).$$

Recall that $\eta^{-1}\Psi(f - f^*) \geq \eta^{-1}\rho \geq 5\Psi(f^*)$ and thus, $\Psi(f) - \Psi(f^*) \geq (3/5)\eta^{-1}\rho$. Hence, if $\|f - f^*\|_{L_2} \geq r(\rho)$ then

$$P_N\mathcal{L}_f^\lambda \geq (\theta/2)\|f - f^*\|_{L_2}^2 + \lambda\rho \cdot \frac{3}{5\eta} > 0.$$

On the other hand, by the choice of λ, if $\|f - f^*\|_{L_2} \leq r(\rho)$ then

$$\begin{aligned} P_N\mathcal{L}_f^\lambda &\geq -\left|\frac{1}{N}\sum_{i=1}^N \xi_i(f - f^*)(X_i) - \mathbb{E}\xi(f - f^*)(X)\right| + \lambda\left(\Psi(f) - \Psi(f^*)\right) \\ &\geq -\left|\frac{1}{N}\sum_{i=1}^N \xi_i(f - f^*)(X_i) - \mathbb{E}\xi(f - f^*)(X)\right| + \lambda\rho \cdot \frac{3}{5\eta} > 0. \end{aligned}$$

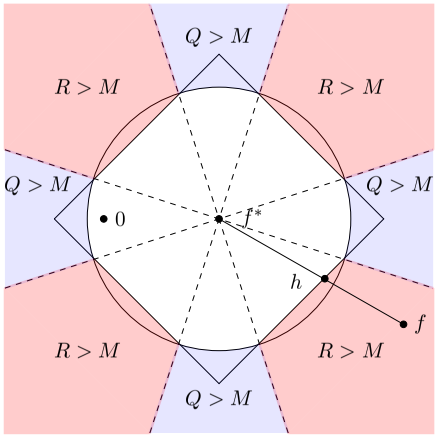

Figure 2: $P_N\mathcal{L}_f^\lambda > 0$ for two different reasons: either $Q > M$ – the quadratic component dominates the multiplier component, or $R > M$ – the regularization component dominates the multiplier component. Unlike Theorem 3.2 in Lecué and Mendelson (to appear), here we choose $\rho \sim \Psi(f^*)$ to ensure that $0 \in F \cap K_\rho(f^*)$.

It should be noted that the same proof shows that on the event $\mathcal{A}$, for every $f \in F_2$,

$$P_N\mathcal{L}_f + \frac{\lambda}{2\eta^2}(\Psi(f) - \Psi(f^*)) > 0, \tag{2.2}$$

a fact that will be used below. Indeed, $(\lambda/2\eta^2)\cdot(\Psi(f) - \Psi(f^*)) \geq (\lambda/2\eta^2)\cdot(3\rho/5\eta)$ and by (2.1), if $\|f - f^*\|_{L_2} \leq r(\rho)$ then $P_N\mathcal{L}_f \geq -(3/80)\cdot(\lambda\rho/\eta^3)$.

Step 2. Let $f \in F\backslash F_1$ and note that by the convexity of F and the continuity of Ψ on rays, there is some $h \in F_2$ and $R > 1$ for which $f = f^* + R(h - f^*)$. Thus,

$$P_N\mathcal{L}_f^\lambda = \frac{R^2}{N}\sum_{i=1}^N (h-f^*)^2(X_i) + \frac{2R}{N}\sum_{i=1}^N \xi_i(h-f^*)(X_i) + \lambda\left(\Psi(f) - \Psi(f^*)\right).$$

Observe that

$$\Psi(f) - \Psi(f^*) \geq \frac{R}{2\eta^2}\left(\Psi(h) - \Psi(f^*)\right); \tag{2.3}$$

indeed,

$$\Psi(f^* + R(h-f^*)) \geq \eta^{-1}\Psi(R(h-f^*)) - \Psi(f^*) \geq R\eta^{-1}\Psi(h-f^*) - \Psi(f^*),$$

and thus it suffices to show that

$$\frac{R}{\eta}\Psi(h-f^*) \geq \frac{R}{2\eta^2}\Psi(h) + 2\Psi(f^*).$$

But since $\Psi(h-f^*) \geq 5\eta\Psi(f^*)$, $\eta \geq 1$ and $R \geq 1$, one has

$$\begin{aligned}\frac{R}{\eta}\Psi(h-f^*) &\geq \frac{R}{2\eta}\Psi(h-f^*) + \frac{R}{2}\Psi(f^*) + 2R\Psi(f^*)\\ &\geq \frac{R}{2\eta}\left(\Psi(h-f^*) + \Psi(f^*)\right) + 2\Psi(f^*) \geq \frac{R}{2\eta^2}\Psi(h) + 2\Psi(f^*),\end{aligned}$$

and (2.3) follows.

Finally, applying (2.2) to $h \in F_2$,

$$\begin{aligned}P_N\mathcal{L}_f^\lambda &\geq \frac{R^2}{N}\sum_{i=1}^N (h-f^*)^2(X_i) + \frac{2R}{N}\sum_{i=1}^N \xi_i(h-f^*)(X_i) + \lambda\frac{R}{2\eta^2}\left(\Psi(h) - \Psi(f^*)\right)\\ &\geq R\left(P_N\mathcal{L}_h + \frac{\lambda}{2\eta^2}(\Psi(h) - \Psi(f^*))\right) > 0,\end{aligned}$$

and $\hat{f} \notin F\backslash F_1$.

Step 3. Turning to $F_1 = \{f \in F : \Psi(f-f^*) \leq \rho\} = F \cap K_\rho(f^*)$, recall that if $f \in F_1$ and $\|f - f^*\|_{L_2} \geq r(\rho)$, then $P_N\mathcal{L}_f \geq (\theta/2)\|f-f^*\|_{L_2}^2$; hence, if f is a potential minimizer and $\|f - f^*\|_{L_2} \geq r(\rho)$ then

$$0 \geq P_N\mathcal{L}_f^\lambda \geq (\theta/2)\|f-f^*\|_{L_2}^2 + \lambda\left(\Psi(f) - \Psi(f^*)\right) \geq (\theta/2)\|f-f^*\|_{L_2}^2 - \lambda\Psi(f^*),$$

and

$$\|\hat{f} - f^*\|_{L_2}^2 \leq \frac{2\lambda}{\theta}\Psi(f^*),$$

as claimed. ∎

Remark 2.2 *If Ψ happens to be a norm (which is an assumption slightly stronger than Assumption 1.1), one may apply Theorem 3.2 from Lecué and Mendelson (to appear) directly. Indeed, and using the notation from Lecué and Mendelson (to appear) if $\rho \gtrsim \Psi(f^*)$ then the set $K = \{f : \Psi(f-f^*) \leq \rho/20\}$ contains a Ψ-ball around 0, and $\Gamma_{f^*}(\rho)$ – the collection of norming functionals (i.e., the sub-gradient of Ψ) of any $h \in K$ – is the entire unit ball in the dual space to (E,Ψ). Recall that*

$$\Delta(\rho) = \inf_h \sup_{z^* \in \Gamma_{f^*}(\rho)} z^*(h - f^*),$$

where the infimum is taken in the set

$$\{h \in F : \ \Psi(h-f^*) = \rho \text{ and } \|h - f^*\|_{L_2} \leq r(\rho)\}.$$

Since $\Gamma_{f^*}(\rho)$ is the entire dual unit ball, it follows that $\Delta(\rho) = \rho$, and Theorem 3.2 in Lecué and Mendelson (to appear) may be applied. The desired version of Theorem 1.9 now follows from Remark 3.3 in Lecué and Mendelson (to appear).

3. Towards the examples - preliminary estimates

It is rather obvious that any implementation of Theorem 1.9 requires specific estimates on r_M, r_Q and λ_0. This section is devoted to some preliminary facts that will play an instrumental part in establishing such estimates.

Our main interest is the study of upper bounds on the three processes used to define the parameter r_M, r_Q and $\gamma_{\mathcal{O}}$, and which have the following forms:

$$(*)=\sup_{f\in F}\left|\sum_{i=1}^N \varepsilon_i\xi_i f(X_i)\right|,\quad (**)=\sup_{f\in F}\left|\sum_{i=1}^N (\xi_i f(X_i)-\mathbb{E}\xi f(X))\right| \text{ and } \mathbb{E}\sup_{f\in F}\left|\sum_{i=1}^N \varepsilon_i f(X_i)\right|,$$

where $X_1,...,X_N$ are independent and distributed according to the underlying measure μ, $\xi_1,...,\xi_N$ are independent copies of $\xi\in L_q$ for some $q>2$ (though $(\xi_i)_{i=1}^N$ need not be independent of $(X_i)_{i=1}^N$), and $(\varepsilon_i)_{i=1}^N$ are independent, symmetric $\{-1,1\}$-valued random variables that are independent of $(X_i)_{i=1}^N$ and $(\xi_i)_{i=1}^N$.

Standard symmetrization methods (see, e.g., Giné and Zinn (1984); Ledoux and Talagrand (1991); van der Vaart and Wellner (1996)) show that $(*)$ and $(**)$ are equivalent in expectation and in deviation (up to a slight restriction on the deviation parameter). We will present one example in which this symmetrization argument is carried out in full (Theorem 4.2), but in the other examples we will only consider the symmetrized case.

3.1 Estimates for subgaussian classes

The first result is from Mendelson (2016), under the assumption that F is an L-subgaussian class of functions.

Definition 3.1 *A class of functions $F\subset L_2(\mu)$ is L-subgaussian if for every $f,h\in F\cup\{0\}$ and every $u\geq 1$,*

$$Pr(|f(X)-h(X)|\geq Lu\|f-h\|_{L_2(\mu)})\leq 2\exp(-u^2/2),$$

where X is distributed according to μ.

Let $F\subset L_2(\mu)$ and set $\{G_f: f\in F\}$ to be the centered, canonical Gaussian process indexed by F (i.e., the covariance operator of the process is $\mathbb{E}G_fG_g=\mathbb{E}f(X)g(X)$ for every $f,g\in F$). Put

$$\ell^*(F)=\mathbb{E}\sup_{f\in F}G_f,\quad\text{and}\quad d_2(F)=\sup_{f\in F}\|f\|_{L_2(\mu)}. \tag{3.1}$$

Theorem 3.2 (Corollary 1.10 in Mendelson (2016)) *Let X be distributed according to μ, set $\xi\in L_q$ for some $q>2$ and assume that $F\subset L_2(\mu)$ is an L-subgaussian class. There are constants c,c_0,c_1,c_2 and c_3 that depend only on q, for which, for any $w,u>c$, with probability at least*

$$1-\frac{c_0\log^q N}{w^qN^{q/2-1}}-2\exp\left(-c_1u^2(\ell^*(F)/d_2(F))^2\right),$$

$$\sup_{f\in F}\left|\frac{1}{N}\sum_{i=1}^N \varepsilon_i\xi_i f(X_i)\right|\leq c_2Lwu\|\xi\|_{L_q}\frac{\ell^*(F)}{\sqrt{N}}$$

and

$$\sup_{f\in F}\left|\frac{1}{N}\sum_{i=1}^N \xi_i f(X_i)-\mathbb{E}\xi f(X)\right|\leq c_2Lwu\|\xi\|_{L_q}\frac{\ell^*(F)}{\sqrt{N}}.$$

Corollary 3.3 *Using the notation and assumptions of Theorem 3.2, let $\xi=Y-f^*(X)$ and assume that $\xi\in L_q$ for some $q>2$. Fix $\tau>0$ and $0<\delta<1$, and set $A>0$ for which*

$$c_2Lwu\|\xi\|_{L_q}\ell^*\left(F\cap AD_{f^*}\right)\leq\tau A^2\sqrt{N}. \tag{3.2}$$

If

$$\delta\geq\frac{c_0\log^q N}{w^qN^{q/2-1}}+2\exp\left(-c_1a_0u^2\right) \tag{3.3}$$

then $r_M(F,\tau,\delta)\leq A$.

Proof. Clearly, it follows from Theorem 3.2 that if

$$\delta\geq\frac{c_0\log^q N}{w^qN^{q/2-1}}+2\exp\left(-c_1u^2\left(\frac{\ell^*(F\cap AD_{f^*})}{d_2(F\cap AD_{f^*})}\right)^2\right)$$

then $r_M(F,\tau,\delta)\leq A$. The claim follows because if $F\cap AD_{f^*}$ is nonempty,

$$\frac{\ell^*(F\cap AD_{f^*})}{d_2(F\cap AD_{f^*})}\geq a_0$$

for a suitable absolute constant a_0. ∎

Remark 3.4 *The estimate in Corollary 3.3 can be rather loose. The reason for the suboptimal estimate is that usually, the Gaussian mean-width $\ell^*(F\cap AD_{f^*})$ is much larger than $d_2(F\cap AD_{f^*})$. For example, let $F=\{\langle t,\cdot\rangle: t\in S^{d-1}\}$ be the class of linear functionals on $\mathbb{R}^d$ indexed by the Euclidean unit ball. Assume that X is an isotropic vector – that is, its covariance structure coincides with the standard Euclidean structure on $\mathbb{R}^d$; that $f^*=0$; and that $A\leq 1$. Then $F\cap AD_{f^*}=\{\langle t,\cdot\rangle: \|t\|_2\leq A\}$, $d_2(F\cap AD_{f^*})=A$ and $\ell^*(F\cap AD_{f^*})=A\sqrt{d}$, implying that*

$$\frac{\ell^*(F\cap AD_{f^*})}{d_2(F\cap AD_{f^*})}\geq\sqrt{d} \tag{3.4}$$

which is significantly larger than an absolute constant.

Having said that, the question of an accurate probability estimate is not the main issue of this article and we will not explore that point further.

Next, we provide an estimate on $\gamma_{\mathcal{O}}(\rho,\tau,\delta)$ that follows from Theorem 3.2 when F is L-subgaussian and $\xi\in L_q$ for some $q>2$. The proof is identical to the one of Corollary 3.3 and is omitted.

Corollary 3.5 *Let F be a closed, convex L-subgaussian class of functions and let $\xi = Y - f^*(X) \in L_q$ for some $q > 2$. Set $w, u > c$, $\tau > 0$, $0 < \delta < 1$ and $\rho > 0$. If $A > 0$ satisfies*

$$c_2 Lwu \, \|\xi\|_{L_q} \, \ell^*\left(F \cap K_\rho(f^*) \cap r(\rho) D_{f^*}\right) \leq \tau A \sqrt{N}.$$

and

$$\delta \geq \frac{c_0 \log^q N}{w^q N^{q/2-1}} + 2\exp\left(-c_1 a_0 u^2\right)$$

then $\gamma_{\mathcal{O}}(\rho, \tau, \delta) \leq A$.

Finally, when F is an L-subgaussian class it follows from a standard chaining argument (cf. Talagrand (2005) or Mendelson (2016)) that

$$\mathbb{E} \sup_{f \in F} \left| \frac{1}{N} \sum_{i=1}^N \varepsilon_i f(X_i) \right| \leq \frac{c_0 L \ell^*(F)}{\sqrt{N}}. \tag{3.5}$$

This observation will be used in what follows to upper bound r_Q.

3.2 Estimates under a limited moment condition

In this section we shall consider the case of a class that need not be subgaussian, but rather, the growth of moments of class members is well-behaved up to some point. More accurately, we will assume that there is some p_0 for which, for every $f, h \in F \cup \{0\}$ and $2 \leq p \leq p_0$,

$$\|f - h\|_{L_p} \leq L\sqrt{p} \|f - h\|_{L_2}. \tag{3.6}$$

In contrast, a subgaussian condition is equivalent to having $\|f - h\|_{L_p} \leq L\sqrt{p}\|f - h\|_{L_2}$ for every $p \geq 2$.

The motivation behind this type of limited moment assumption is the LASSO estimator. Recent results on properties of the *basis pursuit algorithm* in $\mathbb{R}^d$ Lecué and Mendelson (2017); Dirksen et al. (2014) indicate that the limited moment assumption (3.6) for $p_0 \sim \log d$ should suffice for an optimal estimate on the performance of the LASSO – as if the class were subgaussian.

When analyzing the LASSO via the computation of the fixed points r_M and r_Q, one encounters the following scenario. Let $X = (x_j)_{j=1}^d$ be a random vector in $\mathbb{R}^d$ and set $X_1, \ldots, X_N$ to be independent copies of X. Let $X_i(j)$ be the j-th coordinate of X_i and thus $(X_i(j))_{i=1}^N$ is a random vector with independent coordinates, distributed as x_j.

Consider the random variables appearing in the definition of r_M and r_Q in the LASSO case:

$$\max_{1 \leq j \leq d} \left| \sum_{i=1}^N \varepsilon_i X_i(j) \right|, \tag{3.7}$$

and

$$\max_{1 \leq j \leq d} \left| \sum_{i=1}^N \varepsilon_i \xi_i X_i(j) \right| \tag{3.8}$$

The aim of this section is to derive upper bounds on (3.7) in expectation and (3.8) in deviation when each x_j satisfies that

$$\|x_j\|_{L_p} \leq L\sqrt{p}\|x_j\|_{L_2}$$

for $p \lesssim \log d$. Note that an upper bound on the centered empirical process involved in the definition of $\gamma_{\mathcal{O}}(\rho)$ will follow from a symmetrization argument and a bound on (3.8).

The obvious difference between (3.7) and (3.8) are the multipliers $(\xi_i)_{i=1}^N$: although the x_j's have $\sim \log d$ moments, ξ may be heavy-tailed, in the sense that it only belongs to L_q for some fixed $q > 2$; this difference makes the analysis of (3.8) more difficult.

Upper bounds on (3.7) and (3.8) are obtained under the following assumption.

Assumption 3.1 *Let $N \leq d$, $t \geq 4$ and set $p_0 = t \log d$. Assume that $p_0 \lesssim N$ (and note that $p_0 \geq \log N$) and that for every $1 \leq j \leq d$ and $p \leq p_0$, $\|x_j\|_{L_p} \leq L\sqrt{p}\|x_j\|_{L_2}$. Consider $\xi \in L_q$ for some $q > 2$; let $r = \min\{1/2 + q/4, 2\}$; set r' to be the conjugate index of r; and assume that $4r' \max\{2, 1 + a_0/a_1\} \leq t \log N$ (where a_0 and a_1 are two absolute constants to be specified later – in Lemma 7.3 and Lemma 7.4).*

Under this assumption we will prove the following:

Theorem 3.6 *Let the random vector X and $\xi = Y - f^*(X)$ satisfy Assumption 3.1. Then,*

$$\mathbb{E} \max_{1 \leq i \leq d} \left| \frac{1}{\sqrt{N}} \sum_{i=1}^N \varepsilon_i X_i(j) \right| \leq c_0 \sqrt{\log d} \cdot L \max_{1 \leq j \leq d} \|x_j\|_{L_2}. \tag{3.9}$$

Also, for every $u > 2, v > 0, w \geq 2$ and for $p = p_0/2$ and $m = p/\log(eN/p)$, one has that with probability at least

$$1 - \frac{\exp(-p/2)}{u^{2p}} - \frac{4\exp(-p/2)}{u^{c_1 m}} - \frac{c_2 \log^q N}{w^q N^{q/2-1}} - 2\exp(-v^2 t \log d), \tag{3.10}$$

$$\max_{1 \leq j \leq d} \left| \sum_{i=1}^N \varepsilon_i \xi_i X_i(j) \right| \leq c_3(q)(uw + u^2 v) L \|\xi\|_{L_q} \sqrt{N} \sqrt{t \log d} \max_{1 \leq j \leq d} \|x_j\|_{L_2}. \tag{3.11}$$

The proofs of both estimates in Theorem 3.6 follow from a more general result, established in Mendelson (2016), on the supremum of a centered multiplier process under a limited moment assumption like (3.6). Although the estimate in Mendelson (2016) is stated for the centered empirical process (cf. Section 4 there) its proof is actually based on an estimate on the symmetrized process. The proof of Theorem 3.6 will be presented in a final section of this article.

4. The LASSO under a limited moment assumption

In this section, we obtain complexity-dependent error rates for the LASSO. Our aim is to show that the LASSO (almost) achieves the minimax rates of convergence in the true model. Observe that in this case, the true model is the smallest ℓ_1^d-ball centered at 0 that contains t^*. Thus, the price one has to pay for not knowing $\|t^*\|_1$ is rather minimal.

The rate we shall be comparing the LASSO's performance to is the minimax rate of the following problem. Let $X \sim \mathcal{N}(0, I_{d\times d})$ and set $\xi \sim \mathcal{N}(0,\sigma^2)$ to be independent of X. Let $\rho > 0$, consider an unknown $t_0 \in \rho B_1^d$ and put $Y = \langle X, t_0\rangle + \xi$.

Let c_0, c_1 and c_2 be well-chosen absolute constants and consider the cases $\log d \le N \le c_0 d$ or $c_1 d \le N$. Following Lecué and Mendelson, if

$$s_M^2(\rho) = c_2 \begin{cases} \frac{\sigma^2 d}{N} & \text{if } \rho^2 N \ge \sigma^2 d^2 \\ \rho\sigma\sqrt{\frac{1}{N}\log\left(\frac{e\sigma d}{\rho\sqrt{N}}\right)} & \text{if } \sigma^2 \log d \le \rho^2 N \le \sigma^2 d^2 \\ \rho\sigma\sqrt{\frac{\log d}{N}} & \text{if } \rho^2 N \le \sigma^2 \log d \end{cases} \quad \text{and} \quad s_Q^2(\rho) \begin{cases} = 0 & \text{if } N \ge c_0 d \\ \lesssim \rho^2/d & \text{if } c_0 d \le N \le c_1 d \\ \sim \frac{\rho^2}{N}\log\left(\frac{d}{N}\right) & \text{if } N \le c_1 d, \end{cases}$$

then the minimax rate of convergence in the class ρB_1^d is

$$\max\left\{s_M^2(\rho), s_Q^2(\rho)\right\} \tag{4.1}$$

when $\rho \ge \sigma\sqrt{(\log d)/N}$ and ρ^2 when $\rho \le \sigma\sqrt{(\log d)/N}$. Note that when $c_0 d \le N \le c_1 d$ (i.e. $N \sim d$), $s_Q^2(\rho)$ decays rapidly from $\frac{\rho^2}{N}\log(d/N)$ to 0 and there are no precise estimates on the minimax rate in that range.

It turns out that for this problem – the so-called Gaussian linear model – the minimax rate in ρB_1^d is achieved by the Empirical Risk Minimization procedure (see, e.g., Lecué and Mendelson); however, an underlying assumption is that ρ is given. Thanks to regularization, and specifically, thanks to the LASSO, one does not need to know the value of $\|t_0\|_1$ in advance to achieve the minimax rate, at least up to a logarithmic term. In fact, as will be explained below, the optimal rate can be achieved using regularization in a much more general framework than just the Gaussian linear model.

In what follows we focus on the performance of the LASSO in the high-dimensional case, that is, when $N \le c_1 d$. One may do the same when $N \ge c_0 d$ and we leave that to the reader.

Let X be a random vector in $\mathbb{R}^d$ and consider the class of linear functionals $F = \{f_t = \langle\cdot, t\rangle : t \in \mathbb{R}^d\}$. In particular, if $Y \in L_2$ is an arbitrary target random variable then $f^* = f_{t^*} = \langle\cdot, t^*\rangle$ satisfies

$$t^* \in \operatorname*{argmin}_{t\in\mathbb{R}^d} \mathbb{E}\big(Y - \langle X, t\rangle\big)^2. \tag{4.2}$$

As noted in the introduction, the regularization function associated with the LASSO is the ℓ_1^d-norm: for every $t = (t_j)_{j=1}^d \in \mathbb{R}^d$,

$$\Psi(f_t) = \|t\|_1 = \sum_{j=1}^d |t_j|.$$

Clearly, as a norm, the ℓ_1^d-regularization function satisfies Assumption 1.1 for $\eta = 1$.

The LASSO with regularization parameter λ produces

$$\hat{t} \in \operatorname*{argmin}_{t\in\mathbb{R}^d}\Big(\frac{1}{N}\sum_{i=1}^N \big(Y_i - \langle X_i, t\rangle\big)^2 + \lambda\|t\|_1\Big), \tag{4.3}$$

and one would like to control $\|f_{\hat{t}} - f_{t^*}\|_{L_2}^2 = \mathbb{E}\langle X, \hat{t} - t^*\rangle^2$, where the expectation is taken with respect to X conditionally on the data.

It should be noted that despite the LASSO's popularity, there are relatively few results in the random design scenario we are interested in (see, e.g., Bartlett et al. (2012), Massart and Meynet (2011) and chapter 8.2 in Koltchinskii (2011)). The overwhelming majority of existing results have been obtained for the linear model with subgaussian noise and a fixed design (i.e., each data point is of the form $Y_i = \langle t^*, z_i\rangle + \xi_i$), and the deterministic design matrix, whose rows are the vectors z_i, which satisfies some form of the *restricted isometry property* – for example, the *Restricted Eigenvalue Condition* (REC) from Bickel et al. (2009) or the *Compatibility Condition* (CC) from van de Geer (2007)).

To define the restricted eigenvalue condition, let us introduce the following notation: for $x \in \mathbb{R}^d$ and a set $S_0 \subset \{1,\dots,d\}$ of cardinality $|S_0| \le s$, let S_1 be the set of indices of the m largest coordinates of $(|x_i|)_{i=1}^d$ that are outside S_0. Let $x_{S_{01}}$ be the restriction of x to the set $S_{01} = S_0 \cup S_1$.

Definition 4.1 (Bickel et al. (2009)) *Let Γ be an $N \times d$ matrix. For $c_0 \ge 1$ and an integer $1 \le s \le m \le d$ for which $m + s \le d$, the* ***restricted eigenvalue constant*** *is*

$$\kappa(s, m, c_0) = \min\left\{\frac{\|\Gamma x\|_2}{\|x_{S_{01}}\|_2} : S_0 \subset \{1,\dots,d\}, |S_0| \le s, \left\|x_{S_0^c}\right\|_1 \le c_0\|x_{S_0}\|_1\right\}.$$

The matrix Γ satisfies the ***Restricted Eigenvalue Condition (REC) of order s with a constant c*** *if $\kappa(s, s, 3) \ge c$.*

One can show (see, Bickel et al. (2009), Bühlmann and van de Geer (2011)) that if Γ satisfies REC and $\lambda \gtrsim \sigma\sqrt{(\log d)/N}$, then with high probability (with respect to the noise), simultaneously for every $1 \le p \le 2$,

$$\left\|\hat{t} - t^*\right\|_p^p \lesssim_p \|t^*\|_0\left(\frac{\sigma}{\kappa(s,s,3)}\sqrt{\frac{\log d}{N}}\right)^p \tag{4.4}$$

where $\|t^*\|_0$ is the cardinality of the support of t^*.

The main result in this section is an estimate on $\|\hat{f} - f^*\|_{L_2}^2$ that depends on $\|t^*\|_1$ rather than on the cardinality of the support of t^* (we refer to Lecué and Mendelson (to appear) for sparsity-dependent rates of convergence for the LASSO in the same framework as we consider here). Such a result follows from Theorem 1.9, and to that end, one has to construct a function $r(\cdot)$ as in (1.13) and to compute $\lambda_0(\delta,\gamma)$ as in Definition 1.8. We will do so in the following case: Set $a_2 \ge 4$, $2 \le p_0 = a_2 \log d \lesssim N$, $q > 2$, $r = \min\{1/2 + q/4, 2\}$ and r' that is the conjugate index of r. Assume that $4r'\max\{2, 1 + a_0/a_1\} \le a_2 \log N$ (which is equivalent to assuming that $q > 2 + c_1/\log N$ for some constant $c_1 = c_1(a_0, a_1, a_2)$). Let $X = (x_j)_{j=1}^d$ be a random vector and note that the coordinates $x_1, ..., x_d$ need not be independent.

Assumption 4.1 *Using the above notation, assume that there are constants κ_0, κ and ε for which the following holds:*

- *For every* $1 \le j \le d$ *and every* $2 \le p \le p_0$, $\|x_j\|_{L_p} \le \kappa_0 \sqrt{p}\, \|x_j\|_{L_2}$.
- X *satisfies a small-ball condition with constants* κ *and* ε*; that is, for every* $t \in \mathbb{R}^d$,

$$Pr\left(|\langle X, t\rangle| \ge \kappa \left\|\langle X, t\rangle\right\|_{L_2} \right) \ge \varepsilon. \tag{4.5}$$

- $\xi = Y - f^*(X) \in L_q$.

To put this assumption in some perspective, note that an obvious underlying condition in any estimation problem with respect to the squared loss is that $\mathbb{E}(f(X)-Y)^2$ is defined for any $f \in F$, and in particular, that $\xi = Y - f^*(X) \in L_2$. Thus, assuming that $\xi \in L_q$ for some $q > 2 + c_1/\log N$ is not very restrictive. Also, as noted previously, the small-ball assumption is rather minimal.

The most restrictive component of Assumption 4.1 is the moment assumption on the coordinates of X, namely that their moments exhibit a subgaussian behavior, up to, roughly, $p \sim \log d$.

While this assumption can be weakened to other types of moment growth condition (e.g., $\|x_j\|_{L_p} \le \kappa_0 p^\alpha \|x_j\|_{L_2}$ for some $\alpha \ge 1/2$ and up to $p \sim \log d$), the resulting analysis is more involved (see Lecué and Mendelson (2017)), and will not be explored here.

Finally, Lecué and Mendelson (2017) shows that even if one assumes a subgaussian behavior of the coordinates x_i, but only up to $p \sim (\log d)/(\log\log d)$, Basis Pursuit may fail to recover even a 1-sparse vector, implying that the choice of p_0 in Assumption 4.1 can not be relaxed significantly.

Given any $\rho \ge 0$, set $M = \max_{1\le j\le d} \|x_j\|_{L_2}$, let $\sigma_q = \|\xi\|_q$ and put

$$\Lambda(\rho) = \frac{\kappa_0 \rho M}{\kappa^2 \varepsilon} \sqrt{\frac{\log d}{N}}.$$

Moreover, for $R(t) = \mathbb{E}(Y - \langle X, t\rangle)^2$, one has

$$R(t) - R(t^*) = \mathbb{E}\langle X, t - t^*\rangle^2,$$

because $\langle X, t^*\rangle$ is the best approximation of Y in a closed subspace of L_2. Thus, the estimation bounds also lead to excess risk bounds.

Theorem 4.2 *There are absolute constants* $c_0, ..., c_6$ *for which the following holds. Assume that* X *and* $\xi = Y - f^*(X)$ *satisfy Assumption 4.1 and that* $N \le d$. *Let* $u > 2, v > 0$ *and* $w \ge 2$, *and set* $p = (a_2/2)\log d$ *and* $m = p/\log(eN/p)$. *Put*

$$\delta = \frac{\exp(-p/2)}{u^{2p}} - \frac{4\exp(-p/2)}{u^{c_0 m}} - \frac{c_1 \log^q N}{w^q N^{q/2-1}} - 2\exp(-v^2 t \log d) \tag{4.6}$$

and set

$$r^2(\rho) = c_2 \begin{cases} (uw + u^2 w)\sigma_q \Lambda(\rho) & \text{if } N \ge (\kappa\varepsilon/32)^2 d \\ \max\left\{ (uw + u^2 v)\sigma_q \Lambda(\rho), \kappa^2 \Lambda^2(\rho) \right\} & \text{otherwise.} \end{cases}$$

If $\hat{t}$ *is produced by the LASSO for a regularization parameter*

$$\lambda > c_4(uw + u^2 v)\kappa_0 \|\xi\|_{L_q} \eta^3 M \sqrt{\frac{\log d}{N}},$$

then with probability at least $1 - 5\delta - 2\exp(-\varepsilon^2 N/2)$,

$$R(\hat{t}) - R(t^*) = \left\|\langle X, \hat{t} - t^*\rangle\right\|_{L_2}^2 \le c_5 \max\left\{ r^2(c_6 \|t^*\|_1), \frac{\lambda}{\kappa^2 \varepsilon} \|t^*\|_1 \right\}.$$

Observe that like known estimates on the LASSO, and despite imposing considerably weaker assumptions on X and Y, the regularization parameter in Theorem 4.2 is of the order of $\|\xi\|_{L_q}\sqrt{(\log d)/N}$. And, when $\|\xi\|_{L_q}$ is equivalent to σ – the L_2 norm of ξ – then for $N \lesssim d$, the rate of convergence is

$$c(M) \max\left\{ \sigma \|t^*\|_1 \sqrt{\frac{\log d}{N}}, \|t^*\|_1^2 \frac{\log d}{N} \right\}$$

for a constant $c(M)$ that depends only on M.

Hence, up to a logarithmic factor, the LASSO attains the minimax rate in $\|t^*\|_1 B_1^d$ when $\log d \le N \lesssim d$ and when $\|t^*\|_1 \ge \sigma\sqrt{\log d/N}$; moreover, it does so without knowing in advance the identity of the true model $\|t^*\|_1 B_1^d$.

Note that one may want to combine the sparsity-dependent error rate from Theorem 1.3 in Lecué and Mendelson (to appear) and the complexity-dependent error rate from Theorem 4.2. To simplify the formulation we assume that X is subgaussian, in which case the probability estimate in Theorem 4.2 can be improved and the third condition in Assumption 4.1 (i.e. that $q > 2 + c_1/\log N$) can be relaxed to only $q > 2$ (see more details in the next section, and, in particular, Theorem 5.4). Combining the two approaches, one has that when X is isotropic and L-subgaussian, and when $\xi \in L_q$ for some $q > 2$ then for any $u, w > c$ with probability larger than $1 - \delta$ for

$$\delta = 2\exp(-c_2 N/L^8) - \frac{c_0 \log^q N}{w^q N^{q/2-1}} - c_0 \exp(-c_1 u^2/L^2),$$

the LASSO estimator $\hat{t}$ with the universal regularization parameter $\|\xi\|_{L_q}\sqrt{(\log d)/N}$ satisfies that

$$\left\|\hat{t} - t^*\right\|_2^2 \lesssim_{L,q} \min\left\{ \frac{\|t^*\|_0 \sigma^2 \log d}{N}, \max\left\{ \sigma \|t^*\|_1 \sqrt{\frac{\log d}{N}}, \|t^*\|_1^2 \frac{\log d}{N} \right\} \right\} \tag{4.7}$$

when $N \gtrsim \|t^*\|_0 \log(d/\|t^*\|_0)$.

Observe that (4.7) seemingly exhibits a different rate than Corollary 9.1 in Koltchinskii (2011) (see also (1.4)), the difference being the extra (and necessary) $\|t^*\|_1^2 \frac{\log d}{N}$ term in (4.7). This extra term appears only in the random design scenario, and the rates of convergence of the LASSO appear to deteriorate when

$$\sigma\sqrt{\frac{N}{\log d}} \le \|t^*\|_1 \le \sigma\sqrt{\|t^*\|_0}. \tag{4.8}$$

However, the sparsity-dependent error rate, and therefore Equation (4.7), holds only when $N \gtrsim \|t^*\|_0 \log(d/\|t^*\|_0)$. And, when $N \gtrsim \|t^*\|_0 \log d$ (which is only slightly larger than $\|t^*\|_0 \log(d/\|t^*\|_0)$), the error rates in the two scenarii (random and deterministic design) are the same and are given by

$$\min\left\{\frac{\sigma^2 \|t^*\|_0 \log d}{N}, \sigma \|t^*\|_1 \sqrt{\frac{\log d}{N}}\right\}.$$

Proof of Theorem 4.2. As noted previously, since $\|\cdot\|_1$ is a norm, $\Psi(t) = \|t\|_1$ satisfies Assumption 1.1 for $\eta = 1$ and Theorem 1.9 may be applied. To that end, one has to control $r(\rho) \equiv \max\{r_M(\rho), r_Q(\rho)\}$ and $\lambda_0(\delta,\tau)$. In what follows we will invoke the results of Section 3 and estimate these parameters.

Set $F(f^*,\rho) = F \cap K_\rho(f^*) - f^*$ and recall that $r_Q(\rho) = r_Q(F \cap K_\rho(f^*), \kappa\varepsilon/32)$ is determined by the behavior of

$$(\star) = \mathbb{E} \sup_{f \in F(f^*,\rho)\cap rD} \left|\frac{1}{\sqrt{N}} \sum_{i=1}^N \varepsilon_i f(X_i)\right|; \tag{4.9}$$

as a consequence, it suffices to upper bound $(\star)$. Let $\mathcal{E} = \{t \in \mathbb{R}^d : \mathbb{E}\langle X,t\rangle^2 \le 1\}$, put $\mathcal{E}^\circ$ to be the polar of $\mathcal{E}$ (that is, $\mathcal{E}^\circ = \{u : \sup_{t\in\mathcal{E}} |\langle u,t\rangle| \le 1\}$), and set $\|t\|_{\mathcal{E}} = \sup_{x\in\mathcal{E}}\langle x,t\rangle$. Thus,

$$(\star) = \mathbb{E} \sup_{t\in\rho B_1^d \cap r\mathcal{E}} \left|\frac{1}{\sqrt{N}} \sum_{i=1}^N \varepsilon_i\langle X_i,t\rangle\right| \le \min\left\{\mathbb{E}\sup_{t\in\rho B_1^d}\left|\frac{1}{\sqrt{N}} \sum_{i=1}^N \varepsilon_i\langle X_i,t\rangle\right|, \mathbb{E}\sup_{t\in r\mathcal{E}}\left|\frac{1}{\sqrt{N}} \sum_{i=1}^N \varepsilon_i\langle X_i,t\rangle\right|\right\}$$
$$= \min\left\{\rho\mathbb{E}\left\|\frac{1}{\sqrt{N}} \sum_{i=1}^N \varepsilon_i X_i\right\|_{\ell_\infty^d}, r\mathbb{E}\left\|\frac{1}{\sqrt{N}} \sum_{i=1}^N \varepsilon_i X_i\right\|_{\mathcal{E}^\circ}\right\}.$$

It is standard to verify (see, for instance, the proof of Lemma 2.2 in Lecué and Mendelson (2016)) that

$$\mathbb{E}\left\|\frac{1}{\sqrt{N}} \sum_{i=1}^N \varepsilon_i X_i\right\|_{\mathcal{E}^\circ} \le \sqrt{d}.$$

Moreover, by (3.9),

$$\mathbb{E}\left\|\frac{1}{\sqrt{N}} \sum_{i=1}^N \varepsilon_i X_i\right\|_{\ell_\infty^d} = \mathbb{E}\max_{1\le j\le d}\left|\frac{1}{\sqrt{N}} \sum_{i=1}^N \varepsilon_i X_i(j)\right| \le c_0\kappa_0\sqrt{\log d}\max_{1\le j\le d}\|x_j\|_{L_2}.$$

Therefore,

$$(\star) \le \min\left\{c_0\rho\kappa_0\sqrt{\log d}\max_{1\le j\le d}\|x_j\|_{L_2}, r\sqrt{d}\right\}, \tag{4.10}$$

and setting $\gamma = \kappa\varepsilon/32$, one has

$$r_Q(\rho) \le \begin{cases} 0 & \text{if } N \ge \gamma^2 d \\ \frac{c_0\rho\kappa_0}{\gamma}\sqrt{\frac{\log d}{N}}M & \text{otherwise.}\end{cases}$$

Next, let us establish a high probability upper bound on $r_M(\rho) = r_M(F\cap K_\rho(f^*), \kappa^2\varepsilon/80, \delta/4)$. Note that

$$\phi_N(F\cap K_\rho(f^*), f^*, s) = \sup_{t\in\rho B_1^d\cap s\mathcal{E}}\left|\frac{1}{\sqrt{N}}\sum_{i=1}^N \varepsilon_i\xi_i\langle X_i,t\rangle\right| \le \rho\max_{1\le j\le d}\left|\frac{1}{\sqrt{N}}\sum_{i=1}^N \varepsilon_i\xi_i X_i(j)\right|.$$

Applying the second part of Theorem 3.6 for $u > 2, v > 0$, $w \ge 2$, $p = (a_2/2)\log d, m = p/\log(eN/p)$ and

$$\delta = \frac{\exp(-p/2)}{u^{2p}} - \frac{4\exp(-p/2)}{u^{c_0 m}} - \frac{c_1\log^q N}{w^q N^{q/2-1}} - 2\exp(-v^2 t\log d), \tag{4.11}$$

it follows that with probability at least $1-\delta$,

$$\phi_N(F\cap K_\rho(f^*), f^*, s) \le c_2\kappa_0(uw+u^2v)\|\xi\|_{L_q}\rho M\sqrt{\log d};$$

thus,

$$r_M^2(\rho) \le \frac{c_3\kappa_0(uw+u^2v)}{\kappa^2\varepsilon}\|\xi\|_{L_q}\rho M\sqrt{\frac{\log d}{N}}.$$

Finally, let us identify an upper bound on $\lambda_0(\delta,\tau)$ for $\tau = 3/(80\eta^3)$. Let $\{e_1,\dots,e_d\}$ be the canonical basis of $\mathbb{R}^d$. Since $K_\rho(f^*) = \{t : \|t-t^*\|_1 \le \rho\}$, we have

$$(\star_1) = \sup_{f\in F\cap K_\rho(f^*)\cap r(\rho)D_{f^*}}\left(\frac{1}{N}\sum_{i=1}^N \xi_i(f-f^*)(X_i) - \mathbb{E}\xi(f-f^*)(X)\right)$$
$$\le \rho\max_{t-t^*\in\{\pm e_1,\dots,\pm e_d\}}\left(\frac{1}{N}\sum_{i=1}^N \xi_i\langle X_i,t-t^*\rangle - \mathbb{E}\xi\langle X,t-t^*\rangle\right)$$
$$= \rho\max_{t\in\{\pm e_1,\dots,\pm e_d\}}\left(\frac{1}{N}\sum_{i=1}^N \xi_i\langle X_i,t\rangle - \mathbb{E}\xi\langle X,t\rangle\right).$$

Recall that $X = (x_j)_{j=1}^d$. By a standard symmetrization argument (see, for example, Lemma 2.3.7 in van der Vaart and Wellner (1996)), if $z \ge 4\max_{1\le j\le d}\sqrt{\mathrm{Var}(\xi x_j)/N}$ then

$$Pr\Big(\max_{t\in\{\pm e_1,\dots,\pm e_d\}}\frac{1}{N}\sum_{i=1}^N \xi_i\langle X_i,t\rangle - \mathbb{E}\xi\langle X,t\rangle \ge z\Big) \le 4Pr\Big(\max_{t\in\{\pm e_1,\dots,\pm e_d\}}\frac{1}{N}\sum_{i=1}^N \varepsilon_i\xi_i\langle X_i,t\rangle \ge \frac{z}{4}\Big).$$

Note that $\sqrt{\mathrm{Var}(\xi x_j)} \le \sqrt{\mathbb{E}\xi^2 x_j^2} \le \|\xi\|_{L_q}\|x_j\|_{L_{2q'}}$ where q' is the conjugate index of $q/2$. Therefore, $\sqrt{\mathrm{Var}(\xi x_j)} \le \kappa_0\sqrt{2q'}\|\xi\|_{L_q}M$ as long as $2q' \le a_2\log d$, i.e., when $q \ge 2+$

$2/(a_2 \log d - 1)$ – which is the case under Assumption 4.1. Therefore, applying the second part of Theorem 3.6 for δ as in (4.11), it follows that with probability at least $1-\delta$,

$$(\star_1) \leq \rho c_0 \kappa_0 (uw + u^2 v) \|\xi\|_{L_q} M \sqrt{\frac{\log d}{N}},$$

and, for $\tau = 3/(80\eta^3)$ one may select

$$\lambda_0(\delta, \tau) = c_4 \kappa_0 (uw + u^2 v) \|\xi\|_{L_q} \eta^3 w M \sqrt{\frac{\log d}{N}}.$$

■

5. Regularization methods for subgaussian classes

In this section, we assume that X is a random vector that takes its values in a Hilbert space $\mathcal{H}$. The main examples we consider are when $\mathcal{H}$ is the d-dimensional Euclidean space and when it is the space of $m \times T$ matrices endowed with the Frobenius norm.

The inner product in $\mathcal{H}$ is denoted by $\langle \cdot, \cdot \rangle$, and the norm and unit ball endowed by the inner product are denoted by $\|\cdot\|_{\mathcal{H}}$ and $B_{\mathcal{H}} = \{t \in \mathcal{H} : \|t\|_{\mathcal{H}} \leq 1\}$ respectively.

There is another natural Hilbertian structure on $\mathcal{H}$, endowed by $\Sigma = \mathbb{E} X X^{\top}$, the covariance operator associated with the random vector X. The corresponding unit ball $\mathcal{E} = \{t \in \mathcal{H} : \mathbb{E}\langle X, t\rangle^2 \leq 1\}$, is an ellipsoid in $\mathcal{H}$.

Let $T \subset \mathcal{H}$ be a closed and convex set and put

$$t^* \in \operatorname*{argmin}_{t \in T} \mathbb{E}(Y - \langle X, t\rangle)^2.$$

Let $\Psi(\cdot)$ be a regularization function on $\mathcal{H}$ that satisfies Assumption 1.1 and set

$$\hat{t} \in \operatorname*{argmin}_{t \in T} \left(\frac{1}{N} \sum_{i=1}^N \left(Y_i - \langle X_i, t\rangle\right)^2 + \lambda \Psi(t) \right) \tag{5.1}$$

for a well-chosen regularization parameter λ.

Unlike the results of the previous section, in what follows we assume that $F = \{\langle t, \cdot \rangle : t \in T\}$ is an L-subgaussian class (see Definition 3.1). Moreover, F satisfies a small-ball property with constants that depend only on L. Indeed, observe that for every $t \in T$

$$\|\langle X, t\rangle\|_{L_4} \lesssim L \|\langle X, t\rangle\|_{L_2},$$

and applying the Paley-Zygmund inequality (see, e.g., Corollary 3.3.2 in de la Peña and Giné (1999)),

$$Pr\left(|\langle X, t\rangle| \geq \kappa \|\langle X, t\rangle\|_{L_2} \right) \geq \varepsilon \text{ for } \kappa = 1/2 \text{ and } \varepsilon = c/L^4. \tag{5.2}$$

From here on we say that the random vector X taking its values in $\mathcal{H}$ is L-subgaussian if the class consisting of all the linear functionals on $\mathcal{H}$, i.e., $\{\langle t, \cdot \rangle : t \in \mathcal{H}\}$, is L-subgaussian. Also, throughout this section, we assume that $\xi = Y - f^*(X) \in L_q$ for some $q > 2$, and denote $\sigma_q = \|\xi\|_{L_q}$ and

$$T \cap K_\rho(t^*) = \{t \in T : \Psi(t - t^*) \leq \rho\}.$$

5.1 'Heavy tailed' noise

Thanks to the subgaussian assumption, both $r(\rho)$ and $\lambda_0 = \lambda_0(\delta, 3/(80\eta^3))$ may be determined using the Gaussian mean-widths of the sets $T \cap K_\rho(t^*)$ for all $\rho > 0$. Recall that for $T_0 \subset \mathcal{H}$ the Gaussian mean-width of T_0 is $\ell^*(T_0) = \mathbb{E}\sup_{t \in T_0} G_t$, where $(G_t)_{t \in T_0}$ is the centered canonical Gaussian process indexed by T_0 with covariance structure given by $\mathbb{E} G_{t_1} G_{t_2} = \mathbb{E}\langle X, t_1\rangle \langle X, t_2\rangle$ for every $t_1, t_2 \in T$.

Definition 5.1 *Let $r\mathcal{E}_{t^*} = \left\{t \in \mathcal{H} : \|\langle t - t^*, \cdot\rangle\|_{L_2(\mu)} \leq r\right\} = t^* + r\mathcal{E}$, and for $\alpha, \beta > 0$ set*

$$\tilde{r}_Q(\rho, \alpha) = \inf\left\{ r > 0 : \ell^*\left(T \cap K_\rho(t^*) \cap r\mathcal{E}_{t^*}\right) \leq \alpha r \sqrt{N} \right\}$$

and

$$\tilde{r}_M(\rho, \beta) = \inf\left\{ r > 0 : \ell^*\left(T \cap K_\rho(t^*) \cap r\mathcal{E}_{t^*}\right) \leq \beta r^2 \sqrt{N} \right\}.$$

Let c_0 be an absolute constant to be specified later. Fix $u, w > c$, and ε and κ as in (5.2). Consider

$$\alpha = \frac{\kappa \varepsilon}{c_0 L}, \quad \beta = \frac{\kappa^2 c_1 \varepsilon}{Lwu \|\xi\|_{L_q}}, \quad \text{and} \quad \gamma = c_0 \eta^3 L w u \|\xi\|_{L_q}, \tag{5.3}$$

put

$$r(\rho) \geq \max\left\{\tilde{r}_Q(\rho, \alpha), \tilde{r}_M(\rho, \beta)\right\} \tag{5.4}$$

and set

$$\lambda_0(\gamma) = \gamma \sup_{\rho > 0, t^* \in T} \frac{\ell^*\left(T \cap K_\rho(t^*) \cap r(\rho)\mathcal{E}_{t^*}\right)}{\rho \sqrt{N}}. \tag{5.5}$$

The first result we present is rather general and holds for any closed and convex subset $T \subset \mathcal{H}$ and any regularization function satisfying Assumption 1.1. It allows one to take into account an additional constraint on the "signal" $t^* \in T$.

Theorem 5.2 *There are absolute constants c, c_1 and c_2 for which the following holds. Let Ψ be a regularization function satisfying Assumption 1.1. Assume that X is L-subgaussian for some $L > 0$ and that $\xi = Y - \langle X, t^*\rangle$ is in L_q for some $q > 2$.*

If $\hat{t}$ is given by (5.1) for a regularization parameter $\lambda > \lambda_0(\gamma)$ as in (5.5), then with probability larger than

$$1 - 2\exp(-N\varepsilon^2/8) - \frac{c_0 \log^q N}{w^q N^{q/2-1}} - c_0 \exp(-c_1 u^2/L^2), \tag{5.6}$$

$$\|\langle X, \hat{t} - t^*\rangle\|_{L_2}^2 \leq \max\left\{ r(10\eta\Psi(t^*))^2, (32/\kappa^2\varepsilon)\lambda\Psi(t^*) \right\}$$

for $r(\cdot)$ given by (5.4).

Proof. The proof follows from Theorem 1.9 by estimating $r(\rho)$ and λ_0 using the 'local' Gaussian mean-widths of the sets $T \cap K_\rho(t^*)$.

Since X is L-subgaussian, the process $\{\langle X,t\rangle : t\in\mathcal{H}\}$ is L-subgaussian. Setting $F=\{\langle t,\cdot\rangle : t\in\mathcal{H}\}$ and $f^*=\langle t^*,\cdot\rangle$, a standard chaining argument shows that

$$\mathbb{E}\sup_{f\in F\cap K_\rho(f^*)\cap rD_{f^*}}\Big|\frac{1}{N}\sum_{i=1}^N\varepsilon_i(f-f^*)(X_i)\Big|\le c_0L\frac{\ell^*(T\cap K_\rho(t^*)\cap r\mathcal{E}_{t^*})}{\sqrt{N}}.$$

Thus,

$$r_Q\Big(F\cap K_\rho(f^*),\frac{\kappa\varepsilon}{32}\Big)\le\tilde{r}_Q(\rho,\alpha). \tag{5.7}$$

As for the fixed point associated with the multiplier process, it follows from Corollary 3.3 that

$$r_M\Big(F\cap K_\rho(f^*),\frac{\kappa^2\varepsilon}{160},\frac{\delta}{4}\Big)\le\tilde{r}_M(\rho,\beta) \tag{5.8}$$

for β as defined in (5.3), and as long as

$$\frac{\delta}{4}\ge\frac{c_0\log^q N}{w^qN^{q/2-1}}+2\exp(-c_1u^2/L^2).$$

Finally by Corollary 3.5, $\lambda_0(\delta,\gamma)\le\lambda_0(\gamma)$. The claim now follows from Theorem 1.9. ∎

If one is to apply Theorem 5.2, an essential component is an upper bound on $\ell^*(T\cap K_\rho(t^*)\cap r\mathcal{E}_{t^*})$, leading to estimates on r and λ. To simplify the analysis we shall use an additional assumption on Ψ:

Assumption 5.1 *Assume that for every $x,y\in\mathcal{H}$ and $\lambda\ge0$,*

$$\Psi(x)=\Psi(-x),\qquad\Psi(x+y)\le\eta\big(\Psi(x)+\Psi(y)\big)\ \text{and}\ \Psi(\lambda x)\le\lambda\Psi(x). \tag{5.9}$$

Also, recall that $\mathcal{E}=\{t\in\mathcal{H}:\mathbb{E}\langle X,t\rangle^2\le1\}$, $\sigma_q=\|\xi\|_q$ and set $K=\{t\in\mathcal{H}:\Psi(t)\le1\}$.

Theorem 5.3 *Assume that Ψ satisfies Assumption 5.1 and that the assumptions of Theorem 5.2 hold. Let $\Lambda(\rho)\ge\rho\ell^*(K)/\sqrt{N}$ for every $\rho>0$, $w,u>c$ and consider the RERM*

$$\hat{t}\in\operatorname*{argmin}_{t\in\mathcal{H}}\Big(\frac{1}{N}\sum_{i=1}^N(Y_i-\langle X_i,t\rangle)^2+c_0\eta^3Lwu\sigma_q\Lambda(\Psi(t))\Big).$$

Then, with probability larger than the one in (5.6),

$$R(\hat{t})-R(t^*)=\big\|\langle X,\hat{t}-t^*\rangle\big\|_{L_2}^2\le c_0r^2(10\eta\Psi(t^*))$$

where, for α and β defined in (5.3) and, for any $\rho\ge0$,

$$r^2(\rho)=\begin{cases}\frac{\Lambda(\rho)}{\beta} & \text{if } N\ge\big(\ell^*(\mathcal{E})/\alpha\big)^2\\ \max\Big\{\frac{\Lambda(\rho)}{\beta},\frac{\Lambda^2(\rho)}{\alpha^2}\Big\} & \text{otherwise.}\end{cases} \tag{5.10}$$

Proof. The result follows immediately from Theorem 5.2. Indeed, for every $\rho>0$, $r>0$ and $t^*\in T=\mathcal{H}$,

$$\ell^*(T\cap K_\rho(t^*)\cap r\mathcal{E}_{t^*})=\ell^*(K_\rho(0)\cap r\mathcal{E})\le\ell^*(\rho K\cap r\mathcal{E})\le\min\{\rho\ell^*(K),r\ell^*(\mathcal{E})\},$$

because $K_\rho(0)\subset\rho K=\{\rho t:t\in K\}$.

∎

Note that in a d-dimensional space, the trivial bound $\ell^*(\mathcal{E})\le\sqrt{d}$ holds (see, e.g., Lemma 2.2 in Lecué and Mendelson (2016)). Therefore, one only needs to control $\ell^*(K)$. In the next section, we provide several examples of applications of Theorem 5.3 that follow from estimates on $\ell^*(K)$. We will simplify the analysis further by assuming that there is some compatibility between the norm $\|\cdot\|_{\mathcal{H}}$ and the one endowed by the covariance structure of X:

Assumption 5.2 *Assume that X is isotropic; that is, for every $t\in\mathcal{H}$, $\big(\mathbb{E}\langle X,t\rangle^2\big)^{1/2}=\|t\|_{\mathcal{H}}$.*

Observe that Assumption 5.2 implies that $\ell^*(K)=\mathbb{E}\sup_{t\in K}G_t$, where $(G_t)_{t\in K}$ is the canonical Gaussian process indexed by K with the covariance $\mathbb{E}G_{t_1}G_{t_2}=\langle t_1,t_2\rangle$ for every $t_1,t_2\in K$. Indeed, this follows because the inner-product in $\mathcal{H}$ coincides with the one endowed by $L_2(\mu)$.

5.2 Regularization methods in $\mathbb{R}^d$

Consider a regularization function $\Psi(\cdot)$ satisfying Assumption 5.1. Assume that X is L-subgaussian and isotropic in $\mathbb{R}^d$ with respect to the standard Euclidean inner-product, and that $\xi\in L_q$ for some $q>2$. Let $u,w>c$. For any $\rho\ge0$ set $\Lambda(\rho)\ge\rho\ell^*(K)/\sqrt{N}$ and put

$$r^2(\rho)\sim_{L,q}\begin{cases}wu\sigma_q\Lambda(\rho) & \text{when } N\gtrsim_L d\\ \max\big\{wu\sigma_q\Lambda(\rho),\Lambda^2(\rho)\big\} & \text{otherwise.}\end{cases}$$

It follows from Theorem 5.3 that if

$$\hat{t}\in\operatorname*{argmin}_{t\in\mathbb{R}^d}\Big(\frac{1}{N}\sum_{i=1}^N(Y_i-\langle X_i,t\rangle)^2+c_0\eta^3Lwu\sigma_q\Lambda(\Psi(t))\Big) \tag{5.11}$$

then with probability larger than the one in (5.6)

$$\big\|\langle\hat{t}-t^*,\cdot\rangle\big\|_{L_2(\mu)}^2\lesssim r^2(10\eta\Psi(t^*)).$$

As a consequence, one can derive an estimation result for (5.11) whenever $\ell^*(K)$ may be controlled from above. In the following section, we shall apply this observation to some classical problems and compare the error rates obtained by the RERM (5.11) to the minimax rate in the true model $\{t\in T:\Psi(t)\le\Psi(t^*)\}$.

Example: ℓ_p-regularization for $1\le p\le\infty$. Consider the regularization function $\Psi(t)=\|t\|_p$ for some $p\ge1$. Assumption 5.1 holds with $\eta=1$ because $\|\cdot\|_p$ is a norm. In order to apply the general result for the RERM in (5.11), one has to estimate the Gaussian mean-width of the unit ball associated with the regularization function $\Psi(\cdot)=\|\cdot\|_p$.

In the range $1\le p\le1+(\log d)^{-1}$, we obtain the same performance as the LASSO, because $B_1^d\subset B_p^d\subset cB_1^d$ for a suitable absolute constant c, implying that $\ell^*(B_p^d)\sim\ell^*(B_1^d)\sim\sqrt{\log(ed)}$.

When $1+(\log(ed))^{-1}\le p$, set r to be the conjugate index for p and one may easily verify that $\ell^*(B_p^d)\sim\sqrt{r}d^{1/r}$.

Applying Theorem 5.3, one has the following:

Theorem 5.4 *Under the assumptions of Theorem 5.3 and using its notation,*

- *If* $1 \le p \le 1 + 1/(\log d)$ *and*

$$\hat{t} \in \operatorname*{argmin}_{t \in \mathbb{R}^d} \Big(\frac{1}{N} \sum_{i=1}^N (Y_i - \langle X_i, t \rangle)^2 + c_2 \eta_p^3 L w u \sigma_q \|t\|_p \sqrt{\frac{\log d}{N}} \Big)$$

then with probability larger than the one in (5.6),

$$\big\|\hat{t} - t^*\big\|_2^2 \lesssim_{p,L,q} \begin{cases} w u \sigma_q \|t^*\|_p \sqrt{\frac{\log d}{N}} & \text{if } N \gtrsim_L d, \\ \max\Big\{ w u \sigma_q \|t^*\|_p \sqrt{\frac{\log d}{N}}, \|t^*\|_p^2 \frac{\log d}{N} \Big\} & \text{otherwise.} \end{cases}$$

- *If* $p \ge 1 + 1/(\log d)$ *and*

$$\hat{t} \in \operatorname*{argmin}_{t \in \mathbb{R}^d} \Big(\frac{1}{N} \sum_{i=1}^N (Y_i - \langle X_i, t \rangle)^2 + c_2 \sigma_q L w u \|t\|_p \frac{\sqrt{p/(p-1)} d^{(p-1)/p}}{\sqrt{N}} \Big),$$

then with probability larger than the one in (5.6)

$$\big\|\hat{t} - t^*\big\|_2^2 \lesssim_{L,q} \begin{cases} w u \sigma_q \|t^*\|_p \frac{d^{(p-1)/p}}{p\sqrt{N}} & \text{if } N \gtrsim_L d, \\ \max\Big\{ w u \sigma_q \|t^*\|_p \frac{d^{(p-1)/p}}{\sqrt{N}}, \|t^*\|_p^2 \frac{d^{2(p-1)/p}}{N} \Big\} & \text{otherwise.} \end{cases}$$

Remark. [**the case** $0 < p < 1$] Despite being a non-convex function, ℓ_p-regularization for $0 < p < 1$ has attracted much attention in the context of Signal Processing and High-Dimensional Statistics. Among the problems studied using ℓ_p regularization were the linear regression model with a deterministic design (cf. Raskutti et al. (2011); Rigollet and Tsybakov (2011); Verzelen (2012)); the sequence space model Donoho and Johnstone (1994); Abramovich et al. (2006); and the random design linear regression model Wang et al. (2014).

From our point of view, there is no particular restriction on p as long as the regularization function satisfies Assumption 5.1. We can therefore consider the regularization function $\Psi(t) = \|t\|_p$ for any $0 < p < 1$. In that range of p, Assumption 5.1 holds for $\eta = \eta_p = 2^{1/p}$ (see, for example, page 2 in Edmunds and Triebel (1996)) and the Gaussian mean width of the "unit ball" associated with $\Psi(\cdot) = \|\cdot\|_p$ for $0 < p < 1$ can also be computed.

To that end, let $\{e_1, \dots, e_d\}$ be the canonical basis of $\mathbb{R}^d$. Since $\{\pm e_1, \dots, \pm e_d\} \subset B_p^d \subset B_1^d$ for $p < 1$, it is evident that $\ell^*(B_p^d) \sim \sqrt{\log d}$. Thus, the error rates of the LASSO from Theorem 4.2 dominate all the ℓ_p-regularization rates when $0 < p \le 1$.

However, the resulting rate is not the minimax rate in the true model, as can be seen from Raskutti et al. (2011). Indeed, fix $0 < p \le 1$. Consider an unknown $t^* \in \rho B_p^d$ and the corresponding Gaussian linear model $Y_i = \langle x_i, t^* \rangle + W_i, i = 1, \dots, N$, where the matrix whose rows are $(x_i)_{i=1}^N$ satisfies some RIP property and $W_1, \cdots, W_N$ are independent, centered Gaussian variables with variance σ^2. For specific asymptotic rates in N and d (see

Raskutti et al. (2011) for a precise formulation), the authors show that minimax rate of the problem is given by

$$\sigma^2 \rho \Big(\frac{\log d}{N} \Big)^{1 - \frac{p}{2}},$$

and similar results have been obtained in Wang et al. (2014). Thus, our estimate recovers the minimax rate in the true model only when $p = 1$. When $0 < p < 1$, it is possible that the choice of the $\Psi(t) = \|t\|_p$ is suboptimal, and instead one should use $\Psi(t) = \|t\|_p^p$ as was suggested in Rohde and Tsybakov (2011) for the problem of S_p-regularization for $0 < p \le 1$.

Example: weak-ℓ_p-regularization for $0 < p \le 1$. Weak-ℓ_p norms have been used to model sparsity in High-Dimensional Statistics (see, for instance, Abramovich et al. (2006); Wang et al. (2014)). To define those norms, let $t_1^* \ge t_2^* \ge \ldots \ge t_d^*$ be the non-increasing rearrangement of $(|t_i|)_{i=1}^d$. Set $\|t\|_{p\infty} = \max_{1 \le j \le d} j^{1/p} t_j^*$ and put $B_{p\infty}^d = \{t \in \mathbb{R}^d : t_j^* \le j^{-1/p} \text{ for every } 1 \le j \le d\}$.

One can use the following well-known fact (see, e.g., Theorem B in Gordon et al. (2007)) to control the Gaussian mean-width of the unit ball associated with $\|\cdot\|_{p\infty}$.

Proposition 5.5 *For* $0 < p \le 1$,

$$\ell^*(B_{p\infty}) \lesssim \begin{cases} \frac{\sqrt{\log d}}{p-1} & \text{if } 0 < p < 1 \\ \big(\log d\big)^{3/2} & \text{if } p = 1. \end{cases}$$

Applying Theorem 5.3, one has the following:

Theorem 5.6 *Under the assumptions of Theorem 5.3 and using its notation,*

- *If* $p < 1$ *and*

$$\hat{t} \in \operatorname*{argmin}_{t \in \mathbb{R}^d} \Big(\frac{1}{N} \sum_{i=1}^N (Y_i - \langle X_i, t \rangle)^2 + c_2 \eta_p^3 \sigma_q L w u \|t\|_{p\infty} \sqrt{\frac{\log d}{N}} \Big),$$

then with probability larger than the one in (5.6)

$$\big\|\hat{t} - t^*\big\|_2^2 \lesssim_{p,L,q} \begin{cases} \sigma_q w u \|t^*\|_{p\infty} \sqrt{\frac{\log d}{N}} & \text{if } N \gtrsim_L d, \\ \max\Big\{ \sigma_q w u \|t^*\|_p \sqrt{\frac{\log d}{N}}, \|t^*\|_{p\infty}^2 \frac{\log d}{N} \Big\} & \text{otherwise.} \end{cases}$$

- *If* $p = 1$ *and*

$$\hat{t} \in \operatorname*{argmin}_{t \in \mathbb{R}^d} \Big(\frac{1}{N} \sum_{i=1}^N (Y_i - \langle X_i, t \rangle)^2 + c_2 \eta_1^3 \sigma_q \|t\|_{1\infty} \sqrt{\frac{\log^3 d}{N}} \Big),$$

then with probability larger than the one in (5.6)

$$\big\|\hat{t} - t^*\big\|_2^2 \lesssim_{L,\delta,q} \begin{cases} \sigma_q w u \|t^*\|_{1\infty} \sqrt{\frac{\log^3 d}{N}} & \text{if } N \gtrsim_L d, \\ \max\Big\{ \sigma_q w u \|t^*\|_{1\infty} \sqrt{\frac{(\log d)^3}{N}}, \|t^*\|_{1\infty}^2 \frac{\log^3 d}{N} \Big\} & \text{otherwise.} \end{cases}$$

Example: the Micchelli, Morales and Pontil's regularization functions.
Let Θ be a nonempty convex cone in $[0,\infty)^d$, and for every $t \in \mathbb{R}^d$ set

$$\Omega(t|\Theta) = \inf_{\theta\in\Theta} \frac{1}{2}\sum_{j=1}^d \Big(\frac{t_j^2}{\theta_j} + \theta_j\Big). \tag{5.12}$$

It was shown in Maurer et al. (2010) that $\Omega(\cdot|\Theta)$ is a norm on $\mathbb{R}^d$.

This family of norms captures several classical regularization functions, by an appropriate choice of the cone Θ. For instance, the ℓ_1^d-norm is obtained by selecting $\Theta = [0,\infty)^d$. Also, the *group LASSO* introduced in Yuan and Lin (2006) is generated by a cone: indeed, if $(G_1,\cdots,G_T)$ is a partition of $\{1,\dots,d\}$ and

$$\Theta = \{\theta \in [0,\infty)^d \text{ that is constant within each group } G_\ell\}, \tag{5.13}$$

then

$$\Omega(t|\Theta) = \sum_{\ell=1}^T \sqrt{|G_\ell|}\,\|t_{|G_\ell}\|_2\,,$$

where $|G_\ell|$ is the cardinality of the set of coordinates G_ℓ and $t_{|G_\ell}$ is the restriction of t to G_ℓ.

Error bounds for procedures that use $\Psi(t) = \Omega(t|\Theta)$ as regularization functions have been established in Maurer and Pontil (2012), under the assumption that the loss functions is bounded and Lipschitz (see Theorem 1 there). Naturally, the squared loss is not covered by such a result because it is not bounded in $\mathbb{R}^d$, nor is it Lipschitz. Our aim is to provide a version of the result from Maurer and Pontil (2012) for the quadratic loss and when X is subgaussian and the noise belongs to L_q for some $q > 2$. The first step in that direction is the following estimate on the Gaussian mean width of the corresponding unit ball.

Proposition 5.7 *Let Θ be a nonempty convex cone in $[0,\infty)^d$ and set $\mathcal{B} = \{t : \Omega(t|\Theta) \le 1\}$. Let S_1^{d-1} be the unit sphere of ℓ_1^d and put $\mathcal{E}x$ to be the set of extreme points of $\Theta \cap S_1^{d-1}$. If $M = \max_{a\in\mathcal{E}x}\|a\|_\infty^{1/2}$, then, for an absolute constant c,*

$$\ell^*(\mathcal{B}) \le 1 + cM\sqrt{2\log\big(|\mathcal{E}x|\big)}. \tag{5.14}$$

The proof of Proposition 5.7 may be derived in various ways (see a similar result in Maurer and Pontil (2012)), though we will use a chaining argument which actually leads to a stronger estimate than (5.14).

Definition 5.8 *Let $T \subset \mathbb{R}^d$ and set $\|\cdot\|$ to be a norm on $\mathbb{R}^d$. For every $\alpha > 1$ let*

$$\gamma_\alpha(T,\|\cdot\|) = \inf_{(T_s)}\sup_{t\in T}\sum_{s=0}^\infty 2^{s/\alpha}\,\|\pi_{s+1}t - \pi_s t\|\,;$$

the infimum is taken with respect to all sequences (T_s) of subsets of T for which $|T_0| = 1$ and for $s \ge 1$, $|T_s| \le 2^{2^s}$, and $\pi_s t$ denotes the nearest point to t in T_s with respect to $\|\cdot\|$.

Clearly, if T is finite then $\gamma_\alpha(T,\|\ \|) \lesssim \sup_{t\in T}\|t\|\cdot\log^{1/\alpha}|T|$.

Proof of Proposition 5.7. It is straightforward to verify (see, e.g., Maurer et al. (2010)) that the dual norm to $\Omega(\cdot|\Theta)$ is

$$\Omega^*(t|\Theta) = \max_{a\in\mathcal{E}x}\Big(\sum_{j=1}^d a_j t_j^2\Big)^{1/2}. \tag{5.15}$$

Let $g_1,\dots,g_d$ be independent, standard Gaussian random variables, Applying a Bernstein type inequality for a sum of independent ψ_1 random variables (see Corollary 2.10 in Talagrand (1994)), it follows that for every $a_1,\dots,a_N$, every $u > 0$ and any $s \in \mathbb{N}$,

$$Pr\left[\Big|\sum_{j=1}^d a_j(g_j^2-1)\Big| \ge u2^{s/2}\|a\|_2 + u^2 2^s\|a\|_\infty\right] \le 2\exp(c_1 2^s u^2).$$

Hence, using a standard chaining argument,

$$\mathbb{E}\sup_{a\in\mathcal{E}x}\sum_{j=1}^d a_j g_j^2 \le 1 + c_2\left(\gamma_2(\mathcal{E}x,\|\ \|_2) + \gamma_1(\mathcal{E}x,\|\ \|_\infty)\right).$$

Now one may apply the trivial estimates on γ_1 and γ_2. Firstly, $\gamma_1(\mathcal{E}x,\|\cdot\|_\infty) \lesssim M^2\log(|\mathcal{E}x|)$, and secondly, noting that $|\sum_{j=1}^d a_j| \le \|a\|_1 = 1$ and thus $\|a\|_2 \le \|a\|_\infty^{1/2}$, one has $\gamma_2(\mathcal{E}x,\|\cdot\|_2) \lesssim M\sqrt{\log(|\mathcal{E}x|)}$. Therefore, by Jensen's inequality,

$$\mathbb{E}\sup_{a\in\mathcal{E}x}\Big(\sum_{j=1}^d a_j g_j^2\Big)^{1/2} \le 1 + cM\sqrt{\log(|\mathcal{E}x|)}.$$

■

Theorem 5.9 *Using the notation above and of Theorem 5.3, let*

$$\Lambda(t) = \Omega(t|\Theta)M\sqrt{\frac{\log(|\mathcal{E}x|)}{N}}.$$

If

$$\hat{t} \in \operatorname*{argmin}_{t\in\mathbb{R}^d}\Big(\frac{1}{N}\sum_{i=1}^N (Y_i - \langle X_i,t\rangle)^2 + c_2\sigma_q L w u\Lambda(t)\Big)$$

then with probability larger than the one in (5.6)

$$\|\langle\hat{t}-t^*,\cdot\rangle\|_{L_2(\mu)}^2 \lesssim_{L,q} \begin{cases} \sigma_q w u\Lambda(t^*) & \text{if } N \gtrsim_L d,\\ \max\left\{\sigma_q L w u\Lambda(t^*),\Lambda^2(t^*)\right\} & \text{otherwise.}\end{cases}$$

When $\Theta = [0,\infty)^d$ then $M\sqrt{\log(\mathcal{E}x)} \lesssim \sqrt{\log d}$. Hence, Theorem 5.9 yields the same error rate as the one obtained for the LASSO in Theorem 4.2 and in Theorem 5.4, though under a stronger assumption on X. This is not surprising because when $\Theta = [0,\infty)^d$, $\Omega(t|\Theta) = \|t\|_1$ and the resulting RERM is just the LASSO.

In the case of the group LASSO, for Θ as in (5.13), one has $M\sqrt{\log(\mathcal{E}x)} \lesssim \sqrt{\log|T|}$, and $\Lambda(t^*) \sim \Omega(t^*|\Theta)M\sqrt{(\log|T|)/N}$.

Example: The SLOPE regularization

In Su and Candès (2016); Bogdan et al. (2015), the authors introduced the regularization function:

$$\Psi(t) = \|t\|_{SLOPE} = \sum_{j=1}^d \lambda_j t_j^*$$

where $\lambda_1 \geq \cdots \geq \lambda_d \geq 0$ and $t_1^* \geq \cdots \geq t_d^* \geq 0$ is the non-increasing rearrangement of $(|t_i|)_{i=1}^d$.

In Su and Candès (2016) the given data is generated by the Gaussian linear model $Y_i = \langle X_i, t^*\rangle + W_i, i = 1,\ldots,N$ for a Gaussian design $X_i \sim \mathcal{N}(0, N^{-1}I_{d\times d})$ (note that the covariance matrix is normalized by $1/N$) and a centered Gaussian noise W_i with variance σ^2 that is independent of the design X_i. Setting $\Phi^{-1}(\alpha)$ to be the α-th quantile of a standard normal distribution and $q \in (0,1)$, the weights were chosen to be

$$\lambda_i = \Phi^{-1}(1 - iq/(2d)), \tag{5.16}$$

and, for this choice of weights, SLOPE was defined by

$$\hat{t} \in \operatorname*{argmin}_{t\in\mathbb{R}^d}\Big(\frac{1}{2N}\sum_{i=1}^N (Y_i - \langle X_i, t\rangle)^2 + \sigma\frac{\|t\|_{SLOPE}}{\sqrt{N}}\Big).$$

The result in Su and Candès (2016) is of an asymptotic nature:

Theorem 5.10 (Theorem 1.2 Su and Candès (2016)) *Let $0 < \varepsilon < 1$ and set $1 \leq k \leq d$ that satisfy $k/d = o(1)$ and $(k\log d)/N = o(1)$ when $N \to \infty$. Then,*

$$\lim_{N\to\infty}\sup_{\|t^*\|_0\leq k} Pr\Big(\frac{N\left\|\hat{t} - t^*\right\|_2^2}{2\sigma^2 k\log(d/k)} > 1 + 3\varepsilon\Big) = 0,$$

where the supremum is taken with respect to all vectors that are supported on at most k coordinates.

It was shown in Su and Candès (2016) that $2\sigma^2 k\log(d/k)/N$ is the (asymptotic) minimax rate for t^* that is k-sparse.

The article Su and Candès (2016) (see Section 6 there) raises the question of extending Theorem 5.10 beyond the Gaussian case, especially when the coordinates of X may be correlated. We study this question in the context of sparse recovery and for an arbitrary choice of weights in Lecué and Mendelson (to appear), leading to error bounds that depend on $\|t^*\|_0$. Here, we obtain a complexity-dependent error rate that depends on $\|t^*\|_{SLOPE}$.

Proposition 5.11 *Set $\mathcal{B} = \{t \in \mathbb{R}^d : \|t\|_{SLOPE} \leq 1\}$. There exists an absolute constant C, for which, if $M = \max_{1\leq j\leq d}\lambda_j^{-1}\sqrt{\log(ed/j)}$, then $\ell^*(\mathcal{B}) \leq CM$.*

Proof. The proof is an outcome of a standard binomial estimate. Let $G = (g_i)_{i=1}^d$ be a standard Gaussian vector and observe that

$$\ell^*(\mathcal{B}) = \mathbb{E}\sup_{t\in\mathcal{B}}\langle G, t\rangle \leq \mathbb{E}\sup_{t\in\mathcal{B}}\sum_{j=1}^d g_j^* t_j^* \leq \mathbb{E}\sup_{t\in\mathcal{B}}\sum_{j=1}^d \frac{g_j^*}{\lambda_j}\lambda_j t_j^* \leq \mathbb{E}\max_{1\leq j\leq d}\frac{g_j^*}{\lambda_j}.$$

For $u \geq 1$,

$$Pr\Big(\max_{1\leq j\leq d}\frac{g_j^*}{\lambda_j} \geq u\Big) \leq \sum_{j=1}^d Pr\left(g_j^* \geq u\lambda_j\right) \leq \sum_{j=1}^d \binom{d}{j} Pr^j\left(|g| \geq u\lambda_j\right)$$
$$\leq 2\sum_{j=1}^d \exp\Big(j\log\Big(\frac{ed}{j}\Big) - c_1 j u^2\lambda_j^2\Big) \leq 2\exp(-c_2u^2),$$

where the last inequality follows if one sets $u^2 \geq \max_j \lambda_j^{-2}\log(ed/j)$. The proof is concluded by integrating the tails. ∎

Theorem 5.3 leads to estimation properties of SLOPE.

Theorem 5.12 *Using the notation of Theorem 5.3, if $\Psi(t) = \|t\|_{SLOPE}$, $\max_j \lambda_j^{-1}\sqrt{\log(ed/j)} \leq C$ and*

$$\hat{t} \in \operatorname*{argmin}_{t\in\mathbb{R}^d}\Big(\frac{1}{N}\sum_{i=1}^N (Y_i - \langle X_i, t\rangle)^2 + c_2\sigma_q Lwu\frac{\|t\|_{SLOPE}}{\sqrt{N}}\Big),$$

then with probability larger than the one in (5.6),

$$\left\|\hat{t} - t^*\right\|_2^2 \lesssim_{L,q,C} \begin{cases} \frac{\sigma_q wu\|t^*\|_{SLOPE}}{\sqrt{N}} & \text{if } N \gtrsim_L d, \\ \max\Big\{\frac{\sigma_q Lwu\|t^*\|_{SLOPE}}{\sqrt{N}}, \frac{\|t^*\|_{SLOPE}^2}{N}\Big\} & \text{otherwise.}\end{cases}$$

As in the case of the LASSO, one may combine the sparsity-dependent error rate for SLOPE from Lecué and Mendelson (to appear) and the complexity-dependent error rate from Theorem 5.12. To that end, assume that X is isotropic, L-subgaussian and that the noise ξ is in L_q for some $q > 2$. Then, with probability larger than the one in (5.6)

$$\left\|\hat{t} - t^*\right\|_2^2 \lesssim_{L,q,C} \min\left\{\frac{\sigma_q\|t^*\|_0}{N}\log\Big(\frac{ed}{\|t^*\|_0}\Big), \max\left\{\frac{\sigma_q wu\|t^*\|_{SLOPE}}{\sqrt{N}}, \frac{\|t^*\|_{SLOPE}^2}{N}\right\}\right\},$$

for $N \gtrsim \|t^*\|_0\log(ed/\|t^*\|_0)$.

5.3 Regularization methods in $\mathbb{R}^{m\times T}$

In this section, we assume that X takes values in the set of $m\times T$ matrices, endowed with the inner product $\langle A,B\rangle=\sum_{u,v}A_{uv}B_{uv}$. We consider $A^*\in\operatorname{argmin}_{A\in\mathbb{R}^{m\times T}}\mathbb{E}\big(Y-\langle X,A\rangle\big)^2$ and thus $\langle X,A^*\rangle$ is the best (linear) approximation of Y in the L_2 sense.

Let $\Lambda(\rho)\geq\rho\ell^*(K)/\sqrt{N}$ for all $\rho>0$, $u,w>C$ and set

$$\hat{A}\in\operatorname*{argmin}_{A\in\mathbb{R}^{m\times T}}\Big(\frac{1}{N}\sum_{i=1}^N(Y_i-\langle X_i,A\rangle)^2+c_2\eta^3\sigma_q Lwu\Lambda(\Psi(A))\Big). \tag{5.17}$$

By Theorem 5.3, with probability larger than the one in (5.6)

$$\Big\|\hat{A}-A\Big\|_2^2=\Big\|\langle X,\hat{A}-A^*\rangle\Big\|_{L_2}^2\lesssim r(10\eta\Psi(A^*))^2$$

where for $\rho\geq 0$,

$$r(\rho)^2\sim_{L,q}\begin{cases}\sigma_q wu\Lambda(\rho) & \text{when } N\gtrsim_L mT\\ \max\Big\{\sigma_q wu\Lambda(\rho),\Lambda^2(\rho)\Big\} & \text{otherwise.}\end{cases}$$

Let us turn to estimates on $\ell^*(K)$ for the unit balls of the regularization functions used in the *matrix completion* and *collaborative filtering* problems.

Example: S_p-regularization for $p\geq 1$.

For any $A\in\mathbb{R}^{m\times T}$, let $\sigma_1(A)\geq\sigma_2(A)\geq\cdots\geq\sigma_{m\wedge T}(A)$ be the ordered singular values of A and set $m\wedge T=\min\{m,T\}$. Recall that the p-Schatten norm $\|\cdot\|_{S_p}$ of A is defined by

$$\|A\|_{S_p}=\Big(\sum_{j=1}^{m\wedge T}\sigma_j(A)^p\Big)^{1/p}.$$

Schatten norms have been used extensively in *matrix completion* and in *collaborative filtering*. Exact reconstruction properties of various procedures have been established via the minimization of the S_1-norm, constrained to matching the data (see, e.g., Candès and Plan (2011); Candès and Tao (2010); Candès and Recht (2009); Gross (2011); Chandrasekaran et al. (2012)). S_1 regularization has also been used in the noisy setup for independent subgaussian noise and, in most cases, for subgaussian or deterministic designs, in Koltchinskii et al. (2011); Rohde and Tsybakov (2011); Koltchinskii (2011); Negahban and Wainwright (2012); Gaïffas and Lecué (2011); Klopp (2014).

A result that is closely related to ours is Theorem 9.2 from Koltchinskii (2011), in which X is isotropic and L-subgaussian; ξ is a symmetric random variable that is independent of X and for which $\|\xi\|_{\psi_\alpha}<\infty$ for some $\alpha\geq 1$ (cf. Rao and Ren (1991) for more details on the ψ_α-norms); and the target is $Y=\langle X,A^*\rangle+\xi$.

Let $N\gtrsim m\cdot\operatorname{rank}(A^*)$ and set

$$\lambda\gtrsim\max\left\{\|\xi\|_2\sqrt{\frac{m(t+\log m)}{N}},\|\xi\|_{\psi_\alpha}\log^{1/\alpha}\Big(\frac{\|\xi\|_{\psi_\alpha}}{\|\xi\|_{L_2}}\Big)\frac{\sqrt{m}(t+\log N)(t+\log m)}{N}\right\}.$$

The S_1-regularization procedure with regularization parameter λ satisfies that for every $t>0$, with probability larger than $1-3\exp(-t)-\exp(-c_0N)$,

$$\Big\|\hat{A}-A^*\Big\|_{S_2}^2\lesssim\min\left\{\lambda\|A^*\|_{S_1},\lambda^2\operatorname{rank}(A^*)\right\}. \tag{5.18}$$

In comparison, an estimation result for S_p-norm regularization (for any $p\geq 1$) follows from Theorem 5.3, and does not require any assumptions on the "noise" $\xi=Y-\langle A^*,X\rangle$, other than $\xi\in L_q$ for some $q>2$. in particular, ξ need not belong to ψ_α, nor does it have to be independent of X. The result uses the following estimate on the Gaussian mean-width of the unit ball of S_p-norms (see, for instance, Proposition 1.4.4 in Chafaï et al. (2012)):

Proposition 5.13 *Let $p\geq 1$ and set B_p^{mT} to be the unit ball of $\|\cdot\|_{S_p}$. Then*

$$\ell^*(B_p^{mT})\sim\min\{m,T\}^{1-1/p}\sqrt{m+T}.$$

Combining the previous result with Theorem 5.3, one obtains the following:

Theorem 5.14 *Assume that the assumptions of Theorem 5.3 hold. Let $\Lambda_p(\rho)=\rho\min\{m,T\}^{1-1/p}\sqrt{\frac{m+T}{N}}$ and*

$$\hat{A}\in\operatorname*{argmin}_{A\in\mathbb{R}^{m\times T}}\Big(\frac{1}{N}\sum_{i=1}^N(Y_i-\langle X_i,A\rangle)^2+c_2\sigma_q Lwu\Lambda_p(\|A\|_{S_p})\Big).$$

Then with probability at least $1-\delta$,

$$\Big\|\hat{A}-A^*\Big\|_{S_2}^2\lesssim_{p,L,q}\begin{cases}\sigma_q wu\Lambda_p(\|A^*\|_{S_p}) & \text{if } N\gtrsim_L mT,\\ \max\Big\{\sigma_q wu\Lambda_p(\|A^*\|_{S_p}),\Lambda_p^2(\|A^*\|_{S_p})\Big\} & \text{otherwise.}\end{cases}$$

Remark. As in the vector case mentioned earlier, Theorem 5.3 also applies for S_p-regularization for $0<p<1$. In that case, Assumption 1.1 is satisfied for $\eta=2^{1/p}$ and the Gaussian mean width of the S_p-unit ball satisfies $\ell^*(B_p^{mT})\lesssim\sqrt{m+T}$. It therefore follows from Theorem 5.3 that under the same assumptions as in Theorem 5.3 and for $\Lambda(\rho)=\rho\sqrt{(m+T)/N}$ for all $\rho>0$, the RERM

$$\hat{A}\in\operatorname*{argmin}_{A\in\mathbb{R}^{m\times T}}\Big(\frac{1}{N}\sum_{i=1}^N(Y_i-\langle X_i,A\rangle)^2+c_2\sigma_q Lwu\Lambda(\|A\|_{S_p})\Big),$$

satisfies, with probability larger than the one in (5.6),

$$\Big\|\hat{A}-A^*\Big\|_{S_2}^2\lesssim_{p,L,q}\begin{cases}\sigma_q wu\Lambda(\|A^*\|_{S_p}) & \text{if } N\gtrsim_L mT,\\ \max\Big\{\sigma_q wu\Lambda(\|A^*\|_{S_p}),\Lambda^2(\|A^*\|_{S_p})\Big\} & \text{otherwise.}\end{cases}$$

Observe that just as in the vector case, when $0<p<1$ this rate is not the minimax rate in the true model $\|A^*\|_{S_p}B_p^{mT}$. Indeed, Rohde and Tsybakov (2011) provides the minimax rate, and, in fact, also shows that the minimax rate may be attained using $\Psi(A)=\|A\|_{S_p}^p$

as a regularization function. To be more accurate, Rohde and Tsybakov (2011) considers the following problem: let $x_1, \dots, x_N$ be N deterministic matrices in $\mathbb{R}^{m\times T}$ satisfying some RIP property and set W_i to be N independent, standard Gaussian variables with variance σ^2. Set $Y_i = \langle x_i, A^*\rangle + W_i, i = 1, \dots, N$, leading to the so-called matrix regression model with Gaussian noise and a deterministic design. It is shown in Rohde and Tsybakov (2011) that when ρB_p^{mT} for some $0 < p \le 1$, the minimax rate of the problem in ρB_p^{mT} is

$$\sigma^2\rho^p\Big(\frac{m+T}{N}\Big)^{1-\frac{p}{2}}$$

in some specific range of N, σ and ρ. Our result recovers this rate only for $p = 1$.

Example: Max-norm regularization. The max-norm of a matrix is defined by

$$\|A\|_{max} = \inf_{A=UV^\top} \|U\|_{2\to\infty}\|V\|_{2\to\infty},$$

with the infimum taken with respect to all pairs of matrices U, V for which $A = UV^\top$.

Constrained empirical risk minimization procedures that are based on the max-norm have been used in Cai and Zhou (2016); Nathan and Adi (2005) for bounded and Lipschitz loss functions, and in Lecué and Mendelson for the squared loss and for a subgaussian and isotropic design vector X and a subgaussian noise ξ independent of X. Consider the matrix regression model $Y_i = \langle X_i, A^*\rangle + W_i, i = 1, \dots, N$ where $X_1, \dots, X_N$ are independent isotropic and subgaussian matrices, $W_1, \dots, W_N$ are independent centered gaussian variables with variance σ^2 that are independent of the X_i's and A^* belongs to the max-norm ball of radius ρ. One may show that the minimax rate in this case is

$$\max\left\{\sigma\rho\sqrt{\frac{(mT)(m+T)}{N}}, \frac{\rho^2(mt)(m+T)}{N}\right\}, \tag{5.19}$$

at least in some specific regime of ρ, σ and N (cf. Lecué and Mendelson).

To apply Theorem 5.3, let us estimate the Gaussian mean-width of the unit ball of the max-norm ball, that is, of $\mathcal{B} = \{A \in \mathbb{R}^{m\times T} : \|A\|_{max} \le 1\}$.

Lemma 5.15 *There exists an absolute constant c for which, for every m and T,*

$$\ell^*(\mathcal{B}) \lesssim \sqrt{(mT)(m+T)}.$$

Proof. An application of Grothendieck's inequality (see, e.g., Nathan and Adi (2005)) shows that

$$\mathrm{conv}(\mathcal{X}_\pm) \subset \mathcal{B} \subset K_G\mathrm{conv}(\mathcal{X}_\pm)$$

where K_G is the Grothendieck constant and $\mathcal{X}_\pm = \{uv^\top : u \in \{\pm1\}^m, v \in \{\pm1\}^T\}$. If $\mathfrak{G} = (g_{ij})_{1\le u\le m:1\le v\le T}$ is a standard $m \times T$ Gaussian matrix, it follows from the Gaussian maximal inequality (see, e.g., Chapter 3 in Ledoux and Talagrand (1991)) that

$$\begin{aligned}\ell^*(\mathcal{B}) &= \mathbb{E}\sup_{A\in\mathcal{B}}|\langle\mathfrak{G}, A\rangle| \le K_G\mathbb{E}\sup_{A\in\mathrm{conv}(\mathcal{X}_\pm)}|\langle\mathfrak{G}, A\rangle| \\ &= K_G\mathbb{E}\sup_{A\in\mathcal{X}_\pm}|\langle\mathfrak{G}, A\rangle| \lesssim \max_{A\in\mathcal{X}_\pm}\|A\|_{HS}\sqrt{\log|\mathcal{X}_\pm|} \lesssim \sqrt{(mT)(m+T)}.\end{aligned}$$

■

Theorem 5.16 *Using the assumptions and notation of Theorem 5.3, and setting $\Lambda(\rho) = \rho\sqrt{(mT)(m+T)/N}$, if*

$$\hat{A} \in \operatorname*{argmin}_{A\in\mathbb{R}^{m\times T}}\Big(\frac{1}{N}\sum_{i=1}^N(Y_i - \langle X_i, A\rangle)^2 + c_2\sigma_q L w u\Lambda(\|A\|_{max})\Big),$$

then with probability larger than the one in (5.6)

$$\|\hat{A} - A^*\|_{S_2}^2 \lesssim_{L,q} \begin{cases} \sigma_q w u\Lambda(\|A^*\|_{max}) & \text{if } N \gtrsim_L mT, \\ \max\Big\{\sigma_q w u\Lambda(\|A^*\|_{max}), \Lambda^2(\|A^*\|_{max})\Big\} & \text{otherwise.}\end{cases}$$

As a consequence, we recover the minimax rate of convergence in the matrix regression model with subgaussian design and gaussian noise in the class $\|A^*\|_{max}\mathcal{B}$ thanks to max-norm regularization and without knowing $\|A^*\|_{max}$ in advance.

Example: Atomic-norm regularization.

The atomic-norm has been used in Chandrasekaran et al. (2012) in the context of exact and robust recovery using few Gaussian linear measurements of a signal or of a matrix.

Given $\mathcal{A} \subset \mathbb{R}^{m\times T}$, the elements in $\mathcal{A}$ are called *atoms*. Set $\mathrm{conv}(\mathcal{A})$ to be the convex hull of $\mathcal{A}$ and put

$$\|A\|_{\mathcal{A}} = \inf\{t > 0 : A \in t\cdot\mathrm{conv}(\mathcal{A})\}. \tag{5.20}$$

Even though $\|\cdot\|_{\mathcal{A}}$ need not be a norm (because $\mathrm{conv}(\mathcal{A})$ need not be centrally-symmetric), it is positive homogeneous and satisfies a triangle inequality: for every $A, B \in \mathbb{R}^{m\times T}$ and $\lambda \ge 0$:

$$\|A + B\|_{\mathcal{A}} \le \|A\|_{\mathcal{A}} + \|B\|_{\mathcal{A}} \text{ and } \|\lambda A\|_{\mathcal{A}} = \lambda\|A\|_{\mathcal{A}}.$$

And, if we assume that $\mathcal{A}$ is centrally-symmetric, then $\|\ \|_{\mathcal{A}}$ is a norm, (5.9) is satisfied and Theorem 5.3 applies.

Set $\mathcal{B}$ to be the unit ball with respect to $\|\ \|_{\mathcal{A}}$ and note that $\ell^*(\mathcal{B}) = \ell^*(\mathcal{A})$. For example, assume that $m = T$ and put $\mathcal{A}$ to be the set of all orthogonal matrices. Since the unit ball of the spectral norm is the convex hull of the set of orthogonal matrices, one has $\|\cdot\|_{\mathcal{A}} = \|\cdot\|_{S_2}$ and

$$\ell^*(\mathcal{B}) = \mathbb{E}\|\mathfrak{G}\|_{S_2} \le \sqrt{m}\mathbb{E}\|\mathfrak{G}\|_{S_\infty} \lesssim m.$$

Theorem 5.17 *Using the assumptions and notation of Theorem 5.3, let $\mathcal{A} \subset \mathbb{R}^{m\times T}$ be a centrally-symmetric set of atoms and set $\Lambda(\rho) \ge \rho\ell^*(\mathcal{A})/\sqrt{N}$. If*

$$\hat{A} \in \operatorname*{argmin}_{A\in\mathbb{R}^{m\times T}}\Big(\frac{1}{N}\sum_{i=1}^N(Y_i - \langle X_i, A\rangle)^2 + c_2\sigma_q L w u\Lambda(\|A\|_{\mathcal{A}})\Big)$$

then with probability larger than the one in (5.6)

$$\Big\|\hat{A} - A^*\Big\|_{S_2}^2 \lesssim_{L,q} \begin{cases} \sigma_q w u\Lambda(\|A^*\|_{\mathcal{A}}) & \text{if } N \gtrsim_L mT, \\ \max\Big\{\sigma_q w u\Lambda(\|A^*\|_{\mathcal{A}}), \Lambda^2(\|A^*\|_{\mathcal{A}})\Big\} & \text{otherwise.}\end{cases}$$

6. Conclusions

We have presented a general result (Theorem 1.9) describing statistical properties of a constrained regularized procedure in the learning theoretical framework. This result highlights the role played by the quadratic and multiplier processes in calibrating the regularization parameter λ as well as their effect on the estimation error rate. It appears that:

1. The rates of convergence depend on $\Psi(f^*)$ and we recover the minimax rate in the true model $\{f \in F : \Psi(f) \leq \Psi(f^*)\}$ – up to a logarithmic factor – in many well-studied examples .

2. No statistical model is needed to study RERM; all the analysis has been carried out in the general learning theory setup, and thus without assuming any statistical model. Theorem 1.9 and all its corollaries and applications are true regardless of any relation between the target Y and the input X. For instance, when predicting Y using linear functionals there is no need to assume that $Y = \langle t_0, X\rangle + W$ for an independent noise W; our results hold even if Y were, for instance, a noisy version of a quadratic function of a linear functional of X (e.g. phase retrieval).

   Our analysis shows that despite considering this general framework, the error rate and the regularization parameter used to construct RERM almost match the ones that would have been obtained with more information – namely, a given statistical model. In the examples we considered, statistical models are superfluous to the analysis of RERM and as a consequence, they may actually hide what really determines the error rate and the right choice of a regularization parameter:

   - calibration of the regularization parameter depends only on the multiplier process – which measures the empirical correlation between the noise $Y - f^*(X)$ and the class F. When this correlation is small or even null (in the free-noise case) the regularization parameter will also be small.
   - the key parameters are the structure of the "unit ball" of the regularization function (measured here using the Gaussian mean width) and the noise level, which is measured through the L_q norm of $Y - f^*(X)$.

7. Proof of Theorem 3.6

Following Mendelson (2016), the proof of Theorem 3.6 is based on properties of the following norm:

Definition 7.1 *For a random variable Z and $p \geq 1$, set*

$$\|Z\|_{(p)} = \sup_{1\leq q\leq p} \frac{\|Z\|_{L_q}}{\sqrt{q}}.$$

The $\|\cdot\|_{(p)}$ norm is a 'local' version of the ψ_2 norm. While

$$\|Z\|_{\psi_2} \sim \sup_{q\geq 1} \frac{\|Z\|_{L_q}}{\sqrt{q}},$$

$\|Z\|_{(p)}$ captures the subgaussian behavior of Z up to the p-th moment.

Under Assumption 3.1, a high probability bound on (3.7) can be derived using the next result.

Proposition 7.2 (Lemma 2.8 in Lecué and Mendelson (2017)) *There exists an absolute constant c_0 for which the following holds. Let Z be a mean-zero real-valued random variable and let $Z_1, ..., Z_N$ be independent copies of Z. Let $p_1 \geq 1$ and assume that $\|Z\|_{(p_1)} \leq L$, then*

$$\left\| \frac{1}{\sqrt{N}} \sum_{i=1}^N Z_i \right\|_{(p_1)} \leq c_0 L.$$

Setting $U_j = N^{-1/2} \sum_{i=1}^N \varepsilon_i X_i(j)$ and $p_1 = \log d$ (recalling that $t \geq 1$ and $d \geq N$ in Assumption 3.1), it follows from Proposition 7.2 that

$$\|U_j\|_{L_{p_1}} \leq c_0 L \sqrt{p_1} \|x_j\|_{L_2}.$$

Therefore,

$$Pr\left(\max_{1\leq j\leq d} |U_j| \geq u \right) \leq \sum_{j=1}^d Pr\left(|U_j| \geq u\right) \leq \sum_{j=1}^d \left(\frac{\|U_j\|_{L_{p_1}}}{u} \right)^{p_1}$$
$$\leq d \left(\frac{c_0 L \sqrt{p_1} \max_{1\leq j\leq d} \|x_j\|_{L_2}}{u} \right)^{p_1} = d \left(\frac{c_0 L \sqrt{\log d} \max_{1\leq j\leq d} \|x_j\|_{L_2}}{u} \right)^{\log d}.$$

Let $w \geq e$ and set $u = c_0 L w \sqrt{\log d} \max_{1\leq j\leq d} \|x_j\|_{L_2}$; therefore,

$$Pr\left(\max_{1\leq j\leq d} |U_j| \geq c_1 L w \sqrt{\log d} \max_{1\leq j\leq d} \|x_j\|_{L_2} \right) \leq \left(\frac{e}{w} \right)^{\log d}, \tag{7.1}$$

which is a high probability estimate on (3.7) under a limited moment assumption. Integrating the tail,

$$\mathbb{E} \max_{1\leq j\leq d} \left| \frac{1}{\sqrt{N}} \sum_{i=1}^N \varepsilon_i X_i(j) \right| \lesssim L \sqrt{\log d} \max_{1\leq j\leq d} \|x_j\|_{L_2}$$

proving (3.9).

Next, we obtain high probability bounds on (3.8),—estimates that require some preparation.

Let $j \in \{1, \dots, d\}$ and set $Z_i = X_i(j)$. Consider the Bernoulli sums

$$Q_j = \sum_{i=1}^N \varepsilon_i \xi_i X_i(j) = \sum_{i=1}^N \varepsilon_i \xi_i Z_i.$$

Denote by $(a_i^*)_{i=1}^N$ the non-increasing rearrangement of $(|a_i|)_{i=1}^N$. A straightforward application of Höffding's inequality shows that conditioned on $(\xi_i)_{i=1}^N$ and $(Z_i)_{i=1}^N$, for any $v > 0$,

with probability at least $1-2\exp(-v^2/2)$ relative to $(\varepsilon_i)_{i=1}^N$,

$$|Q_j| \leq \sum_{i\leq m}\xi_i^* Z_i^* + v\left(\sum_{i\geq m}(\xi_i^* Z_i^*)^2\right)^{1/2} \tag{7.2}$$
$$\leq \left(\sum_{i\leq m}(\xi_i^*)^2\right)^{1/2}\left(\sum_{i\leq m}(Z_i^*)^2\right)^{1/2} + v\left(\sum_{i\geq m}(\xi_i^*)^{2r}\right)^{1/2r}\left(\sum_{i\geq m}(Z_i^*)^{2r'}\right)^{1/2r'},$$

where r and r' are conjugate indices.

As a consequence, high probability bounds on the rearrangements (ξ_i^*) and (Z_i^*) can be used to obtain high probability bounds on $|Q_j|$ (and therefore, on $\max_{1\leq j\leq d}|Q_j|$ as well, using the union bound).

The next two observations, whose proofs may be found in Mendelson (2016), give information on the structure of a typical $(Z_i)_{i=1}^N$ when Z has at least $\sim \log d$ subgaussian moments. It turns out that one may decompose $(Z_i)_{i=1}^N$ to a sum of two vectors, supported on disjoint sets: one consists of the largest m coordinates of $(|Z_i|)_{i=1}^N$, and its ℓ_2^N norm is determined by relatively high moments of Z; the other consists of the $N-m$ smaller coordinates of $(|Z_i|)_{i=1}^N$, and if $Z\in L_{q_1}$, its ℓ_r^N norm is well-behaved for $r<q_1$.

The 'level' m depends on the desired probability estimate and on the moments of Z: if one wishes to obtain a probability estimate of $1-2\exp(-p)$ for $p\geq \log N$ (as we will), then Z should have roughly p moments and one should select $m\sim p/\log(eN/p)$.

First, let us consider the smaller coordinates:

Lemma 7.3 (Lemma 3.2 in Mendelson (2016)) *There exist absolute constants a_0 and c_1 for which the following holds. Let $1\leq r_1<q_1$, set $Z\in L_{q_1}$ and put $Z_1,\ldots,Z_N$ to be independent copies of Z. Fix $1\leq p\leq N$, let $u>2$ and set*

$$m=\left\lceil \frac{a_0 p}{((q_1/r_1)-1)\log(4+eN/p)}\right\rceil.$$

If $m>1$, then, with probability at least $1-2u^{-mq_1}\exp(-p)$,

$$\left(\sum_{i=m}^N (Z_i^*)^{r_1}\right)^{1/r_1} \leq c_1\left(\frac{q_1}{q_1-r_1}\right)^{1/r_1} uN^{1/r_1}\|Z\|_{L_{q_1}}$$

and, if $m=1$ and $0<\beta<q_1/r_1-1$ then with probability at least $1-c_2u^{-q_1}N^{-\beta}$,

$$\left(\sum_{i=1}^N |Z_i|^{r_1}\right)^{1/r_1} \leq c_1\Big(\frac{q_1}{q_1-(\beta+1)r_1}\Big)u\,\|Z\|_{L_{q_1}}N^{1/r_1}.$$

Next, we consider the larger coordinates:

Lemma 7.4 (Lemma 3.4 in Mendelson (2016)) *There exists absolute constants a_1 and c_0 for which the following holds. Let $Z_1,\ldots,Z_N$ be independent copies of a random variable Z, set $p\geq \log N$ and put $1\leq m\leq N/2e$ that satisfy $m\leq a_1 p/\log\big(eN/p\big)$. Then, for every $u>1$, with probability at least $1-u^{-2p}\exp(-p)$, one has*

$$\left(\sum_{i=1}^m (Z_i^*)^2\right)^{1/2} \leq c_0 u\sqrt{p}\|Z\|_{(2p)}.$$

In particular, under Assumption 3.1, we apply Lemma 7.3 and Lemma 7.4 to p, q_1 and r_1 defined by

$$2p=t\log d, r_1=2r' \text{ and } q_1=r_1\max\Big\{2,1+\frac{a_0}{a_1}\Big\},$$

where a_0 and a_1 are the absolute constants from Lemma 7.3 and 7.4. We also set

$$m=\left\lceil \frac{a_0 p}{\log(4+eN/p)}\right\rceil \tag{7.3}$$

and observe that if

$$m_0=\left\lceil \frac{a_0 p}{((q_1/r_1)-1)\log(4+eN/p)}\right\rceil \text{ then } m_0\leq m\leq \frac{a_1 p}{\log(eN/p)}$$

and $m_0 q_1\sim m$. Moreover, if κ_0 is a large enough absolute constant and $t\geq\kappa_0$, then $m_0>1$. Recalling that $p\geq 2\log d$ and setting $Z_i=X_i(j)$ for $i=1,\ldots,N$, it follows that for any $u>2$, with probability at least $1-u^{-2p}\exp(-p/2)-2u^{-c_0 m}\exp(-p/2)$, for every $1\leq j\leq d$

$$\left(\sum_{i=1}^m (Z_i^*)^2\right)^{1/2} \lesssim u\sqrt{p}\,\|Z\|_{(2p)} \lesssim uL\sqrt{t\log d}\,\|x_j\|_{L_2} \tag{7.4}$$

and

$$\left(\sum_{i=m}^N (Z_i^*)^{2r'}\right)^{1/2r'} \lesssim u\,\|Z\|_{L_{q_1}}N^{1/2r'} \lesssim uL\sqrt{r'}\,\|x_j\|_{L_2}N^{1/2r'}. \tag{7.5}$$

Let $\xi_1,\ldots,\xi_N$ be independent copies of ξ and recall that $(\xi_i^*)_{i=1}^N$ is the monotone non-increasing rearrangement of $(|\xi_i|)_{i=1}^N$. We apply Lemma 7.3 for $q_1=q$, $r_1=2r$ and set

$$m_1=\left\lceil \frac{a_0 p}{((q_1/r_1)-1)\log(4+eN/p)}\right\rceil.$$

Thus, $m_1>1$ when $t\geq\kappa_0$ for a large enough constant κ_0, and if m is as in (7.3) one has $m\geq m_1$ and $m_1 q_1\sim m$. Hence, for $p=(t/2)\log d$, with probability larger than $1-2u^{-c_0 m}\exp(-p)$,

$$\left(\sum_{i=m}^N (\xi_i^*)^{2r}\right)^{1/2r} \leq c(q)u\,\|\xi\|_{L_q}N^{1/2r}. \tag{7.6}$$

This provides a high probability bound on the smaller coordinates of $(|\xi_i|)_{i=1}^N$. Next, let us turn to estimating the larger ones.

Lemma 7.5 (Lemma 4.3 in Mendelson (2016)) *Let $q > 2$ and assume that $\xi \in L_q$. If $\xi_1, \ldots, \xi_N$ are independent copies of ξ then for every $w > 1$ with probability larger than $1 - c_0 w^{-q} N^{-((q/2)-1)} \log^q N$,*

$$\left(\sum_{i=1}^m \xi_i^2\right)^{1/2} \leq \left(\sum_{i=1}^N \xi_i^2\right)^{1/2} \leq c_1 w \|\xi\|_{L_q} \sqrt{N}.$$

Setting $Z_i = X_i(j)$ for $i = 1, \ldots, N$ and applying (7.4), (7.5), (7.6) and Lemma 7.5, we obtain, with probability larger than

$$1 - \frac{\exp(-p/2)}{u^{2p}} - \frac{4\exp(-p/2)}{u^{c_0 m}} - \frac{c_0 \log^q N}{w^q N^{q/2-1}}$$

that for every $j = 1, \ldots, d$

$$\left(\sum_{i\leq m} (\xi_i^*)^2\right)^{1/2} \left(\sum_{i\leq m} (Z_i^*)^2\right)^{1/2} \lesssim uwL\sqrt{t\log d}\|x_j\|_{L_2}\|\xi\|_{L_q}\sqrt{N}$$

and

$$\left(\sum_{i\geq m} (\xi_i^*)^{2r}\right)^{1/2r} \left(\sum_{i\geq m} (Z_i^*)^{2r'}\right)^{1/2r'} \leq c(q)u^2 L\|\xi\|_{L_q}\sqrt{N}\|x_j\|_{L_2}.$$

Then, by plugging those inequalities in (7.2), it is evident that under Assumption 3.1, for $u > 2, v > 0$, $w \geq 2$, $2p = t\log d$ and $m \sim p/\log(eN/p)$, with probability at least

$$1 - \frac{\exp(-p/2)}{u^{2p}} - \frac{4\exp(-p/2)}{u^{c_0 m}} - \frac{c_1 \log^q N}{w^q N^{q/2-1}} - 2\exp(-v^2 t\log d),$$

$$\max_{1\leq j\leq d}\left|\sum_{i=1}^N \varepsilon_i\xi_i X_i(j)\right| = \max_{1\leq j\leq d}|Q_j| \lesssim_q (uw + u^2 v)L\|\xi\|_{L_q}\sqrt{N}\sqrt{t\log d}\max_{1\leq j\leq d}\|x_j\|_{L_2}.$$

Abstract

This paper considers the problem of matrix completion when the observed entries are noisy and contain outliers. It begins with introducing a new optimization criterion for which the recovered matrix is defined as its solution. This criterion uses the celebrated Huber function from the robust statistics literature to downweigh the effects of outliers. A practical algorithm is developed to solve the optimization involved. This algorithm is fast, straightforward to implement, and monotonic convergent. Furthermore, the proposed methodology is theoretically shown to be stable in a well defined sense. Its promising empirical performance is demonstrated via a sequence of simulation experiments, including image inpainting.

Keywords: ES-Algorithm, Huber function, robust methods, Soft-Impute, stable recovery

1. Introduction

The goal of matrix completion is to impute those missing entries of a large matrix based on the knowledge of its relatively few observed entries. It has many practical applications, ranging from collaborative filtering (Rennie and Srebro, 2005) to computer visions (Weinberger and Saul, 2006) to positioning (Montanari and Oh, 2010). In addition, its application to recommender systems is perhaps the most well known example, widely made popularized by the so-called Netflix prize problem (Bennett and Lanning, 2007). In this problem a large matrix of movie ratings is partially observed. Each row of this matrix consists of ratings from a particular customer while each column records the ratings on a particular movie. In the Netflix data set, there are around 5×10^5 customers and 2×10^4 movies, with less than 1% of the ratings are observed. Without any prior knowledge, a reasonable full recovery of the matrix is virtually impossible. To overcome this issue, it is common to assume that the matrix is of low rank, reflecting the belief that the users' ratings are based on a relatively small number of factors. This low rank assumption is very sensible in many applications, although the resulting optimizations are combinatorially hard (Srebro and Jaakkola, 2003). To this end, various convex relaxations and related optimization algorithms have been proposed to provide computationally feasible solutions; see, for example, Candès and Recht (2009); Candès and Plan (2010); Keshavan et al. (2010b,a); Mazumder et al. (2010); Marjanovic and Solo (2012) and Hastie et al. (2014).

In addition to computational advances, the theoretical properties of matrix completion using nuclear norm minimization have also been well studied. For example, when the observed entries are noiseless, Candès and Recht (2009) show that perfect recovery of a low rank matrix is possible; see also Keshavan et al. (2010b), Gross (2011) and Recht (2011). This result of Candès and Recht (2009) has been extended to noisy measurements by Candès and Plan (2010): with high probability, the recovery is subject to an error bound proportional to the noise level. Techniques that achieve this desirable property are often referred as *stable*. See also Keshavan et al. (2010a) and Koltchinskii et al. (2011) for other theoretical developments of matrix completion from noisy measurements.

The original formulation of matrix completion assumes those observed entries are noiseless, and is later extended to the more realistic situation where the entries are observed with noise. This paper further extend the formulation to simultaneously allow for both noisy entries and outliers. To the authors knowledge, such an extension has not been considered before, although similar work exists. In Candès et al. (2011) a method called principal component pursuit (PCP) is developed to recover a matrix observed with mostly noiseless entries and otherwise a small amount of outliers. This is done by modeling the observed matrix as a sum of a low rank matrix and a sparse matrix. Zhou et al. (2010) extend this PCP method to noisy entries but assumes the matrix is fully observed, thus it does not fall into the class of matrix completion problems. Lastly Chen et al. (2011) extend PCP to safeguard against special outlying structures, namely outlying columns. However, it works only on outliers and otherwise noiseless entries. Due to the similarity between the matrix completion and principal component analysis, it is worthmentioning that there are some related work (Karhunen, 2011; Luttinen et al., 2012) on robust principal component analysis with missing values.

The primary contribution of this paper is the development of a new robust matrix completion method that can be applied to recover a matrix with missing, noisy and/or outlying entries. This method is shown to be stable in the sense of Candès and Plan (2010), as discussed above. As opposed to the above referenced PCP approach that decomposes the matrix into a sum of a low rank and a sparse matrix, the new approach is motivated by the statistical literature of robust estimation which modifies the least squares criterion to downweigh the effects of outliers. Particularly, we make use of the Huber function for this modification. We provide a theoretical result that establishes an intrinsic link between the two different approaches. To cope with the nonlinearity introduced by the Huber function, we propose a fast, simple, and easy-to-implement algorithm to perform the resulting nonlinear optimization problem. This algorithm is motivated by the ES-Algorithm for robust nonparametric smoothing (Oh et al., 2007). As to be shown below, it can transform a rich class of (non-robust) matrix completion algorithms into algorithms for robust matrix completion.

The rest of this paper is organized as follows. Section 2 provides further background of matrix completion and proposes a new optimization criterion for robust matrix recovery. Fast algorithms are developed in Section 3 for practically computing the robust matrix estimate. Theoretical and empirical properties of the proposed methodology are studied

in Section 4 and Section 5 respectively. Concluding remarks are given in Section 6, while technical details are relegated to the appendix.

2. Matrix Completion with Noisy Observations and Outliers

Suppose X is an $n_1 \times n_2$ matrix which is observed for only a subset of entries $\Omega_{\text{obs}} \subseteq [n_1] \times [n_2]$, where $[n]$ denotes $\{1, \ldots, n\}$. Let $\Omega_{\text{obs}}^{\perp}$ be the complement of Ω_{obs}. Define the projection operator $\mathcal{P}_{\Omega_{\text{obs}}}$ as $\mathcal{P}_{\Omega_{\text{obs}}} B = C$, where $C_{ij} = B_{ij}$ if $(i,j) \in \Omega_{\text{obs}}$ and $C_{ij} = 0$ if $(i,j) \notin \Omega_{\text{obs}}$, for any $n_1 \times n_2$ matrix $B = (B_{ij})_{i \in [n_1], j \in [n_2]}$. The following is a standard formulation for matrix completion using a low rank assumption:

$$\begin{aligned} \underset{Y}{\text{minimize}} \quad & \text{rank}(Y) \\ \text{subject to} \quad & \frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}} X - \mathcal{P}_{\Omega_{\text{obs}}} Y\|_F^2 \leq e, \end{aligned}$$

where $e > 0$ and $\|\cdot\|_F$ is the Frobenius norm. Carrying out this rank minimization enables a good recovery of any low rank matrix with missing entries. Note that for the reason of accommodating noisy measurements, the constraint above allows for a slight discrepancy between the recovered and the observed matrices.

However, this minimization is combinatorially hard (e.g., Srebro and Jaakkola, 2003). To achieve fast computation, the following convex relaxation is often used:

$$\begin{aligned} \underset{Y}{\text{minimize}} \quad & \|Y\|_* \\ \text{subject to} \quad & \frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}} X - \mathcal{P}_{\Omega_{\text{obs}}} Y\|_F^2 \leq e, \end{aligned}$$

where $\|Y\|_*$ represents the nuclear norm of Y (i.e., the sum of singular values of Y). The Lagrangian form of this optimization is

$$\underset{Y}{\text{minimize}} \quad f(Y|X) \equiv \frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}} X - \mathcal{P}_{\Omega_{\text{obs}}} Y\|_F^2 + \gamma \|Y\|_*, \tag{1}$$

where $\gamma > 0$ has a one-to-one correspondence to e. The squared loss in the first term is used to measure the fitness of the recovered matrix to the observed matrix. It is widely known that such a squared loss is very sensitive to outliers and often leads to unsatisfactory recovery results if such outliers exist. Motivated by the literature of robust statistics (e.g., Huber and Ronchetti, 2011), we propose replacing this squared loss by the Huber loss function

$$\rho_c(x) = \begin{cases} x^2, & |x| \leq c \\ c(2|x| - c), & |x| > c \end{cases},$$

with tuning parameter c. When comparing with the squared loss, the Huber loss downweighs the effects of extreme measurements. Our proposed solution for robust matrix completion is given by the following minimization:

$$\underset{Y}{\text{minimize}} \quad g(Y) \equiv \frac{1}{2} \sum_{(i,j) \in \Omega_{\text{obs}}} \rho_c(X_{ij} - Y_{ij}) + \gamma \|Y\|_*. \tag{2}$$

Note that the convexity of ρ_c guarantees the convexity of the objective criterion (2).

For many robust statistical estimation problems the tuning parameter c is pre-set as $c = 1.345\hat{\sigma}$ to achieve a 95% statistical efficiency, where $\hat{\sigma}$ is an estimate of the standard deviation of the noise. For the current problem, however, the choice of c is suggested by Theorem 4 below: $c = \gamma/\sqrt{n_{(1)}p}$, where $n_{(1)} = \max\{n_1, n_2\}$ and p is the percentage of missing entries. This choice of c was used throughout all our numerical work.

3. Fast Algorithms for Minimization of (2)

Since the gradient of the Huber function is non-linear, (2) is a harder optimization problem when comparing to many typical matrix completion formulations such as (1). As an example, consider (1) when X is fully observed; i.e., $\Omega_{\text{obs}} = [n_1] \times [n_2]$. Through sub-gradient analysis (e.g., Cai et al., 2010; Ma et al., 2011), one can derive a closed-form solution to (1), denoted as $S_\gamma(X)$, where S_γ is the soft-thresholding operator defined in Mazumder et al. (2010), also given in (6) below. However, even if X was fully observed, (2) does not have a closed-form solution. The goal of this section is to develop fast methods for minimizing (2).

3.1 A General Algorithm

In Oh et al. (2007) a method based on the so-called theoretical construct *pseudo data* is proposed for robust wavelet regression. The idea is to transform a Huber-type minimization problem into a sequence of fast and well understood squared loss minimization problems. This subsection modifies this idea and proposes an algorithm to minimizing (2).

As similar to Oh et al. (2007), we define a *pseudo data matrix* as

$$Z = \mathcal{P}_{\Omega_{\text{obs}}} \tilde{Y} + \frac{1}{2}\psi_c(E), \tag{3}$$

where $\tilde{Y}$ is the current estimate of the target matrix, $E = \mathcal{P}_{\Omega_{\text{obs}}} X - \mathcal{P}_{\Omega_{\text{obs}}} \tilde{Y}$ is the "residual matrix", and $\psi_c = \rho_c'$ is the derivative of ρ_c. With a slight notation abuse, when ψ_c is applied to a matrix, it means ψ_c is evaluated in an element-wise fashion. Straightforward algebra shows that the sub-gradient of $f(Y|Z)$ (with respect to Y) evaluated at $\tilde{Y}$,

$$-(\mathcal{P}_{\Omega_{\text{obs}}} Z - \mathcal{P}_{\Omega_{\text{obs}}} \tilde{Y}) + \gamma \partial \|\tilde{Y}\|_*, \tag{4}$$

is equivalent to the sub-gradient of $g(Y)$ (with respect to Y) evaluated at $\tilde{Y}$,

$$-\frac{1}{2}\psi_c(\mathcal{P}_{\Omega_{\text{obs}}} X - \mathcal{P}_{\Omega_{\text{obs}}} \tilde{Y}) + \gamma \partial \|\tilde{Y}\|_*. \tag{5}$$

The proposed algorithm iteratively updates $\tilde{Y} = \arg\min_Y f(Y|Z)$ and Z using (3). Upon convergence (implied by Proposition 1 below), the sub-gradient (4) contains 0 at the converged $\tilde{Y}$ and thus the sub-gradient (5) also contains 0 at this converged $\tilde{Y}$. Therefore this $\tilde{Y}$ is the solution to (2). Details of this algorithm based on pseudo data matrix are given in Algorithm 1.

Algorithm 1 has several attractive properties. First, it can be paired with any existing (non-robust) matrix completion algorithm (or software), as can be easily seen in Step 2(c). This is a huge advantage, as a rich body of existing (non-robust) methods can be made

Algorithm 1 The General Robust Algorithm

1: Perform (non-robust) matrix completion on X and assign $Y^{\text{old}} \leftarrow \arg\min_Y f(Y|X)$. This Y^{old} is the initial estimate (starting point of the algorithm).
2: Repeat:
   (a) Compute $E \leftarrow \mathcal{P}_{\Omega_{\text{obs}}} X - \mathcal{P}_{\Omega_{\text{obs}}} Y^{\text{old}}$.
   (b) Compute $Z \leftarrow \mathcal{P}_{\Omega_{\text{obs}}} Y^{\text{old}} + \frac{1}{2}\psi_c(E)$.
   (c) Perform (non-robust) matrix completion on Z and assign $Y^{\text{new}} \leftarrow \arg\min_Y f(Y|Z)$.
   (d) If
$$\frac{\|Y^{\text{new}} - Y^{\text{old}}\|_F^2}{\|Y^{\text{old}}\|_F^2} < \varepsilon,$$
   exit.
   (e) Assign $Y^{\text{old}} \leftarrow Y^{\text{new}}$.
3: Output Y^{new}.

robust against outliers. Second, once such an (non-robust) algorithm is available, the rest of the implementation is straightforward and simple, and no expensive matrix operations are required. Lastly, it has strong theoretical backup, as to be reported in Section 4.

3.2 Further Integration with Existing Matrix Completion Algorithms

Many existing matrix completion algorithms are iterative. A direct application of Algorithm 1 would lead to an algorithm that is iterations-within-iterations. Although our extensive numerical experience suggests that these direct implementations would typically converge within a few iterations to give a reasonably fast execution time, it would still be advantageous to speed up the overall procedure. Here we show that it is possible to further improve the speed of the overall robust algorithm by embedding the pseudo data matrix idea directly into a non-robust algorithm.

We shall illustrate this with the Soft-Impute algorithm proposed by Mazumder et al. (2010). To proceed we first recall the definition of their thresholding operator S_γ: for any matrix Z of rank r,

$$S_\gamma(Z) = UD_\gamma V^\intercal, \tag{6}$$

where $Z = UDV^\intercal$ is the singular value decomposition of Z, $D = \text{diag}[d_1, \ldots, d_r]$ and $D_\gamma = \text{diag}[(d_1 - \gamma)_+, \ldots, (d_r - \gamma)_+]$. Now the main idea is to suitably replace an iterative matrix estimate with the pseudo data matrix estimate given by (3). With Soft-Impute, the resulting robust algorithm is given in Algorithm 2. We shall call this algorithm Robust-Impute. As to be shown by the numerical studies below, Robust-Impute is very fast and produces very promising empirical results. Our algorithm also has the sparse-plus-low-rank structure in the singular value thresholding step (Step 2a(iii)). This linear algebra structure has positive impact on the computational complexity. See Section 5 of Mazumder et al. (2010) for details. Moreover, the monotonicity and convergence of our algorithm is guaranteed by Proposition 1 and Theorem 2.

Algorithm 2 Robust-Impute

1: Initialize $Y^{\text{old}} = S_{\gamma_1}(\mathcal{P}_{\Omega_{\text{obs}}} X)$ and $Z = X$.
2: Do for $\gamma_1 > \gamma_2 > \cdots > \gamma_K$:
   (a) Repeat:
      (i) Compute $E \leftarrow \mathcal{P}_{\Omega_{\text{obs}}} X - \mathcal{P}_{\Omega_{\text{obs}}} Y^{\text{old}}$.
      (ii) Compute $Z \leftarrow \mathcal{P}_{\Omega_{\text{obs}}} Y^{\text{old}} + \frac{1}{2}\psi_c(E)$
      (iii) Compute $Y^{\text{new}} \leftarrow S_{\gamma_k}(\mathcal{P}_{\Omega_{\text{obs}}} Z + \mathcal{P}_{\Omega_{\text{obs}}^\perp} Y^{\text{old}})$.
      (iv) If
$$\frac{\|Y^{\text{new}} - Y^{\text{old}}\|_F^2}{\|Y^{\text{old}}\|_F^2} < \varepsilon,$$
      exit.
      (v) Assign $Y^{\text{old}} \leftarrow Y^{\text{new}}$.
   (b) Assign $\hat{Y}_{\gamma_k} \leftarrow Y^{\text{new}}$.
3: Output the sequence of solutions $\hat{Y}_{\gamma_1}, \ldots, \hat{Y}_{\gamma_K}$.

4. Theoretical Properties

This section presents some theoretical backups for the proposed methodology.

4.1 Monotonicity and global convergence

We first present the following proposition concerning the monotonicity of the algorithms. The proof can be found in Appendix A.1. We also provide an alternative proof suggested by a referee, based on the idea of alternating minimization, in Appendix A.1

Proposition 1 (Monotonicity) *Let* $Y^{(k)}$ *and*

$$Z^{(k)} = \mathcal{P}_{\Omega_{\text{obs}}} Y^{(k-1)} + \psi_c(\mathcal{P}_{\Omega_{\text{obs}}} X - \mathcal{P}_{\Omega_{\text{obs}}} Y^{(k-1)})/2$$

be, respectively, the estimate and the pseudo data matrix in the k*-th iteration. If* $Y^{(k+1)}$ *is the next estimate such that* $f(Y^{(k+1)}|Z^{(k+1)}) \le f(Y^{(k)}|Z^{(k+1)})$*, then* $g(Y^{(k+1)}) \le g(Y^{(k)})$.

For the general version (Algorithm 1), it is obvious that the condition $f(Y^{(k+1)}|Z^{(k+1)}) \le f(Y^{(k)}|Z^{(k+1)})$ is satisfied as the result of the minimization $Y^{\text{old}} \leftarrow \arg\min_Y f(Y|Z)$. For the specialized version Robust-Impute (Algorithm 2), this condition is implied by Lemma 2 of Mazumder et al. (2010). Therefore both versions are monotonic.

As pointed out by a referee, the proposed algorithms can also be viewed as an instance of the majorization-minimization (MM) algorithm (Lange et al., 2000; Hunter and Lange, 2004). It can be shown that, for $(i, j) \in \Omega_{\text{obs}}$,

$$\begin{aligned}\rho_c(X_{ij} - Y_{ij}) &\le \rho_c(X_{ij} - Y_{ij}^{\text{old}}) - (Y_{ij} - Y_{ij}^{\text{old}})\psi_c(X_{ij} - Y_{ij}^{\text{old}}) + 2 \cdot \frac{1}{2}(Y_{ij} - Y_{ij}^{\text{old}})^2 \\ &= \left[Y_{ij} - Y_{ij}^{\text{old}} - \frac{1}{2}\psi_c(X_{ij} - Y_{ij}^{\text{old}})\right]^2 + \textit{constant} \\ &= (Y_{ij} - Z_{ij})^2 + \textit{constant}.\end{aligned}$$

Therefore, subject to an additive constant that does not depend on Y, $h(Y|Y^{\text{old}}) = f(Y|Z) = (1/2)\sum_{(i,j)\in\Omega_{\text{obs}}}(Z_{ij} - Y_{ij})^2 + \gamma\|Y\|_*$ is a majorization of the objective function g. With this majorization, Algorithm 1 can be viewed as an MM algorithm. Additionally, one can majorize the unobserved entries by $(Y_{ij} - Z_{ij})^2 = (Y_{ij} - Y_{ij}^{\text{old}})^2 \geq 0$ and, together with the above majorization of the observed entries, Algorithm 2 can also be shown as an MM algorithm. Therefore the monotonicity of the proposed algorithms can also be obtained by the general theory of MM algorithm (e.g., Lange, 2010). Moreover, the explicit connection to the MM algorithm allows possible extensions of the current algorithm to other robust loss functions such as Tukey's biweight loss. However, due to non-differentiability of the objective function, the typical convergence analysis of MM algorithm (e.g., Lange, 2010, Ch. 15) does not apply to our case.

We summarize the global convergence rates of both Algorithm 1 and Algorithm 2 in the following theorem.

Theorem 2 *Let $Y^{(k)}$ and $Y^{(0)}$ be, respectively, the estimate in the k-th iteration and the starting point of Algorithm 1 or Algorithm 2 Then for any $k \geq 1$,*

$$\textit{Algorithm 1:} \qquad g(Y^{(k)}) - g(Y^*) \leq \frac{\|\mathcal{P}_{\Omega_{\text{obs}}}Y^{(0)} - \mathcal{P}_{\Omega_{\text{obs}}}Y^*\|_F^2}{2k}, \qquad \forall Y^* \in \mathcal{Y},$$

$$\textit{Algorithm 2:} \qquad g(Y^{(k)}) - g(Y^*) \leq \frac{\|Y^{(0)} - Y^*\|_F^2}{2k}, \qquad \forall Y^* \in \mathcal{Y},$$

where $\mathcal{Y}$ be the set of all global minimizers of g (i.e. $\mathcal{Y} = \arg\min_{Y\in\mathbb{R}^{n_1\times n_2}} g(Y)$).

The global convergence analysis of Algorithm 1 can be carried out similarly as in Beck and Teboulle (2009) for proximal gradient method, despite that Algorithm 1 is not a proximal gradient method. For completeness, we give the proof of Theorem 2 for Algorithm 1 in Appendix A.2.

As for Robust-Impute (Algorithm 2), we can rewrite it as an instance of the proximal gradient method applied to $g(Y) = g_1(Y_1)+g_2(Y_2)$, where $g_1(Y) = (1/2)\sum_{(i,j)\in\Omega_{\text{obs}}}\rho_c(X_{ij}-Y_{ij})$ and $g_2(Y) = \gamma\|Y\|_*$. In our case, the proximal gradient method with step size L iterates over $Y^{(k+1)} = \xi_L(Y^{(k)})$ with

$$\xi_L(\tilde{Y}) = \arg\min_{Y}\left\{g_2(Y) + \frac{L}{2}\left\|Y - \left(\tilde{Y} - \frac{1}{L}\nabla g_1(\tilde{Y})\right)\right\|_F^2\right\},$$

where L is a constant greater than or equal to the Lipstchiz constant of g_1. Note that g_1 has a Lipschitz contant 1. If we take $L = 1$, we have the following simplification.

$$\begin{aligned} g_2(Y) + \frac{L}{2}\left\|Y - \left(\tilde{Y} - \frac{1}{L}\nabla g_1(\tilde{Y})\right)\right\|_F^2 &= g_2(Y) + \frac{1}{2}\left\|Y - \left\{\tilde{Y} + \frac{1}{2}\psi_c(\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y})\right\}\right\|_F^2 \\ &= g_2(Y) + \frac{1}{2}\left\|Y - \left\{\mathcal{P}_{\Omega_{\text{obs}}^\perp}\tilde{Y} + \mathcal{P}_{\Omega_{\text{obs}}}Z\right\}\right\|_F^2. \end{aligned}$$

The minimization of ξ_1 is equivalent to Step 2a(iii) of Algorithm 2. Therefore, the proximal gradient method is the same as Robust-Impute. This connection allows us to apply the convergence results of proximal gradient method to Robust-Impute directly. Theorem 2 for Algorithm 2 follows from Theorem 3.1 of Beck and Teboulle (2009). Lastly, the Nesterov's method (Nesterov, 2007) can be applied directly to accelerate Algorithm 2. The resulted accelerated version is expected to be faster in terms of convergence. However, the acceleration in the Nesterov's method ruins the computationally beneficial sparse-plus-low-rank structure (Mazumder et al., 2010) in the singular vaue thresholding step (Step 2a(iii)). Hence, for large matrices, the non-accelerated version is still preferred in terms of overall computations. The detailed discussion can be found in Section 5 of Mazumder et al. (2010).

4.2 Stable Recovery

Recall the stable property of Candès and Plan (2010) implies that, with high probability, the recovered matrix is subject to an error bound proportional to the noise level. This subsection shows that the robust matrix completion defined by (2) is also stable.

Although the formulation of (2) has its root from classical robust statistics, it is also related to the more recent principal component pursuit (PCP) proposed by Candès et al. (2011). PCP assumes that the entries of the observed matrix are noiseless, and that this matrix can be decomposed as the sum of a low rank matrix and a sparse matrix, where the sparse matrix is treated as the gross error. In Candès et al. (2011) it is shown that using PCP perfect recovery is possible with or without missing entries in the observed matrix. Another notable work by Chandrasekaran et al. (2011) provide completely deterministic conditions for the PCP to succeed under no missing data. See Section 1.5 of Candès et al. (2011) for a detailed comparison between these two pieces of work. For the case of noisy measurements without missing entries, Zhou et al. (2010) extend PCP to stable PCP (SPCP), which is shown to be stable. However, to the best of our knowledge, there is no existing theoretical results for the case of noisy (and/or outlying) measurements with missing entries.

Inspired by She and Owen (2011), we first establish an useful link between robust matrix completion (2) and PCP in the following proposition. The proof can be found in Appendix A.3.

Proposition 3 (Equivalence) *The minimization (2) is equivalent to*

$$\underset{L,S}{\text{minimize}} \quad \frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}(L+S)\|_F^2 + \gamma\|L\|_* + c\|S\|_1. \tag{7}$$

That is, the minimizing Y of (2) and the minimizing L of (7) coincide.

Minimization (7) has a high degree of similarity to both PCP and SPCP. It is equivalent to

$$\begin{aligned} \underset{L,S}{\text{minimize}} \quad & \|L\|_* + \lambda\|S\|_1 \\ \text{subject to} \quad & \|\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}(L+S)\|_F^2 \leq \delta^2, \end{aligned} \tag{8}$$

where $\lambda = c/\gamma$ and $\delta > 0$ has a one-to-one correspondence to γ. When comparing with PCP, (7) permits the observed matrix to be different from the recovered matrix $(L + S)$ to allow for noisy measurements. When comparing with SPCP, (7) permits missing entries, which is necessary for matrix completion problems.

Proposition 3 has two immediate implications. First, the proposed Algorithm 1 provides a general methodology to turn a large and well-developed class of matrix completion algorithms into algorithms for solving SPCP with missing entries. Second, many useful results from PCP can be borrowed to study the theoretical properties of robust matrix completion (2). In particular, we show that (2) leads to stable recovery. With Proposition 3, it suffices to show that (7) achieves stable recovery of (L_0, S_0') from the data $\mathcal{P}_{\Omega_{\text{obs}}}(X)$ generated by $\mathcal{P}_{\Omega_{\text{obs}}}(L_0 + S_0)$ obeying $\|\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}(L_0 + S_0)\|_F \leq \delta$ and $S_0' = \mathcal{P}_{\Omega_{\text{obs}}}S_0$. Note that $L_0 = X_0$.

We need some notations to proceed. For simplicity, we assume $n = n_1 = n_2$ but our results can be easily extended to rectangular matrices ($n_1 \neq n_2$). The Euclidean inner product $\langle Q, R\rangle$ is defined as trace$(Q^\intercal R)$. Let p_0 be the proportion of observed entries. Write $\Gamma \subset \Omega_{\text{obs}}$ as the set of locations where the measurements are noisy (but not outliters), and $\Omega = \Omega_{\text{obs}}\backslash\Gamma$ as the support of $S_0' = \mathcal{P}_{\Omega_{\text{obs}}}S_0$; i.e., locations of outliers. Denote their complements as, respectively, $\Gamma^\perp$ and $\Omega^\perp$. We define $\mathcal{P}_\Gamma$, $\mathcal{P}_\Omega$, $\mathcal{P}_{\Gamma^\perp}$ and $\mathcal{P}_{\Omega^\perp}$ similarly to the definition of $\mathcal{P}_{\Omega_{\text{obs}}}$. Let r be the rank of L_0 and $UDV^\intercal$ be the corresponding singular value decomposition of L_0, where $U, V \in \mathbb{R}^{n\times r}$ and $D \in \mathbb{R}^{r\times r}$. Similar to Candès et al. (2011), we consider the linear space of matrices

$$T := \{UQ^\intercal + RV^\intercal : Q, R \in \mathbb{R}^{n\times r}\}.$$

Write $\mathcal{P}_T$ and $\mathcal{P}_{T^\perp}$ as the projection operator to T and $T^\perp$ respectively. As in Zhou et al. (2010), we define a set of notations for any pair of matrices $M = (L, S)$. Here, let $\|M\|_F := \sqrt{\|L\|_F^2 + \|S\|_F^2}$ and $\|M\|_\diamond := \|L\|_* + \lambda\|S\|_1$. We also define the projection operators $\mathcal{P}_T \times \mathcal{P}_{\Gamma^\perp} : (L, S) \mapsto (\mathcal{P}_T L, \mathcal{P}_{\Gamma^\perp} S)$ and $\mathcal{P}_{T^\perp} \times \mathcal{P}_\Gamma : (L, S) \mapsto (\mathcal{P}_{T^\perp} L, \mathcal{P}_\Gamma S)$. In our theoretical development, we consider the following special subspaces

$$\Psi := \{(L, S) : L, S \in \mathbb{R}^{n\times n}, \mathcal{P}_{\Omega_{\text{obs}}}L = \mathcal{P}_{\Omega_{\text{obs}}}S, \mathcal{P}_{\Omega_{\text{obs}}^\perp}L = \mathcal{P}_{\Omega_{\text{obs}}^\perp}S = 0\},$$
$$\Psi^\perp := \{(L, S) : L, S \in \mathbb{R}^{n\times n}, \mathcal{P}_{\Omega_{\text{obs}}}L + \mathcal{P}_{\Omega_{\text{obs}}}S = 0\}.$$

And we write the corresponding projection operators as $\mathcal{P}_\Psi$ and $\mathcal{P}_{\Psi^\perp}$ respectively. Let $M_0 = (L_0, S_0')$. Lastly, for any linear operator $\mathcal{A}$, the operator norm, denoted by $\|\mathcal{A}\|$, is $\sup_{\{\|Q\|_F=1\}} \|\mathcal{A}Q\|_F$. In below, we write that an event occurs with high probability if it holds with probability at least $1 - \mathcal{O}(n^{-10})$.

To avoid certain pathological cases (see, e.g., Candès and Recht, 2009), an incoherence condition on U and V is usually assumed. To be specific, this condition with the parameter μ is:

$$\max_i \|U^\intercal e_i\|^2 \leq \frac{\mu r}{n_1}, \quad \max_i \|V^\intercal e_i\|^2 \leq \frac{\mu r}{n_2}, \quad \text{and} \quad \|UV^\intercal\|_\infty \leq \sqrt{\frac{\mu r}{n_1 n_2}}, \tag{9}$$

where $\|Q\|$ is the operator norm or 2-norm of matrix Q (i.e., the largest singular value of Q) and $\|Q\|_\infty = \max_{i,j} |Q_{i,j}|$. This condition guarantees that, for small μ, the singular vectors are reasonably spread out.

Theorem 4 (Stable Recovery) *Suppose that L_0 obeys (9) and Ω_{obs} is uniformly distributed among all sets of cardinality $m = p_0 n^2$ with $p_0 > 0$ being the proportion of observed entries. Further suppose that each observed entry is grossly corrupted to be an outlier with probability τ independently of the others. Suppose L_0 and S_0 satisfy $r \leq \rho_r n \mu^{-1} (\log n)^{-2}$ and $\tau \leq \tau_s$ with ρ_r, τ_s being positive numerical constants. Choose $\lambda = 1/\sqrt{np_0}$. Then, with high probability (over the choices of Ω and Ω_{obs}), for any X obeying $\|\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}(L_0 + S_0)\|_F \leq \delta$, the solution $(\hat{L}, \hat{S})$ to (8) satisfies*

$$\|\hat{L} - L_0\|_F \leq \left\{2 + 8\sqrt{n}\left(1 + \sqrt{\frac{8}{p_0}}\right)\right\}\delta \quad \textit{and} \quad \|\hat{S} - S_0'\|_F \leq \left\{2 + 8\sqrt{n}\left(1 + \sqrt{\frac{8}{p_0}}\right)\right\}\sqrt{np_0}\delta,$$

where $S_0' = \mathcal{P}_{\Omega_{\text{obs}}}(S_0)$.

The proof of this theorem can be found in Appendix A.4.

5. Empirical Performances

Two sets of numerical experiments and a real data application were conducted to evaluate the practical performances of the proposed methodology. In particular the performance of the proposed procedure Robust-Impute is compared to the performance of Soft-Impute developed by Mazumder et al. (2010). The reasons Soft-Impute is selected for comparison are that it is one of the most popular matrix completion methods due to its simplicity and scalability, and that it is shown by Mazumder et al. (2010) that it generally produces superior results to other common matrix completion methods such as MMMF of Rennie and Srebro (2005), SVT of Cai et al. (2010) and OptSpace of Keshavan et al. (2010b)

5.1 Experiment 1: Gaussian Entries

This experiment covers those settings used in Mazumder et al. (2010, Section 9) and additional settings with different proportions of missing entries and outliers. For each simulated data set, the target matrix was generated as $X_0 = UV^\intercal$, where U and V are random matrices of size $100 \times r$ with independent standard normal Gaussian entries. Then each entry of X_0 is contaminated by additional independent Gaussian noise with standard deviation σ, which is set to a value such that the signal-to-noise ratio (SNR) is 1. Here SNR is defined as

$$\text{SNR} = s = \sqrt{\frac{\text{Var}(X_0)}{\sigma^2}},$$

where $\text{Var}(X_0)$ is the variance over all the entries of X_0 conditional on U and V. Next, for each entry, with probability p yet another independent Gaussian noise with $\sigma/4$ is added; these entries are treated as outliers. We call this contaminated version of X_0 as X. Lastly, Ω_{obs} is uniformly random over the indices of the matrix with missing proportion as q. In this study, we used two values for r (5, 10), three values for p (0, 0.05, 0.1) and three values for q (0.25, 0.5, 0.75). Thus in total we have 18 simulation settings. For each setting 200 simulated data sets were generated, and both the non-robust method Soft-Impute and the proposed Robust-Impute were applied to recover X_0. We also provide two oracle fittings as references. They are produced by applying Soft-Impute to the simulated data set with outlying observed entries removed (i.e., treated as missing entries), and with outlying observed entries replaced by non-outlying contaminated entries (i.e., contaminated by independent Gaussian noise with standard deivation σ) respectively.

The first oracle fitting is referred to as oracle1 while the second one is called oracle2 in the following.

For the two simulation settings with $r = 10$ and $q = 0.5$, and one with $p = 0$ while the other with $p = 0.1$, Figure 1 summarizes the average number of singular value decompositions (SVDs) used and the average test error. Here test error is defined as

$$\text{Test error} = \frac{\|\mathcal{P}_{\Omega_{\text{obs}}^{\perp}}(X_0 - \hat{X})\|_F^2}{\|\mathcal{P}_{\Omega_{\text{obs}}^{\perp}} X_0\|_F^2},$$

where $\mathcal{P}_{\Gamma}$ is the projection operator to the set of locations of the observed noisy entries (but not outliers) Γ, and $\hat{X}$ is an estimate of X_0. From Figure 1 (Top), one can see that the performance of Robust-Impute is slightly inferior to Soft-Impute in the case of no outliers ($p = 0$), while Robust-Impute gave significantly better results when outliers were present ($p = 0.1$). The inferior performance of Robust-Impute under the absence of outliers is not surprising, as it is widely known in the statistical literature that a small fraction of statistical efficiency would be lost when a robust method is applied to a data set without outliers. However, it is also known that the gain could be substantial if outliers did present.

As for computational requirements, one can see from Figure 1 (Bottom) that Robust-Impute only used slightly more SVDs on average. For ranks greater than 5, the number of SVDs used by Robust-Impute only differs from Soft-Impute on average by less than 1. This suggests that Robust-Impute is slightly more computationally demanding than Soft-Impute.

Similar experimental results were obtained for the remaining 16 simulation settings. For brevity, the corresponding results are omitted here but can be found in the supplementary document.

From this experiment some empirical conclusions can be drawn. When there is no outlier, Soft-Impute gives slightly better results, while with outliers, results from Robust-Impute are substantially better. Since that in practice one often does not know if outliers are present or not, and that Robust-Impute is not much more computationally demanding than Soft-Impute, it seems that Robust-Impute is the choice of method if one wants to be more conservative.

5.2 Experiment 2: Image Inpainting

In this experiment the target matrix is the so-called Lena image that has been used by many authors in the image processing literature. It consists of 256×256 pixels and is shown in Figure 2 (Left). The simulated data sets were generated via contaminating this Lena image by adding Gaussian noises and/or outliers in the following manner. First independent Gaussian noise was added to each pixel, where the standard deviation of the noise was set such that the SNR is 3. Next, 10% of the pixels were selected as outliers, and to them additional independent Gaussian noises with SNR 3/4 were added. In terms of selecting missing pixels, two mechanisms were considered. In the first one 40% of the pixels were randomly chosen as missing pixels, while in the second mechanism only 10% were missing but they were clustered together to form patches. Two typical simulated data sets are shown in Figure 2 (Middle). Note that Theorem 4 does not cover the second missing mechanism.

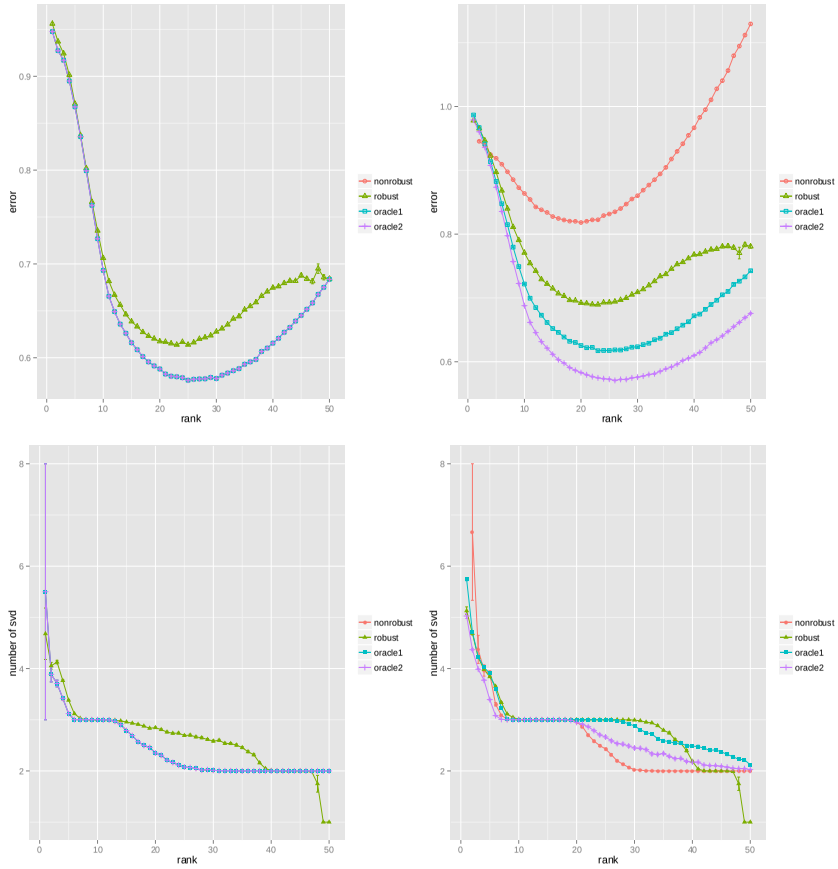

Figure 1: Top: The average test errors with their standard error bands (plus or minus one standard error). Bottom: The average number of singular value decompositions used with standard error bands (plus or minus one standard error). Left: results for the simulation setting: $r = 10$, $p = 0$ and $q = 0.5$. Right: results for the simulation setting: $r = 10$, $p = 0.1$ and $q = 0.5$.

		training error				testing error			
	rank	50	75	100	125	50	75	100	125
independent missing	Soft-Impute	0.0499	0.0351	0.0221	0.0113	0.0578	0.0565	0.0581	0.0620
	Robust-Impute	0.0486	0.0371	0.0282	0.0252	0.0546	0.0540	0.0557	0.0571
clustered missing	Soft-Impute	0.0487	0.0386	0.0296	0.0214	0.0756	0.0751	0.0760	0.0781
	Robust-Impute	0.0468	0.0390	0.0321	0.0268	0.0716	0.0714	0.0723	0.0742

Table 1: The average training and testing errors for the Lena experiment.

For each missing mechanism, 200 data sets were generated and both Soft-Impute and Robust-Impute were applied to reconstruct Lena.

The average training and testing errors[1] of the recovered images of matrix ranks 50, 75, 100 and 125 are reported in Table 1. For both missing mechanisms, Soft-Impute tends to have lower training errors, but larger testing errors when compared to Robust-Impute. In other words, Soft-Impute tends to over-fit the data, and Robust-Impute seems to provide better results. Lastly, for visual evaluation, the recovered image of rank 100 using Robust-Impute is displayed in Figure 1 (Right). From this one can see that the proposed Robust-Impute provided good recoveries under both missing mechanisms.

5.3 Real data application: Landsat Thematic Mapper

In this application the target matrix is an image from a Landsat Thematic Mapper data set publicly available at `http://ternauscover.science.uq.edu.au/`. This data set contains 149 multiband images of 100×100 pixels, with each image consists of six bands (blue, green and red with three infrared bands). The scene is centered on the Tumbarumba flux tower on the western slopes of the Snowy Mountains in Australia. Due to wild fires or related reasons, some pixels are of value zero which can be treated as missing. Also, due to detector malfunctioning, some isolated pixels have values much higher than the remaining pixels, which can be treated as outliers. We selected an image band with a high missing rate (27.6%) to test our procedure.

To evaluate the recovered matrix, the observed pixels were split into training, validation and testing sets consisting 80%, 10% and 10% of the observed (nonzero) entries respectively. We used the validation set to tune γ. The validation errors are computed in two ways: mean squared error (MSE) $\sqrt{\sum_{(i,j)\in\mathcal{V}}(X_{ij}-\hat{X}_{ij})^2/|\mathcal{V}|}$ and mean absolute deviation (MAD) $\text{median}\{|X_{ij}-\hat{X}_{ij}| : (i,j)\in\mathcal{V}\}$, where $\mathcal{V}$ represents the validation set. Similarly, we compute the testing errors in terms of MSE and MAD. Note that the validation and testing sets may contain outliers and therefore MAD serves as a robust and reliable performance measure. The corresponding results are shown in Table 2. From this table it can be seen that with the presence of outliers, Robust-Imputeprovided better results.

1. The solution path (formed by the pre-specified set of γ's) may not contain any solution of rank 50, 75, 100 and 125. Thus, the average errors were computed over those fittings that contained the corresponding fitted ranks. At most 2% of these fittings were discarded due to this reason.

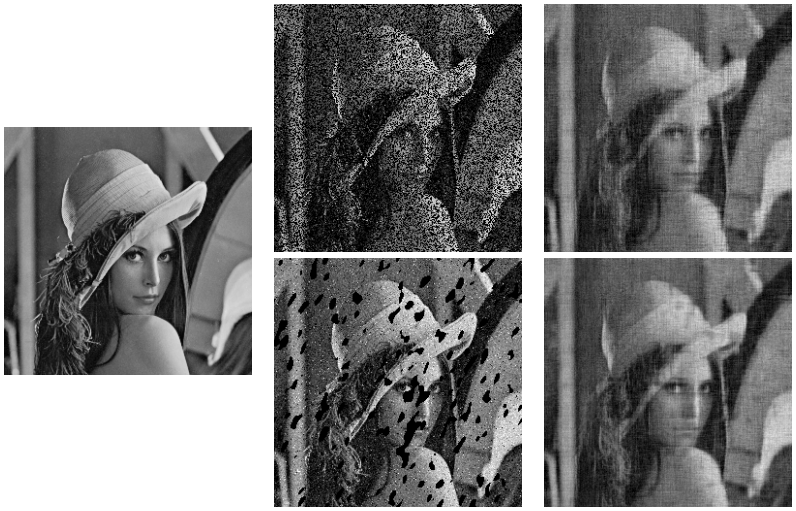

Figure 2: Left: the Lena image. Middle: degraded Lena images by the independent missing mechanism (Top) and the clustered missing mechanism (Down). Right: corresponding recovered images of rank 100 via Robust-Impute.

	tuning by MSE			tuning by MAD		
	rank	MSE	MAD	rank	MSE	MAD
Soft-Impute	24	45.20	31.15	21	45.23	31.15
Robust-Impute	24	44.63	29.00	29	44.57	28.76

Table 2: Rank and testing errors of the real data application.

6. Concluding remarks

In this paper a classical idea from robust statistics has been brought to the matrix completion problem. The result is a new matrix completion method that can handle noisy and outlying entries. This method uses the Huber function to downweigh the effects of outliers. A new algorithm is developed to solve the corresponding optimization problem. This algorithm is relatively fast, easy to implement and monotonic convergent. It can be paired with any existing (non-robust) matrix completion methods to make such methods robust against outliers. We also developed a specialized version of this algorithm, called Robust-Impute. Its promising empirical performance has been illustrated via numerical experiments. Lastly, we have shown that the proposed method is stable; that is, with high probability, the error of recovered matrix is bounded by a constant proportional to the noise level.

Acknowledgments

The authors are most grateful to the referees and the action editor for their many constructive and useful comments, which led to a much improved version of the paper. The work of Wong was partially supported by the National Science Foundation under Grants DMS-1612985 and DMS-1711952 (subcontract). The work of Lee was partially supported by the National Science Foundation under Grants DMS-1512945 and DMS-1513484.

Appendix A. Technical Details

In this section, we provide technical details of our theoretical results.

A.1 Proofs of Proposition 1

Proof By rewriting

$$\begin{aligned}&\|\mathcal{P}_{\Omega_{\text{obs}}}Z^{(k+1)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}\|_F^2\\&=\|\mathcal{P}_{\Omega_{\text{obs}}}Z^{(k+1)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}\|_F^2+\|\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}\|_F^2\\&\quad 2\times\text{trace}\left[\{\mathcal{P}_{\Omega_{\text{obs}}}Z^{(k+1)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}\}\{\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}\}^\intercal\right],\end{aligned}$$

and using $f(Y^{(k+1)}|Z^{(k+1)})\le f(Y^{(k)}|Z^{(k+1)})$, we have

$$\begin{aligned}&\frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}\|_F^2+\text{trace}\left[\{\mathcal{P}_{\Omega_{\text{obs}}}Z^{(k+1)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}\}\{\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}\}^\intercal\right]\\&\quad+\gamma\|Y^{(k+1)}\|_*\le\gamma\|Y^{(k)}\|_*.\end{aligned}$$

Thus, by substituting $Z^{(k+1)}=\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}+\frac{1}{2}\rho_c'(\mathcal{P}_{\Omega_{\text{obs}}}X-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)})$,

$$\begin{aligned}&\frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}\|_F^2+\frac{1}{2}\text{trace}\left[\rho_c'(\mathcal{P}_{\Omega_{\text{obs}}}X-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)})\{\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}\}^\intercal\right]\\&\quad+\gamma\|Y^{(k+1)}\|_*\le\gamma\|Y^{(k)}\|_*.\end{aligned}\tag{10}$$

Here we abuse the notation slightly so that ρ_c' of a matrix simply means the matrix formed by applying ρ_c' to its entries. Note that for each $(i,j)\in\Omega_{\text{obs}}$, by Taylor's expansion,

$$\begin{aligned}\rho_c(X_{ij}-Y_{ij}^{(k+1)})&=\rho(X_{ij}-Y_{ij}^{(k)})+(Y_{ij}^{(k)}-Y_{ij}^{(k)})\rho_c'(X_{ij}-Y_{ij}^{(k)})\\&\quad+\int_{X_{ij}-Y_{ij}^{(k)}}^{X_{ij}-Y_{ij}^{(k+1)}}(X_{ij}-Y_{ij}^{(k+1)}-t)\rho_c''(t)dt,\end{aligned}$$

and the last integral term is less than or equal to $(Y_{ij}^{(k)}-Y_{ij}^{(k+1)})^2$ due to $\rho_c''\le 2$ almost everywhere. Thus,

$$\begin{aligned}\sum_{(i,j)\in\Omega_{\text{obs}}}\rho_c(X_{ij}-Y_{ij}^{(k+1)})&\le\sum_{(i,j)\in\Omega_{\text{obs}}}\rho_c(X_{ij}-Y_{ij}^{(k)})\\&\quad+\text{trace}\left[\rho_c'(\mathcal{P}_{\Omega_{\text{obs}}}X-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)})\{\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}\}^\intercal\right]\\&\quad+\|\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}\|_F^2.\end{aligned}$$

Now, plugging it into (10), we have $g(Y^{(k+1)})\le g(Y^{(k)})$. ■

Proof (Alternative proof of Proposition 1) Similar to the proof of Proposition 3 in Section A.3, one can show that

$$g(Y)=\min_S\frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}X-\mathcal{P}_{\Omega_{\text{obs}}}Y-\mathcal{P}_{\Omega_{\text{obs}}}S\|_F^2+\gamma\|Y\|_*+c\|S\|_1,\tag{11}$$

where the minimizer is $S(Y)=(1/2)\psi_c(\mathcal{P}_{\Omega_{\text{obs}}}X-\mathcal{P}_{\Omega_{\text{obs}}}Y)$. Now, one can show that

$$\begin{aligned}Z^{(k+1)}&=\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}+(1/2)\psi_c(\mathcal{P}_{\Omega_{\text{obs}}}X-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)})\\&=\mathcal{P}_{\Omega_{\text{obs}}}X+(1/2)\psi_c(\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}-\mathcal{P}_{\Omega_{\text{obs}}}X)\\&=\mathcal{P}_{\Omega_{\text{obs}}}X-(1/2)\psi_c(\mathcal{P}_{\Omega_{\text{obs}}}X-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)})\\&=\mathcal{P}_{\Omega_{\text{obs}}}X-S(Y^{(k)}).\end{aligned}$$

Now, due to (11),

$$\begin{aligned}g(Y^{(k+1)})&=\min_S\frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}X-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}-\mathcal{P}_{\Omega_{\text{obs}}}S\|_F^2+\gamma\|Y^{(k+1)}\|_*+c\|S\|_1\\&\le\frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}X-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}-\mathcal{P}_{\Omega_{\text{obs}}}S(Y^{(k)})\|_F^2+\gamma\|Y^{(k+1)}\|_*+c\|S(Y^{(k)})\|_1\\&=f(Y^{(k+1)}|X-S(Y^{(k)}))+c\|S(Y^{(k)})\|_1\\&=f(Y^{(k+1)}|\mathcal{P}_{\Omega_{\text{obs}}}X-S(Y^{(k)}))+c\|S(Y^{(k)})\|_1\\&=f(Y^{(k+1)}|Z^{(k+1)})+c\|S(Y^{(k)})\|_1\\&\le f(Y^{(k)}|Z^{(k+1)})+c\|S(Y^{(k)})\|_1\\&=\frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}X-\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}-\mathcal{P}_{\Omega_{\text{obs}}}S(Y^{(k)})\|_F^2+\gamma\|Y^{(k)}\|_*+c\|S(Y^{(k)})\|_1\\&=g(Y^{(k)}).\end{aligned}$$

■

A.2 Proof of Theorem 2 for Algorithm 1

Proof This proof closely follows the proofs of Lemma 2.3 and Theorem 3.1 in Beck and Teboulle (2009) by modifying their approximation model to

$$\begin{aligned}\zeta(Y,\tilde{Y}) &= g_1(\tilde{Y}) + \langle Y-\tilde{Y}, \nabla g_1(\tilde{Y})\rangle + \frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}Y - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y}\|_F^2 + g_2(Y)\\ &= g_1(\tilde{Y}) - \frac{1}{2}\langle Y-\tilde{Y}, \psi_c(\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y})\rangle + \frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}Y - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y}\|_F^2 + g_2(Y)\\ &= g_1(\tilde{Y}) - \frac{1}{2}\langle \mathcal{P}_{\Omega_{\text{obs}}}Y - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y}, \psi_c(\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y})\rangle + \frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}Y - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y}\|_F^2\\ &\quad + g_2(Y),\end{aligned}$$

where $\langle X, Y\rangle = \sum_{i,j} X_{ij}Y_{ij}$. Note that $\arg\min_Y \zeta(Y,\tilde{Y})$ is the same as $\arg\min_Y f(Y|Z)$, where $Z = \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y} + (1/2)\psi_c(\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y})$, in Steps 2(a)-(c) of Algorithm 1. Let $\Pi(\tilde{Y}) = \arg\min_Y \zeta(Y,\tilde{Y})$. Therefore $Y^{(k+1)} = \Pi(Y^{(k)})$. Moreover,

$$g_1(Y) \le g_1(\tilde{Y}) + \langle Y-\tilde{Y}, \nabla g_1(\tilde{Y})\rangle + \frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}Y - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y}\|_F^2,$$

for any Y and $\tilde{Y}$. Therefore, $g(\Pi(\tilde{Y})) \le \zeta(\Pi(\tilde{Y}),\tilde{Y})$ for any $\tilde{Y} \in \mathbb{R}^{n_1\times n_2}$.

To proceed, we need a modified version of Lemma 2.3 in Beck and Teboulle (2009).

Lemma 5 *For any $\tilde{Y}, Y \in \mathbb{R}^{n_1\times n_2}$,*

$$g(Y) - g(\Pi(\tilde{Y})) \ge \frac{1}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}\Pi(\tilde{Y}) - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y}\|_F^2 + \langle \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y} - \mathcal{P}_{\Omega_{\text{obs}}}Y, \mathcal{P}_{\Omega_{\text{obs}}}\Pi(\tilde{Y}) - \mathcal{P}_{\Omega_{\text{obs}}}Y\rangle.$$

This lemma is proved as follows. Since $\Pi(\tilde{Y})$ is the minimizer of the convex function $\zeta(\cdot,\tilde{Y})$, there exists a $b(\tilde{Y}) \in \partial g_2(\Pi(\tilde{Y}))$, the subdifferential of g_2 at $\Pi(\tilde{Y})$, such that $\nabla g_1(\tilde{Y}) + \mathcal{P}_{\Omega_{\text{obs}}}\Pi(\tilde{Y}) - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y} + b(\tilde{Y}) = 0$. By the convexity of g_1 and g_2,

$$\begin{aligned} g_1(Y) &\ge g_1(\tilde{Y}) - \frac{1}{2}\langle Y-\tilde{Y}, \psi_c(\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y})\rangle\\ g_2(Y) &\ge g_2(\Pi(\tilde{Y})) - \langle Y - \Pi(\tilde{Y}), b(\tilde{Y})\rangle.\end{aligned}$$

Therefore,

$$g(Y) \ge g_1(\tilde{Y}) - \frac{1}{2}\langle Y-\tilde{Y}, \psi_c(\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}\tilde{Y})\rangle + g_2(\Pi(\tilde{Y})) - \langle Y - \Pi(\tilde{Y}), b(\tilde{Y})\rangle. \quad (12)$$

Since $g(\Pi(\tilde{Y})) \le \zeta(\Pi(\tilde{Y}),\tilde{Y})$, we have $g(Y) - g(\Pi(\tilde{Y})) \ge g(Y) - \zeta(\Pi(\tilde{Y}),\tilde{Y})$. Plugging in (12), the definition of ζ and the condition for b, the conclusion of the lemma follows.

Using Lemma 5 with $Y = Y^*$ and $\tilde{Y} = Y^{(k)}$, we have

$$2\{g(Y^*) - g(Y^{(k)})\} \ge \|\mathcal{P}_{\Omega_{\text{obs}}}Y^* - \mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)}\|_F^2 - \|\mathcal{P}_{\Omega_{\text{obs}}}Y^* - \mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}\|_F^2.$$

Summing it over $k = 0,\ldots,m-1$,

$$2\left\{mg(Y^*) - \sum_{k=0}^{m-1} g(Y^{(k)})\right\} \ge \|\mathcal{P}_{\Omega_{\text{obs}}}Y^* - \mathcal{P}_{\Omega_{\text{obs}}}Y^{(m)}\|_F^2 - \|\mathcal{P}_{\Omega_{\text{obs}}}Y^* - \mathcal{P}_{\Omega_{\text{obs}}}Y^{(0)}\|_F^2. \quad (13)$$

Applying Lemma 5 with $Y = \tilde{Y} = Y^{(k)}$,

$$2\left\{g(Y^{(k)}) - g(Y^{(k+1)})\right\} \ge \|\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)} - \mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}\|_F^2.$$

Multiplying it by k and summing over $k = 0,\ldots,m-1$,

$$2\left\{-mg(Y^{(m)}) + \sum_{k=0}^{m-1} g(Y^{(k+1)})\right\} \ge \sum_{k=0}^{m-1} k\|\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)} - \mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}\|_F^2. \quad (14)$$

Adding (13) and (14),

$$\begin{aligned}2\left\{g(Y^*) - g(Y^{(m)})\right\} &\ge \|\mathcal{P}_{\Omega_{\text{obs}}}Y^* - \mathcal{P}_{\Omega_{\text{obs}}}Y^{(m)}\|_F^2 - \|\mathcal{P}_{\Omega_{\text{obs}}}Y^* - \mathcal{P}_{\Omega_{\text{obs}}}Y^{(0)}\|_F^2\\ &\quad + \sum_{k=0}^{m-1} k\|\mathcal{P}_{\Omega_{\text{obs}}}Y^{(k+1)} - \mathcal{P}_{\Omega_{\text{obs}}}Y^{(k)}\|_F^2.\end{aligned}$$

Therefore,

$$g(Y^{(m)}) - g(Y^*) \le \frac{\|\mathcal{P}_{\Omega_{\text{obs}}}Y^* - \mathcal{P}_{\Omega_{\text{obs}}}Y^{(0)}\|_F^2}{2m}.$$

■

A.3 Proof of Proposition 3

Proof Since both (2) and (7) are convex, we only need to consider the sub-gradients. The sub-gradient conditions for minimizier of (2) are given as follows:

$$0 \in -\frac{1}{2}\rho_c'(\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}Y) + \gamma\partial\|Y\|_*, \quad (15)$$

where $\partial\|\cdot\|_*$ represents the set of subgradients of the nuclear norm. The sub-gradient conditions for minimizier of (7) are given as follows:

$$0 \in -\mathcal{P}_{\Omega_{\text{obs}}}(X - L - S) + \gamma\partial\|L\|_* \quad (16)$$

$$0 \in -\mathcal{P}_{\Omega_{\text{obs}}}(X - L - S) + c\partial\|S\|_1, \quad (17)$$

where $\partial\|\cdot\|_1$ represents the set of subgradients of $\|\cdot\|_1$. Here (17) implies, for $(i,j) \in \Omega_{\text{obs}}$,

$$S_{ij} = \begin{cases} X_{ij} - L_{ij} - c, & X_{ij} - L_{ij} > c\\ 0, & |X_{ij} - L_{ij}| \le c\\ X_{ij} - L_{ij} + c, & X_{ij} - L_{ij} < -c\end{cases} \quad (18)$$

and $S_{ij} = 0$ for $(i,j) \in \Omega_{\text{obs}}^{\perp}$. Note, for $(i,j) \in \Omega_{\text{obs}}$, $X_{ij} - L_{ij} - S_{ij} = \rho_c'(X_{ij} - L_{ij})/2$. Plugging it into (16), we have (15) and thus this proves the proposition. ■

A.4 Proof of Theorem 4

To prove Theorem 4, we first show three lemmas and one proposition.

Lemma 6 (Modified Lemma A.2 in Candès et al. 2011) *Assume that for any matrix Q, $\|\mathcal{P}_T\mathcal{P}_{\Gamma^\perp}Q\|_F \le n\|\mathcal{P}_{T^\perp}\mathcal{P}_{\Gamma^\perp}Q\|_F$. Suppose there is a pair (W,F) obeying*

$$\begin{cases}\mathcal{P}_T W = 0, \quad \|W\| < 1/2,\\ \mathcal{P}_{\Gamma^\perp}F = 0, \quad \|F\|_\infty < 1/2,\\ UV^\intercal + W + \mathcal{P}_T D = \lambda(\mathrm{sgn}(S_0') + F) \quad \text{with} \quad \|\mathcal{P}_T D\|_F \le n^{-2}.\end{cases} \tag{19}$$

Then for any perturbation $H = (H_L, H_S)$ satisfying $\mathcal{P}_{\Omega_{\text{obs}}}H_L + \mathcal{P}_{\Omega_{\text{obs}}}H_S = 0$,

$$\|M_0 - H\|_\Diamond \ge \|M_0\|_\Diamond + \left(\frac{1}{2} - \frac{1}{n}\right)\|\mathcal{P}_{T^\perp}H_L\|_* + \left(\frac{\lambda}{2} - \frac{n+1}{n^2}\right)\|\mathcal{P}_\Gamma H_L\|_1.$$

The proof of this lemma can be found in Candès et al. (2011). To procced, we write $\|M\|_{F,\lambda}^2 = \|L\|_F^2 + \lambda^2\|S\|_F^2$ for any pair of matrices $M = (L,S)$.

Lemma 7 *Let $M = (M_L, M_S)$ be any pair of matrices. Suppose $\|\mathcal{P}_T\mathcal{P}_\Omega\|^2 \le p_0/8$ and $\|\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T M_L\|_F^2 \ge p_0\|\mathcal{P}_T M_L\|_F^2/2$. Then*

$$\|\mathcal{P}_\Psi(\mathcal{P}_T \times \mathcal{P}_\Omega)M\|_{F,\lambda}^2 \ge \frac{(1+\lambda^2)p_0}{16}\|(\mathcal{P}_T \times \mathcal{P}_\Omega)M\|_F^2.$$

Proof (Proof of Lemma 7) Note that for any $M' = (M_L', M_S')$,

$$\mathcal{P}_\Psi M' = \left(\frac{\mathcal{P}_{\Omega_{\text{obs}}}(M_L' + M_S')}{2}, \frac{\mathcal{P}_{\Omega_{\text{obs}}}(M_L' + M_S')}{2}\right).$$

Thus

$$\begin{aligned}\|\mathcal{P}_\Psi(\mathcal{P}_T \times \mathcal{P}_\Omega)M\|_{F,\lambda}^2 &= \frac{1+\lambda^2}{4}\|\mathcal{P}_{\Omega_{\text{obs}}}(\mathcal{P}_T M_L + \mathcal{P}_\Omega M_S)\|_F^2\\ &= \frac{1+\lambda^2}{4}\left(\|\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T M_L\|_F^2 + \|\mathcal{P}_\Omega M_S\|_F^2 + 2\langle\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T M_L, \mathcal{P}_\Omega M_S\rangle\right),\end{aligned}$$

where the last equality is due to $\Omega \subset \Omega_{\text{obs}}$. By $\|\mathcal{P}_T\mathcal{P}_\Omega\|^2 \le p_0/8$,

$$\begin{aligned}\langle\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T M_L, \mathcal{P}_\Omega M_S\rangle &= \langle\mathcal{P}_T M_L, \mathcal{P}_\Omega M_S\rangle\\ &= \langle\mathcal{P}_T M_L, (\mathcal{P}_T\mathcal{P}_\Omega)\mathcal{P}_\Omega M_S\rangle\\ &\ge -\|\mathcal{P}_T\mathcal{P}_\Omega\|\|\mathcal{P}_T M_L\|_F\|\mathcal{P}_\Omega M_S\|_F\\ &\ge -\frac{\sqrt{p_0}}{2\sqrt{2}}\|\mathcal{P}_T M_L\|_F\|\mathcal{P}_\Omega M_S\|_F.\end{aligned}$$

Combining with $\|\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T M_L\|_F^2 \ge p_0\|\mathcal{P}_T M_L\|_F^2/2$, we have

$$\|\mathcal{P}_\Psi(\mathcal{P}_T \times \mathcal{P}_\Omega)M\|_{F,\lambda}^2 \ge \frac{1+\lambda^2}{4}\left(\frac{p_0}{2}\|\mathcal{P}_T M_L\|_F^2 + \|\mathcal{P}_\Omega M_S\|_F^2 - \sqrt{\frac{p_0}{2}}\|\mathcal{P}_T M_L\|_F\|\mathcal{P}_\Omega M_S\|_F\right).$$

As $2(x^2+y^2-xy) \ge x^2+y^2$ for $x, y \ge 0$,

$$\|\mathcal{P}_\Psi(\mathcal{P}_T \times \mathcal{P}_\Omega)M\|_{F,\lambda}^2 \ge \frac{1+\lambda^2}{8}\left(\frac{p_0}{2}\|\mathcal{P}_T M_L\|_F^2 + \|\mathcal{P}_\Omega M_S\|_F^2\right) \ge \frac{(1+\lambda^2)p_0}{16}\|(\mathcal{P}_T \times \mathcal{P}_\Omega)M\|_F^2.$$

■

Lemma 8 *Let $M = (M_L, M_S)$ be any pair of matrices. Then $\|\mathcal{P}_\Psi M\|_{F,\lambda}^2 \le \|M\|_{F,\lambda}^2/2$.*

Proof (Proof of Lemma 8) Write $M^\Psi = (M_L^\Psi, M_S^\Psi) = \mathcal{P}_\Psi M$. Since $\|M_L^\Psi\|_F^2 = \|M_S^\Psi\|_F^2$,

$$\begin{aligned}\|\mathcal{P}_\Psi M\|_{F,\lambda}^2 &= \|M_L^\Psi\|_F^2 + \lambda^2\|M_S^\Psi\|_F^2\\ &= \frac{1}{2}(\|M_L^\Psi\|_F^2 + \|M_S^\Psi\|_F^2) + \frac{\lambda^2}{2}(\|M_L^\Psi\|_F^2 + \|M_S^\Psi\|_F^2)\\ &= \frac{1}{2}\|M^\Psi\|_F^2 + \frac{\lambda^2}{2}\|M^\Psi\|_F^2\\ &\le \frac{1}{2}\|M\|_F^2 + \frac{\lambda^2}{2}\|M\|_F^2 = \frac{1}{2}\|M\|_{F,\lambda}^2.\end{aligned}$$

■

Proposition 9 *Assume that for any matrix Q,*

$$\|\mathcal{P}_T\mathcal{P}_{\Gamma^\perp}Q\|_F \le n\|\mathcal{P}_{T^\perp}\mathcal{P}_{\Gamma^\perp}Q\|_F \quad \text{and} \quad \|\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T Q\|_F \ge p_0\|\mathcal{P}_T Q\|_F/2.$$

Further suppose $4/n < \lambda \le 1$, $n \ge 3$, $p_0 > 0$, $\|\mathcal{P}_T\mathcal{P}_\Omega\|^2 \le p_0/8$ and that there exists a pair (W,F) obeying (19). Then the solution $\hat{M} = (\hat{L}, \hat{S})$ to (7) satisfies

$$\|\hat{M} - M_0\|_{F,\lambda} \le \left[\sqrt{1+\lambda^2} + 4\left(1 + \sqrt{\frac{8}{p_0}}\right)(\sqrt{n} + n\lambda\sqrt{p_0})\right]\delta.$$

where $M_0 = (L_0, S_0')$ such that $\|\mathcal{P}_{\Omega_{\text{obs}}}X - \mathcal{P}_{\Omega_{\text{obs}}}(L_0 + S_0))\|_F^2 \le \delta$ and $S_0' = \mathcal{P}_{\Omega_{\text{obs}}}S_0$. Further, if $\lambda = 1/\sqrt{np_0}$ (which implies $1/n < p_0 < n/16$), we obtain

$$\|\hat{L} - L\|_F \le \left\{2 + 8\sqrt{n}\left(1 + \sqrt{\frac{8}{p_0}}\right)\right\}\delta \quad \text{and} \quad \|\hat{S} - S_0'\|_F \le \left\{2 + 8\sqrt{n}\left(1 + \sqrt{\frac{8}{p_0}}\right)\right\}\sqrt{np_0}\delta.$$

Proof (Proof of Proposition 9) Write $\hat{M} = M_0 + H$, where $H = (H_L, H_S)$, and $H^\Psi = (H_L^\Psi, H_S^\Psi) = \mathcal{P}_\Psi H$ and $H^{\Psi^\perp} = (H_L^{\Psi^\perp}, H_S^{\Psi^\perp}) = \mathcal{P}_{\Psi^\perp}H$. We want to bound

$$\begin{aligned}\|H\|_{F,\lambda} &= \|H^\Psi + H^{\Psi^\perp}\|_{F,\lambda}\\ &\le \|H^\Psi\|_{F,\lambda} + \|H^{\Psi^\perp}\|_{F,\lambda}\\ &\le \|H^\Psi\|_{F,\lambda} + \|(\mathcal{P}_{T^\perp} \times \mathcal{P}_\Gamma)H^{\Psi^\perp}\|_{F,\lambda} + \|(\mathcal{P}_T \times \mathcal{P}_{\Gamma^\perp})H^{\Psi^\perp}\|_{F,\lambda}.\end{aligned} \tag{20}$$

We start with the first term of (20). Since $H_L^\Psi = H_S^\Psi = (1/2)\mathcal{P}_{\Omega_{\text{obs}}}(H_L + H_S)$,

$$\begin{aligned}\|H^\Psi\|_{F,\lambda} &= \frac{\sqrt{1+\lambda^2}}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}(H_L + H_S)\|_F \\ &= \frac{\sqrt{1+\lambda^2}}{2}\|\mathcal{P}_{\Omega_{\text{obs}}}(\hat{L} + \hat{S} - L_0 - S_0')\|_F \\ &\le \frac{\sqrt{1+\lambda^2}}{2}\left(\|\mathcal{P}_{\Omega_{\text{obs}}}(\hat{L} + \hat{S} - X)\|_F + \|\mathcal{P}_{\Omega_{\text{obs}}}(L_0 + S_0' - X)\|_F\right) \\ &\le \delta\sqrt{1+\lambda^2},\end{aligned}$$

where the last inequality is due to the fact that both M_0 and $\hat{M}$ are feasible.

Then we focus on the second term of (20). First, we have

$$\|M_0\|_\diamond \ge \|\hat{M}\|_\diamond = \|M_0 + H\|_\diamond \ge \|M_0 + H^{\Psi^\perp}\|_\diamond - \|H^\Psi\|_\diamond.$$

By Lemma 6,

$$\|M_0 + H^{\Psi^\perp}\|_\diamond \ge \|M_0\|_\diamond + a(n)\|\mathcal{P}_{T^\perp}H_L^{\Psi^\perp}\|_* + b(n,\lambda)\|\mathcal{P}_\Gamma H_L^{\Psi^\perp}\|_1,$$

where

$$a(n) = \frac{1}{2} - \frac{1}{n} \quad \text{and} \quad b(n,\lambda) = \frac{\lambda}{2} - \frac{n+1}{n^2}.$$

Now, combining the above inequalities,

$$\|H^\Psi\|_\diamond \ge a(n)\|\mathcal{P}_{T^\perp}H_L^{\Psi^\perp}\|_* + b(n,\lambda)\|\mathcal{P}_\Gamma H_L^{\Psi^\perp}\|_1. \tag{21}$$

By the assumption that $\lambda > 4/n$ and $n \ge 3$,

$$a(n) = \frac{1}{2} - \frac{1}{n} > 0 \quad \text{and} \quad b(n,\lambda) = \frac{\lambda}{2} - \frac{n+1}{n^2} > \frac{2}{n} - \frac{1}{n} - \frac{1}{n^2} = \frac{1}{n} - \frac{1}{n^2} > 0.$$

Therefore (21) implies $\|H^\Psi\|_\diamond \ge a(n)\|\mathcal{P}_{T^\perp}H_L^{\Psi^\perp}\|_*$ and $\|H^\Psi\|_\diamond \ge b(n,\lambda)\|\mathcal{P}_\Gamma H_L^{\Psi^\perp}\|_1$.

Now, we are ready to establish a bound for the second term of (20).

$$\begin{aligned}\|(\mathcal{P}_{T^\perp} \times \mathcal{P}_\Gamma)H^{\Psi^\perp}\|_{F,\lambda} &\le \|\mathcal{P}_{T^\perp}H_L^{\Psi^\perp}\|_F + \lambda\|\mathcal{P}_\Gamma H_S^{\Psi^\perp}\|_F \\ &\le \|\mathcal{P}_{T^\perp}H_L^{\Psi^\perp}\|_* + \lambda\|\mathcal{P}_\Gamma H_S^{\Psi^\perp}\|_1 \\ &\le \left\{\frac{1}{a(n)} + \frac{\lambda}{b(n,\lambda)}\right\}\|H^\Psi\|_\diamond \\ &\le 4(\|H_L^\Psi\|_* + \lambda\|H_S^\Psi\|_1).\end{aligned}$$

As for the third term of (20), we apply Lemma 7 and the bound of the second term in (20). As $\mathcal{P}_\Psi H^{\Psi^\perp} = 0$, $\mathcal{P}_\Psi(\mathcal{P}_T \times \mathcal{P}_{\Gamma^\perp})H^{\Psi^\perp} + \mathcal{P}_\Psi(\mathcal{P}_{T^\perp} \times \mathcal{P}_\Gamma)H^{\Psi^\perp} = 0$. Therefore, due to Lemma 8,

$$\|\mathcal{P}_\Psi(\mathcal{P}_T \times \mathcal{P}_{\Gamma^\perp})H^{\Psi^\perp}\|_{F,\lambda} = \|\mathcal{P}_\Psi(\mathcal{P}_{T^\perp} \times \mathcal{P}_\Gamma)H^{\Psi^\perp}\|_{F,\lambda} \le \frac{1}{\sqrt{2}}\|(\mathcal{P}_{T^\perp} \times \mathcal{P}_\Gamma)H^{\Psi^\perp}\|_{F,\lambda}.$$

As $\mathcal{P}_{\Omega_{\text{obs}}^\perp}H_S$ does not affect the feasibility of $M+H$ and H is chosen such that $\|M+H\|_\diamond$ is minimized, thus $\mathcal{P}_{\Omega_{\text{obs}}^\perp}H_S^{\Psi^\perp} = \mathcal{P}_{\Omega_{\text{obs}}^\perp}H_S = 0$ which implies $(\mathcal{P}_T \times \mathcal{P}_{\Gamma^\perp})H^{\Psi^\perp} = (\mathcal{P}_T \times \mathcal{P}_\Omega)H^{\Psi^\perp}$. Thus, by Lemma 7,

$$\|(\mathcal{P}_T \times \mathcal{P}_{\Gamma^\perp})H^{\Psi^\perp}\|_F \le \sqrt{\frac{8}{(1+\lambda^2)p_0}}\|(\mathcal{P}_{T^\perp} \times \mathcal{P}_\Gamma)H^{\Psi^\perp}\|_{F,\lambda} \le \sqrt{\frac{8}{p_0}}\|(\mathcal{P}_{T^\perp} \times \mathcal{P}_\Gamma)H^{\Psi^\perp}\|_{F,\lambda}.$$

And $\|(\mathcal{P}_T \times \mathcal{P}_{\Gamma^\perp})H^{\Psi^\perp}\|_{F,\lambda} \le \|(\mathcal{P}_T \times \mathcal{P}_{\Gamma^\perp})H^{\Psi^\perp}\|_F$ as $\lambda \le 1$.

Collecting all the above bounds for the three terms, we derive the bound for $\|H\|_{F,\lambda}$:

$$\|H\|_{F,\lambda} \le \delta\sqrt{1+\lambda^2} + 4\left(1 + \sqrt{\frac{8}{p_0}}\right)(\|H_L^\Psi\|_* + \lambda\|H_S^\Psi\|_1).$$

Finally, $\|H_L^\Psi\|_* \le \sqrt{n}\|H_L^\Psi\|_F$, $\|H_S^\Psi\|_1 = \sqrt{p_0 n^2}\|H_S^\Psi\|_F$ (since H_S^Ψ is supported on Ω_{obs}) and $\|H_L^\Psi\|_F = \|H_S^\Psi\| = \|\mathcal{P}_{\Omega_{\text{obs}}}(H_L + H_S)\|_F/2 \le \delta$. Therefore,

$$\|H\|_{F,\lambda} \le \delta\left[\sqrt{1+\lambda^2} + 4\left(1 + \sqrt{\frac{8}{p_0}}\right)(\sqrt{n} + n\lambda\sqrt{p_0})\right].$$

Assume that $\lambda = 1/\sqrt{np_0}$. First we note that, due to $\lambda > 4/n$, this condition imposes a reasonable coverage of p_0: $1/n < p_0 < n/16$. Now we focus on simplifying the bound for $\|H\|_{F,\lambda}$.

$$\sqrt{1+\lambda^2} + 4\left(1 + \sqrt{\frac{8}{p_0}}\right)(\sqrt{n} + n\lambda\sqrt{p_0}) \le 2 + 8\sqrt{n}\left(1 + \sqrt{\frac{8}{p_0}}\right).$$

This implies

$$\|H_L\|_F \le \left\{2 + 8\sqrt{n}\left(1 + \sqrt{\frac{8}{p_0}}\right)\right\}\delta \qquad \text{and} \qquad \|H_S\|_F \le \left\{2 + 8\sqrt{n}\left(1 + \sqrt{\frac{8}{p_0}}\right)\right\}\sqrt{np_0}\delta.$$

■

To prove Theorem 4, we establish one additional lemma.

Lemma 10 *Suppose* $\|\mathcal{P}_T - p_0^{-1}\mathcal{P}_T\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T\| \le 1/2$. *Then for any matrix* Q,

$$\|\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T Q\|_F^2 \ge \frac{p_0}{2}\|\mathcal{P}_T Q\|_F^2.$$

Proof (Proof of Lemma 10) By the assumptions, for any matrix Q,

$$\begin{aligned}\|\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T Q\|_F^2 &= \langle \mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T Q, \mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T Q\rangle \\ &= \langle \mathcal{P}_T Q, \mathcal{P}_T\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T Q\rangle \\ &= p_0\langle \mathcal{P}_T Q, p_0^{-1}\mathcal{P}_T\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T Q\rangle \\ &= p_0\left[\|\mathcal{P}_T Q\|_F^2 + \langle \mathcal{P}_T Q, (p_0^{-1}\mathcal{P}_T\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T - \mathcal{P}_T)Q\rangle\right] \\ &\le p_0\left(\|\mathcal{P}_T Q\|_F^2 - \frac{1}{2}\|\mathcal{P}_T Q\|_F^2\right) \\ &= \frac{p_0}{2}\|\mathcal{P}_T Q\|_F^2.\end{aligned}$$

■

Proof (Proof of Theorem 4) Recall that we write that an event occurs with high probability if it holds with probability at least $1 - \mathcal{O}(n^{-10})$. Due to the asymptotic nature of Theorem 4, we only require the conditions of Proposition 9 to hold asymptotically with large probability. By Lemma A.3 of Candès et al. (2011), $\|\mathcal{P}_T\mathcal{P}_{\Gamma^\perp}Q\|_F \leq n\|\mathcal{P}_{T^\perp}\mathcal{P}_{\Gamma^\perp}Q\|_F$ for all Q, with high probability. By Lemma 10 and Theorem 2.6 of Candès et al. (2011) (see also Candès and Recht, 2009, Theorem 4.1), $\|\mathcal{P}_{\Omega_{\text{obs}}}\mathcal{P}_T Q\|_F^2 \geq \frac{p_0}{2}\|\mathcal{P}_T Q\|_F^2$ for all Q, with high probability. Further, by Candès and Recht (2009), $\|\mathcal{P}_T\mathcal{P}_\Omega\|^2 \leq p_0/8$ occurs with high probability. Candès et al. (2011, pp. 33-35) show that there exist dual certificates (W, F) obeying (19) with high probability. For sufficiently large n, the conditions of λ and p_0 in Proposition 9 are fulfilled. Therefore, Theorem 4 follows from Proposition 9. ■

Abstract

A main question in graphical models and causal inference is whether, given a probability distribution P (which is usually an underlying distribution of data), there is a graph (or graphs) to which P is faithful. The main goal of this paper is to provide a theoretical answer to this problem. We work with general independence models, which contain probabilistic independence models as a special case. We exploit a generalization of ordering, called preordering, of the nodes of (mixed) graphs. This allows us to provide sufficient conditions for a given independence model to be Markov to a graph with the minimum possible number of edges, and more importantly, necessary and sufficient conditions for a given probability distribution to be faithful to a graph. We present our results for the general case of mixed graphs, but specialize the definitions and results to the better-known subclasses of undirected (concentration) and bidirected (covariance) graphs as well as directed acyclic graphs.

Keywords: causal discovery, compositional graphoid, directed acyclic graph, faithfulness, graphical model selection, independence model, Markov property, mixed graph, structural learning

1. Introduction

Graphs have been used in graphical models in order to capture the conditional independence structure of probability distributions. Generally speaking, nodes of the graph correspond to random variables and missing edges to conditional independencies (Lauritzen, 1996). The connection between graphs and probability distributions is usually established in the literature by the concept of Markov property (Clifford, 1990; Pearl, 1988; Studený, 1989), which ensures that if there is a specific type of separation between node subsets A and B of the graph "given the node subset C" then random vectors X_A and X_B are conditionally independent given the random vector X_C in the probability distribution. However, the "ultimate" connection between probability distributions and graphs requires the other direction to hold, namely for every conditional independence in the probability distribution to correspond to a separation in the graph. This connection has been called faithfulness of the probability distribution and the graph in Spirtes et al. (2000), and the graph has been called the perfect map of such a distribution in Pearl (1988).

However, "given a probability distribution P whether there is a graph (or graphs) to which P is faithful" is an open problem, and consequently so is the problem of finding these graphs. This problem can be raised for any type of graph existing in the literature of graphical models ranging from different types of mixed graphs with three types of edges (Richardson and Spirtes, 2002; Wermuth, 2011; Sadeghi, 2016) and different types of chain graphs (Lauritzen and Wermuth, 1989; Frydenberg, 1990; Andersson et al., 2001; Cox and Wermuth, 1993; Wermuth, 2011) to better-known classes of undirected (concentration) (Darroch et al., 1980) and bidirected (covariance) (Kauermann, 1996) graphs as well as directed acyclic graphs (Kiiveri et al., 1984; Pearl, 1988). Our goal is to provide an answer to this problem. A similar problem of "given a graph whether there is a family of distributions faithful to it" has been answered for very specific types of graphs and specific types of distributions; for example, for Gaussian distributions and undirected graphs in Lněnička and Matúš (2007), DAGs in Pearl (1988); Geiger et al. (1990); Spirtes et al. (2000), ancestral graphs in Richardson and Spirtes (2002), and LWF chain graphs in Peña (2011); and discrete distributions and DAGs in Geiger et al. (1990); Meek (1995) and LWF chain graphs in Peña (2009).

The concept of faithfulness was originally defined for the purpose of causal inference (Spirtes et al., 2000; Pearl, 1988), and the theory developed in this paper can be interpreted in causal language. A main approach to causal inference is based on graphical representations of causal structures, usually represented by *causal graphs* that are directed acyclic with nodes as random variables (that is a Bayesian network). Causal graphs are assumed to capture the true causal structure; see, for example, Neapolitan (2004). A main assumption made is called the *causal faithfulness condition* (CFC) stating that the true probability distribution is faithful to the true causal graph. Although the distribution being faithful to the "true underlying causal graph" is a much stronger assumption, it necessarily means that it must be faithful to "some graph" in order for one to be able to use graphical methods for causal inference. For an extensive discussion on the CFC, see Zhang and Spirtes (2008), and for related philosophical discussions, see, for example, Woodward (1998); Steel (2006). Although the results in this paper cover those of causal Bayesian networks, we have developed our theory to a much more general case of simultaneous representation of "direct effects", "confounding", and "non-causal symmetric dependence structures"; see, for example, Pearl (2009).

In this paper, we work with the general independence model $\mathcal{J}$. Independence models $\mathcal{J}(P)$ induced by probability distributions P are a special case. We provide necessary and sufficient conditions for $\mathcal{J}$ to be graphical, that is to be faithful to a graph. In short, as proved in Theorem 17, $\mathcal{J}$ is graphical if and only if it satisfies the so-called compositional graphoid axioms as well as singleton-transitivity, and what we call ordered upward- and downward-stability.

As apparent from their names, ordered upward- and downward-stability depend on a generalization of ordering of variables, and consequently the nodes of the graph (called preordering). We provide our results for the most general case of mixed graphs, which contains almost all classes of graphs used in graphical models as subclasses with the exception of the chain graphs with the AMP Markov property (Andersson et al., 2001) and its generalizations (Peña, 2014). However, based on the preordering w.r.t. which ordered upward- and downward-stability are satisfied, one can deduce to what type (or types) of graph P is faithful.

Since many of the subclasses of mixed graphs are not as well-known or used as some simpler classes of graphs, we provide a specialization of definitions and the main results for undirected and bidirected graphs as well as directed acyclic graphs at the end of the paper. We advise the readers that are only familiar with or interested in these simpler subclasses to skip the general definitions and results for mixed graphs, and focus on the specialization.

The structure of the paper is as follows: In the next section, we provide the basic definitions for graphs as well as different classes of graphs in graphical models, and independence models. In Section 3, we define and provide basic results for Markovness and faithfulness of independence models and graphs. In Section 4, we define and exploit the preordering for (so-called anterial) graphs, and then we define the concept of upward- and downward-stability. In Section 5, we provide sufficient conditions for an independence model to be so-called minimally Markov to a graph, and then we provide necessary and sufficient conditions for an independence model to be faithful to a graph. In Section 6, we specialize the definitions and results to the classes of undirected and bidirected graphs as well as directed acyclic graphs. In Section 7, we show how other results in the literature concerning faithfulness of certain probability distributions and certain classes of graphs are corollaries of our results. This also provides a nice set of examples for the theory presented in the paper. In Section 8, we end the paper with a short summary, a discussion on the statistical implications of the results, and an outline of future work.

2. Definitions and Concepts

In this section, we provide the basic definitions and concepts needed for the paper.

2.1 Graph Theoretical Definitions and Concepts

A *graph* G is a triple consisting of a *node* set or *vertex* set V, an *edge* set E, and a relation that with each edge associates two nodes (not necessarily distinct), called its *endpoints*. When nodes i and j are the endpoints of an edge, they are *adjacent*. We call a node adjacent to the node i, a *neighbour* of i, and denote the set of all neighbours of i by $\mathrm{ne}(i)$. We say that an edge is *between* its two endpoints. We usually refer to a graph as an ordered pair $G = (V, E)$. Graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ are called *equal* if $(V_1, E_1) = (V_2, E_2)$. In this case we write $G_1 = G_2$.

Notice that our graphs are *labeled*, that is every node is considered a different object. Hence, for example, graph $i \text{——} j \text{——} k$ is not equal to $j \text{——} i \text{——} k$.

A *loop* is an edge with the same endpoints. Here we only discuss graphs without loops. *Multiple edges* are edges with the same pair of endpoints. A *simple graph* has neither loops nor multiple edges.

Graphs in this paper are so-called *mixed graphs*, which contain three types of edges: *lines* ($i \text{——} j$), *arrows* ($i \text{——>} j$), and *arcs* ($i \text{<—>} j$), where in the two latter cases, we say that there is an *arrowhead* at j. If we remove all arrowheads from edges of the graph G, the obtained undirected graph is called the *skeleton* of G. The simple graph whose edge ij indicates whether there is an edge (or multiple edges) between i and j in G is called the *adjacency graph* of G. It is clear that if a graph is simple then its adjacency graph is the same as its skeleton. In this paper, only skeleton of anterial graphs or its subclasses are used, which, as will be defined later, are simple graphs; hence, we denote the simple skeleton by $\mathrm{sk}(G)$. We say that we *direct* the edges of a skeleton by putting arrowheads at the edges in order to obtain mixed graphs.

A *subgraph* of a graph G_1 is graph G_2 such that $V(G_2) \subseteq V(G_1)$ and $E(G_2) \subseteq E(G_1)$ and the assignment of endpoints to edges in G_2 is the same as in G_1. We define a subgraph *induced by edges* $A \subseteq E$ of $G = (V, E)$ to be a subgraph that contains V as the node set and all and only edges in A as the edge set.

A *walk* is a list $\langle v_0, e_1, v_1, \ldots, e_k, v_k \rangle$ of nodes and edges such that for $1 \leq i \leq k$, the edge e_i has endpoints v_{i-1} and v_i. A *path* is a walk with no repeated node or edge. A maximal set of nodes in a graph whose members are connected by some paths constitutes a *connected component* of the graph. A *cycle* is a walk with no repeated nodes or edges except for $v_0 = v_k$.

We say a walk is *between* the first and the last nodes of the list in G. We call the first and the last nodes *endpoints* of the walk and all other nodes *inner nodes*.

A *subwalk* of a walk $\omega = \langle i_0, e_1, i_1, \ldots, e_n, i_n \rangle$ is a walk $\langle i_r, e_{r+1}, i_{r+1}, \ldots, e_p, i_p \rangle$ that is a subsequence of ω between two occurrences of nodes (i_r, i_p, $0 \leq r \leq p \leq n$). If a subwalk forms a path then it is called a *subpath* of ω.

A walk $\omega = \langle i = i_0, i_1, \ldots, i_n = j \rangle$ is *directed* from i to j if all edges $i_k i_{k+1}$, $0 \leq k \leq n-1$, are arrows pointing from i_k to i_{k+1}. If there is a directed walk from i to j then i is an *ancestor* of j and j is a *descendant* of i. We denote the set of ancestors of j by $\mathrm{an}(j)$.

A walk $\omega = \langle i = i_0, i_1, \ldots, i_n = j \rangle$ is *semi-directed* from i to j if it has at least one arrow, no arcs, and every arrow $i_k i_{k+1}$ is pointing from i_k to i_{k+1}. A walk between i and j is *anterior* from i to j if it is semi-directed from i to j or if it is undirected. If there is an anterior walk from i to j then we also say that i is an *anterior* of j. We use the notation $\mathrm{ant}(j)$ for the set of all anteriors of j. For a set A, we define $\mathrm{ant}(A) = \bigcup_{j \in A} \mathrm{ant}(j) \setminus A$.

Notice that, unlike in most places in the literature (for example Richardson and Spirtes 2002), we use walks instead of paths to define ancestors and anteriors. Because of this and the fact that ancestral graphs have no arrowheads pointing to lines, our definition of anterior extends the notion of anterior for ancestral graphs in Richardson and Spirtes (2002) with the modification that in this paper, a node is not an anterior of itself. Using walks instead of paths is immaterial, as shown in Lauritzen and Sadeghi (2017).

A *section* ρ of a walk is a maximal subwalk consisting only of lines, meaning that there is no other subwalk that only consists of lines and includes ρ. Thus, any walk decomposes uniquely into sections; these are not necessarily edge-disjoint and sections may also be single nodes. A section ρ on a walk ω is called a *collider section* if one of the following walks is a subwalk of ω: $i \text{——>} \rho \text{<——} j$, $i \text{<—>} \rho \text{<——} j$, $i \text{<—>} \rho \text{<—>} j$. All other sections on ω are called *non-collider* sections. Notice that a section may be a collider on one walk and a non-collider on another, but we may speak of collider or non-collider sections without mentioning the relevant walk when this is apparent from the context.

2.2 Different Classes of Graphs

All the subclasses of graphs included here are *acyclic* in the sense that they do not contain semi-directed cycles. The most general class of graphs discussed here is the class of *chain mixed graphs* (CMGs) (Sadeghi, 2016) that contains all mixed graphs without semi-directed cycles. They may have multiple edges containing an arc and a line or an arc and an

arrow but not a combination of an arrow and a line or arrows in opposite directions, as such combinations would constitute semi-directed cycles. In this paper, in using the term "graph" we mean a CMG unless otherwise stated.

A general class of graphs that plays an important role in this paper is the class of *anterial graphs* (AnGs) (Sadeghi, 2016). AnGs are CMGs in which an endpoint of an arc cannot be an anterior of the other endpoint.

CMGs include *summary graphs* (SGs) (Wermuth, 2011) and *acyclic directed mixed graphs* (ADMGs) (Richardson, 2003) as a subclass, but not include *AMP chain graphs* (Andersson et al., 2001), and AnGs include *ancestral graphs* (AGs) (Richardson and Spirtes, 2002) but not SGs or ADMGs. These have typically been introduced to describe independence structures obtained by marginalization and conditioning in DAG independence models; see for example Sadeghi (2013).

AnGs also contain *undirected and bidirected chain graphs* (CGs). A chain graph is an acyclic graph so that if we remove all arrows, all connected components of the resulting graph—called *chain components*—contain one type of edge only. If all chain components contain lines, the chain graph is an undirected chain graph (UCG) (known as *LWF chain graphs*); if all chain components contain arcs it is a bidirected chain graph (BCG) (known as *multivariate regression chain graphs*). AnGs also contain *Regression graphs* (Wermuth and Sadeghi, 2012), which are chain graphs consisting of lines and arcs (although dashed undirected edges have mostly been used instead of arcs in the literature), where there is no arrowhead pointing to lines.

These also contain graphs with only one type of edge; namely *undirected graphs* (UGs), containing only lines; *bidirected graphs* (BGs), containing only bidirected edges; and *directed acyclic graphs* (DAGs), containing only arrows and being acyclic. Clearly, a graph without arrows has no semi-directed cycles, and a semi-directed cycle in a graph with only arrows is a directed cycle. Cox and Wermuth (1993); Kauermann (1996); Wermuth and Cox (1998); Drton and Richardson (2008) used the terms *concentration graphs* and *covariance graphs* for UGs and BGs, referring to their independence interpretation associated with covariance and concentration matrices for Gaussian graphical models. DAGs have been particularly useful to describe causal Markov relations; see for example Kiiveri et al. (1984); Pearl (1988); Lauritzen and Spiegelhalter (1988); Geiger et al. (1990); Spirtes et al. (2000).

For an extensive discussion on the subclasses of acyclic graphs and their relationships and hierarchy, see Lauritzen and Sadeghi (2017).

2.3 Independence Models and Their Properties

An *independence model* $\mathcal{J}$ over a finite set V is a set of triples $\langle X, Y \,|\, Z\rangle$ (called *independence statements*), where X, Y, and Z are disjoint subsets of V; Z may be empty, but $\langle \varnothing, Y \,|\, Z\rangle$ and $\langle X, \varnothing \,|\, Z\rangle$ are always included in $\mathcal{J}$. The independence statement $\langle X, Y \,|\, Z\rangle$ is read as "X is independent of Y given Z". Independence models may in general have a probabilistic interpretation, but not necessarily. Similarly, not all independence models can be easily represented by graphs. For further discussion on general independence models, see Studený (2005).

In order to define probabilistic independence models, consider a set V and a collection of random variables $\{X_\alpha\}_{\alpha\in V}$ with state spaces $\mathcal{X}_\alpha, \alpha \in V$ and joint distribution P. We let

$X_A = \{X_v\}_{v\in A}$ etc. for each subset A of V. For disjoint subsets A, B, and C of V we use the short notation $A \perp\!\!\!\perp B \,|\, C$ to denote that X_A is *conditionally independent of* X_B *given* X_C (Dawid, 1979; Lauritzen, 1996), that is that for any measurable $\Omega \subseteq \mathcal{X}_A$ and P-almost all x_B and x_C,

$$P(X_A \in \Omega \,|\, X_B = x_B, X_C = x_C) = P(X_A \in \Omega \,|\, X_C = x_C).$$

We can now induce an independence model $\mathcal{J}(P)$ by letting

$$\langle A, B \,|\, C\rangle \in \mathcal{J}(P) \text{ if and only if } A \perp\!\!\!\perp B \,|\, C \text{ w.r.t. } P.$$

Similarly we use the notation $A \not\perp\!\!\!\perp B \,|\, C$ for $\langle A, B \,|\, C\rangle \notin \mathcal{J}(P)$.

In order to use graphs to represent independence models, the notion of *separation* in a graph is fundamental. For three disjoint subsets A, B, and C, we use the notation $A \perp B \,|\, C$ if A and B are *separated* given C, and $A \not\perp B \,|\, C$ for A and B not separated given C.

The separation can be unified under one definition for all graphs by using walks instead of paths: A walk π is *connecting* given C if every collider section of π has a node in C and all non-collider sections are disjoint from C. For pairwise disjoint subsets (A, B, C), $A \perp B \,|\, C$ if there are no connecting walks between A and B given C. This is in wording the same as the definition in Studený and Bouckaert (1998) for undirected (LWF) chain graphs (although it is in fact a generalization as collider sections are generalized), and a generalization of the *m-separation* used with different wordings in Richardson and Spirtes (2002); Wermuth (2011); Wermuth and Sadeghi (2012) for AGs and SGs, and of the *d-separation* of Pearl (1988). For UGs, the notion has a direct intuitive meaning, so that $A \perp B \,|\, C$ if all paths from A to B pass through C.

If A, B, or C has only one member $\{i\}$, $\{j\}$, or $\{k\}$, for better readability, we write $\langle i, j \,|\, k\rangle \in \mathcal{J}$ instead of $\langle\{i\}, \{j\} \,|\, \{k\}\rangle \in \mathcal{J}$; and similarly for $i \perp j \,|\, k$ and $i \perp\!\!\!\perp j \,|\, k$. We also write $A \perp B$ when $C = \varnothing$; and similarly $A \perp\!\!\!\perp B$.

A graph G induces an independence model $\mathcal{J}(G)$ by separation, letting

$$\langle A, B \,|\, C\rangle \in \mathcal{J}(G) \iff A \perp B \,|\, C \text{ in } G.$$

An independence model $\mathcal{J}$ over a set V is a *semi-graphoid* if it satisfies the four following properties for disjoint subsets A, B, C, and D of V:

1. $\langle A, B \,|\, C\rangle \in \mathcal{J}$ if and only if $\langle B, A \,|\, C\rangle \in \mathcal{J}$ (*symmetry*);
2. if $\langle A, B \cup D \,|\, C\rangle \in \mathcal{J}$ then $\langle A, B \,|\, C\rangle \in \mathcal{J}$ and $\langle A, D \,|\, C\rangle \in \mathcal{J}$ (*decomposition*);
3. if $\langle A, B \cup D \,|\, C\rangle \in \mathcal{J}$ then $\langle A, B \,|\, C \cup D\rangle \in \mathcal{J}$ and $\langle A, D \,|\, C \cup B\rangle \in \mathcal{J}$ (*weak union*);
4. if $\langle A, B \,|\, C \cup D\rangle \in \mathcal{J}$ and $\langle A, D \,|\, C\rangle \in \mathcal{J}$ then $\langle A, B \cup D \,|\, C\rangle \in \mathcal{J}$ (*contraction*).

Notice that the reverse implication of contraction clearly holds by decomposition and weak union. A semi-graphoid for which the reverse implication of the weak union property holds is said to be a *graphoid*; that is, it also satisfies

5. if $\langle A, B \,|\, C \cup D\rangle \in \mathcal{J}$ and $\langle A, D \,|\, C \cup B\rangle \in \mathcal{J}$ then $\langle A, B \cup D \,|\, C\rangle \in \mathcal{J}$ (*intersection*).

Furthermore, a graphoid or semi-graphoid for which the reverse implication of the decomposition property holds is said to be *compositional*, that is, it also satisfies

6. if $\langle A, B \,|\, C\rangle \in \mathcal{J}$ and $\langle A, D \,|\, C\rangle \in \mathcal{J}$ then $\langle A, B \cup D \,|\, C\rangle \in \mathcal{J}$ (*composition*).

Separation in graphs satisfies all these properties; see Theorem 1 in Lauritzen and Sadeghi (2017):

Proposition 1 *For any graph G, the independence model $\mathcal{J}(G)$ is a compositional graphoid.*

On the other hand, probabilistic independence models are always semi-graphoids (Pearl, 1988), whereas the converse is not necessarily true; see Studený (1989). If, for example, P has strictly positive density, the induced independence model is always a graphoid; see, for example, Proposition 3.1 in Lauritzen (1996). See also Peters (2015) for a necessary and sufficient condition for the intersection property to hold. If the distribution P is a regular multivariate Gaussian distribution, $\mathcal{J}(P)$ is a compositional graphoid; for example see Studený (2005). Probabilistic independence models with positive densities are not in general compositional; this only holds for special types of multivariate distributions such as, for example, Gaussian distributions and the symmetric binary distributions used in Wermuth et al. (2009).

Another important property that is satisfied by separation in all graphs, but not necessarily for probabilistic independence models, is *singleton-transitivity* (also called *weak transitivity* in Pearl (1988), where it is shown that for Gaussian and binary distributions P, $\mathcal{J}(P)$ always satisfies it). For i, j, and k, single elements in V,

7. if $\langle i, j \,|\, C\rangle \in \mathcal{J}$ and $\langle i, j \,|\, C \cup \{k\}\rangle \in \mathcal{J}$ then $\langle i, k \,|\, C\rangle \in \mathcal{J}$ or $\langle j, k \,|\, C\rangle \in \mathcal{J}$ (singleton-transitivity).

A singleton-transitive compositional graphoid is equivalent to what is called a *Gaussoid* in Lněnička and Matúš (2007) with a rather different axiomatization. The name reminds one that these are the axioms satisfied by the independence model of a regular Gaussian distribution (Pearl, 1988).

Proposition 2 *For a graph G, $\mathcal{J}(G)$ satisfies singleton-transitivity.*

Proof If there is a walk between i and k given C and a walk between j and k given C then by connecting these two walks, we obtain a walk π between i and j. Except the section ρ that contains k, all collider sections on π have a node in C and all non-collider sections are outside C. Hence depending on ρ being a collider or non-collider, π is connecting given $C \cup \{k\}$ or C respectively. ■

3. Markov and Faithful Independence Models

In this section, we define and discuss the concepts of Markovness and faithfulness for probability distributions, independence models, and graphs.

3.1 Markov Properties

For a graph $G = (V, E)$, an independence model $\mathcal{J}$ defined over V satisfies the *global Markov property* w.r.t. G, or is simply *Markov* to G, if for disjoint subsets A, B, and C of V it holds that

$$A \perp B \,|\, C \implies \langle A, B \,|\, C\rangle \in \mathcal{J},$$

or equivalently $\mathcal{J}(G) \subseteq \mathcal{J}$. In particular, the graphical independence $\mathcal{J}(G)$ is trivially Markov to its graph G.

For a probability distribution P, we simply say P is *Markov to* a graph G if $\mathcal{J}(P)$ is Markov to G, that is if $\mathcal{J}(G) \subseteq \mathcal{J}(P)$. Notice that every independence model over V is Markov to the complete graph with the node set V.

For a graph $G = (V, E)$, an independence model $\mathcal{J}$ defined over V satisfies a *pairwise Markov property* w.r.t. a graph G, or is simply *pairwise Markov to* G, if for every non-adjacent pair of nodes i, j, it holds that $\langle i, j \,|\, C(i,j)\rangle \in \mathcal{J}$, for some $C(i,j)$, where $C(i,j)$ is *the conditioning set* of the pairwise Markov property and does not include i and j.

The independence model $\mathcal{J}(G)$ only satisfies pairwise Markov properties w.r.t. what is called *maximal graphs*, which are graphs where the lack of an edge between i and j corresponds to a conditional separation statement for i and j. For a probability distribution P, we say P is *pairwise Markov to* a graph G if $\mathcal{J}(P)$ is pairwise Markov to G.

For maximal graphs, a pairwise Markov property is defined by letting $C(i,j) = \text{ant}(i) \cup \text{ant}(j) \setminus \{i, j\}$ (Lauritzen and Sadeghi, 2017), which we henceforth use as "the" pairwise Markov property. The conditioning set of the pairwise Markov property simplifies for DAGs, $C(i,j) = an(i) \cup \text{an}(j) \setminus \{i, j\}$ (Richardson and Spirtes, 2002; Sadeghi and Lauritzen, 2014); for BGs, $C(i,j) = \varnothing$ (as defined in Wermuth and Cox 1998); and for connected UGs, $C(i,j) = V \setminus \{i, j\}$ (as defined in Lauritzen 1996).

This pairwise Markov property, is in fact equivalent to the global Markov property under compositional graphoids; see Theorem 4 of Lauritzen and Sadeghi (2017):

Proposition 3 *Let G be a maximal graph. If the independence model $\mathcal{J}$ is a compositional graphoid, then $\mathcal{J}$ is pairwise Markov to G if and only if $\mathcal{J}$ is Markov to G.*

In particular, for UGs, the equivalence of the global and pairwise Markov properties holds under graphoids, and for BGs under compositional semi-graphoids.

Two undirected or two bidirected graphs G and H, where $G \neq H$, induce different independence models; that is $\mathcal{J}(G) \neq \mathcal{J}(H)$. This is not necessarily true for larger subclasses. We call two graphs G and H such that $\mathcal{J}(G) = \mathcal{J}(H)$ *Markov equivalent*. Conditions for Markov equivalence for most subclasses of graphs are known; see Verma and Pearl (1990); Ali et al. (2009); Wermuth and Sadeghi (2012). Notice that two Markov equivalent maximal graphs have the same skeleton.

3.2 Faithfulness and Minimal Markovness

We say that an independence model $\mathcal{J}$ and a probability distribution P are *faithful* if $\mathcal{J} = \mathcal{J}(P)$. Similarly, we say that $\mathcal{J}$ and a graph G are faithful if $\mathcal{J} = \mathcal{J}(G)$. We also say that P and G are faithful if $\mathcal{J}(P) = \mathcal{J}(G)$. If P and G are faithful then we may sometimes also say that P is *faithful to* G or vice versa, although in principle faithfulness is a symmetric relation; the same holds for saying that $\mathcal{J}$ is faithful to G or P. Notice that

we are extending the definition of faithfulness to include the relation between independence models and graphs as well as independence models and probability distributions rather than only that between graphs and probability distributions as originally used in Spirtes et al. (2000).

Thus, if $\mathcal{J}$ and G are faithful then $\mathcal{J}$ is Markov to G, but it also requires every independence statement to correspond to a separation in G. We say that $\mathcal{J}$ or G is *probabilistic* if there is a distribution P that is faithful to $\mathcal{J}$ or G respectively. If there is a graph that is faithful to $\mathcal{J}$ or P then we say that $\mathcal{J}$ or P is *graphical*.

Our main goal is to characterize graphical probability distributions, and in addition, if existent, to provide graphs that are faithful to a given P. We solve this problem for the general case of independence models $\mathcal{J}$.

For a given independence model $\mathcal{J}$, we define the *skeleton* of $\mathcal{J}$, denoted by $\mathrm{sk}(\mathcal{J})$, to be the undirected graph that is obtained from $\mathcal{J}$ as follows: we define the node set of $\mathrm{sk}(\mathcal{J})$ to be V, and for every pair of nodes i, j, we check whether $\langle i, j \,|\, C\rangle \in \mathcal{J}$ holds for some $C \subseteq V \setminus \{i, j\}$; if it does not then we draw an edge between i and j. One can similarly define $\mathrm{sk}(P)$ for a probability distribution P by checking whether $i \perp\!\!\!\perp j \,|\, C$. This is the same as the graph obtained by the first step of the SGS algorithm (Glymour et al., 1987). Notice that this is not necessarily the same as the undirected graph obtained by the pairwise Markov property for UGs; see Section 6.1.

For UGs and BGs, the skeleton of $\mathcal{J}$ uniquely determines the graph, whereas for other subclasses, there are several graphs with the same skeleton $\mathrm{sk}(\mathcal{J})$. As will be seen, the preordering, defined in the next section, enables us to direct the edges of the skeleton.

Proposition 4 *If an independence model $\mathcal{J}$ is Markov to a graph G then* $\mathrm{sk}(\mathcal{J})$ *is a subgraph of* $\mathrm{sk}(G)$.

Proof Suppose that there is no edge between i and j in $\mathrm{sk}(G)$. Since the global Markov property w.r.t. G implies the pairwise Markov property, it holds that $\langle i, j \,|\, C(i, j)\rangle \in \mathcal{J}$, which implies i is not adjacent to j in $\mathrm{sk}(\mathcal{J})$. ■

Hence, if $\mathcal{J}$ is Markov to a graph G such that $\mathrm{sk}(G) = \mathrm{sk}(\mathcal{J})$ then G has the fewest number of edges among those to which $\mathcal{J}$ is Markov. We say that $\mathcal{J}$ is *minimally Markov* to a graph G if $\mathcal{J}$ is Markov to G and $\mathrm{sk}(G) = \mathrm{sk}(\mathcal{J})$. The same can be defined for probability distributions, and has been used in the literature under the name of *(causal) minimality assumption* (Pearl, 2009; Spirtes et al., 2000; Zhang and Spirtes, 2008; Neapolitan, 2004). Minimally Markov independence models to a graph are important since only these can also be faithful to the graph:

Proposition 5 *If an independence model $\mathcal{J}$ and a graph G are faithful then $\mathcal{J}$ is minimally Markov to G.*

Proof Since $\mathcal{J}$ is Markov to G, we need to prove that $\mathrm{sk}(G) = \mathrm{sk}(\mathcal{J})$. By Proposition 4, $\mathrm{sk}(\mathcal{J})$ is a subgraph of $\mathrm{sk}(G)$. Now, suppose that there is no edge between i and j in $\mathrm{sk}(\mathcal{J})$. By the construction of $\mathrm{sk}(\mathcal{J})$, it holds that $\langle i, j \,|\, C\rangle \in \mathcal{J}$ for some C. Since $\mathcal{J}$ and G are faithful, $i \perp j \,|\, C$ in G. This implies that i is not adjacent to j in G. ■

Hence, we need to discuss conditions under which $\mathcal{J}$ is minimally Markov to a graph as well as conditions for faithfulness of minimally Markov independence models and graphs. These will be presented in Section 5.

4. Preordering in Graphs and Ordered Stabilities

In this section, we first define the preordering for sets and its validity for nodes of the graphs, and then use preordering to define some new properties of conditional independence.

4.1 Preordering of the Nodes of a Graph

Over a set V, a *partial order* is a binary relation $\leq$ that satisfies the following properties for all members $a, b, c \in V$:

- $a \leq a$ (*reflexivity*);
- if $a \leq b$ and $b \leq a$ then $a = b$ (*antisymmetry*);
- if $a \leq b$ and $b \leq c$ then $a \leq c$ (*transitivity*).

If $a \leq b$ or $b \leq a$ then a and b are *comparable*; otherwise they are *incomparable*. A partial order under which every pair of elements is comparable is called a *total order* or a *linear order*.

A *preorder* $\lesssim$ over V, on the other hand, is a binary relation that is only reflexive and transitive. Given a preorder $\lesssim$ over V, one may define an equivalence relation $\sim$ on V such that $a \sim b$ if and only if $a \lesssim b$ and $b \lesssim a$. This explains the use of the notation $\lesssim$. It then holds that

- if $a \lesssim b$ and $b \sim c$ then $a \lesssim c$; and
- if $a \lesssim b$ and $a \sim c$ then $c \lesssim b$.

We also use the notation $a < b$ indicating that $a \lesssim b$ and $a \not\sim b$.

We first provide the following result; see Section 5.2.1 of Schröder (2003):

Proposition 6 *Let $\lesssim$ be a preorder over the set V, and $\sim$ the equivalence relation on V as defined above. Let also Q be the set of all equivalence classes of V w.r.t. $\sim$. Then the relation $\leq$ defined over Q by $\big[[a] \leq [b] \iff a \lesssim b\big]$ is a partial order over Q.*

We say that a graph $G = (V, E)$ admits a *valid preorder* $\lesssim$ if, for nodes i and j of G, the following holds:

- if $i \text{ —— } j$ then $i \sim j$;
- if $i \longrightarrow j$ then $j < i$;
- if $i \dashleftarrow\!\dashrightarrow j$ then i and j are incomparable.

The global interpretation of a valid preorder on graphs is as follows:

Proposition 7 *Let $\lesssim$ be a valid preorder for a graph G. It then holds for nodes i and j of G that if $i \in \mathrm{ant}(j)$ then $j \lesssim i$; in particular,*

1. *if there is a semi-directed path from i to j then $j < i$; and*
2. *if i and j are connected by a path consisting only of lines then $i \sim j$.*

Proof The proof follows from transitivity of both preorders and anterior paths. ■

Corollary 8 *Let $\lesssim$ be a valid preorder for a graph G and G_- its subgraph induced by lines. The equivalence classes of G based on $\lesssim$ are the connected components of G_-. In addition, $\leq$ defines a partial order over the connected components of G_- by [if $i \longrightarrow j$, $i \in \tau$ and $j \in \delta$ then $\tau > \delta$], for τ and δ two connected components of G_-.*

Proof The results follows from Propositions 7 and 6. ■

For example, consider the graph in Fig. 1. The graph admits a valid preorder with the preorder provided over the nodes, or equivalently over the connected components of G_- (with the abuse of the notation for numbering). The notation implies that two nodes with label 2 are in the same equivalence class, $2 > 1$ and $2' > 1'$, but a, b', and c'', $a, b, c \in \{1, 2\}$, are not comparable.

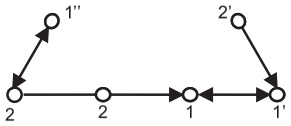

Figure 1: A preordered graph.

There may be many different preorders that are valid for a graph. If there is a valid preordering and we expect the other direction of Proposition 7 to hold then we obtain a unique preordering for the graph: Given a graph G, if $i \notin \text{ant}(j)$ and $j \notin \text{ant}(i)$ then set i and j to be incomparable. Otherwise, let $i \sim j$ when $i \multimap\!\!-\!\!\multimap j$, and $i > j$ when $i \longrightarrow j$. It is easy to see that this, in fact, is a preorder for the nodes of G. We call this preordering the *minimal preorder* for G since it gives the fewest possible comparable pairs of nodes. For example, the preordering in the graph of Fig. 1 is minimal. In this paper, we mostly deal with this type of preorderings for graphs. It is easy to observe the following:

Proposition 9 *If G is anterial then the minimal preorder for G is a valid preorder for G.*

In fact, in general, we have the following:

Proposition 10 *A graph admits a valid preorder if and only if it is anterial.*

Proof If a graph G admits a valid preorder then by Proposition 7, there cannot be a directed cycle, nor can there be an arc with one endpoint anterior of the other. The converse is Proposition 9. ■

Therefore, in addition to CMGs, SGs (and ADMGs) do not admit a valid preorder, but AGs do. However, notice that for every CMG, there exists a Markov equivalent AnG (see Sadeghi 2016); and the same for SGs and AG. Hence, the question of whether there is a CMG that is faithful to $\mathcal{J}$ is the same as whether there is an AnG that is faithful to $\mathcal{J}$; and the same holds for SG and AG.

As discussed above, there is a one-to-one correspondence between AnGs and the minimal preorder for the AnGs. When the skeleton of the concerned graph is known, we have the following trivial result:

Proposition 11 *Given the skeleton of a graph G and a preorder $\lesssim$ of its nodes, G can be constructed uniquely by directing the edges of* $\text{sk}(G)$. *In addition, $\lesssim$ is a valid preorder for G.*

Let $\mathcal{J}$ be defined over V. We introduce preordering in this paper in order to stress that, in principle, a preordering of members of V (which are possibly random variables) is defined irrespective of graphs to which they are Markov or faithful. However, for our purposes, knowing the skeleton of such graphs, one can directly discover the directions of the edges of the graph, which correspond to the minimal preordering for the graph, rather than working directly on the set V.

Suppose that there exists a preorder $\lesssim$ over V. Proposition 11 implies that we can direct the edges of $\text{sk}(\mathcal{J})$ based on $\lesssim$ in order to define a *dependence graph* $G(\mathcal{J}, \lesssim)$ induced by $\mathcal{J}$ and $\lesssim$. Notice that, by Proposition 10, $G(\mathcal{J}, \lesssim)$ is anterial. Similarly, for P, one can define $G(P, \lesssim) = G(\mathcal{J}(P), \lesssim)$.

As mentioned, we are only interested in preorderings that are minimal preorders of graphs. Given $\mathcal{J}$, we define a preordering $\lesssim$ to be *$\mathcal{J}$-compatible* if $\lesssim$ is the minimal preorder for $G(\mathcal{J}, \lesssim)$. Similarly, one can define a P-compatible preorder.

4.2 Ordered Upward- and Downward-stabilities

We now exploit the preodering for independence models in order to define two other properties in addition to the seven properties defined in Section 2.3 (namely singleton-transitive compositional graphoid axioms). We say that an independence model $\mathcal{J}$ over the set V respectively satisfies *ordered upward-* and *downward-stability* w.r.t. a preorder $\lesssim$ of V if the following hold:

8. if $\langle i, j \,|\, C\rangle \in \mathcal{J}$ then $\langle i, j \,|\, C \cup \{k\}\rangle \in \mathcal{J}$ for every $k \in V \setminus \{i, j\}$ such that $l \lesssim k$ for some $l \in \{i, j\}$ or $l \sim k$ for some $l \in C$ (ordered upward-stability);

9. if $\langle i, j \,|\, C\rangle \in \mathcal{J}$ then $\langle i, j \,|\, C \setminus \{k\}\rangle \in \mathcal{J}$ for every $k \in V \setminus \{i, j\}$ such that $l \not\lesssim k$ for every $l \in \{i, j\}$ and $l \not\sim k$ for every $l \in C \setminus \{k\}$ (ordered downward-stability).

Ordered upward-stability is a generalization of a modification of *upward stability*, defined in Fallat et al. (2017), and *strong union*, defined in Pearl and Paz (1985), for undirected graphs, with singletons instead of node subsets.

Proposition 12 *Let G be an AnG and $\lesssim$ the minimal preorder for G. Then $\mathcal{J}(G)$ satisfies ordered upward- and downward-stability w.r.t. $\lesssim$.*

Proof First we prove that $\mathcal{J}(G)$ satisfies ordered upward-stability w.r.t. the minimal preorder: If $k \in C$, the result is obvious, thus suppose that $k \notin C$. Suppose that there is a connecting walk π between i and j given $C \cup \{k\}$. If k is not on π then we are done; otherwise, k is on a collider section with no other node in C on π. Notice that $l \lesssim k$ means here that $k \in \text{ant}(l)$, and $l \sim k$ that k and l are connected by a path consisting of lines.

If $l \in C$ then denote the path of lines between k and l by ω. The walk consisting of the subwalk of π from i to k, ω, ω in the reverse direction (from l to k), and the subwalk of π from k to j is connecting given C. This is because on this walk k and l are in the same collider section with l in C.

Now denote an anterior path from k to $l \in \{i, j\}$ by ϖ. Without loss of generality we can assume that $l = j$. We now consider two cases: 1) If ϖ has no nodes in C then the walk containing the subwalk of π between i and k and ϖ is connecting given C between i and j since k and all nodes on ϖ are on non-collider sections on this walk. 2) If ϖ has a node in C then consider the one closest to k and call it h. Then the walk consisting of the subwalk of π from i to k, the subpath of ϖ from k to h, the reverse of the subpath from h to k, and the subwalk of π from k to j is connecting given C as proven as follows: 1) if there is an arrow on ϖ then k is on a non-collider section in both instances in which it appears on this walk, and h is on a collider section and in C. 2) if ϖ only consists of lines then k and h are in the same collider section with a node (h) in C.

Now we prove that $\mathcal{J}(G)$ satisfies ordered downward-stability: If $k \notin C$ then the result is obvious, thus suppose that $k \in C$. Suppose that there is a connecting walk π between i and j given $C \setminus \{k\}$. If k is not on π then we are done. Otherwise, first it is clear that since π is connecting given $C \setminus \{k\}$, k cannot be the only node on a collider section that is in C.

If k is on the same section as another member of C then π is clearly connecting given C. The only case that is left is when k is on a non-collider section on π; but this is impossible: there is no arrowhead at the section containing k from one side on π, say from the j side. By moving towards j from k, it can be implied that k is either an anterior of a node in a collider section that is in C, or an anterior of j, but both are impossible since the former implies $l < k$ for $l \in C$, and the latter implies $j \lesssim k$. ■

5. Characterization of Graphical Independence Models

In this section, we first provide sufficient conditions for minimal Markovness, and then necessary and sufficient conditions for faithfulness.

5.1 Sufficient Conditions for Minimal Markovness

Here we provide sufficient conditions for an independence model to be minimally Markov to a graph. First, we have the following trivial result:

Proposition 13 *If $\mathcal{J}$ is minimally Markov to an anterial graph G then $G = G(\mathcal{J}, \lesssim)$ for the minimal preorder $\lesssim$ for G.*

By Proposition 5, the above statement also holds when $\mathcal{J}$ and G are faithful.

Proposition 14 *Suppose that there exists a $\mathcal{J}$-compatible preorder $\lesssim$ over V w.r.t. which $\mathcal{J}$ satisfies ordered downward- and upward-stability. It then holds that $\mathcal{J}$ is pairwise Markov to $G(\mathcal{J}, \lesssim)$.*

Proof Suppose that there are non-adjacent nodes i and j in $G(\mathcal{J}, \lesssim)$. These are non-adjacent in $\mathrm{sk}(\mathcal{J})$ too. By definition of $\mathrm{sk}(\mathcal{J})$, it holds that $\langle i, j \,|\, C\rangle \in \mathcal{J}$ for some $C \subseteq V \setminus \{i, j\}$.

Since $\mathcal{J}$ satisfies ordered downward-stability and since the preorder is $\mathcal{J}$-compatible, as long as a node $k \in C$ is not an anterior of $\{i, j\}$ or there is no semi-directed path from it to $C \setminus \{k\}$, it can be removed from the conditioning set, that is we have that $\langle i, j \,|\, C \setminus k\rangle \in \mathcal{J}$. Since $G(\mathcal{J}, \lesssim)$ is acyclic, as long as $\mathrm{ant}(\{i, j\}) \subset C$, such a k exists. Now consider a node $k' \in C \setminus \{k\}$ that is not an anterior of $\{i, j\}$ or there is no semi-directed path from it to $C \setminus \{k, k'\}$ and apply downward-stability again. By an inductive argument we imply that $\langle i, j \,|\, C \cap \mathrm{ant}(\{i, j\})\rangle \in \mathcal{J}$. Now since P satisfies ordered upward-stability, nodes outside C that are in $\mathrm{ant}(\{i, j\})$ can be added to the conditioning set. Hence, it holds that $\langle i, j \,|\, \mathrm{ant}(\{i, j\}) \setminus \{i, j\}\rangle \in \mathcal{J}$. This completes the proof. ■

In principle, a compatible preorder w.r.t. which $\mathcal{J}$ satisfies ordered downward- and upward-stability can be found by going through all such preorderings. Finding such a preorder efficiently is a structural learning task. We believe we have an efficient way to do this when the skeleton of $\mathcal{J}$ has been learned, but this is beyond the scope of this paper.

Theorem 15 *Suppose, for an independence model $\mathcal{J}$ over V, that*

1. *$\mathcal{J}$ is a compositional graphoid; and*
2. *there exists a $\mathcal{J}$-compatible preorder $\lesssim$ over V w.r.t. which $\mathcal{J}$ satisfies ordered downward- and upward-stability.*

It then holds that $\mathcal{J}$ is minimally Markov to $G(\mathcal{J}, \lesssim)$.

Proof The proof follows from Proposition 14, the fact that $\mathrm{sk}(\mathcal{J}) = \mathrm{sk}(G(\mathcal{J}, \lesssim))$, and Proposition 3. ■

5.2 Conditions for Faithfulness

In this section, we present the main result of this paper, which provides necessary and sufficient conditions for faithfulness of independence models (and probability distributions) and a (not necessarily known) graph in the general case. In Section 6, we specialize the result to the more well-known subclasses as corollaries.

Proposition 16 *Let $\mathcal{J}$ be an independence model over V. Suppose that $\mathcal{J}$ is minimally Markov to an anterial graph G. It then holds that $\mathcal{J}$ and G are faithful if and only if*

1. *$\mathcal{J}$ satisfies singleton-transitivity; and*
2. *$\mathcal{J}$ satisfies ordered downward- and upward-stability w.r.t. the minimal preorder for G.*

Proof Suppose that $\mathcal{J}$ and G are faithful. This is equivalent to $\mathcal{J} = \mathcal{J}(G)$. By Proposition 2, $\mathcal{J}$ satisfies singleton-transitivity, and by Proposition 12, the result follows.

Conversely, suppose that $\mathcal{J}$ satisfies singleton-transitivity as well as ordered downward- and upward-stability w.r.t. the minimal preorder $\lesssim$ for G. By Proposition 13, $G = G(\mathcal{J}, \lesssim)$. We show that $\mathcal{J}$ and G are faithful. We need to show that if $\langle A, B \,|\, C\rangle \in \mathcal{J}$ then $A \perp B \,|\, C$ in G. Consider $i \in A$ and $j \in B$. By decomposition, we have that $\langle i, j \,|\, C\rangle \in \mathcal{J}$, which implies that i and j are not adjacent in G.

If, for contradiction, C does not separate nodes i and j then there exists a connecting walk $\pi = \langle i = i_1, i_2, \ldots, i_r = j \rangle$, on which all collider sections have a node in C and all non-collider sections are outside C. In addition, for every node i_q, $2 \leq q \leq r-1$, on π define C_{i_q} as follows: If $i_q \notin C$ then $C_{i_q} = \varnothing$; if $i_q \in C$ then C_{i_q} is the set of all $l \in C \setminus \pi$ such that there is a semi-directed path from i_q to l but not from any $i_p \in C$ to l, $p \in \{q+1, \ldots, r-1\}$. Let $C_\pi = \bigcup_{q=2}^{r-1} C_{i_q}$.

We prove by induction along nodes of π that for every q, $2 \leq q \leq r$, it holds that $\langle i_1, i_q \,|\, (\cup_{p=2}^{q-1} C_{i_p}) \cup [C \setminus (\{i_q, \ldots, i_r\} \cup C_\pi)] \rangle \notin \mathcal{J}$. The base for $q = 2$ is trivial since by the construction of $G(\mathcal{J}, \lesssim)$, adjacent nodes are dependent given anything. Suppose now that the result holds for q and we prove it for $q+1$.

First, again by the construction of $G(\mathcal{J}, \lesssim)$, it holds that $\langle i_q, i_{q+1} \,|\, (\cup_{p=2}^{q-1} C_{i_p}) \cup [C \setminus (\{i_q, \ldots, i_r\} \cup C_\pi)] \rangle \notin \mathcal{J}$. By singleton-transitivity, this and the induction hypothesis imply (a): $\langle i_1, i_{q+1} \,|\, (\cup_{p=2}^{q-1} C_{i_p}) \cup [C \setminus (\{i_q, \ldots, i_r\} \cup C_\pi)] \rangle \notin \mathcal{J}$; or (b): $\langle i_1, i_{q+1} \,|\, \{i_q\} \cup (\cup_{p=2}^{q-1} C_{i_p}) \cup [C \setminus (\{i_q, \ldots, i_r\} \cup C_\pi)] \rangle \notin \mathcal{J}$. We now have two cases:

1) If i_q is on a collider section: The section containing i_q has a node in C. We again consider two subcases:

1.i) If i_q is in C: If (a) holds then first notice that i_q is not an anterior of $\{i_1, i_{q+1}\}$ nor is there a semi-directed path from i_q to $(\cup_{p=2}^{q-1} C_{i_p}) \cup [C \setminus (\{i_q, \ldots, i_r\} \cup C_\pi)]$. We apply downward-stability to (a) to obtain (b). If $C_{i_q} \neq \varnothing$ then consider a highest order node l in C_{i_q}. Again by downward-stability, we obtain $\langle i_1, i_{q+1} \,|\, \{l\} \cup (\cup_{p=2}^{q-1} C_{i_p}) \cup [C \setminus (\{i_{q+1}, \ldots, i_r\} \cup C_\pi)] \rangle \notin \mathcal{J}$. By an inductive argument along the members of C_{i_q} (by, at each step, choosing a highest order node in C_{i_q} that has not yet been chosen), we eventually obtain $\langle i_1, i_{q+1} \,|\, (\cup_{p=2}^{q} C_{i_p}) \cup [C \setminus (\{i_{q+1}, \ldots, i_r\} \cup C_\pi)] \rangle \notin \mathcal{J}$. Notice that i_q is in the conditioning set of this dependency.

1.ii) If i_q is not in C: If (b) holds then observe that i_q is in the same equivalence class as that of either i_{q+1} or a node $i_s \in C$, $s < q$. Hence we can apply upward-stability to obtain (a). Since $C_{i_2} = \varnothing$, (a) is clearly the same as $\langle i_1, i_{q+1} \,|\, (\cup_{p=2}^{q} C_{i_p}) \cup [C \setminus (\{i_{q+1}, \ldots, i_r\} \cup C_\pi)] \rangle \notin \mathcal{J}$. Notice that i_q is not in the conditioning set of this dependency.

2) If i_q is on a non-collider section: We have that $i_q \notin C$, and $i_q \in \text{ant}(\{i_1, i_{q+1}\})$. Hence, by upward-stability, from (b) we obtain (a). Again, since $C_{i_q} = \varnothing$, we obtain the result.

Therefore, we established that $\langle i_1, i_q \,|\, (\cup_{p=2}^{q-1} C_{i_p}) \cup [C \setminus (\{i_q, \ldots, i_r\} \cup C_\pi)] \rangle \notin \mathcal{J}$, for all q, where depending on whether $i_q \in C$ or not, the conditioning set contains or does not contain i_q. By letting $q = r$, we obtain $\langle i_1, i_r \,|\, C \rangle \notin \mathcal{J}$, a contradiction. Therefore, it holds that $i \perp j \,|\, C$ in G. By the composition property for separation for graphs (Proposition 1), we obtain the result. ■

We follow the arguments in the proof for the following example.

Example 1 *Consider the undirected (LWF) chain graph G in Fig. 2. Suppose that a probability distribution P is minimally Markov to G, and $\mathcal{J}(P)$ satisfies singleton-transitivity and ordered downward- and upward-stability w.r.t. the minimal preorder for G. In order to prove faithfulness, one needs to show that if two sets of nodes are not separated given a third set then they are not independent either.*

For example, we have that $l \not\perp j \,|\, l_2$. Notice that this is a case where there is no path that connects l and j. In order to show that $l \not\perp j \,|\, l_2$, (as in the proof of the above theorem) we start from $l = l_1$ and move towards $j = l_7$ via the connecting walk $\langle l_1, l_2, l_3, l_4, l_5, l_6, l_7 \rangle$ given l_2.

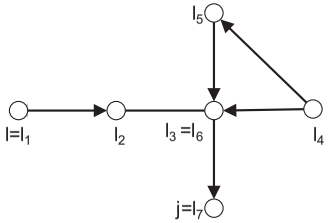

Figure 2: An undirected (LWF) chain graph.

We abbreviate singleton-transitivity, ordered upward-stability, and ordered downward stability by "st", "ous", and "ods" respectively. We write the arguments in a condensed from. For example, the first implication (on the left hand side) says that $l_1 \not\perp l_2$ and $l_2 \not\perp l_3$, using singleton-transitivity, imply that either $l_1 \not\perp l_3$ or $l_1 \not\perp l_3 \,|\, l_2$; but now ordered downward-stability implies that we must have $l_1 \not\perp l_3 \,|\, l_2$.

$$
\begin{array}{ccccccccc}
l_1 \not\perp l_2 & & l_1 \not\perp l_3 & & l_4 \not\perp l_5 \,|\, l_2 & & l_1 \not\perp l_5 \,|\, \{l_2, l_4\} & & l_6 \not\perp l_7 \,|\, l_2 & & l_1 \not\perp l_7 \,|\, \{l_2, l_6\} \\
& \overset{st}{\Rightarrow} or \;\; \Downarrow ods & & & & \overset{st}{\Rightarrow} or \;\; \Downarrow ous & & & & \overset{st}{\Rightarrow} or \;\; \Downarrow ous & \\
l_2 \not\perp l_3 & l_1 \not\perp l_3 \,|\, l_2 & & & l_1 \not\perp l_4 \,|\, l_2 & & l_1 \not\perp l_5 \,|\, l_2 & & l_1 \not\perp l_6 \,|\, l_2 & & l_1 \not\perp l_7 \,|\, l_2. \\
& & & \overset{st}{\Rightarrow} or \;\; \Uparrow ous & & & & \overset{st}{\Rightarrow} or \;\; \Uparrow ous & & & \\
& & l_3 \not\perp l_4 \,|\, l_2 & l_1 \not\perp l_3 \,|\, \{l_2, l_3\} & & l_5 \not\perp l_6 \,|\, l_2 & & l_1 \not\perp l_6 \,|\, \{l_2, l_5\} & & &
\end{array}
$$

The following example shows how singleton-transitivity and ordered stabilities are necessary for faithfulness.

Example 2 *Consider the DAG G in Fig. 3. If an independence model $\mathcal{J}$ is minimally Markov to G then we must have $\langle h, k \,|\, \{j, l\} \rangle \in \mathcal{J}$ and $\langle j, l \,|\, k \rangle \in \mathcal{J}$. Now, in violation of faithfulness, if only $\langle h, k \,|\, \varnothing \rangle \in \mathcal{J}$ in addition to these holds then upward-stability is violated since for $j > h$, $\langle h, k \,|\, j \rangle \in \mathcal{J}$ must hold. If, in violation of faithfulness, only $\langle h, k \,|\, j \rangle \in \mathcal{J}$ in addition to the original statements holds then singleton-transitivity is violated since $\langle h, k \,|\, j \rangle \in \mathcal{J}$ and $\langle h, k \,|\, \{j, l\} \rangle \in \mathcal{J}$ must imply either $\langle h, l \,|\, j \rangle \in \mathcal{J}$ or $\langle k, l \,|\, j \rangle \in \mathcal{J}$, which are both impossible due to minimality since h, l and k, l are adjacent in G.*

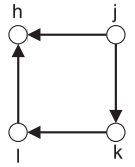

Figure 3: A DAG.

Without assuming the Markov assumption we have the following:

Theorem 17 *Let $\mathcal{J}$ be an independence model defined over V. It then holds that $\mathcal{J}$ is graphical if and only if*

1. *$\mathcal{J}$ is a singleton-transitive compositional graphoid; and*
2. *there exists a $\mathcal{J}$-compatible preorder $\lesssim$ over V w.r.t. which $\mathcal{J}$ satisfies ordered downward- and upward-stability.*

In addition, if 1 and 2 hold then $\mathcal{J}$ is faithful to $G(\mathcal{J}, \lesssim)$.

Proof ($\Rightarrow$) follows from Propositions 1, 2, and 12, and the fact that there is always an AnG that is Markov equivalent to a given CMG. To prove ($\Leftarrow$) and the last statement of the theorem, consider $G(\mathcal{J}, \lesssim)$. Theorem 15 implies that $\mathcal{J}$ is minimally Markov to $G(\mathcal{J}, \lesssim)$. This together with the $\mathcal{J}$-compatibility of the preorder, using Proposition 16, implies that $\mathcal{J}$ and $G(\mathcal{J}, \lesssim)$ are faithful. ■

Hence, for probability distributions, we have the following characterization:

Corollary 18 *Let P be a probability distribution defined over $\{X_\alpha\}_{\alpha \in V}$. It then holds that P is graphical if and only if*

1. *$\mathcal{J}(P)$ satisfies intersection, composition, and singleton-transitivity; and*
2. *there exists a P-compatible preorder $\lesssim$ over V w.r.t. which $\mathcal{J}(P)$ satisfies ordered downward- and upward-stability.*

In addition, if 1 and 2 hold then P is faithful to $G(P, \lesssim)$.

In fact, we have shown in Theorem 17 that if $\mathcal{J}$ is graphical then for every $\mathcal{J}$-compatible preorder w.r.t. which $\mathcal{J}$ satisfies ordered downward- and upward-stability, $G(\mathcal{J}, \lesssim)$ is a graph that is faithful to $\mathcal{J}$. A consequence of Proposition 13 implies that such graphs (that is $G = G(\mathcal{J}, \lesssim)$ for some preorder $\lesssim$ w.r.t. which $\mathcal{J}$ satisfies ordered downward- and upward-stability) constitute the set of all graphs that are faithful to $\mathcal{J}$, that is a Markov equivalence class of graphs whose members are faithful to $\mathcal{J}$. Every member of the equivalence class corresponds to a different preorder w.r.t. which $\mathcal{J}$ satisfies ordered downward- and upward-stability. This equivalence set can be represented by one member (a graph with the least number of arrowheads) similar to the idea of a CPDAG for the Markov equivalence class of DAGs (see Spirtes et al. 2000), but we do not go through the details of this here.

Of course, if the goal is to verify whether $\mathcal{J}$ and a given G are faithful then we can use the following corollary:

Corollary 19 *Let $\mathcal{J}$ be an independence model defined over V, and G an AnG with node set V. It then holds that if*

1. *$\mathcal{J}$ is a singleton-transitive compositional graphoid; and*
2. *$\mathcal{J}$ satisfies ordered downward- and upward-stability w.r.t. the minimal preorder for G,*

then $\mathcal{J}$ and G are faithful.

It is also important to note that singleton-transitivity and ordered upward or downward-stability are necessary in the sense that they are not implied by one another, although there are different ways to axiomatize singleton-transitive compositional graphoids that satisfy ordered upward- and downward-stability.

If P is Gaussian then we have the following:

Corollary 20 *Let P be regular Gaussian distribution. It then holds that P is graphical if and only if there exists a P-compatible preorder $\lesssim$ w.r.t. which $\mathcal{J}(P)$ satisfies ordered downward- and upward-stability.*

Proof The proof follows from the fact that regular Gaussian distributions satisfy intersection, composition, and singleton-transitivity. ■

6. Specialization to Subclasses

The definitions and results presented in this paper can be specialized to any subclass of CMGs including ancestral graphs and LWF chain graphs. However, here we only focus on the three of the most used classes of undirected (concentration), bidirected (covariance), and directed acyclic graphs.

6.1 Specialization to Undirected and Bidirected Graphs

For connected UGs, every two nodes are in the same equivalence class, and for BGs every two nodes are incomparable; hence, the minimal (pre)ordering is trivial and uninteresting in these cases. More precisely, ordered upward- and downward-stabilities can be specialized for these two types of trivial preordering:

8a. if $\langle i, j \,|\, C\rangle \in \mathcal{J}$ then $\langle i, j \,|\, C \cup \{k\}\rangle \in \mathcal{J}$ for every $k \in V \setminus \{i, j\}$ (*upward-stability*);

9a. if $\langle i, j \,|\, C\rangle \in \mathcal{J}$ then $\langle i, j \,|\, C \setminus \{k\}\rangle \in \mathcal{J}$ for every $k \in V \setminus \{i, j\}$ (*downward-stability*).

Proposition 21 *An independence model $\mathcal{J}$ satisfies ordered upward- and downward-stability (8) and (9) w.r.t. the minimal preorder if and only if,*

1. *for connected undirected graphs, it satisfies upward-stability (8a);*
2. *for bidirected graphs, it satisfies downward-stability (9a).*

In addition, if, for undirected graphs, $\mathcal{J}$ satisfies (8a) then it satisfies (8).

Proof The proof of 1 and 2 are straightforward since in 1 all nodes are in the same equivalence class, and in 2 all nodes are incomparable. The second part is trivial. ■

Analogous to Proposition 12, it is also straightforward to show the following:

Proposition 22 *It holds that*

1. *for an undirected graph G, $\mathcal{J}(G)$ satisfies upward-stability;*

2. for a bidirected graph G, $\mathcal{J}(G)$ satisfies downward-stability.

For UGs and BGs, denote the unique and trivial valid preorders by $\lesssim_u^*$ and $\lesssim_b^*$ respectively. For UGs, $G_u^*(\mathcal{J}) := G(\mathcal{J}, \lesssim_u^*) = \mathrm{sk}(\mathcal{J})$, whereas for BGs, $G_b^*(\mathcal{J}) := G(\mathcal{J}, \lesssim_b^*)$ is $\mathrm{sk}(\mathcal{J})$ with all edges directed to be bidirected. Another way to construct induced UGs and BGs by $\mathcal{J}$ is to construct them based on their corresponding pairwise Markov property, that is to connect every pair of nodes i and j if $\langle i, j \,|\, V \setminus \{i, j\}\rangle \notin \mathcal{J}$ for UGs, and if $\langle i, j \,|\, \varnothing\rangle \notin \mathcal{J}$ for BGs. Denote these graphs by $G_u(\mathcal{J})$ and $G_b(\mathcal{J})$ respectively. We then have the following:

Proposition 23 *It holds that,*

1. *for undirected graphs, $G_u^*(\mathcal{J}) = G_u(\mathcal{J})$ if $\mathcal{J}$ satisfies upward-stability;*
2. *for bidirected graphs, $G_b^*(\mathcal{J}) = G_b(\mathcal{J})$ if $\mathcal{J}$ satisfies downward-stability.*

For upward- and downward-stability, we also have the following observation:

Lemma 24 *For an independence model $\mathcal{J}$ the following holds:*

1. *If $\mathcal{J}$ is a semi-graphoid and satisfies upward-stability then $\mathcal{J}$ satisfies composition.*
2. *If $\mathcal{J}$ is a semi-graphoid and satisfies downward-stability then $\mathcal{J}$ satisfies intersection.*

Proof 1. Suppose that $\langle A, B \,|\, C\rangle \in \mathcal{J}$ and $\langle A, D \,|\, C\rangle \in \mathcal{J}$. By decomposition, it holds, for $i \in A$, $j \in B$, and $k \in D$, that $\langle i, j \,|\, C\rangle \in \mathcal{J}$ and $\langle i, k \,|\, C\rangle \in \mathcal{J}$. By upward-stability, we obtain $\langle i, j \,|\, C \cup \{k\}\rangle \in \mathcal{J}$. Contraction implies $\langle i, \{j, k\} \,|\, C\rangle \in \mathcal{J}$. By an inductive argument, we obtain the result.

2. Suppose that $\langle A, B \,|\, C \cup D\rangle \in \mathcal{J}$ and $\langle A, D \,|\, C \cup B\rangle \in \mathcal{J}$. By decomposition, it holds, for $i \in A$, $j \in B$, and $k \in D$, that $\langle i, j \,|\, C \cup \{k\}\rangle \in \mathcal{J}$ and $\langle i, k \,|\, C \cup \{j\}\rangle \in \mathcal{J}$. By downward-stability, we obtain $\langle i, k \,|\, C\rangle \in \mathcal{J}$. Contraction implies $\langle i, \{j, k\} \,|\, C\rangle \in \mathcal{J}$. By an inductive argument, we obtain the result. ■

Lemma 25 *Let $\mathcal{J}$ be an independence model, and suppose that $\mathcal{J}$ is a graphoid. It then holds that $\mathcal{J}$ satisfies ordered downward-stability (9) w.r.t. the minimal preorder for $G_u(\mathcal{J})$.*

Proof By definition, we know that $\mathcal{J}$ is pairwise Markov to $G_u(\mathcal{J})$. It is known that under graphoid, this implies that $\mathcal{J}$ is Markov to $G_u(\mathcal{J})$; see Pearl (1988). Now suppose that $\langle i, j \,|\, C\rangle \in \mathcal{J}$. The only applicable k in the definition of (9) is not in the same connected component as that of i or j. Hence, since $i \perp j \,|\, C \setminus \{k\}$, by the global Markov property, it holds that $\langle i, j \,|\, C \setminus \{k\}\rangle \in \mathcal{J}$. ■

As a consequence of Theorem 15, we have the following for UGs and BGs:

Corollary 26 *It holds that*

1. *if $\mathcal{J}$ is a graphoid and satisfies upward-stability then $\mathcal{J}$ is minimally Markov to the undirected graph $G_u(\mathcal{J})$;*
2. *if $\mathcal{J}$ is a compositional semi-graphoid and satisfies downward-stability then $\mathcal{J}$ is minimally Markov to the bidirected graph $G_b(\mathcal{J})$.*

Proof The proof follows from Propositions 23 and 21, and Lemmas 24 and 25. ■

For other classes of graphs, the preordering (or ordering) of nodes (and consequently random variables) is necessary since the conditioning set $C(i, j)$ for the pairwise Markov property depends on the preordering of the variables. This implies that in general one cannot construct more than the skeleton of graphs based on the pairwise Markov property if there is no given preordering.

Proposition 16 specializes to the following two corollaries:

Corollary 27 *Suppose that an independence model $\mathcal{J}$ is Markov to $G_u(\mathcal{J})$. Then $\mathcal{J}$ and $G_u(\mathcal{J})$ are faithful if and only if $\mathcal{J}$ satisfies singleton-transitivity and upward-stability.*

Proof The proof follows from Propositions 21, 22, and 23, and Lemma 25. ■

Similarly, for BGs, we have the following:

Corollary 28 *Suppose that an independence model $\mathcal{J}$ is Markov to $G_b(\mathcal{J})$. Then $\mathcal{J}$ and $G_b(\mathcal{J})$ are faithful if and only if $\mathcal{J}$ satisfies singleton-transitivity and downward-stability.*

The main conditions for an independence model to be faithful to a UG or BG (consequence of Theorem 17) are as follows; see also Theorem 3 of Pearl and Paz (1985) for a similar result for UGs:

Corollary 29 *Let $\mathcal{J}$ be an independence model defined over V. It then holds that $\mathcal{J}$ is faithful to an undirected graph if and only if it is an upward-stable singleton-transitive graphoid. In addition, if the conditions hold then $\mathcal{J}$ is faithful to $G_u(\mathcal{J})$.*

Proof The proof follows from Propositions 21, 22, and 23, and Lemmas 24 and 25. ■

Corollary 30 *Let $\mathcal{J}$ be an independence model defined over V. It then holds that $\mathcal{J}$ is faithful to a bidirected graph if and only if it is a downward-stable singleton-transitive compositional semi-graphoid. In addition, if the conditions hold then $\mathcal{J}$ is faithful to $G_b(\mathcal{J})$.*

Therefore, a probability distribution is faithful to an undirected graph if and only if it satisfies intersection, singleton-transitivity, and upward-stability; and to a bidirected graph if and only if it satisfies composition, singleton-transitivity, and downward-stability.

Finally, as a consequence of Corollary 20, we have the following:

Corollary 31 *Let P be a regular Gaussian distribution. It then holds that P being faithful to an undirected graph is equivalent to it satisfying upward-stability; and P being faithful to a bidirected graph is equivalent to it satisfying downward-stability.*

6.2 Specialization to Directed Acyclic Graphs

For DAGs, the valid preorder specializes to a valid (partial) order since there are no lines in the graph: If $i \longrightarrow\!\!\!\!\!\succ j$ then $i > j$. In the minimal order for a DAG, two nodes are incomparable if and only if neither is an ancestor of the other. Therefore, we define ordered stabilities w.r.t. ordering $\leq$ for DAGs:

8b. if $\langle i, j \,|\, C\rangle \in \mathcal{J}$ then $\langle i, j \,|\, C \cup \{k\}\rangle \in \mathcal{J}$ for every $k \in V \setminus \{i, j\}$ such that $l < k$ for some $l \in \{i, j\}$ (*ordered upward-stability*);

9b. if $\langle i, j \,|\, C\rangle \in \mathcal{J}$ then $\langle i, j \,|\, C \setminus \{k\}\rangle \in \mathcal{J}$ for every $k \in V \setminus \{i, j\}$ such that $l \not< k$ for every $l \in \{i, j\} \cup C \setminus \{k\}$ (*ordered downward-stability*).

As a consequence of Proposition 12, we have the following:

Corollary 32 *For a directed acyclic graph G, the induced independence model by d-separation $\mathcal{J}(G)$ satisfies ordered upward- and downward-stability (8b) and (9b) w.r.t. the minimal order for G.*

As a consequence of Theorem 15, and for $G(\mathcal{J}, \leq)$, the DAG obtained by directing the edges of $\mathrm{sk}(\mathcal{J})$ based on the order $\leq$, we have the following:

Corollary 33 *Suppose, for an independence model $\mathcal{J}$ over V, that*

1. *$\mathcal{J}$ is a compositional graphoid; and*
2. *there exists a $\mathcal{J}$-compatible order $\leq$ over V w.r.t. which $\mathcal{J}$ satisfies ordered downward- and upward-stability, (8b) and (9b).*

Then $\mathcal{J}$ is minimally Markov to the directed acyclic graph $G(\mathcal{J}, \leq)$.

The main conditions for an independence model to be faithful to a DAG (consequence of Theorem 17) is as follows:

Corollary 34 *Let $\mathcal{J}$ be an independence model defined over V. It then holds that $\mathcal{J}$ is faithful to a directed acyclic graph G if and only if*

1. *$\mathcal{J}$ is a singleton-transitive compositional graphoid; and*
2. *there exists a $\mathcal{J}$-compatible order $\leq$ over V w.r.t. which $\mathcal{J}$ satisfies ordered downward- and upward-stability, (8b) and (9b).*

In addition, if the conditions hold then $\mathcal{J}$ is faithful to $G(\mathcal{J}, \leq)$.

For a probability distribution P, the first condition of the above corollary simplifies to that P satisfies intersection, composition, and singleton-transitivity.

7. Comparison to the Results in the Literature

All results in the literature concerning faithfulness of certain probability distributions and certain types of graphs can be considered corollaries (or examples) of Theorem 17. Here we verify this for some of the more well-known or interesting results. For brevity, we leave out some interesting results such as faithfulness of Gaussian and discrete distributions and LWF chain graphs; see Peña (2011) and Peña (2009); Studený and Bouckaert (1998) respectively.

7.1 Faithfulness of MTP_2 Distributions and Undirected Graphs

Multivariate totally positive of order 2 (MTP_2) distributions (Karlin and Rinott, 1980) are distributions whose density f is MTP_2, that is $f(x)f(y) \leq f(x \wedge y)f(x \vee y)$, for all vectors x, y, where $x \wedge y = (\min(x_1, y_1), \ldots, \min(x_m, y_m))$ and $x \vee y = (\max(x_1, y_1), \ldots, \max(x_m, y_m))$. In Fallat et al. (2017), it was shown that when an MTP_2 distribution P is a graphoid, it holds that P and what we denote here by $G_u(P)$ are faithful. It is known that MTP_2 distributions satisfy both singleton-transitivity and upward-stability, but not necessarily the intersection property; see Fallat et al. (2017). Hence, this result is a direct implication of Corollary 29.

7.2 Faithfulness of Gaussian Distributions and Undirected Graphs

Lněnička and Matúš (2007) provides regular Gaussian distributions that are faithful to any undirected graph; see Corollary 3 of the mentioned paper. In order to do so, given an undirected graph $G = (V, E)$, they provide the following matrix $A^{G,\epsilon}$, which acts as the covariance matrix of a Gaussian distribution that is faithful to G:

$$A^{G,\epsilon} = \begin{cases} 1 & \text{if } i = j, \\ \epsilon & \text{if } i \neq j \text{ and } i \text{ and } j \text{ are adjacent in } G, \\ 0 & \text{otherwise,} \end{cases}$$

where $i, j \in V$.

It is known that, for sufficiently small $\epsilon > 0$, the corresponding Gaussian distribution is regular, and by Corollary 31, we only need to show that it satisfies upward-stability. It is straightforward to show that for sufficiently small $\epsilon > 0$, the inverse of $A^{G,\epsilon}$, which is the concentration matrix of the Gaussian distribution, is an *M-matrix*, that is all its on-diagonal elements are positive and all its off-diagonal elements are non-positive. This is equivalent to the Gaussian distribution being MTP_2; see Karlin and Rinott (1983). Hence, upward-stability is satisfied as discussed above.

7.3 Unfaithfulness of Certain Gaussian Distributions and Undirected Graphs and DAGs

There are many examples in the literature for, and in fact it is easy to construct examples of, probability distributions that are not faithful to undirected graphs; for one of the first observations of this behaviour in a data set, see Example 4 of Cox and Wermuth (1993). As a constructed example, let us discuss Example 1 of Soh and Tatikonda (2014), which provided the Gaussian distribution for $X = (X_1, X_2, X_3, X_4)$ with zero mean and positive definite covariance matrix

$$\Sigma = \begin{bmatrix} 3 & 2 & 1 & 2 \\ 2 & 4 & 2 & 1 \\ 1 & 2 & 7 & 1 \\ 2 & 1 & 1 & 6 \end{bmatrix}.$$

It can be seen that the concentration matrix Σ^{-1} has no zero entries, but $X_1 \perp\!\!\!\perp X_3 \,|\, X_2$ since $\Sigma_{13} = \Sigma_{12}\Sigma_{22}^{-1}\Sigma_{23}$. Hence, the distribution and its complete skeleton are not faithful. This is clearly a consequence of the violation of upward-stability.

For DAGs too, it is easy to construct or observe examples where faithfulness is violated. One of the simplest of such examples, is what is related to the so-called "transitivity of causation" in philosophical causality; see, for example, Ramsey et al. (2006), where the goal is to show how the PC algorithm (Spirtes et al., 2000) errs. Consider the graph $a \dashrightarrow b \dashrightarrow c$, where $a \perp\!\!\!\perp c$ and $a \not\perp\!\!\!\perp c \,|\, b$. This, in our language, is a clear violation of singleton-transitivity since the graph implies that a, b and b, c are always dependent.

7.4 Faithfulness of Gaussian and Discrete Distributions and DAGs

It was shown in Meek (1995) that, in certain measure-theoretic senses, almost all the regular Gaussian and discrete distributions that are Markov to a given DAG are faithful to it. It is known, for DAGs, that the global Markov property is equivalent to the *factorization property* (see Lauritzen 1996), which holds if the joint density can factorize as follows:

$$f_V(x) = \prod_{v \in V} f_V(x_v \,|\, x_{\mathrm{pa}(v)}).$$

Since Gaussian and discrete distributions satisfy singleton-transitivity, in order to prove the result, one needs to show that ordered upward- and downward-stabilities, (8b) and (9b), are satisfied for almost all distributions that factorize w.r.t. the DAG. We refrain from showing this explicitly here due to technicality of the proof, but the general idea is similar to the proofs in Appendix B of Meek (1995): For (9b), we have that the probabilistic conditional independence holds for the marginal probability over (i, j, C, k), and we need to exploit the factorization to show that the same conditional independence formula holds for the marginal probability over (i, j, C) when $k \notin \mathrm{an}(\{i, j\} \cup C$. In this case the corresponding resulting polynomials are much simpler than those of Meek (1995) since one needs to consider extra marginalization over only one variable k. For (8b), we will need to prove the other direction in a similar fashion.

7.5 Faithfulness of Gaussian Distributions and Ancestral Graphs

The main goal of Richardson and Spirtes (2002) is to capture the conditional independence structure of a DAG model after marginalization and conditioning; see also Sadeghi (2013). This was done by introducing the class of AGs, and it was shown that every AG is probabilistic. In fact, there is a Gaussian distribution faithful to any AG, which is indeed the Gaussian distribution faithful to a DAG after marginalization and conditioning; see Theorem 7.5 of this paper.

However, by using our results, without going through the standard theory of ancestral graphs, it is possible to show that distributions that are faithful to a DAG are graphical after marginalization and conditioning: In order to do so, we use the notation in Sadeghi (2013), for an independence model $\mathcal{J}$, to define the *independence model after marginalization over M and conditioning on C*, denoted by $\alpha(\mathcal{J}; M, C)$, for disjoint subsets M and C of V:

$$\alpha(\mathcal{J}; M, C) = \{\langle A, B \,|\, D\rangle : \langle A, B \,|\, D \cup C\rangle \in \mathcal{J} \text{ and } (A \cup B \cup D) \cap (M \cup C) = \varnothing\}.$$

First, we show that $\alpha(\mathcal{J}; M, C)$ satisfies condition 1 of Theorem 17.

Proposition 35 *If $\mathcal{J}$ satisfies singleton-transitivity, intersection, and composition then so does $\alpha(\mathcal{J}; M, C)$.*

Proof For composition, assume that $\langle A, B \,|\, C'\rangle \in \alpha(\mathcal{J}; M, C)$ and $\langle A, D \,|\, C'\rangle \in \alpha(\mathcal{J}; M, C)$. By definition, we have $\langle A, B \,|\, C' \cup C\rangle \in \mathcal{J}$ and $\langle A, D \,|\, C' \cup C\rangle \in \mathcal{J}$. Composition for $\mathcal{J}$ implies $\langle A, B \cup D \,|\, C' \cup C\rangle \in \mathcal{J}$. Therefore, $\langle A, B \cup D \,|\, C'\rangle \in \alpha(\mathcal{J}; M, C)$. Proof of the others is similar to this one and as straightforward. ■

Denote by $\alpha(G; M, C)$, the generated AG from the DAG G and M and C two disjoint subsets of its node set that are marginalized over and conditioned on respectively. Here we do not go through the generating process of AGs from DAGs; for more details, see Richardson and Spirtes (2002); Sadeghi (2013). Without explicitly using the theory of stability under marginalization and conditioning for AGs, we show the following.

Proposition 36 *If $\mathcal{J}$ and a DAG G are faithful then $\alpha(\mathcal{J}; M, C)$ and the ancestral graph $\alpha(G; M, C)$ are faithful.*

Proof By Proposition 35, we only need to show that w.r.t. the ordering associated with $\alpha(G; M, C)$, condition 2 of Theorem 17 is also satisfied by $\alpha(\mathcal{J}; M, C)$.

To prove ordered upward-stability, assume that $\langle i, j \,|\, C' \cup \{k\}\rangle \notin \alpha(\mathcal{J}; M, C)$, where k is an anterior of a node l, $l \in \{i, j\}$ or connected by lines to l, $l \in C'$ in $H = \alpha(G; M, C)$. We have that $\langle i, j \,|\, C \cup C' \cup \{k\}\rangle \notin \mathcal{J}$. Since $\mathcal{J}$ and G are faithful, there is a connecting walk π between i and j given $C \cup C' \cup \{k\}$. If k is not on π, π is connecting given $C \cup C'$. Otherwise, it holds that k must be a collider on π. By Lemma 2 in Sadeghi (2013), k is in ancestor of a node $l' \in \{i, j\} \cup C \cup C'$. By replacing the subwalk of π from l' to k by the directed path from k to l' if $l' \in \{i, j\}$, or by adding the directed path from k to l' plus the reverse from l' to k to π if $l' \in C \cup C'$, we conclude that $\langle i, j \,|\, C \cup C'\rangle \notin \mathcal{J}$. Hence, $\langle i, j \,|\, C'\rangle \notin \alpha(\mathcal{J}; M, C)$.

To prove ordered downward-stability, assume that $\langle i, j \,|\, C' \setminus \{k\}\rangle \notin \alpha(\mathcal{J}; M, C)$, where $k \in C'$ is not an anterior of any node $l \in \{i, j\} \cup C'$ in H. We have that $\langle i, j \,|\, C \cup C' \setminus \{k\}\rangle \notin \mathcal{J}$. Since $\mathcal{J}$ and G are faithful, there is a connecting walk π between i and j given $C \cup C' \setminus \{k\}$. Node k cannot be on π since k must be a non-collider and consequently an ancestor of a node in $\{i, j\} \cup C \cup C'$ in G, which by Lemma 3 in Sadeghi (2013), implies that $k \in \mathrm{an}(l)$ in H. Hence, k is not on π, and consequently π is connecting given $C \cup C'$. We conclude that $\langle i, j \,|\, C \cup C'\rangle \notin \mathcal{J}$. Hence, $\langle i, j \,|\, C'\rangle \notin \alpha(\mathcal{J}; M, C)$. ■

This shows that, for every AG, there is a distribution faithful to it since, for every AG, there is a DAG that, after marginalization and conditioning, results in the given AG.

8. Summary and Future Work

We provided sufficient and necessary conditions for an independence model, and consequently a probability distribution, to be faithful to a chain mixed graph. All the definitions and results concerning independence models are true for probabilistic independence models. The conditions can be divided into two main categories: 1) Those that ensure that the distribution is Markov to a graph whose skeleton is the same as the skeleton of the distribution—these properties are namely intersection, composition, and ordered upward- and downward-stabilities. If the distribution is already pairwise Markov to the graph then intersection and composition suffice. Ordered upward- and downward-stabilities direct the edges of the skeleton of the distribution so that the pairwise Markov property is satisfied.

2) Those that ensure that a Markov distribution is also faithful to the graph. These are singleton-transitivity and ordered upward- and downward-stabilities.

The type of preordering or preorderings w.r.t. which the distribution satisfies ordered upward- and downward-stabilities implies the type or types of graphs that are faithful to the distribution. In order to only deal with simpler classes of graphs, it is enough to search through a more refined set of preorderings determined by the conditions that graphs of a specific class must satisfy. It is indeed true that when the skeleton of the graph or distribution is known, the preordering is equivalent to different ways the edges of the skeleton can be directed, but in principle the preordering of the variables is unrelated to the skeleton of the distribution.

The conditions of faithfulness provided in this paper for probability distributions are sufficient and necessary. Thus, based on these conditions many families of distributions can be shown not to be suitable for graphical modeling. This also shows the importance of Gaussian distributions in graphical models as the provided conditions (other than ordered upward- and downward-stabilities) are clearly satisfied by the regular Gaussian distributions. In addition, these conditions help those who devise new parametric models to ensure that their models satisfy the provided conditions for faithfulness.

It is clearly important to study the characteristics of distributions that satisfy these conditions. The intersection property is well-studied and, in addition to positivity of the density that has been known to be a sufficient condition, necessary and sufficient conditions for a probabilistic independence to satisfy this property are known; see Peters (2015). For composition and singleton-transitivity, more studies are needed; in particular, it would be worthwhile to find simple sufficient conditions for probability distributions in order to satisfy these properties.

Another approach is to devise algorithms that test whether these conditions are satisfied given data or an independence model. Indeed one can argue for an alternative approach to determine whether a distribution is faithful to some graph: one first applies the structure learning algorithm (taking as input the distribution and outputting a graph) and then one tests whether the separation relationships in the found graph correspond to the conditional independencies in the distribution. However, testing our conditions are much more efficient. As an example, in the case of undirected graphs and Gaussian distributions, by our results, one only needs to test upward-stability for non-adjacent single elements i and j (starting with a minimal node cut-set as the conditioning set) rather than testing all global conditional independencies implied by the graph.

As another algorithmic consequence that the results in this paper may prompt, they lead to a *constraint-based* structural learning algorithm (as opposed to score-based, for example, Chickering 2003) most similar to the Fast Causal Inference (FCI) algorithm (Spirtes et al., 2000)—it finds the skeleton of the graph and then explores directions of the edges of the graph on the skeleton. Directing the edges of the skeleton is performed based on an exploitation of the preordering of the variables (and consequently the nodes of the graph) so that w.r.t. such a preordering ordered upward- and downward-stabilities are satisfied. This algorithm would have two advantages over the known constraint-based algorithms in the literature: Firstly, it is devised for a larger class of AnGs, which can be thought of as learning the LWF chain graphs with hidden and selection variables; see Sadeghi (2016). Secondly, the exploitation of ordered upward- and downward-stability for structural learning can be combined with actually testing whether these conditions are satisfied, and the theory in the paper ensures the faithfulness of the generated graphs. We plan on providing the details of this algorithm elsewhere.

When dealing with data, another issue is that obtaining a faithful graph is very sensitive to hypothesis testing errors for inferring the independence statements from data; see Uhler et al. (2013). The concept of *strong faithfulness* (Zhang and Spirtes, 2003) has been suggested for the Gaussian case in order to deal with this issue. Although strong faithfulness, by nature, does not seem to be characterizable in this way, it is an interesting problem to study which of the equivalent conditions to faithfulness are more prone to such sensitivity.

Acknowledgments

The original idea of this paper was inspired by discussions at the American Institute of Mathematics workshop “Positivity, Graphical Models, and the Modeling of Complex Multivariate Dependencies” in October 2014. The author thanks the AIM and NSF for their support of the workshop and is indebted to other participants of the discussion group, especially to Shaun Fallat, Steffen Lauritzen, Nanny Wermuth, and Piotr Zwiernik for follow-up discussions. The author is also grateful to Rasmus Petersen for valuable discussions. This work was partly supported by grant #FA9550-12-1-0392 from the U.S. Air Force Office of Scientific Research (AFOSR) and the Defense Advanced Research Projects Agency (DARPA).

Abstract

Multilayer networks are a useful way to capture and model multiple, binary or weighted relationships among a fixed group of objects. While community detection has proven to be a useful exploratory technique for the analysis of single-layer networks, the development of community detection methods for multilayer networks is still in its infancy. We propose and investigate a procedure, called Multilayer Extraction, that identifies densely connected vertex-layer sets in multilayer networks. Multilayer Extraction makes use of a significance based score that quantifies the connectivity of an observed vertex-layer set through comparison with a fixed degree random graph model. Multilayer Extraction directly handles networks with heterogeneous layers where community structure may be different from layer to layer. The procedure can capture overlapping communities, as well as background vertex-layer pairs that do not belong to any community. We establish consistency of the vertex-layer set optimizer of our proposed multilayer score under the multilayer stochastic block model. We investigate the performance of Multilayer Extraction on three applications and a test bed of simulations. Our theoretical and numerical evaluations suggest that Multilayer Extraction is an effective exploratory tool for analyzing complex multilayer networks. Publicly available code is available at `https://github.com/jdwilson4/MultilayerExtraction`.

1. Introduction

Networks are widely used to represent and analyze the relational structure among interacting units of a complex system. In the simplest case, a network model is an unweighted, undirected graph $G = (V, E)$, where V is a set of vertices that represent the units, or *actors*, of the modeled system, and E is an edge set containing all pairs of vertices $\{u, v\}$ such that actors u and v share a physical or functional relationship. Networks have been successfully applied in a wide array of fields, including the social sciences to study social relationships among individuals (Wasserman and Galaskiewicz, 1994), biology to study interactions among genes and proteins (Bader and Hogue, 2003), and neuroscience to study the structure and function of the brain (Sporns, 2011).

In many cases, the vertices of a network can be divided into groups (often disjoint) with the property that there are many edges between vertices in the same group, but relatively few edges between vertices in different groups. Vertex groups of this sort are commonly referred to as *communities*. The unsupervised search for communities in a network is known as *community detection*. Community structure has been used to identify functionally relevant groups in gene and protein interaction systems (Lewis et al., 2010; Parker et al., 2015), structural brain networks (Bassett et al., 2011), and social networks (Onnela et al., 2011; Greene et al., 2010). As communities are often associated with important structural characteristics of a complex system, community detection is a common first step in the understanding and analysis of networks. The search for communities that optimize a given quantitative performance criterion is typically an NP-hard problem, so in most cases one must rely on approximate algorithms to identify community structure.

The focus of this paper is community detection in *multilayer* networks. Formally, an (m, n)-multilayer network is a collection $\mathbf{G}(m, n) = (G_1, \ldots, G_m)$ of m simple graphs $G_\ell = ([n], E_\ell)$ having common vertex set $[n] = \{1, \ldots, n\}$, where the edge sets E_ℓ may vary from layer to layer. The graph G_ℓ will be referred to as the ℓth *layer* of the network. We assume that the vertices of the multilayer network are registered, in the sense that a fixed vertex $u \in [n]$ refers to the same actor across all layers. Thus the graph G_ℓ reflects the relationships between identified actors $1, \ldots, n$ in circumstance ℓ. There are no edges between vertices in different layers, and the layers are regarded as unordered so that the indices $\ell \in [m]$ do not reflect an underlying spatial or temporal order among the layers.

In general, the actors of a multilayer network may not exhibit the same community structure across all layers. For example in social networks, a group of individuals may be well connected via friendships on Facebook; however, this common group of actors will likely, for example, not work at the same company. In realistic situations such as these, a given vertex community will only be present in a subset of the layers, and different communities may be present in different subsets of layers. We refer to such multilayer systems as heterogeneous as each layer may exhibit noticeably different community structure. Complex and differential relationships between actors will be reflected in the heterogenous behavior of different layers of a multilayer network. In spite of this heterogeneity, many existing community detection methods for multilayer networks typically assume that the community structure is the same across all, or a substantial fraction of, the layers (Berlingerio et al., 2011; Rocklin and Pinar, 2013; Barigozzi et al., 2011; Berlingerio et al., 2013; Holland et al., 1983; Paul and Chen, 2015).

We develop and investigate a multilayer community detection method called Multilayer Extraction, which efficiently handles multilayer networks with heterogeneous layers. Theoretical and numerical evaluation of our method reveals that Multilayer Extraction is an effective exploratory tool for analyzing complex multilayer networks. Our contributions to the current literature of statistical analysis of multilayer networks are threefold

1. We develop a testing-based algorithm for identifying densely connected vertex-layer sets (B, L), where $B \subseteq [n]$ is a set of vertices and $L \subseteq [m]$ is a set of layers such that the vertices in B are densely connected across the layers in L. The strength of the connections in (B, L) is measured by a local modularity score derived from a null random network model that is based on the degree sequence of the observed multilayer network. Identified communities can have overlapping vertex or layer sets, and some vertex-layer pairs may not belong to any community. Vertex-layer pairs that are not assigned to any community are interpreted as background as they are not strongly connected to any other. Overlap and background are common features of real networks that can have deleterious effects on partition based methods (Lancichinetti et al., 2011; Wilson et al., 2013, 2014). The Multilayer Extraction procedure directly addresses community heterogeneity in multilayer networks.

2. We assess the consistency of the global optimizer of the aforementioned local modularity score under a generative model for multilayer networks with communities. The generative model studied is a multilayer generalization of the stochastic 2 block model from Snijders and Nowicki (1997); Wang and Wong (1987) for multilayer networks, which we call the Multilayer Stochastic Block Model (MSBM). The MSBM is a generative model that characterizes preferential (or a-preferential) behavior of pre-specified vertex-layer communities in a multilayer network, via specification of inter- and intra-community probabilities. We are able to show that under the MSBM, the number of mis-clustered vertices and layers from the vertex-layer community that maximizes our proposed significance score vanishes to zero, with high probability, as the number of vertices tends to infinity. There has been considerable work in the area of consistency analysis for single-layer networks (e.g. Zhao et al., 2012); however, to the best of our knowledge, we are the first to address the joint optimality properties for *both* vertices and layers in multilayer networks. Furthermore, we provide complete and explicit expressions of all error bounds in the proof, as we anticipate future analyses where the number of layers is allowed to grow with the size of the network. Our proof involves a novel inductive argument, which, to our knowledge, has not been employed elsewhere.

3. We apply Multilayer Extraction to three diverse and important multilayer network types, including a multilayer social network, a transportation network, and a collaboration network. We compare and contrast Multilayer Extraction with contemporary methods, and highlight the advantages of our approach over single layer and aggregate alternatives. Our findings reveal important insights about these three complex relational systems.

1.1 Related Work

Multilayer network models have been applied to a variety of problems, including modeling and analysis of air transportation routes (Cardillo et al., 2013), studying individuals with multiple sociometric relations (Fienberg et al., 1980, 1985), and analyzing relationships between social interactions and economic exchange (Ferriani et al., 2013). Kivelä et al. (2014) and Boccaletti et al. (2014) provide two recent reviews of multilayer networks. We note that $\mathbf{G}(m, n)$ is also sometimes referred to as a *multiplex* network.

While there is a large and growing literature concerning community detection in standard, single-layer, networks (Fortunato, 2010; Newman, 2004; Porter et al., 2009), the development of community detection methods for multilayer networks is still relatively new. One common approach to multilayer community detection is to project the multilayer network in some fashion onto a single-layer network and then identify communities in the single layer network (Berlingerio et al., 2011; Rocklin and Pinar, 2013). A second common approach to multilayer community detection is to apply a standard detection method to each layer of the observed network separately (Barigozzi et al., 2011; Berlingerio et al., 2013). The first approach fails to account for layer-specific community structure and may give an oversimplified or incomplete summary of the community structure of the multilayer network; the second approach does not enable one to leverage or identify common structure between layers. In addition to the methods above, there have also been several generalizations of single-layer methods to multilayer networks. For example, Holland et al. (1983) and Paul and Chen (2015) introduce multilayer generalizations of the stochastic block model from Wang and Wong (1987) and Snijders and Nowicki (1997). Notably, these generative models require the community structure to be the same across layers.

Peixoto (2015) considers a multilayer generalization of the stochastic block model for weighted networks that models hierarchical community structure as well as the degree distribution of an observed network. Paul and Chen (2016) describe a class of null models for multilayer community detection based on the configuration and expected degree model. We utilize a similar model in our consideration. Stanley et al. (2016) considered the clustering of layers of multilayer networks based on recurring community structure throughout the network. Peixoto (2015) and Mucha et al. (2010) generalized the notion of modularity to multilayer networks, and De Domenico et al. (2014) generalized the map equation, which measures the description length of a random walk on a partition of vertices, to multilayer networks. De Domenico et al. (2013) discuss a generalization of the multilayer method in Mucha et al. (2010) using tensor decompositions. Approximate optimization of either multilayer modularity or the map equation results in vertex-layer communities that form a partition of $[n] \times [m]$. By contrast, the communities identified by Multilayer Extraction need not form a partition of $[n] \times [m]$ as some vertices and or layers may be considered background and not significantly associated with any community.

1.2 Overview of the Paper

In the next section we describe the null multilayer random graph model and the scoring of vertex-layer sets. In Section 3 we present and prove theoretical results regarding the asymptotic consistency properties of our proposed score for multilayer networks. Section 5 provides a detailed description of the proposed Multilayer Extraction procedure. We apply

Multilayer Extraction to three real-world multilayer networks and compare and contrast its performance with existing community detection methods in Section 6. In Section 7 we evaluate the performance of Multilayer Extraction on a test bed of simulated multilayer networks. We conclude the main paper with a discussion of future research directions in Section 8. The Appendix is divided into three sections. In Appendix A, we prove supporting lemmas contributing to the results given in Section 3. In Appendix B, we discuss competing methods to Multilayer Extraction. In Appendix C, we give the complete details of our simulation framework.

2. Scoring a Vertex-Layer Group

Seeking a vertex partition that optimizes, or approximately optimizes, an appropriate score function is a standard approach to single layer community detection. Prominent examples of score-based approaches include modularity maximization (Newman, 2006b), likelihood maximization for a stochastic block model (Wang and Wong, 1987), as well as minimization of the conductance of a partition (Chung, 1997). Rather than scoring a partition of the available network, Multilayer Extraction makes use of a significance based score that is applicable to individual vertex-layer sets. Below, we describe the multilayer null model, and then the proposed score.

2.1 The Null Model

Our significance-based score for vertex-layer sets in multilayer networks relies on the comparison of an observed multilayer network with a null multilayer network model. Let $\mathbf{G}(m,n)$ be an observed (m,n)-multilayer network. For each layer $\ell \in [m]$ and pair of vertices $u, v \in [n]$, let

$$x_\ell(u,v) = \mathbb{I}(\{u,v\} \in E_\ell)$$

indicate the presence or absence of an edge between u and v in layer ℓ of $\mathbf{G}(m,n)$. The *degree* of a vertex $u \in [n]$ in layer ℓ, denoted by $d_\ell(u)$, is the number of edges incident on u in G_ℓ. Formally,

$$d_\ell(u) \;=\; \sum_{v\in[n]} x_\ell(u,v).$$

The *degree sequence* of layer ℓ is the vector $\boldsymbol{d}_\ell = (d_\ell(1), \ldots, d_\ell(n))$ of degrees in that layer; the degree sequence of $\mathbf{G}(m,n)$ is the list $\boldsymbol{d} = (\boldsymbol{d}_1, \ldots, \boldsymbol{d}_m)$ containing the degree sequence of each layer in the network.

Let $\mathcal{G}(m,n)$ denote the family of all (m,n)-multilayer networks. Given the degree sequence $\boldsymbol{d}$ of the observed network $\mathbf{G}(m,n)$, we define a multilayer configuration model and an associated probability measure $\mathbb{P}_{\boldsymbol{d}}$ on $\mathcal{G}(m,n)$, as follows. In layer G_1, each node is given $d_1(u)$ half-stubs. Pairs of these edge stubs are then chosen uniformly at random, to form edges until all half-stubs are exhausted (disallowing self-loops and multiple edges). This process is done for every subsequent layer $G_2, \ldots, G_m$ independently, using the corresponding degree sequence from each layer.

In the multilayer network model described above, each layer is distributed according to the configuration model, first introduced by Bollobás and Universitet (1979) and Bender and Canfield (1978). The probability of an edge between nodes u and v in layer ℓ depends

only on the degree sequence $\boldsymbol{d}_\ell$ of the observed graph G_ℓ. The distribution $\mathbb{P}_{\boldsymbol{d}}$ has two complementary properties that make it useful for identifying communities in an observed multilayer network: (i) it preserves the degree structure of the observed network; and (ii) subject to this restriction, edges are assigned at random, without regard to the higher order connectivity structure of the network. Because of these characteristics, the configuration model has long been taken as the appropriate null model against which to judge the quality of a proposed community partition.

The configuration model is the null model which motivates the modularity score of a partition in a network (Newman, 2004, 2006b). Consider a single-layer observed network $\mathbf{G}(n)$ with n nodes and degree sequence $\boldsymbol{d}$. For fixed $K > 0$, let $c_u \in [K]$ be the community assignment of node u. The modularity score of the partition associated with the assignment $c_1, \ldots, c_n$ is defined as

$$M(c_1, \ldots, c_n;\ \mathbf{G}(n)) := \frac{1}{2|E|} \sum_{i\in[K]} \sum_{u<v\in[n]} \left(x(u,v) - \frac{d(u)d(v)}{\sum_{w\in[n]} d(w)} \right) \mathbb{I}(c_u = c_v = i). \quad (1)$$

Above, the ratio $\frac{d(u)d(v)}{\sum_{w\in[n]} d(w)}$ is the approximate expected number of edges between u and v under the configuration model. If the partition $c_1, \ldots, c_n$ represents communities with a large observed intra-edge count relative to what is expected under the configuration model, it receives a high modularity score. The identification of the communities that (approximately) maximize the modularity of a partition is among the most common techniques for community detection in networks.

2.2 Multilayer Extraction Score

Rather than scoring a partition, the Multilayer Extraction method scores individual vertex-layer sets. We define a multilayer node score that is based on the single-layer modularity score (1) and amenable to iterative maximization. We first define a local *set* modularity for a collection of vertices $B \subseteq [n]$ in the layer $\ell \in [m]$:

$$Q_\ell(B) := \frac{1}{n\binom{|B|}{2}^{1/2}} \sum_{u,v\in B: u<v} \left(x_\ell(u,v) - \frac{d_\ell(u)d_\ell(v)}{\sum_{w\in[n]} d_\ell(w)} \right). \quad (2)$$

The scaling term in the equation above is related to the total number of vertices in the network and the total number of possible edges between the vertices in B. This score is one version of the various set-modularities considered in Fasino and Tudisco (2016), and is reminiscent of the *local* modularity score introduced in Clauset (2005).

Our Multilayer Extraction procedure seeks communities that are *assortative* across layers, in the sense that $Q_\ell(B)$ is large and positive for each $\ell \in L$. In light of this, we define the *multilayer set score* as

$$H(B,L) := \frac{1}{|L|} \left(\sum_{\ell\in L} Q_\ell(B)_+ \right)^2, \quad (3)$$

where Q_+ denotes the positive part of Q. Generally speaking, the score acts as a yardstick with which one can measure the connection strength of a vertex-layer set. Large values of the score signify densely connected communities.

We note that the multilayer score $H(B, L)$ is reminiscent of a chi-squared test-statistic computed from $|L|$ samples. That is, under appropriate regularity assumptions on $Q_\ell(B)$, the score in (3) will be approximately chi-squared with one degree of freedom.

3. Consistency Analysis

In this section we give theoretical results establishing the asymptotic consistency of the Multilayer Extraction score introduced in Section 2.2. Explicitly, we show that the global optimizer of the score has bounded misclassification error under a 2-community multilayer stochastic block model.

We note that our results are particular to the performance of the score, rather than the performance of the algorithm to maximize the score. This approach to consistency analysis is common in the community detection literature, particularly for modularity-based methods, as maximizing modularity is NP-hard (Brandes et al., 2006). For instance, Bickel and Chen (2009) showed that under the standard (single-layer) stochastic block model, the global optimizer of the modularity partition score converges (in classification error) to the partition given by the model. Zhao et al. (2012) extended this result to a generalized class of partition scores, which includes both modularity and the SBM likelihood, and established conditions under which global optimizers of those scores are consistent under the *degree-corrected* stochastic block model (an extension of the standard version, see Coja-Oghlan and Lanka, 2009). In Zhao et al. (2011), a global-optimizer consistency result for a *local* set score, one *not* based on the modularity metric, was established in similar fashion. Many other analyses assess the theoretical "detectability" of the community structure in the stochastic block model (e.g. Decelle, Krzakala, Moore, and Zdeborová, 2011; Mossel, Neeman, and Sly, 2012; Nadakuditi and Newman, 2012).

As with the theorems we present in this section, most results from the aforementioned publications establish, or help to establish, asymptotic "with high probability" statements, and apply only to the *global* maximizers of the scores under study. In other words, they do not directly regard in-practice approaches to local maximization of the scores. Regardless, the demonstration of global optimizer consistency for a given score provides the measure of comfort that any local optimization method has a sensible target. The following analyses will serve our method in accordance with this intuition.

3.1 The Multilayer Stochastic Block Model

We assess the consistency of the Multilayer Extraction score under the multilayer stochastic block model (MSBM) with two vertex communities, defined as a probability distribution $\mathbb{P}_{m,n} = \mathbb{P}_{m,n}(\cdot|\boldsymbol{P}, \pi_1, \pi_2)$ on the family of undirected multilayer networks with m layers, n vertices and 2 communities. The distribution is fully characterized by (i) containment probabilities $\pi_1, \pi_2 > 0$, which satisfy $\pi_1 + \pi_2 = 1$, and (ii) a sequence of symmetric 2×2 matrices $\boldsymbol{P} = \{P_1, \ldots, P_m\}$ where $P_\ell = \{P_\ell(i, j)\}$ with entries $P_\ell(i, j) \in (0, 1)$. Under the distribution $\mathbb{P}_{m,n}$, a random multilayer network $\widehat{\boldsymbol{G}}(m, n)$ is generated using two simple steps:

1. A subset of $\lceil \pi_1 n \rceil$ vertices are placed in community 1, and remaining vertices are placed in community 2. Each vertex u in community j is assigned a community label $c_u = j$.

2. An edge is placed between nodes $u, v \in [n]$ in layer $\ell \in [m]$ with probability $P_\ell(c_u, c_v)$, independently from pair to pair and across layers, and no self-loops are allowed.

For a fixed n and m, the community labels $\mathbf{c}_n = (c_1, \ldots, c_n)$ are chosen once and only once, and the community labels are the same across each layer of $\widehat{\boldsymbol{G}}(m, n)$. On the other hand, the inner and intra community connection probabilities (and hence the assortativity) can be different from layer to layer, introducing heterogeneity among the layers. Note that when $m = 1$, the MSBM reduces to the (single-layer) stochastic block model from Wang and Wong (1987).

3.2 Consistency of the Score

We evaluate the consistency of the Multilayer Extraction score under the MSBM described above. Our first result addresses the vertex set maximizer of the score given a fixed layer set $L \subseteq [m]$. Our second result (Theorem 3 in Section 3.2.1) leverages the former to analyze the global maximizer of the score across layers and vertex sets. Explicitly, consider a multilayer network $\widehat{\boldsymbol{G}}(m, n)$ with distribution under the multilayer stochastic block model $\mathbb{P}_{m,n} = \mathbb{P}_{m,n}(\boldsymbol{P}, \pi_1, \pi_2)$. For a fixed vertex set $B \subseteq [n]$ and layer set $L \subseteq [m]$, define the random score by

$$\widehat{H}(B, L) := \frac{1}{|L|} \left(\sum_{\ell \in L} \widehat{Q}_\ell(B)_+ \right)^2,$$

where $\widehat{Q}_\ell(B)$ is the set-modularity of B in layer ℓ under $\mathbb{P}_{m,n}$. Our main results address the behavior of $\widehat{H}(B, L)$ under various assuptions on the parameters of the MSBM.

Toward the first result, for a fixed layer set $L \subseteq [m]$, let $\widehat{B}_{opt}(n)$ denote the node set that maximizes $\widehat{H}(B, L)$ (if more than one set does, any may be chosen arbitrarily). To define the notion of a "misclassified" node, for any two sets $B_1, B_2 \subseteq [n]$ let $d_h(B_1, B_2)$ denote the Hamming distance (rigorously defined as the cardinality of the symmetric difference between B_1 and B_2). We then define the number of misclassified nodes by a set B by

$$\texttt{Error}(B) := \min\{d_h(B, C_1),\ d_h(B, C_2)\}.$$

Note that this definition accounts for arbitrary labeling of the two communities. As the nodes and community assignments are registered across layers, neither d_h nor `Error` depend on the choice of L. Before stating the main theorem, we define a few quantities that will be used throughout its statement and proof:

Definition 1 *Let "*det*" denote matrix determinant. For a fixed layer set $L \subseteq [m]$, define*

$$\delta_\ell := \det P_\ell \quad \delta(L) := \min_{\ell \in [L]} \delta_\ell \quad \pi := (\pi_1, \pi_2)^t \quad \kappa_\ell := \pi^T P_\ell \pi \quad \kappa(L) := \min_{\ell \in [L]} \kappa_\ell \tag{4}$$

We now state the fixed-layer-set consistency result:

Theorem 2 *Fix m and let $\{\widehat{\boldsymbol{G}}(m,n)\}_{n>1}$ be a sequence of multilayer stochastic 2 block models where $\widehat{\boldsymbol{G}}(m,n)$ is a random graph with m layers and n nodes generated under $\mathbb{P}_{m,n}(\cdot|\boldsymbol{P},\pi_1,\pi_2)$. Assume $\pi_1 \leqslant \pi_2$, and that π_1, π_2, and $\mathbb{P}$ do not change with n. Fix a layer set $L \subseteq [m]$. If $\delta(L) > 0$ then there exist constants $A, \eta > 0$ depending on π_1 and $\delta(L)$ such that for all fixed $\varepsilon \in (0,\eta)$,*

$$\mathbb{P}_{m,n}\left(\texttt{Error}\left(\widehat{B}_{opt}(n)\right) < An^{\varepsilon}\log n\right) \geqslant 1 - \exp\left\{-\frac{\kappa(L)^2\varepsilon}{32}n^{\varepsilon}(\log n)^{2-\varepsilon} + \log 4|L|\right\} \quad (5)$$

for large enough n.

Note that the right-hand-side of (5) converges to 1 for all $\varepsilon \in (0,1)$, regardless of η. Furthermore, if $\varepsilon \in (0,\eta)$, we have $n^{\varepsilon} < n^{\varepsilon'}$ for all $\varepsilon' \geqslant \eta$. Therefore, a corollary of Theorem 2 is that for any $\varepsilon \in (0,1)$,

$$\mathbb{P}_{m,n}\left(\texttt{Error}\left(\widehat{B}_{opt}(n)\right) < n^{\varepsilon}\log n\right) \to 1 \ \text{ as } \ n \to \infty.$$

The above statement is perhaps a more illustrative version of the Theorem 2, and shows that the constants A and η play a role only in bounding the convergence rate of the probability.

The proof of Theorem 2 is given in Section 4.1. We note that the assumption that $\pi_1 \leqslant \pi_2$ is made without loss of generality, since the community labels are arbitrary. When $m = 1$, Theorem 2 implies asymptotic $n \to \infty$ consistency in the (single-layer) stochastic block model. In this case, the condition that $\delta_\ell = P_\ell(1,1)P_\ell(2,2) - P_\ell(1,2)^2 > 0$ is a natural requirement on the inner community edge density of a block model. This condition appears in a variety of consistency analyses, including the evaluation of modularity (Zhao et al., 2012). When $m > 1$, Theorem 2 implies the vertex set that maximizes $H(B,L)$ will have asymptotically vanishing error with high probability, given that L is a fixed layer set with *all* layers satisfying $\delta_\ell > 0$.

3.2.1 Consistency of the joint optimizer

Theorem 2 does not address the *joint* optimizer of the score across all vertex-layer pairs. First, we point out that for a fixed $B \subseteq [n]$, the limiting behavior of the score $\widehat{H}(B,L)$ depends on $L \subseteq [m]$ through the layer-wise determinants $\{\delta_\ell : \ell \in [n]\}$ and the scaling constant $\frac{1}{|L|}$ inherent to $H(B,L)$, as defined in equation (3). Let $\gamma : \mathbb{N}^+ \mapsto \mathbb{R}^+$ be a non-decreasing function of $|L|$. Define

$$H_\gamma(B,L) := \frac{1}{\gamma(|L|)}\left(\sum_{\ell\in L} Q_\ell(B)_+\right)^2. \quad (6)$$

and let $\widehat{H}_\gamma(B,L)$ be the corresponding random version of this score under an MSBM. We analyze the joint node-set optimizer of H_γ under some representative choices of γ, an analysis which will ultimately motivate the choice $\gamma(|L|) = |L|$.

We first provide an illustrative example. Consider a MSBM with $m > 1$ layers having the following structure: the first layer has positive determinant, and all $m-1$ remaining layers have determinant equal to 0. Note that $\delta_1 > 0$ implies that the first layer has

ground-truth assortative community structure, and that $\delta_\ell = 0$ for all $\ell > 1$ implies that the remaining layers are (independent) Erdos-Renyi random graphs. In this case, the desired global optimizer of $H_\gamma(B,L)$ is community 1 (or 2) and the first layer. However, setting $\gamma(|L|) \equiv 1$ (effectively ignoring the scaling of H) will ensure that, in fact, the *entire* layer set is optimal, since $Q_\ell(B)_+ \geqslant 0$ by definition. It follows that setting $\gamma(|L|)$ to increase (strictly) in $|L|$, which introduces a penalty on the size of the layer set, is desirable.

For a fixed scaling function γ, define the global joint optimizer of $\widehat{H}(B,L)$ by

$$\left(\widehat{B}_{opt}^{(n)}, \widehat{L}_{opt}^{(n)}\right) := \underset{2^{[n]}\times 2^{[m]}}{\arg\max}\ \widehat{H}_\gamma(B,L). \quad (7)$$

Note that $\left(\widehat{B}_{opt}^{(n)}, \widehat{L}_{opt}^{(n)}\right)$ is random, and may contain multiple elements of $2^{[m]} \times 2^{[n]}$. The next theorem addresses the behavior of $\left(\widehat{B}_{opt}^{(n)}, \widehat{L}_{opt}^{(n)}\right)$ under the MSBM for various choices of $\gamma(|L|)$, and shows that setting $\gamma(|L|) = |L|$ is desirable for consistency.

Theorem 3 *Fix m and let $\{\widehat{\boldsymbol{G}}(m,n)\}_{n>1}$ be a sequence of multilayer stochastic 2 block models where $\widehat{\boldsymbol{G}}(m,n)$ is a random graph with m layers and n nodes generated under $\mathbb{P}_{m,n}(\cdot|\boldsymbol{P},\pi_1,\pi_2)$. Assume $\pi_1 \leqslant \pi_2$, and that π_1, π_2, and $\mathbb{P}$ do not change with n. Fix $0 = \delta^{(0)} < \delta^{(1)} < 1$. Suppose the layer set $[m]$ is split according to $[m] = \cup_{i=0,1} L_i$, where $\delta_\ell = \delta^{(i)}$ for all $\ell \in L_i$. Then for any $\varepsilon > 0$, the following hold:*

(a) Let $\widehat{L}^+ := \{\ell : \widehat{Q}_\ell(\widehat{B}_{opt}^{(n)}) > 0\}$. If $\gamma(|L|) \equiv 1$, then for all $n > 1$, $\widehat{L}_{opt}^{(n)} = \widehat{L}^+$, and

$$\mathbb{P}_{m,n}\left(\texttt{Error}\left(\widehat{B}_{opt}^{(n)}\right) < n^{\varepsilon}\log n\right) \to 1 \ \text{ as } \ n \to \infty.$$

(b) If $\gamma(|L|) = |L|$,

$$\mathbb{P}_{m,n}\left(\widehat{L}_{opt}^{(n)} = L_1,\ \texttt{Error}\left(\widehat{B}_{opt}^{(n)}\right) < n^{\varepsilon}\log n\right) \to 1 \ \text{ as } \ n \to \infty.$$

(c) If $\gamma(|L|) = |L|^2$,

$$\mathbb{P}_{m,n}\left(\widehat{L}_{opt}^{(n)} \subseteq 2^{L_1},\ \texttt{Error}\left(\widehat{B}_{opt}^{(n)}\right) < n^{\varepsilon}\log n\right) \to 1 \ \text{ as } \ n \to \infty.$$

The proof of Theorem 3 is given in Section 4.2. Part (a) implies that setting $\gamma(|L|) \equiv 1$ ensures that the optimal layer set will be, simply, all layers with positive modularity, thereby making this an undesirable choice for the function γ. Part (c) says that if $\gamma(|L|) = |L|^2$, the layer set with the highest *average* layer-wise modularity will be optimal (with high probability as $n \to \infty$), which means that all subsets of L_1 are asymptotically equivalent with respect to $\widehat{H}(B,L)$ (with high probability). By part (b), if $\gamma(|L|) = |L|$, then L_1 is the unique asymptotic maximizer of the population score (with high probability). Therefore, $\gamma(|L|) = |L|$ is the most desirable choice of scaling.

3.3 Discussion of theoretical results

As mentioned previously, the theoretical results in Section 3.2 regard the *global* optimizer of the score. The results have the following in-practice implication: if one simulates from an MSBM satisfying the assumptions of the theorem, and subsequently finds the *global* optimizer of the score, the classification error of the optimizer will be vanishingly small with increasingly high probability (as $n \to \infty$). To illustrate this point, consider an MSBM with $m > 1$ layers, each having community structure $\pi_1 = 0.4$ and for $r \in (0, .95)$, $P(1,1) = P(2,2) = 0.05 + r$ and $P(1,2) = 0.05$. Under this model, $\delta_\ell = r(r + 0.1) > 0$ for all $\ell \in [m]$, and the assumptions of Theorem 3 are satisfied. Therefore, if we were to simulate this MSBM and find the global optimizer of H, with high probability (increasingly, $n \to \infty$) we would recover (1) the correct layer set $[m]$, and (2) the optimal node set will have small classification error (vanishingly, $n \to \infty$).

Of course, in practice it is computationally infeasible to find the global optimizer, so we employ the method laid out in Section 5 to find local maxima. We find through simulation (see Section 7) that our method achieves extremely low error rates for relatively small networks, including on the MSBM described above, for many values of r. These results reflect the intuition that theoretical results for global optimizers should have practical implications when local optimization methods are sufficiently effective.

A limitation of our theoretical results is that they assume an MSBM with only two communities. Furthermore, the model does not allow for any notion of overlap between communities. Nevertheless, in the setting we consider we demonstrate that there is a concise condition on the parameters of the model that guarantees consistency, namely, that $\delta(L) > 0$ for a target layer set L. We expect a similar condition to exist in more complicated settings. In particular, at the outset of Section 4.1, we sketch how the $\delta(L) > 0$ condition relates to the maxima of the *population* version of the score, which roughly speaking is the deterministic, limiting form of the score under the MSBM. We expect that, in more complex settings with (say) more than two communities or overlapping nodes, similar conditions on the model parameters would guarantee that the population version of the score be maximized at the correct community/layer partitions, which (as we show) would entail that the classification error of the global maximizer converges in probability to zero. Though the proofs in such settings would undoubtedly be more complicated, the analyses in this paper should serve as a theoretical foundation. Furthermore, we have empirically analyzed those settings via simulation in Section 7.1 (for more than two communities) and Appendix D (for overlapping communities).

4. Proofs

In this section we prove the theoretical results given in Section 3. The majority of the section is devoted to a detailed proof of Theorem 2 and supporting lemmas. This is followed by the proof of Theorem 3, of which we give only a sketch, as many of the results and techniques contributing to the proof of Theorem 2 can be re-used.

4.1 Proof of Theorem 2, and Supporting Lemmas

We prove Theorem 2 via a number of supporting lemmas. We begin with some notation:

Definition 4 *For a fixed vertex set $B \subseteq [n]$ define*

$$\rho_n(B) = \frac{|B \cap C_{1,n}|}{|B|}, \quad s_n(B) = \frac{|B|}{n}, \quad v_n(B) := (\rho_n(B), 1 - \rho_n(B)). \tag{8}$$

We will at times suppress dependence on n and B in the above expressions.

Definition 5 *Define the **population** normalized modularity of a set B in layer ℓ by*

$$q_\ell(B) := \frac{s_n(B)}{\sqrt{2}} \left(v_n(B)^t P_\ell v_n(B) - \frac{(v_n(B)^t P_\ell \pi)^2}{\kappa_\ell} \right). \tag{9}$$

*Define the **population** score function $H_*(\cdot, L) : 2^{[n]} \mapsto \mathbb{R}$ by*

$$H_*(B, L) = |L|^{-1} \left(\sum_{\ell \in [L]} q_\ell(B) \right)^2. \tag{10}$$

Throughout the results in this section, we assume that $L \subseteq [m]$ is a fixed layer set (as in the statement of Theorem 2). We will therefore, at times, suppress the dependence on L from $\delta(L)$ and $\kappa(L)$ (from Definition 1).

4.1.1 Sketch of the Proof of Theorem 2

The proof of Theorem 2 is involved and broken into many lemmas. In this section, we give a rough sketch of the argument, as follows. The lemmas in this section establish that:

1. $C_{1,n}$ maximizes the population score $H_*(\cdot, L)$ (Lemmas 6 and 7).
2. For large enough sets $B \subseteq [n]$, the random score $\widehat{H}(B, L)$ is bounded in probability around the population score $H_*(B, L)$ (Lemmas 9 and 12).
3. **Inductive Step**: For fixed $k > 1$, assume that $d_h(\widehat{B}_{opt}(n), C_{1,n})/n = O_p(b_{n,k})$, where larger k makes $b_{n,k}$ of smaller order. Then, based on concentration properties of the score, in fact $d_h(\widehat{B}_{opt}(n), C_{1,n})/n = O_p(b_{n,k+1})$ (Lemma 13).
4. There exists a constant η such that for any $\varepsilon \in (0, \eta)$, $d_h(\widehat{B}_{opt}(n), C_{1,n})/n = O_p(n^\varepsilon \log n)$ (Theorem 2). This result is shown using the Inductive Step.

4.1.2 Supporting lemmas for the Proof of Theorem 2

Lemma 6 *Define $\phi(L) := (|L|^{-1} \sum_\ell \frac{\det P_\ell}{2\kappa_\ell})^2$. Then:*

1. *For any $B \subseteq [n]$, $q_\ell(B) = \frac{s_n(B)}{\sqrt{2}} (\pi_1 - \rho_n(B))^2 \cdot \frac{\det P_\ell}{2\kappa_\ell}$, and therefore*

$$H_*(B, L) = |L| \phi(L) \frac{s_n(B)^2}{2} (\pi_1 - \rho_n(B))^4.$$

2. *$\delta(L)^2 \leqslant \phi(L) \leqslant \frac{1}{\pi_1^2 \delta(L)^2}$ and therefore $H_*(C_{1,n}, L) \geqslant |L| \frac{\pi_1^2}{2} (1 - \pi_1^4) \delta(L)^2$.*

Lemma 7 *Fix any $n > 1$. Define*

$$\mathcal{R}(t) := \begin{cases} \{B \subseteq [n] : \max\{|s(B) - \pi_1|,\ 1 - \rho(B)\} \leqslant t\}, & \pi_1 < \pi_2 \\ \{B \subseteq [n] : \max\{|s(B) - \pi_1|,\ \rho(B)\} \leqslant 1 - \rho(B) \leqslant t\}, & \pi_1 = \pi_2 \end{cases}$$

Then there exists a constant $a > 0$ depending just on π_1 such that for sufficiently small t, $B \notin \mathcal{R}(t)$ implies $H_*(B, L) < H_*(C_{1,n}, L) - a|L|\phi(L)t$.

The proofs of Lemmas 6-7 are given in Appendix A. We now give a general concentration inequality for $\widehat{H}(B, L)$, which shows that for sufficiently large sets $B \subseteq [n]$, $\widehat{H}(B, L)$ is close to the population score $H_*(B, L)$ with high probability. This result is used in the proof of Lemma 12, and its proof is given in Appendix A. We first give the following definition:

Definition 8 *For fixed $\varepsilon > 0$ and $n > 1$, define $\mathcal{B}_n(\varepsilon) := \{B \subseteq [n] : |B| \geqslant n\varepsilon\}$.*

Lemma 9 *Fix $\varepsilon \in (0, 1)$. Let κ be as in Definition 1. For each $n > 1$ suppose a collection of node sets $\mathcal{B}_n$ is contained in $\mathcal{B}_n(\varepsilon)$. Then for large enough n,*

$$\mathbb{P}_n\left(\sup_{\mathcal{B}_n}\left(\left|\widehat{H}(B, L) - H_*(B, L)\right|\right) > \frac{4|L|t}{n^2} + \frac{52|L|}{\kappa n}\right) \leqslant 4|L||\mathcal{B}_n| \exp\left(-\kappa^2 \frac{\varepsilon t^2}{16n^2}\right)$$

for all $t > 0$.

We now define new notation that will serve the remaining lemmas:

Definition 10 *Let $\gamma_n := \log n/n$, and for any integer $k > 0$, define $b_{n,k} := \gamma_n^{1-\frac{1}{2^k}}$.*

Definition 11 *For any $r \in [0, 1]$ and $C \subseteq [n]$, define the r-neighborhood of C by $N(C, r) := \{B \subseteq [n] : d_h(B, C)/n \leqslant r\}$. For all $n > 1$, any constant $A > 0$, and fixed $k > 1$, define*

$$N_{n,k}(A) := \begin{cases} N\left(C_1, A \cdot b_{n,k-1}\right) \cup N\left(C_2, A \cdot b_{n,k-1}\right), & k > 1 \\ \mathcal{B}_n(A), & k = 1 \end{cases}$$

Lemma 12, stated below, is a concentration inequality for the random variable $\widehat{H}(B, L)$ on particular neighborhoods of C_1:

Lemma 12 *Fix $\varepsilon \in (0, \pi_1)$ and any constant $A > 0$. For $k > 1$ satisfying $1/2^{k-1} < \varepsilon$, we have for sufficiently large n that*

$$\sup_{B \in N_{n,k}(A)} \left|\widehat{H}(B, L) - H_*(B, L)\right| \leqslant 5|L|b_{n,k}. \tag{11}$$

with probability greater than $1 - 2\exp\{-\frac{\kappa^2\varepsilon}{32} n\gamma_n^{1-\varepsilon} \log(n) + \log 4|L|\}$. The conclusion holds with $k = 1$ if $A = \varepsilon$.

The proof of Lemma 12 is given in Appendix A. We now state and prove the key lemma used to drive the induction step in the proof of Theorem 2:

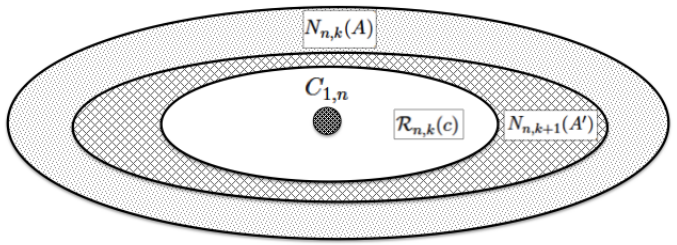

Figure 1: Illustration of relationship between collections of node sets.

Lemma 13 *Fix $\varepsilon \in (0, \pi_1)$ and an integer $k > 1$ satisfying $1/2^{k-1} < \varepsilon$. Suppose there exist constants $A, b > 0$ such that for large enough n,*

$$\mathbb{P}_n\left(\widehat{B}_{opt}(n) \in N_{n,k}(A)\right) \geqslant 1 - b\exp\left\{-\frac{\kappa^2\varepsilon}{32} n\gamma_n^{1-\varepsilon} \log n + \log 4|L|\right\} := 1 - b\beta_n(\varepsilon)$$

Then there exists a constant $A' > 0$ depending only on π_1 and δ such that for large enough n, $\mathbb{P}_n\left(\widehat{B}_{opt}(n) \in N_{n,k+1}(A')\right) \geqslant 1 - (4 + b)\beta_n(\varepsilon)$. The conclusion holds for $k = 1$ if $A = \varepsilon$.

Proof Assume $\pi_1 < \pi_2$; the following argument may be easily adapted to the case where $\pi_1 = \pi_2$, which we explain at the end. Recall $b_{n,k}$ from Definition 10. For $c > 0$, define

$$\mathcal{R}_{n,k}(c) := \left\{B \subset [n] : \max\{|s(B) - \pi_1|,\ 1 - \rho(B)\} \leqslant c \cdot b_{n,k}\right\},$$

Note that sets $B \in \mathcal{R}_{n,k}(c)$ have bounded Hamming distance from $C_{1,n}$, as shown by the following derivation. Writing $s = s(B)$ and $\rho = \rho(B)$, for all $B \in \mathcal{R}_{n,k}(c)$ we have

$$\begin{aligned} n^{-1}|d_h(B, C_{1,n})| &= n^{-1}\left(|B \setminus C_{1,n}| + |C_{1,n} \setminus B|\right) \\ &= n^{-1}\left(|B| - |B \cap C_{1,n}| + |C_{1,n}| - |B \cap C_{1,n}|\right) \\ &= s + \pi_1 - 2\rho s \\ &\leqslant s + (s + c \cdot b_{n,k}) - 2\left(1 - c \cdot b_{n,k}\right)s \\ &= c \cdot b_{n,k} + 2sc \cdot b_{n,k} \leqslant 3c \cdot b_{n,k}. \end{aligned} \tag{12}$$

Therefore, $\mathcal{R}_{n,k}(c) \subseteq N(C_{1,n}, A' \cdot b_{n,k}) \subset N_{n,k+1}(A')$ with $A' = 3c$.

We have assumed $\widehat{B}_{opt}(n) \in N_{n,k}(A)$ with high probability; our aim is to show $\widehat{B}_{opt}(n) \in N_{n,k+1}(A')$. Since $\mathcal{R}_{n,k}(c) \subseteq N_{n,k+1}(A')$, it is sufficient to show that $\widehat{B}_{opt}(n) \notin N_{n,k}(A) \cap \mathcal{R}_{n,k}(c)^c$ with high probability. This is illustrated by figure 1: since $\widehat{B}_{opt}(n)$ is inside the outer oval (with high probability), it is sufficient to show that it cannot be outside the inner

oval. To this end, it is enough to show that, with high probability, $\widehat{H}(B,L) < \widehat{H}(C_{1,n},L)$ for all sets B in $N_{n,k}(A) \cap \mathcal{R}_{n,k}(c)^c$. Note that by Lemma 12,

$$\sup_{B \in N_{n,k}(A)} \widehat{H}(B,L) < H_*(B,L) + 5|L|b_{n,k} \tag{13}$$

for large enough n, with probability at least $1-2\beta_n(\varepsilon)$. Next, since $cb_{n,k} \to 0$ as $n \to \infty$, by Lemma 7 there exists a constant $a > 0$ depending just on π_1 such that for large enough n, $B \in \mathcal{R}_{n,k}(c)^c$ implies $H_*(B,L) < H_*(C_{1,n}) - a|L|\phi(L)cb_{n,k}$. Applying Lemma 12 again, we also have $H_*(C_{1,n},L) < \widehat{H}(C_{1,n}) + 5|L|b_{n,k}$ with probability at least $1-2\beta_n(\varepsilon)$. Furthermore, $\phi(L) \geqslant \delta^2$ by Lemma 6. Applying these inequalities to (13), we obtain

$$\sup_{B \in N_{n,k}(A) \cap \mathcal{R}_{n,k}(c)^c} \widehat{H}(B,L) < \widehat{H}(C_{1,n},L) - a|L|\delta^2 cb_{n,k} + 10|L|b_{n,k} \tag{14}$$

with probability at least $1 - 4\beta_n(\varepsilon)$. With c large enough, (14) implies that $\widehat{H}(B,L) < \widehat{H}(C_{1,n},L)$ for all $B \in N_{n,k}(A) \cap \mathcal{R}_{n,k}(c)^c$. This proves the result in the $\pi_1 < \pi_2$ case.

If $\pi_1 = \pi_2$, the argument is almost identical. We instead define $\mathcal{R}_{n,k}(c)$ as

$$\mathcal{R}_{n,k}(c) := \big\{B \subseteq [n] : \max\{|s(B) - \pi_1|,\ \rho(B),\ 1-\rho(B)\} \leqslant c \cdot b_{n,k}\big\}.$$

A derivation analogous to that giving inequality (12) yields

$$n^{-1}\max\{d_h(B,C_{1,n}),\ d_h(B,C_{2,n})\} \leqslant 3c \cdot b_{n,k},$$

which directly implies that $\mathcal{R}_{n,k}(c) \subseteq N_{n,k+1}(A')$ with $A' = 3c$. The remainder of the argument follows unaltered. ■

4.1.3 Proof of Theorem 2

Recall $Q_\ell(B)$ from Definition 2 and let $\widehat{Q}_\ell(B)$ be its random version under the MSBM, as in Section 3.2. For any $B \subseteq [n]$, we have the inequality

$$\Big\{\widehat{Q}_\ell(B)\Big\}_+ \leqslant \frac{Y_\ell(B)}{n\binom{|B|}{2}^{1/2}} \leqslant \frac{\binom{|B|}{2}}{n\binom{|B|}{2}^{1/2}} \leqslant \frac{|B|}{n}. \tag{15}$$

This yields the following inequality for $\widehat{H}(B,L)$:

$$\widehat{H}(B,L) = |L|^{-1}\left\{\left(\sum_{\ell \in [L]} Q_\ell(B)\right)_+\right\}^2 \leqslant |L|^{-1}\left\{\sum_{\ell \in [L]} Q_\ell(B)_+\right\}^2 \leqslant |L|^{-1}n^{-2}|B|^2. \tag{16}$$

Recall that $\mathcal{B}_n(\varepsilon) := \{B \in 2^{[n]} : |B| \geqslant \varepsilon n\}$. Inequality (16) implies $\widehat{H}(B,L) \leqslant |L|\varepsilon^2$ for all $B \in \mathcal{B}_n(\varepsilon)^c$. By part 2 of Lemma 6, $\phi(L) \geqslant \delta^2$. Therefore, defining $\tau := \frac{\pi_1^2}{2}(1-\pi_1)^4\delta^2/2$,

$$|L|\tau < |L|\phi(L)\frac{\pi_1^2}{2}(1-\pi_1)^4 = H_*(B,L).$$

Therefore, for all $B \in \mathcal{B}_n(\varepsilon)^c$, we have $\widehat{H}(B,L) \leqslant |L|\varepsilon^2 < H_*(C_{1,n},L) - |L|(\tau - \varepsilon^2)$. By Lemma 12, for large enough n we therefore have

$$\sup_{\mathcal{B}_n(\varepsilon)^c} \widehat{H}(B,L) < \widehat{H}(C_{1,n},L) - |L|(\tau - \varepsilon^2) + 5|L|\gamma_n^{1-\varepsilon} \tag{17}$$

with probability greater than $1 - 2\beta_n(\varepsilon)$, where $\beta_n(\varepsilon) := \exp\{-\frac{\kappa^2\varepsilon}{32}n\gamma_n^{1-\varepsilon}\log n + \log 4|L|\}$. For any $\varepsilon < \sqrt{\tau}$, inequality (17) implies $\widehat{H}(B,L) < \widehat{H}(C_{1,n},L)$ for all $B \in \mathcal{B}_n(\varepsilon)$, and therefore $\widehat{B}_{opt}(n) \in \mathcal{B}_n(\varepsilon)$, with probability at least $1 - 2\beta_n(\varepsilon)$. Note that $\varepsilon < \sqrt{\tau} < \pi_1$, and $N_{n,k}(\varepsilon) = \mathcal{B}_n(\varepsilon)$ by Definition 11. Therefore, the conditions for Lemma 13 with $k = 1$ (and $A = \varepsilon$) are satisfied. For any fixed $\varepsilon \in (0,\eta)$ with $\eta := \sqrt{\tau}$, we may now apply Lemma 13 recursively until $1/2^k \leqslant \varepsilon$. This establishes that for sufficiently large n,

$$\mathbb{P}_n\left(\widehat{B}_{opt}(n) \in N_{n,k}(A)\right) \geqslant 1 - (2+4k)\beta_n(\varepsilon). \tag{18}$$

By definition, $\widehat{B}_{opt}(n) \in N_{n,k}(A)$ implies that

$$\texttt{Error}(\widehat{B}_{opt}(n)) := \min_{C = C_1, C_2} d_h(\widehat{B}_{opt}(n), C) \leqslant A \cdot n \cdot b_{n,k}. \tag{19}$$

Since $1/2^k \leqslant \varepsilon$, note that

$$n \cdot b_{n,k} = n\gamma_n^{1-\frac{1}{2^k}} = n \cdot n^{\frac{1}{2^k}-1}(\log n)^{1-\frac{1}{2^k}} < n^\varepsilon \log n.$$

Combined with inequality (18), this completes the proof. ■

4.2 Proof of Theorem 3

To prove part (a), we first note that Theorem 2 implies that on the layer set L_1, for any $\varepsilon > 0$, $\texttt{Error}(\widehat{B}_{opt}^{(n)}) = O_p(n^\varepsilon \log n)$. Lemma 6 can be used to show that $H_*(B,L) = 0$ for any $L \subseteq L_0$ and any $B \subseteq [n]$. Using Lemma 9 and taking a union bound over L_0, it is then straightforward to show (using techniques from the proof of Theorem 2) that on the full layer set $[m]$, for any $\varepsilon > 0$, $\texttt{Error}(\widehat{B}_{opt}) = O_p(n^\varepsilon \log n)$. Considering now $\widehat{L}_{opt}^{(n)}$, observe that if $\widehat{Q}_\ell(B) \leqslant 0$, then $\widehat{H}(B,L) = \widehat{H}(B, L \setminus \{\ell\})$. This immediately implies that $\widehat{L}_{opt}^{(n)} = \widehat{L}^+$.

To prove part (b), we note that it is straightforward to show (using Lemma 6) that $H_*(B,L_1) \geqslant H_*(B,L)$ for any $L \subset [m]$, with equality if and only if $L = L_1$. Using Lemma 9 and a union bound over $[m]$ will show that $\widehat{L}_{opt}^{(n)} = L_1$ with high probability. Applying Theorem 2 completes the part. Part (c) is shown similarly, with the application of Lemma 6 showing that for any $L \subseteq L_1$ and $L' \subseteq [m]$, $H_*(B,L) \geqslant H_*(B,L')$, with equality if and only if $L' \subseteq L_1$. ■

5. The Multilayer Extraction Procedure

The Multilayer Extraction procedure is built around three operations: initialization, extraction, and refinement. In the initialization stage, a family of seed vertex sets is specified.

Next an iterative extraction procedure (**Extraction**) is applied to each of the seed sets. **Extraction** alternately updates the layers and vertices in a vertex-layer community in a greedy fashion, improving the score at each iteration, until no further improvement to the score is possible. The family of extracted vertex-layer communities is then reduced using the **Refinement** procedure, which ensures that the final collection of communities contains the extracted community with largest score, and that the pairwise overlap between any pair of communities is at most β, where $\beta \in [0, 1]$ is a user-defined parameter. The importance and relevance of this parameter is discussed in Section 5.3.1. We describe the Multilayer Extraction algorithm in more detail below.

5.1 Initialization

For each vertex $u \in [n]$ and layer $\ell \in [m]$ let $N(u, \ell) = \{v \in [n] : \{u, v\} \in E_\ell\}$ be the set of vertices connected to u in G_ℓ. We will refer to $N(u, \ell)$ as the neighborhood of u in layer ℓ. Let $\mathcal{B}_0 = \{N(u, \ell), u \in [n], \ell \in [m]\}$ be the family of all vertex neighborhoods in the observed multilayer network $\mathbf{G}(m, n)$. Multilayer Extraction uses the vertex sets in $\mathcal{B}_0$ as seed sets for identifying communities. Our choice of seed sets is motivated by Gleich and Seshadhri (2012), who empirically justified the use of vertex neighborhoods as good seed sets for local detection methods seeking communities with low conductance.

5.2 Extraction

Given an initial vertex set, the **Extraction** procedure seeks a vertex-layer community with large score. The algorithm iteratively conducts a *Layer Set Search* followed by a *Vertex Set Search*, and repeats these steps until a vertex-layer set, whose score is a local maximum, is reached. In each step of the procedure, the score of the candidate community strictly increases, and the procedure is stopped once no improvements to the score are possible. These steps are described next.

Layer Set Search: For a fixed vertex set $B \subseteq [n]$, **Extraction** searches for the layer set L that maximizes $H(B, \cdot)$ using a rank ordering of the layers that depends only on B. In particular let $Q_\ell(B)$ be the local set modularity of layer ℓ from (2). Let L_o be the layer set identified in the previous iteration of the algorithm. We will now update the layer set $L_0 \rightsquigarrow L$. This consists of the following three steps:

(i) Order the layers so that $Q_{\ell_1}(B) \geqslant \cdots \geqslant Q_{\ell_m}(B)$.

(ii) Identify the smallest integer k such that $H(B, \{\ell_1, \ldots, \ell_k\}) \geqslant H(B, \{\ell_1, \ldots, \ell_k, \ell_{k+1}\})$. Write $L_p := \{\ell_1, \ldots, \ell_k\}$ for the proposed change in the layer set.

(iii) *If* $H(B, L_p) > H(B, L_o)$ set $L = L_p$. *Else* set $L = L_o$

In the first iteration of the algorithm (where we take $L_o = \emptyset$), we set $L = L_p$ in step (iii) of the search. The selected layer set L_p is a local maximum for the score $H(B, \cdot)$.

Vertex Set Search: Suppose now that we are given a vertex-layer set (B, L). **Extraction** updates B, one vertex at a time, in a greedy fashion, with updates depending on the layer set L and the current vertex set. In detail, for each $u \in [n]$ let

$$\delta_u(B, L) = \begin{cases} H(B/\{u\}, L) - H(B, L) & \text{if } u \in B \\ H(B \cup \{u\}, L) - H(B, L) & \text{if } u \notin B. \end{cases} \tag{20}$$

Vertex Set Search iteratively updates B using the following steps:

(i) Calculate $\delta_u(B, L)$ for all $u \in [n]$. If $\delta_u(B, L) \leqslant 0$ for all $u \in [n]$, then stop. Otherwise, identify $u^* = \arg\max_{u \in [n]} \delta_u(B, L)$.

(ii) If $u^* \in B$, then remove u^* from B. Otherwise, add u^* to B.

At each iteration of **Extraction**, the score of the updated vertex-layer set strictly increases, and the eventual convergence of this procedure to a local maximum is guaranteed as the possible search space is finite. The resulting local maxima is returned as an extracted community.

5.3 Refinement

Beginning with the n vertex neighborhoods in each layer of the network, the **Extraction** procedure identifies a collection $\mathcal{C}_T = \{(B_t, L_t)\}_{t \in T}$ of at most $m * n$ vertex-layer communities. Given an overlap parameter $\beta \in [0, 1]$, the family $\mathcal{C}_T$ is refined in a greedy fashion, via the **Refinement** procedure, to produce a subfamily $\mathcal{C}_S$, $S \subseteq T$, of high-scoring vertex-layer sets having the property that the overlap between any pair of sets is at most β.

To quantify overlap, we specify a generalized Jaccard match score to measure overlap between two communities. We measure the overlap between two candidate communities (B_q, L_q) and (B_r, L_r) using a generalized Jaccard match score

$$J(q, r) \;=\; \frac{1}{2}\frac{|B_q \cap B_r|}{|B_q \cup B_r|} + \frac{1}{2}\frac{|L_q \cap L_r|}{|L_q \cup L_r|}. \tag{21}$$

It is easy to see that $J(q, r)$ is between 0 and 1. Moreover, $J(q, r) = 1$ if and only if $(B_q, L_q) = (B_r, L_r)$ and $J(q, r) = 0$ if and only if (B_q, L_q) and (B_r, L_r) are disjoint. Larger values of $J(\cdot, \cdot)$ indicate more overlap between communities.

In the first step of the procedure, **Refinement** identifies and retains the community (B_s, L_s) in $\mathcal{C}_T$ with the largest score and sets $S = \{s\}$. In the next step, the procedure identifies the community (B_s, L_s) with largest score that satisfies $J(s, s') \leqslant \beta$ for all $s' \in S$. The index s is then added to S. **Refinement** continues expanding S in this way until no further additions to S are possible, namely when for each $s \in T$, there exists an $s' \in S$ such that $J(s, s') > \beta$. The refined collection $C_S = \{B_s, L_s\}_{s \in S}$ is returned.

5.3.1 Choice of β

Many existing community detection algorithms have one or more tunable parameters that control the number and size of the communities they identify (Von Luxburg, 2007; Leskovec et al., 2008; Mucha et al., 2010; Lancichinetti et al., 2011; Wilson et al., 2014). The family of communities output by Multilayer Extraction depends on the overlap parameter $\beta \in [0, 1]$. In practice, the value of β plays an important role in the structure of the vertex-layer communities. For instance, setting $\beta = 0$ will provide vertex-layer communities that are fully disjoint (no overlap between vertices or layers). On the other hand, when $\beta = 1$ the procedure outputs the full set of extracted communities, many of which may be redundant. In exploratory applications, we recommend investigating the identified communities at multiple values of β, as the structure of communities at different resolutions may

provide useful insights about the network itself (see for instance Leskovec et al. (2008) or Mucha et al. (2010)).

Empirically, we observe that the number of communities identified by the Multilayer Extraction procedure is non-decreasing with β, and there is typically a long interval of β values over which the number and identity of communities remains constant. In practice we specify a default value of β by analyzing the number of communities across a grid of β between 0 and 1 in increments of size 0.01. For fixed i, let $\beta_i = (i-1) * 0.01$ and let $k_i = k(\beta_i)$ denote the number of communities identified at β_i. The default value β' is the smallest β value in the longest stable window, namely

$$\beta' \;=\; \text{smallest } \beta_i \text{ such that } k(\beta_i) = \text{mode}(k_1, \ldots, k_{101}).$$

6. Application Study

In this section, we assess the performance and potential utility of the Multilayer Extraction procedure through an empirical case study of three multilayer networks, including a multilayer social network, transportation network, and collaboration network. We compare and contrast the performance of Multilayer Extraction with six benchmark methods: Spectral Clustering (Newman, 2006a), Label Propagation (Raghavan et al., 2007), Fast and Greedy (Clauset et al., 2004), Walktrap (Pons and Latapy, 2005), multilayer Infomap (De Domenico et al., 2014), and multilayer GenLouvain (Mucha et al., 2010; Jutla et al., 2011). The multilayer Infomap and GenLouvain methods are generalized multilayer methods that can be directly applied to each network considered here. Each of the other four methods have publicly available implementations in the *igraph* package in R and in Python, and each method is a standard single-layer detection method that can handle weighted edges. We apply the first four methods to both the aggregate (weighted) network computed from the average of the layers in the analyzed multilayer network, and to each layer separately. A more detailed description of the competing methods and their parameter settings is provided in the Appendix. For this analysis and the subsequent analysis in Section 7, we set Multlayer Extraction to identify vertex-layer communities that have a large significance score as specified by equation (2).

For each method we calculate a number of quantitative features, including the number and size of the identified communities, as well as the number of identified background vertices. For all competing methods, we define a *background vertex* as a vertex that was placed in a trivial community, namely, a community of size one. We also evaluate the similarity of communities identified by each method. As aggregate and layer-by-layer methods do not provide informative layer information, we compare the vertex sets identified by each of the competing methods with those identified by Multilayer Extraction. To this end, consider two collections of vertex sets $\mathcal{B}, \mathcal{C} \subseteq 2^{[n]}$. Let size$(\mathcal{B})$ denote the number of vertex sets contained in the collection $\mathcal{B}$ and let $|A|$ represent the number of vertices in the vertex set A. Define the coverage of $\mathcal{B}$ by $\mathcal{C}$ as

$$\text{Co}(\mathcal{B};\mathcal{C}) = \frac{1}{\text{size}\,(\mathcal{B})} \sum_{B \in \mathcal{B}} \max_{C \in \mathcal{C}} \left(\frac{|B \cap C|}{|B \cup C|} \right). \tag{22}$$

The value $\text{Co}(\mathcal{B};\mathcal{C})$ quantifies the extent to which vertex sets in $\mathcal{B}$ are contained *in* $\mathcal{C}$. In general, $\text{Co}(\mathcal{B};\mathcal{C}) \neq \text{Co}(\mathcal{C};\mathcal{B})$. The coverage value $\text{Co}(\mathcal{B};\mathcal{C})$ is between 0 and 1, with $\text{Co}(\mathcal{B};\mathcal{C}) = 1$ if and only if $\mathcal{B}$ is a subset of $\mathcal{C}$.

We investigate three multilayer networks of various size, sparsity, and relational types: a social network from an Austrailian computer science department (Han et al., 2014); an air transportation network of European airlines (Cardillo et al., 2013); and a collaboration network of network science authors on arXiv.org (De Domenico et al., 2014). The size and edge density of each network is summarized in Table 1.

Table 2: Quantitative summary of the identified communities in each of the three real applications. Shown are the number of communities (Comm.), the mean and standard deviation of the number of nodes in each community, the number of background nodes per layer (Back.) and the coverage of the M-E with the method (Cov.). Methods run on the aggregate network are followed A. and layer-by-layer methods are followed by L.

Table 2 provides a summary of the quantitative features of the communities identified by each method. For ease of discussion, we will abbreviate Multilayer Extraction by M-E in the next two sections of the manuscript, where we evaluate the performance of the method on real and simulated data.

6.1 AU-CS Network

Individuals interact across multiple modes: for example, two people may share a friendship, business partnership, college roommate, or a sexual relationship, to name a few. Thus multilayer network models are particularly useful for understanding social dynamics. In such

a model, vertices represent the individuals under study and layers represent the type of interaction among individuals. Correspondingly, vertex-layer communities represent groups of individuals that are closely related across a subset of interaction modes. The number and type of layers in a vertex-layer community describes the strength and type of relationships that a group of individuals share.

We demonstrate the use of M-E on a social network by investigating the AU-CS network, which describes online and offline relationships of 61 employees of a Computer Science research department in Australia. The vertices of the network represent the employees in the department. The layers of the network represent five different relationships among the employees: *Facebook*, *leisure*, *work*, *co-authorship*, and *lunch*.

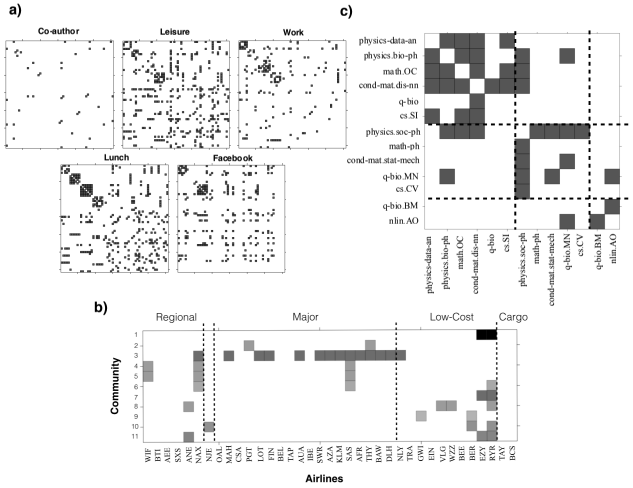

Figure 2: **a)** The AU-CS multilayer network. The vertices have been reordered based on the six communities identified by M-E. **b)** The layers of the eleven extracted significant communities identified in the EU transport network. The layers are ordered according to the type of airline. The darkness of the shaded in blocks represents the score of the identified community. **c)** Adjacency matrix of layers in the arXiv network, where edges are placed between layers that were contained in one or more of the communities identified by M-E. Dotted lines separate three communities of submission types that were identified using spectral clustering.

Results

M-E identified 6 non-overlapping vertex-layer communities, which are illustrated in Figure 2 **a**. These communities reveal several interesting patterns among the individuals in the network. Both the *work* and *lunch* layers were contained in all six of the identified

communities, reflecting a natural co-occurrence of work and lunch interactions among the employees. Of the competing methods, GenLouvain was the only other method to identify this co-occurrence. Furthermore, two of the identified communities by M-E contained the *leisure* and *Facebook* layers, both of which are social activities that sometimes extend beyond work and lunch. Thus these communities likely represent groups of employees with a stronger friendship than those that were simply colleagues. These interpretable features identified by M-E provide an example of how our method can be used to provide useful insights beyond aggregate and layer by layer methods.

With the exception of Infomap, all of the methods identify a similar number of communities (ranging from 5 to 7). Infomap, on the other hand, identified 20 small communities in the multilayer network. The 11 background vertices identified by M-E were sparsely connected, having two or fewer connections in 3 of the layers. As seen by the coverage measure in Table 2, the vertex sets identified by M-E were similar to those identified by the single-layer methods as well as by Infomap. Furthermore, the communities identified by the aggregate approaches are in fact well contained in the family identified by M-E (average coverage = 0.78). In summary, the vertex sets identified by M-E reflect both the aggregate and separate layer community structure of the network, and the layer sets reveal important features about the social relationships among the employees.

6.2 European Air Transportation Network

Multilayer networks have been widely used to analyze transportation networks (Strano et al., 2015; Cardillo et al., 2013). Here, vertices generally represent spatial locations (e.g., an intersection of two streets, a railroad crossing, GPS coordinates, or an airport) and layers represent transit among different modes of transportion (e.g., a car, a subway, an airline, or bus). The typical aim of multilayer analysis of transportation networks is to better understand the efficiency of transit in the analyzed location. Vertex-layer communities in transportation networks contain collections of vehicles (layers) that frequently travel along the same transit route (vertices). Vertex-layer communities reveal similarity, or even redundancy, in transportation among various modes of transportation and enable optimization of travel efficiency in the location.

In the present example, we use M-E to analyze the European air transportation network, where vertices represent 450 airports in Europe and layers represent 37 different airlines. An edge in layer j is present between two airports if airline j traveled a direct flight between the two airports on June 1st, 2011. Notably here, each airline belongs to one of five classes: *major* (18); *low-cost* (10); *regional* (6); *cargo* (2); and *other* (1). A multiplex visualization of this network is shown in Figure 3.

Results

The layer sets of the extracted M-E communities are illustrated in Figure 2 **b**, and a summary of M-E and the competing methods is available in the second major column of Table 2. M-E identified 11 small communities (mean number of vertices = 13.1, mean number of layers = 3.73). This suggests that the airlines generally follow distinct routes containing a small number of unique airports. Furthermore, Figure 2 illustrates that the layers of each community are closely associated with airline classes. Indeed, an average

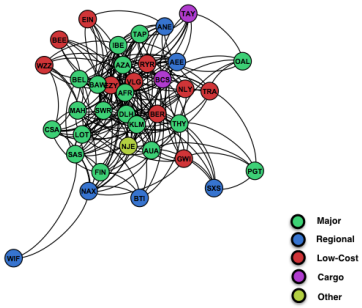

Figure 3: A one-dimensional visualization of the European Air Transportation Network. Edges are placed between airlines that share at least two routes between airports.

of 78 % of the layers in each community belonged to the same airline class. This reflects the fact that airlines of the same class tend to have direct flights between similar airports. Together these two findings suggest that in general there is little redundancy among the travel of airlines in Europe but that airlines of a similar class tend to travel the same routes.

Interestingly, the *regional* airline Norwegian Air Shuttle (NAX) and the *major* airline Scandanavian Airlines (SAS) appeared together in 4 unique communities. These airlines are in fact the top two air carriers in Scandanavia and fly primarily to airports in Norway, Sweden, Denmark, and Finland. Thus, M-E reveals that these two airlines share many of the same transportation routes despite the fact that they are different airline classes.

In comparison to the competing methods, we find that both the single-layer methods and M-E identified on the order of 400 background vertices ($\approx 89\%$), which suggests that many of the airports are not frequented by multiple airlines. This finding aligns with the fact that many airports in Europe are small and do not service multiple airline carriers. Aggregate detection approaches, as well as multilayer GenLouvain, identified a similar number of communities as M-E. In fact, the results of M-E most closely matched those of GenLouvain (Coverage = 0.64). We found that Infomap again identified the most communities (almost 4 times as many as any other method) and, like the aggregate approaches, identified few background vertices.

6.3 arXiv Network

Our final demonstration of M-E is on the multilayer collaboration arXiv network from De Domenico et al. (2014). In a multilayer representation of a collaboration network, vertices represent researchers or other possible collaborators, and layers represent scientific fields or sub-fields under which researchers collaborated. For these applications, multilayer networks provide information about the dissemination and segmentation of scientific research, including the possible overlap of collaborative work under different scientific fields.

Vertex-layer communities in collaborative networks represent groups of individuals who collaborated with one another across a subset of scientific fields. Such communities describe how differing scientific fields overlap, which collaborators are working in a similar area, as well as how to disseminate research across fields and how scientists can most easily take part in interdisciplinary collaborations.

The arXiv network that we analyze represents the authors of all arXiv submissions that contained the word "networks" in its title or abstract between the years 2010 and 2012. The network has 14489 vertices representing authors, and 13 layers representing the arXiv category under which the submission was placed. An edge is placed between two authors in layer ℓ if they co-authored a paper placed in that category. The network is sparse, with each layer having edge density less than 1.5%.

Results

M-E identified 272 multilayer communities, with an average of 2.39 layers per community. The communities were small in size, suggesting that network science collaboration groups are relatively tightly-knit, both in number of authors and number of differing fields. In Figure 2 **c**, we plot an adjacency matrix for layers whose (i, j) entry is 1 if and only if layers i and j were contained in at least one multilayer community. Using the adjacency matrix, the layers of the network were partitioned into communities using Spectral clustering. This figure identifies the existence of three active interdisciplinary working groups among the selected researchers. These results suggest two important insights. First, network researchers can identify his or her primary sub-field community and best disseminate research in this area by communicating with researchers from other fields in the same community. Second, Figure 2 **c** illustrates clear separation of three major areas of study. By promoting cross-disciplinary efforts between each of these three major areas, the dissemination of knowledge among network scientists will likely be much more efficient.

Infomap and the aggregate approaches identify on the order of 1000 small to moderately sized communities (mean number of vertices between 6.04 and 9.80) with approximately 423 background vertices. Notably, the 423 background vertices identified by each of these methods had a 0.92 match. On the other hand M-E, GenLouvain and the single layer approaches identify a smaller number of communities (between 272 and 402), and classify about 12 thousand (roughly 86%) of the vertices as background (of which share a match of 0.9). These findings suggest that the individual layers of the arXiv network have heterogeneous community structure, and that they contain many non-preferentially attached vertices. Once again, GenLouvain had the highest match with M-E (coverage = 0.83).

7. Simulation Study

As noted above, Multilayer Extraction has three key features: it allows community overlap; it identifies background; and it can identify communities that are present in a small subset of the available layers. Below we describe a simulation study that aims to evaluate the performance of M-E with respect to these features. The results of additional simulations are described in the Appendix.

In this simulation study, we are particularly interested in comparing the performance of M-E with off-the-shelf aggregate and layer-by-layer methods. We make this comparison

using the layer-by-layer and aggregate approaches using the community detection methods described in Section 6. Define the *match* between two vertex families $\mathcal{B}$ and $\mathcal{C}$ by

$$M(\mathcal{B};\mathcal{C}) \;=\; \frac{1}{2}\,\mathrm{Co}(\mathcal{B};\mathcal{C}) \;+\; \frac{1}{2}\,\mathrm{Co}(\mathcal{C};\mathcal{B}), \tag{23}$$

where $\mathrm{Co}(\mathcal{B};\mathcal{C})$ is the coverage measure for vertex families from (22). The match $M(\mathcal{B};\mathcal{C})$ is symmetric and takes values in $[0,1]$. In particular, $M(\mathcal{B};\mathcal{C}) = 1$ if and only if $\mathcal{B} = \mathcal{C}$ and $M(\mathcal{B};\mathcal{C}) = 0$ if and only if $\mathcal{B}$ and $\mathcal{C}$ are disjoint.

In our simulations, we compute the match between the family of vertex sets identified by each method and the family of true simulated communities. For the layer-by-layer methods, we evaluate the average match of the communities identified in each layer. Suppose that $\mathcal{T}$ is the true family of vertex sets in a simulation and $\mathcal{D}$ is the family of vertex sets identified by a detection procedure of interest. Note that the value $\mathrm{Co}(\mathcal{D};\mathcal{T})$ quantifies the specificity of $\mathcal{D}$, while $\mathrm{Co}(\mathcal{T};\mathcal{D})$ quantifies its sensitivity; thus, $M(\mathcal{D};\mathcal{T})$ is a quantity between 0 and 1 that summarizes both the sensitivity and specificity of the identified vertex sets $\mathcal{D}$. The results of the simulation study are summarized in Figures 4, 5, and 6 and discussed in more detail below.

7.1 Multilayer Stochastic Block Model

In the first part of the simulation study we generated multilayer stochastic block models with $m \in \{1, 5, 10, 15\}$ layers, $k \in \{2, 5\}$ blocks, and $n = 1000$ vertices such that each layer has the same community structure. In more detail, each vertex is first assigned a community label $\{1, \ldots, k\}$ according to a probability mass function $\pi = (0.4, 0.6)$ for $k = 2$ and $\pi = (0.2, 0.1, 0.2, 0.1, 0.4)$ for $k = 5$. In each layer, edges are assigned independently, based on vertex community membership, according to the probability matrix P with entries $P(i,i) = r + 0.05$ and $P(i,j) = 0.05$ for $i \neq j$. Here r is a parameter representing connectivity strength of vertices within the same community. The resulting multilayer network consists of m independent realizations of a stochastic k block model with the same communities. For each value of m and k we vary r from 0.00 to 0.10 in increments of 0.005. M-E and all other competing methods are run on ten replications of each simulation. The average match of each method to the true communities is given in Figure 4.

Results

In the single-layer ($m = 1$) setting M-E is competitive with the existing single-layer and multilayer methods for $r \geqslant 0.05$, and identifies the true communities without error for $r \geqslant 0.06$. For $m \geqslant 5$ M-E outperforms all competing single-layer methods for $r \geqslant 0.02$. As the number of layers increases, M-E and the multilayer Infomap and GenLouvain methods exhibit improved performance across all values of r. For the two community block model, M-E and the other multilayer methods have comparable performance in networks with five or more layers. M-E outperforms the single-layer and multilayer methods in the $k = 5$ block model when $m > 1$. As expected, aggregate approaches perform well in this simulation, outperforming or matching other methods when $m \leqslant 5$ (results not shown). These results suggest that in homogeneous multilayer networks M-E can outperform or match existing methods when the network contains a moderate to large number of layers.

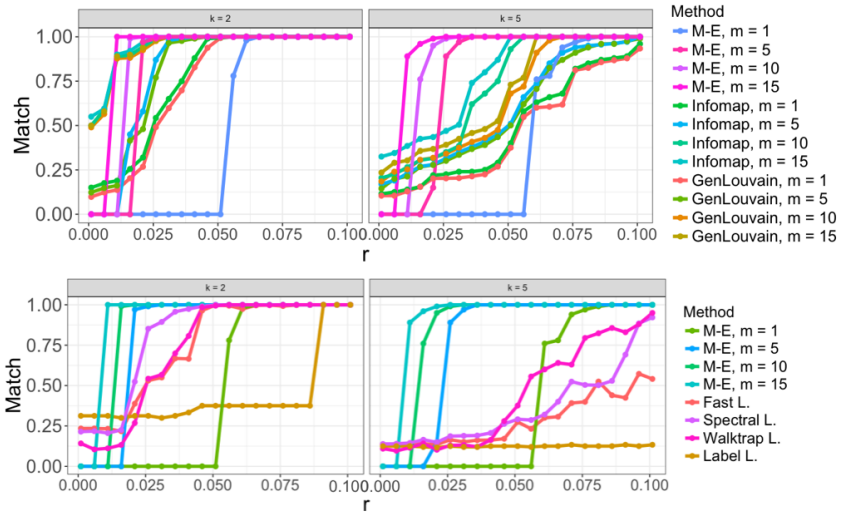

Figure 4: (Color) Simulation results for multilayer stochastic block model. In each plot, we report the match of the identified communities with the true communities where the match is calculated using the match score in (23).

7.2 Persistence

In the second part of the simulation study we consider multilayer networks with heterogeneous community structure. We simulated networks with 50 layers and 1000 vertices. The first $\tau * 50$ layers follow the stochastic block model outlined in Section 7.1 with a fixed connection probability matrix P having entries $P(i,i) = 0.15$ and $P(i,j) = 0.05$ for $i \neq j$. The remaining $(1-\tau)*50$ layers are independent Erdős-Rényi random graphs with $p = 0.10$, so that in each layer every pair of vertices is connected independently with probability 0.10. For each $k \in \{2, 5\}$ we vary the persistence parameter τ from 0.02 to 1 in increments of 0.02, and for each value of τ, we run M-E as well as the competing methods on ten replications. The average match of each method is reported in Figure 5.

Results

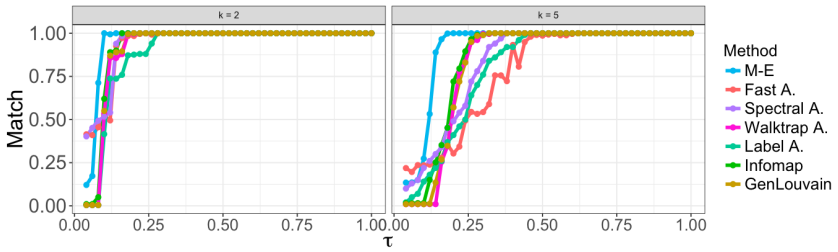

Figure 5: (Color) Simulation results persistence simulations. In each plot, we report the match of the identified communities with the true communities where the match is calculated using the match score in (23).

In both block model settings with $k = 2$ and 5 communities, M-E outperforms competing aggregate and multilayer methods for small values of τ. At these values, aggregate methods perform poorly since the community structure in the layers with signal is hidden by the noisy Erdős-Rényi layers once the layers are aggregated. Though not shown in Figure 6, the layer-by-layer methods are able to correctly identify the community structure of the layers with signal. However, these methods identify on average of 4 or more non-trivial communities in each noisy layer where there is in fact no community structure present. Multilayer GenLouvain and Infomap outperform aggregate methods in this simulation, suggesting that available multilayer methods are able to better handle multilayer networks with heterogeneous layers. Whereas the noisy Erdős-Rényi layers posed a challenge for both single-layer and aggregate methods, M-E never included any of these layers in an identified community. These results highlight M-E's ability to handle networks with noisy and heterogeneous layers.

7.3 Single Embedded Communities

We next evaluate the ability of M-E to detect a single embedded community in a multilayer network. We construct multilayer networks with $m \in \{1, 5, 10, 15\}$ layers and 1000 vertices according to the following procedure. Each layer of the network is generated by embedding a common community of size $\gamma * 1000$ in an Erdős-Rényi random graph with connection probability 0.05 in such a way that vertices within the community are connected independently with probability 0.15. The parameter γ is varied between 0.01 and 0.20 in increments of 0.005; ten independent replications of the embedded network are generated for each γ. For each method, we calculate the coverage $C(E, \mathcal{C})$ of the true embedded community E by the identified collection $\mathcal{C}$. We report the average coverage over the ten replications in Figure 6.

Results

In the single layer setting, M-E is able to correctly identify the embedded community when the embedded vertex set takes up approximately 11 percent ($\gamma = 0.11$) of the layer. As before, the performance of M-E greatly improves as the number of layers in the observed multilayer network increases. For example at $m = 5$ and $m = 10$, the algorithm correctly identifies the embedded community (with at least 90% match) once the community has size taking as little as 6 percent ($\gamma = 0.055$) of each layer. At $m = 15$, M-E correctly extracts communities with size as small as three percent of the graph in each layer.

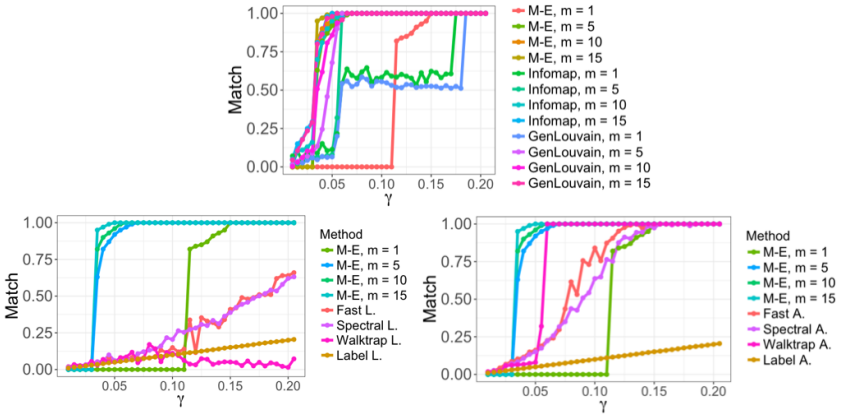

Figure 6: (Color) Simulation results for single embedded simulations. In each plot, we report the match of the identified communities with the true communities where the match is calculated using the match score in (23).

In the lower right plot of Figure 6, we illustrate the results for the aggregate methods applied to the simulated network with $m = 15$ layers. In the lower left plot of Figure 6, we show the results for the layer-by-layer methods in this simulation and the upper part of the figure show the results for the multilayer methods. For $m \geqslant 5$ M-E outperforms all of the competing aggregate methods. In addition, M-E outperforms every layer-by-layer method for all m. Multilayer GenLouvain and Infomap have comparable performance to M-E across all m and γ. These results emphasize the extraction cabilities of M-E and show that the procedure, contrary to aggregate and single-layer competing methods, is able to detect small embedded communities in the presence of background vertices.

8. Discussion

Multilayer networks have been profitably applied to a number of complex systems, and community detection is a valuable exploratory technique to analyze and understand networks. In many applications, the community structure of a multilayer network will differ from layer to layer due to heterogeneity. In such networks, actors interact in tightly connected groups that persist across only a subset of layers in the network. In this paper we have introduced and evaluated the first community detection method to address multilayer networks with heterogeneous communities, Multilayer Extraction. The core of Multilayer Extraction is a significance score that quantifies the connection strength of a vertex-layer set by comparing connectivity in the observed network to that of a fixed degree random network.

Empirically, we showed that Multilayer Extraction is able to successfully identify communities in multilayer networks with overlapping, disjoint, and heterogeneous community structure. Our numerical applications revealed that Multilayer Extraction can identify relevant insights about complex relational systems beyond the capabilities of existing detection methods. We also established asymptotic consistency of the global maximizer of the Multilayer Extraction score under the multilayer stochastic block model. We note that in practice the Multilayer Extraction procedure can identify overlapping community structure in multilayer networks; however, our consistency results apply to a multilayer model with non-overlapping communities. Future work should investigate consistency results like the ones derived here on a multilayer model with overlapping communities, such as a multilayer generalization of the mixed membership block model introduced in Airoldi et al. (2008). We expect that similar theory will hold in an overlapping model and that the theoretical techniques utilized here can be used to prove such results.

The Multilayer Extraction method provides a first step in understanding and analyzing multilayer networks with heterogeneous community structure. This work encourages several interesting areas of future research. For instance, the techniques used in this paper could be applied, with suitable models, to networks having ordered layers (e.g. temporal networks), as well as to networks with weighted edges such as the recent work done in Palowitch et al. (2016); Wilson et al. (2017). Furthermore, one could incorporate both node- and layer-based covariates in the null model to handle exogenous features of the multilayer network. Finally, it would be interesting to evaluate the consistency of Multilayer Extraction in multilayer networks in the high dimensional setting where the number of vertex-layer communities grows with the number of vertices.

Appendix A. Proofs of Lemmas from Section 3.2

A.1 Proof of Lemma 6

It is easy to show that for any 2×2 symmetric matrix A and 2-vectors $\mathbf{x}$, $\mathbf{y}$,

$$(\mathbf{x}^T A\mathbf{x})(\mathbf{y}^T A\mathbf{y}) - (\mathbf{x}^T A\mathbf{y})^2 = (\mathbf{x}_1\mathbf{y}_2 - \mathbf{x}_2\mathbf{y}_1)^2 \det(A).$$

Fix $B \subseteq [n]$ and let s, ρ, and v correspond to B, as in Definition 4. Then for any $\ell \in [L]$, using the fact that $\kappa_\ell := \pi^T P_\ell \pi$ and the identity above, we have

$$v^t P_\ell v - \frac{(\pi^t P_\ell \pi)^2}{\kappa_\ell} = \frac{\kappa_\ell v^t P_\ell v}{\kappa_\ell} - \frac{(v^t P_\ell \pi)^2}{\kappa_\ell} = \frac{(\pi^t P_\ell \pi)(v^t P_\ell v) - (v^t P_\ell \pi)^2}{\kappa_\ell}$$

$$= (\pi_1(1-\rho) - \pi_2\rho)^2 \frac{\det P_\ell}{\kappa_\ell} = (\pi_1 - \rho)^2 \frac{\det P_\ell}{\kappa_\ell}.$$

Recall that $q_\ell(B) := \frac{s}{\sqrt{2}}\left(v^t P_\ell v - (\pi^t P_\ell \pi)^2/\kappa_\ell\right)$ and $H_*(B, L) = |L|^{-1}\left(\sum_\ell q_\ell(B)\right)^2$. Part 1 follows by summation over L. For part 2, note that $\pi_1^2 P_\ell(1,1) + \pi_2^2 P(2,2) \geqslant 2\pi_1\pi_2\sqrt{P_\ell(1,1)P_\ell(2,2)}$. Therefore,

$$\begin{aligned}
\kappa_\ell &= \pi_1^2 P_\ell(1,1) + 2\pi_1\pi_2 P_\ell(1,2) + \pi_2^2 P(2,2) \\
&\geqslant 2\pi_1\pi_2\left(\sqrt{P_\ell(1,1)P_\ell(2,2)} + P_\ell(1,2)\right) \\
&\geqslant 2\pi_1\pi_2\left(\sqrt{P_\ell(1,1)P_\ell(2,2)} + P_\ell(1,2)\right)\left(\sqrt{P_\ell(1,1)P_\ell(2,2)} - P_\ell(1,2)\right) \\
&= 2\pi_1\pi_2\delta \geqslant \pi_1\delta.
\end{aligned}$$

Thus $\delta \leqslant \frac{\det P_\ell}{\kappa_\ell} \leqslant \frac{1}{\pi_1\delta}$. Part 2 follows. ■

A.2 Proof of Lemma 7

Define $g : 2^{[n]} \mapsto \mathbb{R}$ by $g(B) := \frac{s(B)}{2}(\rho(B) - \pi_1)^4$. Recall the function $\phi(L)$ defined in Lemma 6. Note that part 1 of Lemma 6 implies $H_*(B, L) = |L|\phi(L)g(B)$. It is therefore sufficient to show that there exists a constant $a > 0$ such that for sufficiently small t, $B \in \mathcal{R}(t)^c$ implies $g(B) < g(C_{1,n}) - at$. We will show this separately for the $\pi_1 < \pi_2$ and $\pi_1 = \pi_2$ cases.

Part 1 ($\pi_1 < \pi_2$): Define the intervals $I_1 := [0, \pi_1]$, $I_2 := (\pi_1, \pi_2]$, and $I_3 := (\pi_2, 1]$. We trisect $2^{[n]}$, the domain of g, with the collections $\mathcal{D}_{i,n} := \{B \subseteq [n] : s(B) \in I_i\}$, for $i = 1, 2, 3$. We will prove that the inequality $g(B) < g(C_{1,n}) - at$ holds for all $B \in \mathcal{R}(t)$ on each of those collections. We will continually rely on the fact that $B \in \mathcal{R}(t)$ implies at least one of the inequalities (I) $|s(B) - \pi_1| > t$ or (II) $1 - \rho(B) < t$ is true.

Suppose $B \in \mathcal{R}(t)^c \cap \mathcal{D}_{1,n}$ and inequality (I) is true. Then $s(B) < \pi_1 - t$, and

$$\begin{aligned} g(B) := \frac{s(B)^2}{2}(\rho(B) - \pi_1)^4 &\leqslant \frac{s(B)^2}{2}(1-\pi_1)^4 \text{ (since } \pi_1 \leqslant 1/2) \\ &< \frac{(\pi_1 - t)^2}{2}(1-\pi_1)^4 = \frac{\pi_1^2}{2}(1-\pi_1)^4 - 2t(1-\pi_1)^4 + o(t) \\ &< \frac{\pi_1^2}{2}(1-\pi_1)^4 - t(1-\pi_1)^4 = g(C_{1,n}) - t(1-\pi_1)^4 \end{aligned} \tag{24}$$

for sufficiently small t. If inequality (II) is true, then

$$(\rho(B) - \pi_1)^4 \leqslant \max\{(1 - t - \pi_1)^4, \pi_1^4\} = \max\{(\pi_2 - t)^4, \pi_1^4\} = (\pi_2 - t)^4$$

for sufficiently small t, as $\pi_1 < \pi_2$. Therefore,

$$g(B) \leqslant \frac{\pi_1^4}{2}(\pi_2 - t)^4 = \frac{\pi_1^4}{2}\pi_2^4 - 4\pi_2^3 t + o(t) < g(C_{1,n}) - 2\pi_2^3 t \tag{25}$$

for sufficiently small t. Thus for all $B \in \mathcal{R}(t)^c \cap \mathcal{D}_{1,n}$, $g(B) < g(C_{1,n}) - a_1 t$ with $a_1 = \min\{(1-\pi_1)^4, 2\pi_2^3\}$.

Suppose $B \in \mathcal{R}(t)^c \cap \mathcal{D}_{2,n}$ and inequality (I) is true. Then $s(B) > \pi_1 + t$. Note that $0 \leqslant \rho(B)|B| \leqslant |C_{1,n}|$, yielding the useful inequality

$$0 \leqslant \rho(B) \leqslant \pi_1 / s(B). \tag{26}$$

Subtracting through by π_1 gives

$$(\rho(B) - \pi_1)^4 \leqslant \max\{\pi_1^4, \pi_1^4(1/s(B) - 1)^4\} = \pi_1^4(1/s(B) - 1)^4.$$

Therefore,

$$\begin{aligned} g(B) \leqslant \frac{s(B)^2}{2}\pi_1^4(1/s(B) - 1)^4 &= \frac{\pi_1^4}{2}(1/\sqrt{s(B)} - \sqrt{s(B)})^4 \\ &< \frac{\pi_1^4}{2}(1/\sqrt{\pi_1 + t} - \sqrt{\pi_1 + t})^4, \end{aligned} \tag{27}$$

since $F(x) := (1/\sqrt{x} - \sqrt{x})^4$ is decreasing on $(0, 1]$, and $s(B) > \pi_1 + t$. Note that

$$\frac{d}{dt}\left(\frac{1}{\sqrt{\pi_1 + t}} - \sqrt{\pi_1 + t}\right)^4 = -3\left(\frac{1}{\sqrt{\pi_1 + t}} - \sqrt{\pi_1 + t}\right)^3 \left(\frac{1}{2(\pi_1 + t)^{3/2}} + \frac{1}{2\sqrt{\pi_1 + t}}\right). \tag{28}$$

By Taylor's theorem, this implies that

$$(1/\sqrt{\pi_1 + t} - \sqrt{\pi_1 + t})^4 = (1/\sqrt{\pi_1} - \sqrt{\pi_1})^4 - a_2 t + o(t) < (1/\sqrt{\pi_1} - \sqrt{\pi_1})^4 - a_2 t/2$$

for sufficiently small t, where a_2 is the right-hand-side of (28) at $t = 0$. Note further that $(1/\sqrt{\pi_1} - \sqrt{\pi_1})^4 = (\pi_2/\sqrt{\pi_1})^4 = \pi_2^4/\pi_1^2$. Putting these facts together with inequality (27), we obtain

$$g(B) < \frac{\pi_1^4}{2}\frac{\pi_2^4}{\pi_1^2} - a_2 t/2 = \frac{\pi_1}{2}\pi_2^4 - a_2 t/2 = g(C_{1,n}) - a_2 t/2. \tag{29}$$

If inequality (II) is true, $\rho(B) < 1 - t$. If $\rho(B) \leqslant \pi_1$, $(\rho(B) - \pi_1)^4$ is maximized when $\rho(B) = 0$, so that, since $s(B) \leqslant \pi_2$,

$$g(B) \leqslant \frac{\pi_2^2}{2}\pi_1^4 = g(C_{1,n}) + \frac{\pi_2^2}{2}\pi_1^4 - \frac{\pi_1^2}{2}\pi_2^4 = g(C_{1,n}) + \frac{\pi_1^2\pi_2^2}{2}(\pi_2^2 - \pi_1^2) < g(C_{1,n}) - t \tag{30}$$

for sufficiently small t, since π_1 is fixed. If $\rho(B) > \pi_1$, note that inequality (26) implies $s(B) \leqslant \pi_1/s(B)$. Therefore,

$$\begin{aligned} g(B) \leqslant \frac{\pi_1^2}{2\rho(B)^2}(\rho(B) - \pi_1)^4 &= \frac{\pi_1^2}{2}\left(\sqrt{\rho(B)} - \pi_1/\sqrt{\rho(B)}\right)^4 \\ &< \frac{\pi_1^2}{2}\left(\sqrt{1-t} - \pi_1/\sqrt{1-t}\right)^4 \end{aligned} \tag{31}$$

since $G(x) := (\sqrt{x} - \pi_1/\sqrt{x})^4$ is increasing on $(\pi_1, 1]$. A similar Taylor expansion argument to that yielding inequality (29) yields, for a constant a_3 depending only on π_1,

$$g(B) < \frac{\pi_1^2}{2}(1-\pi_1)^4 - a_3 t/2 = g(C_{1,n}) - a_3 t/2, \tag{32}$$

for sufficiently small t. Pulling together inequalities (29), (30), and (32), we have that for all $B \in \mathcal{R}(t)^c \cap \mathcal{D}_{1,n}$, $g(B) < g(C_{1,n}) - a_4$ with $a_4 := \min\{a_2/2, 1, a_3/2\}$.

Suppose $B \in \mathcal{R}(t)^c \cap \mathcal{D}_{3,n}$. Note that $|B| - |C_{2,n}| \leqslant |B \cap C_{1,n}| \leqslant |C_{1,n}|$. Dividing through by $|B|$ yields the useful inequality

$$1 - \pi_2/s(B) \leqslant \rho(B) \leqslant \pi_1/s(B). \tag{33}$$

Subtracting inequality (33) by π_1 gives

$$\pi_2(1 - 1/s(B)) \leqslant \rho(B) - \pi_1^4 \leqslant \pi_1(1/s(B) - 1).$$

Since $\pi_1 < \pi_2$, this implies that $(\rho(B) - \pi_1)^4 \leqslant \pi_2^4(1 - 1/s(B))^4$. Therefore,

$$g(B) \leqslant \frac{s(B)^2}{2}\pi_2^4(1/s(B) - 1)^4 = \frac{\pi_2^4}{2}\left(1/\sqrt{s(B)} - \sqrt{s(B)}\right)^4 < \frac{\pi_2^4}{2}(1/\sqrt{\pi_2} - \sqrt{\pi_2})^4, \tag{34}$$

since $F(x) := (1\sqrt{x} - \sqrt{x})^4$ is decreasing on $I_3 := (\pi_2, 1]$ and $s(B) \in I_3$. Note that $\sqrt{\pi_2} - 1/\sqrt{\pi_2} = -\pi_1/\sqrt{\pi_2}$. Therefore,

$$g(B) < \frac{\pi_2^4}{2}\frac{\pi_1^4}{\pi_2^2} = \frac{\pi_2^2}{2}(0 - \pi_1)^4 = g(C_{2,n}) < g(C_{1,n}) - t$$

for t sufficiently small. Thus, for $a := \min\{a_1, a_4, 1\}$, for sufficiently small t we have $g(B) < g(C_{1,n}) - at$ whenever $B \in \mathcal{R}(t)$. This completes the proof in the case $\pi_1 < \pi_2$.

Part 2 ($\pi_1 = \pi_2$): Recall that when $\pi_1 = \pi_2$ we define $\mathcal{R}(t)$ by

$$\mathcal{R}(t) := \left\{B \subseteq [n] : \max\{|s(B) - \pi_1|,\ \rho(B),\ 1 - \rho(B)\} \leqslant t\right\}.$$

Hence we will use the fact that $B \in \mathcal{R}(t)$ implies at least one of the inequalities (I) $|s(B) - \pi_1| > t$ or (II) $t < \rho(B) < 1 - t$ is true. Define the intervals $I_1 := [0, \pi_1]$, $I_2 := (\pi_1, 1]$. We bisect $2^{[n]}$, the domain of g, with the collections $\mathcal{D}_{i,n} := \{B \subseteq [n] : s(B) \in I_i\}$, for $i = 1, 2$. We will prove that the inequality $g(B) < g(C_{1,n}) - at$ holds for all $B \in \mathcal{R}(t)$ on each of those collections.

Suppose $B \in \mathcal{R}(t)^c \cap \mathcal{D}_{1,n}$ and inequality (I) is true. Then the same derivation yielding inequality (24) gives $g(B) < g(C_{1,n}) - t(1 - \pi_1)^4$ for sufficiently small t. If inequality (II) is true, then

$$(\rho(B) - \pi_1)^4 \leqslant \max\{(1 - t - \pi_1)^4, (\pi_1 - t)^4\} = \max\{(\pi_2 - t)^4, (\pi_1 - t)^4\} = (\pi_2 - t)^4,$$

since $\pi_1 = \pi_2$. Therefore, inequality (25) remains intact. Both inequalities hold on I_2 as well, for the roles of π_1 and π_2 may be interchanged, and the derivations treated symmetrically. This completes the proof in the case $\pi_1 = \pi_2$. ■

A.3 Proof of Lemma 9

Recall the definitions of set modularity and population set modularity from Definitions 2 and 9. Define $W := \sum_{\ell \in [L]} \widehat{Q}_\ell(B)$ and $w := \sum_{\ell \in [L]} q_\ell(B)$. Note that by Part 1 of Lemma 6, $q_\ell(B) \geqslant 0$ regardless of B, a fact which will allow the application of Lemma 16 in what follows. We have $\widehat{H}(B, L) = |L|^{-1} W_+^2$, $H_*(B, L) = |L|^{-1} w^2$, and for any B such that $|B| \geqslant n\varepsilon$,

$$\mathbb{P}_n\left(\left|\widehat{H}(B, L) - H_*(B, L)\right| > \frac{4|L|t}{n^2} + \frac{52|L|}{\kappa n}\right) = \mathbb{P}_n\left(|W_+^2 - w^2| > \frac{4|L|^2 t}{n^2} + \frac{52|L|^2}{\kappa n}\right)$$

$$\leqslant \mathbb{P}_n\left(\max_{\ell \in [L]} \left|\widehat{Q}_\ell(B) - q_\ell(B)\right| > \frac{t}{n^2} + \frac{13}{\kappa n}\right) \leqslant 4|L| \exp\left(-\kappa^2 \frac{\varepsilon t^2}{16 n^2}\right)$$

for large enough $t > 0$, where the first inequality follows from Lemma 16 for large enough n, and the second inequality follows from Lemma 19 and a union bound. Applying a union bound over sets $B \in \mathcal{B}_n$ yields the result. ■

A.4 Proof of Lemma 12

Assume first that $k > 1$. By definition, $B \in N_{n,k}(A)$ implies that at least one of $d_h(B, C_1) \leqslant A \cdot n \cdot b_{n,k-1}$ or $d_h(B, C_2) \leqslant A \cdot n \cdot b_{n,k-1}$ is true. Suppose the first inequality holds. Since $d_h(B, C_1) = |B \setminus C_1| + |C_1 \setminus B|$, we have the inequality

$$\big||B| - n\pi_1\big| = \big||B| - |C_1|\big| \leqslant \big||B| - |B \cap C_1| - |C_1| + |B \cap C_1|\big| \leqslant \big||B| - |B \cap C_1|\big|$$

$$+ \big||C_1| - |B \cap C_1|\big| = |B \setminus C_1| + |C_1 \setminus B| \leqslant A \cdot n \cdot b_{n,k-1}.$$

Alternatively, if $d_h(B, C_2) \leqslant A \cdot n \cdot b_{n,k-1}$, we have the same bound for $\big||B| - n\pi_2\big|$. Therefore, since $\pi_1 \leqslant \pi_2$, $B \in N_{n,k}(A)$ implies that $|B| \geqslant n\pi_1 - A \cdot n \cdot b_{n,k-1}$. Since $b_{n,k-1} = o(1)$ as $n \to \infty$ and $\varepsilon < \pi_1$, this implies that for large enough n, $N_{n,k}(A) \subseteq \mathcal{B}_n(\varepsilon)$. By Lemma 9,

therefore, for large enough n, we have

$$\mathbb{P}_n\left(\sup_{N_{n,k}(A)} \left|\widehat{H}(B, L) - H_*(B, L)\right| > \frac{4|L|t}{n^2} + \frac{52|L|}{\kappa n}\right) \leqslant 4|L||N_{n,k}(A)| \exp\left(-\kappa^2 \frac{\varepsilon t^2}{16 n^2}\right) \tag{35}$$

for all $t > 0$. We now bound the right-hand side of inequality (35) with t replaced by $t_n := n^{1 + \frac{1}{2^k}} (\log n)^{1 - \frac{1}{2^k}}$. Note that

$$\frac{t_n^2}{n^2} = \frac{1}{n^2} n^{2 + \frac{1}{2^{k-1}}} (\log n)^{2 - \frac{1}{2^{k-1}}} = n \cdot n^{\frac{1}{2^{k-1}} - 1} (\log n)^{1 - \frac{1}{2^{k-1}}} \log n = n \cdot b_{n,k-1} \log n.$$

Furthermore, by Corollary 15 (see Appendix B) we have $|N_{n,k}(A)| \leqslant 2 \exp\left[3A \cdot n \cdot b_{n,k-1} \log\left(1/b_{n,k-1}\right)\right]$. These facts yield the bound

$$|N_{n,k}(A)| \exp\left(-\kappa^2 \frac{\varepsilon t_n^2}{16 n^2}\right) \leqslant 2 \exp\left\{-\kappa^2 \frac{\varepsilon}{16} n \cdot b_{n,k-1} \left(\log n - \frac{16}{\kappa^2 \varepsilon} 3A \log\left(1/b_{n,k-1}\right)\right)\right\}$$

$$\leqslant 2 \exp\left(-\kappa^2 \frac{\varepsilon}{32} n \cdot b_{n,k-1} \log n\right) \text{ (for large } n\text{, since } 1/b_{n,k-1} = o(n))$$

$$< 2 \exp\left(-\kappa^2 \frac{\varepsilon}{32} n \gamma_n^{1-\varepsilon} \log n\right),$$

where the final inequality follows from the choice of k satisfying $\frac{1}{2^{k-1}} < \varepsilon$. Therefore,

$$4|L||N_{n,k}(A)| \exp\left(-\kappa^2 \frac{\varepsilon t_n^2}{16 n^2}\right) \leqslant 2 \exp\left\{-\frac{\kappa^2 \varepsilon}{32} n \gamma_n^{1-\varepsilon} \log n + O(\log |L|)\right\} \tag{36}$$

for large enough n. Notice now that $t_n / n^2 = b_{n,k}$ vanishes slower than $1/n$, and is therefore the leading order term in the expression $\frac{4|L|t_n}{n^2} + \frac{52|L|}{\kappa n}$ (see equation 35). Hence for large enough n we have $\frac{4|L|t_n}{n^2} + \frac{52|L|}{\kappa n} \leqslant 5|L| b_{n,k}$. Combining this observation with lines (35) and (36) proves the result in the case $k > 1$.

If $k = 1$, assume $A = \varepsilon$. By definition, then (see Definition 11), $N_{n,k}(A) = \mathcal{B}_n(\varepsilon)$. Returning to inequality (35), we note that $\log |\mathcal{B}_n(\varepsilon)| = O(n)$, and thus we can derive the bound (36) with the same choice of $t_n := n^{1 + \frac{1}{2^k}} (\log n)^{1 - \frac{1}{2^k}} = n\sqrt{n \log n}$. The rest of the argument goes through unaltered. ■

Appendix B. Technical Results

Lemma 14 *Fix $\pi_1 \in [0, 1]$. For each n, let $C_1 \subseteq [n]$ be an index set of size $\lfloor n\pi_1 \rfloor$. Let $C_2 := [n] \setminus C_1$. Let $\gamma_n \in [0, 1]$ be a sequence such that $\gamma_n \to 0$ and $n\gamma_n \to \infty$. Then for large enough n,*

$$|N(C_1, \gamma_n)| \leqslant \exp\{3n\gamma_n \log(1/\gamma_n)\}.$$

Proof Define the boundary of a neighborhood of $C \subseteq [n]$ by

$$\partial N(C, r) := \{B \subseteq [n] : d_h(B, C) = \lfloor nr \rfloor\}.$$

Note that any $B \subseteq [n]$ may be written as the disjoint union $B = \{C_2 \cap B\} \cup \{C_1 \cap B\}$. Since $C_1 \cap B = C_1 \setminus \{C_1 \setminus B\}$, for fixed $k \in [n]$ it follows that each set $B \in \partial N(C, k/n)$ is uniquely identified with choices of $|C_2 \cap B|$ indices from C_2 and $|C_1 \setminus B|$ indices from C_1 such that

$$|B \cap C_2| + |C_1 \setminus B| = |B \setminus C_1| + |C_1 \setminus B| = d_h(B, C_1) = k.$$

Therefore, we have the equality

$$|\partial N(C_1, k)| \;=\; \sum_{m=0}^{k} \left\{ \binom{|C_2|}{m} + \binom{|C_1|}{k-m} \right\}. \tag{37}$$

Note that for positive integers K, N with $K < N/2$, properties of the geometric series yield the following bound:

$$\begin{aligned} \binom{N}{K}^{-1} \sum_{m=0}^{K} \binom{N}{m} &= \sum_{m=0}^{K} \frac{(N-K)!K!}{(N-m)!m!} = \sum_{m=0}^{K} \prod_{j=m+1}^{K} \frac{j}{N-j+1} \\ &< \sum_{m=0}^{K} \left(\frac{K}{N-K+1} \right)^m < \frac{N-(K-1)}{N-(2K-1)}. \end{aligned} \tag{38}$$

For sufficiently small K/N, the right-hand side of inequality (38) is less than 2, and thus $\sum_{m=0}^{K} \binom{N}{m} < 2\binom{N}{K}$ if $K \ll N$. We apply this inequality to equation (37). Choose n large enough so that $n\gamma_n < \frac{1}{2}\min\{|C_1|, |C_2|\}$, which is possible since $\gamma_n \to 0$. Then for fixed $k \leqslant n\gamma_n$, we have that $|\partial N(C_1, k)| < 2\left[\binom{|C_2|}{k} + \binom{|C_1|}{k}\right]$ for large enough n. By another application of the inequality derived from (38), using the fact that $n\gamma_n = o(n)$, we therefore obtain

$$\begin{aligned} |N(C_1, \gamma_n)| = \sum_{k=0}^{\lfloor n\gamma_n \rfloor} |\partial N(C_1, k)| &< \sum_{k=0}^{\lfloor n\gamma_n \rfloor} 2\left\{ \binom{|C_2|}{k} + \binom{|C_1|}{k} \right\} \\ &< 4\left\{ \binom{|C_2|}{\lfloor n\gamma_n \rfloor} + \binom{|C_1|}{\lfloor n\gamma_n \rfloor} \right\} \leqslant 8\binom{n}{\lfloor n\gamma_n \rfloor}. \end{aligned}$$

As $\binom{N}{K} \leqslant \left(\frac{N \cdot e}{K}\right)^K$, we have

$$|N(C_1, \gamma_n)| \leqslant \exp\left(\log(8) + n\gamma_n \left\{\log(e) + \log(1/\gamma_n)\right\}\right) \leqslant \exp(3n\gamma_n \log(1/\gamma_n))$$

for large enough n, since $1/\gamma_n \to \infty$. ■

Here we give a short Corollary to Lemma 14 which directly serves the proof of Lemma 12. Recall $N_{n,k}(A)$ from Definition 11 in Section 4.1.2.

Corollary 15 *Fix an integer $k > 1$. For large enough n,*

$$|N_{n,k}(A)| \leqslant 2\exp\left[3A \cdot n \cdot b_{n,k-1} \log\left(1/b_{n,k-1}\right)\right].$$

Proof The corollary follows from a direct application of Lemma 14 to $N(C_1, A \cdot b_{n,k-1})$ and $N(C_2, A \cdot b_{n,k-1})$. ■

Lemma 16 *Let $x_1, \ldots, x_k \in (0,1)$ be fixed and let $X_1, \ldots, X_k$ be arbitrary random variables. Define $W := \sum_i X_i$ and $w := \sum_i x_i$. Then for t sufficiently small, $\mathbb{P}(|W_+^2 - w^2| > 4k^2 t) \leqslant \mathbb{P}(\max_i |X_i - x_i| > t)$.*

Proof Define $D_i := |X_i - x_i|$ and fix $t < \min_i x_i$. Then if $\max_i D_i \leqslant t$, all X_i's will be positive, and thus $W_+ = W$ and $|W - w| \leqslant kt$, by the triangle inequality. Therefore $\max_i D_i \leqslant t$ implies that

$$|W_+^2 - w^2| = |(W-w)^2 + 2w(W-w)| \leqslant k^2t^2 + 2wkt \leqslant k^2t^2 + 2k^2t. \tag{39}$$

Thus by the law of total probability, we have

$$\mathbb{P}(|W_+^2 - w^2| > 4k^2t) \leqslant \mathbb{P}(\{|W_+^2 - w^2| > 4k^2t\} \cap \{\max_i D_i \leqslant t\}) + \mathbb{P}(\max_i D_i > t).$$

Inequality (39) implies that for sufficiently small t, the first probability on the right-hand side above is equal to 0. The result follows. ■

In what follows we state and prove Lemma 19, a concentration inequality for the modularity of a node set (see Definition 2) from a single-layer SBM with n nodes and two communities. We first give a few short facts about the 2-community SBM. For for all results that follow, let s, ρ, and v (see Definition 4) correspond to the fixed set $B \subseteq [n]$ in each result (though sometimes we will make explicit the dependence on B). Define a matrix V by $V(i,j) := P(i,j)(1 - P(i,j))$ for $i = 1, 2$, where P is the probability matrix associated with the 2-block SBM.

Lemma 17 *Consider a single-layer SBM with $n > 1$ nodes, two communities, and parameters P and π_1. Fix a node set $B \subseteq [n]$ with $|B| \geqslant \alpha n$ for some $\alpha \in (0,1)$. Then*

1. $\left| \mathbb{E}(Y(B)) - \binom{|B|}{2} v^t P v \right| \leqslant 3|B|/2$
2. $\left| \mathbb{E}\left(\sum_{u \in B} \widehat{d}(u) \right) - |B| n v^t P \pi \right| \leqslant |B|$
3. $Var\left(\sum_{u \in B} \widehat{d}(u) \right) \leqslant 9|B|n$

Proof For part 1, note that by definition, $\mathbb{E}\left(Y(B)\right) = \sum_{u,v \in B: u<v} \mathbb{P}\left((u,v) \in \widehat{E}\right) = \frac{1}{2}\sum_{u \neq v: u,v \in B} \mathbb{P}\left((u,v) \in \widehat{E}\right)$ The right-hand sum can be expressed the sum of the entries of a 2×2 symmetric block matrix with zeroes on the diagonal. In this matrix, the upper diagonal block is of size $|B \cap C_1|$ with off-diagonal entries equal to $P(1,1)$. The lower diagonal block is of size $|B \cap C_2|$ with off-diagonal entries equal to $P(2,2)$. The off-diagonal blocks

have entries equal to $P(1,2)$. Therefore, summing over blocks and accounting for the zero diagonal, we have

$$\mathbb{E}\left(Y(B)\right) = \frac{1}{2}\Big(|B\cap C_1|^2 P(1,1) + |B\cap C_1||B\cap C_2|P(1,2) + |B\cap C_2|^2 P(2,2)\Big) - \frac{1}{2}\Big(|B\cap C_1|P(1,1) + |B\cap C_2|P(2,2)\Big).$$

By dividing and multiplying by $|B|^2$ and collapsing cross-products, we get

$$\begin{aligned}\mathbb{E}\left(Y(B)\right) &= \frac{|B|^2}{2}\left(v^tPv - \frac{\rho P(1,1)+(1-\rho)P(2,2)}{|B|}\right)\\ &= \binom{|B|}{2}\left(1+\frac{1}{|B|-1}\right)\left(v^tPv - \frac{\rho P(1,1)+(1-\rho)P(2,2)}{|B|}\right)\\ &= \binom{|B|}{2}\left(v^tPv - \frac{\rho P(1,1)+(1-\rho)P(1,2)}{|B|} + \frac{v^tPv}{|B|-1} - \frac{\rho P(1,1)+(1-\rho)P(2,2)}{|B|(|B|-1)}\right).\end{aligned}$$

Part 1 follows by carrying out the multiplication by $\binom{|B|}{2}$ in the last expression.

For part 2, let $P(\cdot,i)$ denote the i-th column of P. Note that $\mathbb{E}\left(\widehat{d}(u)\right) = n\pi^TP(\cdot,c_u) - P(c_u,c_u)$, with $c_u\in\{1,2\}$ denoting the community index of u. Therefore,

$$\begin{aligned}\mathbb{E}\left(\sum_{u\in B}\widehat{d}(u)\right) &= \sum_{u\in B}\mathbb{E}\left(\widehat{d}(u)\right) = \sum_{u\in B\cap C_1}\mathbb{E}\left(\widehat{d}(u)\right) + \sum_{u\in B\cap C_2}\mathbb{E}\left(\widehat{d}(u)\right)\\ &= |B\cap C_1|\left(n\pi^TP(\cdot,1) - P(1,1)\right) + |B\cap C_2|\left(n\pi^TP(\cdot,2) - P(2,2)\right)\\ &= |B|\left(n\rho\pi^TP(\cdot,1) + n(1-\rho)\pi^TP(\cdot,2) - \rho P(1,1) - (1-\rho)P(2,2)\right)\\ &= |B|nv^tP\pi - |B|\big(\rho P(1,1) + (1-\rho)P(2,2)\big),\end{aligned}$$

which completes part 2.

Finally, for part 3, we have

$$\mathrm{Var}\left(\sum_{u\in B}\widehat{d}(u)\right) = \mathrm{Var}\left(2Y(B)\right) + \sum_{u,v:u\in B,v\in B^C}\mathrm{Var}\left(\widehat{X}(u,v)\right). \tag{40}$$

We address these two terms separately. For the first term, a calculation analogous to that from part 1 yields that $|\mathrm{Var}\left(Y(B)\right) - \binom{|B|}{2}v^tVv| \leqslant 3|B|/2$. Defining $\bar{v} := (\rho(B^C), 1-\rho(B^C))^t$, it is easy to show that $\sum_{u,v:u\in B,v\in B^C}\mathrm{Var}\left(\widehat{X}(u,v)\right) = |B||B^C|v^tV\bar{v}$, which is simply the sum of variances of all edge indicators for edges from B to B^C. Applying these

observations to equation (40), we have

$$\begin{aligned}\mathrm{Var}\left(\sum_{u\in B}\widehat{d}(u)\right) &\leqslant 4\binom{|B|}{2}v^tVv + 12|B|/2 + |B||B^C|v^TV\bar{v}\\ &\leqslant |B|\big(2(|B|-1)v^tVv + 6 + |B^C|v^tV\bar{v}\big) \leqslant 9|B|n.\end{aligned}$$

■

Lemma 18 *Under a single-layer SBM with $n>1$ nodes, two communities, and parameters P and π_1, define $\kappa := \pi^TP\pi$. Then for large enough n, $\mathbb{P}\left(\left|2|\widehat{E}| - n^2\kappa\right| > t+4n\right) \leqslant 2\exp\left\{-\frac{t^2}{n^2}\right\}$ for any $t>0$.*

Proof Note that $|\widehat{E}| = Y([n])$. Thus part 1 of Lemma 17 with $B=[n]$ yields $\left|\mathbb{E}(|\widehat{E}|) - \binom{n}{2}\kappa\right| \leqslant 3n/2$ for large enough n. As $n^2/2 = \binom{n}{2} + n/2$, by the triangle inequality, $\left|\mathbb{E}(|\widehat{E}|) - \frac{n^2}{2}\kappa\right| \leqslant \left|\mathbb{E}(|\widehat{E}|) - \binom{n}{2}\kappa\right| + \frac{n}{2} \leqslant 2n$ Thus for any $t>0$, Hoeffding's inequality gives

$$\begin{aligned}\mathbb{P}\left(\left|2\widehat{E} - n^2\kappa\right| > t+4n\right) &\leqslant \mathbb{P}\left(\left|2\widehat{E} - n^2\kappa\right| > t + 2\left|\mathbb{E}(|\widehat{E}|) - \frac{n^2}{2}\kappa\right|\right)\\ &\leqslant \mathbb{P}\left(\left|2\widehat{E} - 2\mathbb{E}(|\widehat{E}|)\right| > t\right) \leqslant 2\exp\left\{-2\frac{t^2}{4\binom{n}{2}}\right\} \leqslant 2\exp\{-t^2/n^2\}.\end{aligned}$$

■

Lemma 19 *Consider a single-layer 2-block SBM having $n>1$ nodes and parameters P and π. Fix $\alpha\in(0,1)$ and $B\subseteq[n]$ such that $|B|\geqslant \alpha n$. Then for large enough n we have*

$$\mathbb{P}_n\left(\left|\widehat{Q}(B) - q(B)\right| > \frac{t}{n^2} + \frac{8}{\kappa n}\right) \leqslant 4\exp\left(-\frac{\kappa^2\alpha t^2}{16n^2}\right) \tag{41}$$

for any $t>0$.

Proof With notation laid out in Section 2.2, define

$$\widetilde{Q}(B) := n^{-1}\binom{|B|}{2}^{-1/2}\left(Y(B) - \widetilde{\mu}(B)\right), \tag{42}$$

where

$$\widetilde{\mu}(B) := \frac{\sum_{u,v\in B:u<v}\widehat{d}(u)\widehat{d}(v)}{n^2\kappa}. \tag{43}$$

We will prove the inequality in three steps: *Step 1*: bounding $\left|\widehat{Q}(B) - \widetilde{Q}(B)\right|$ in probability; *Step 2*: deriving a concentration inequality for $\widetilde{Q}(B)$; and *Step 3*: showing that $\left|\mathbb{E}\left(\widetilde{Q}(B)\right) - q(B)\right|$ is eventually bounded by a constant.

Step 1. As $\sum_{u,v\in B;u<v} \widehat{d}(u)\widehat{d}(v) \leqslant \sum_{u\in B} \widehat{d}(u)^2$, we have

$$\sum_{u,v\in B;u<v} \widehat{d}(u)\widehat{d}(v) \leqslant \sqrt{\sum_{u,v\in B;u<v} \widehat{d}(u)\widehat{d}(v)}\sqrt{\sum_{u\in B} \widehat{d}(u)^2} \leqslant n\binom{|B|}{2}^{1/2}|\widehat{E}|.$$

Therefore,

$$\left|\widehat{Q}(B) - \widetilde{Q}(B)\right| = n^{-1}\binom{|B|}{2}^{-1/2}\left|\frac{(2|\widehat{E}| - n^2\kappa)\sum_{u,v\in B;u<v} \widehat{d}(u)\widehat{d}(v)}{2|\widehat{E}|n^2\kappa}\right| \leqslant \frac{\left|2|\widehat{E}| - n^2\kappa\right|}{2n^2\kappa}. \quad (44)$$

Combining the inequality in (44) with Lemma 18, for any $t > 0$,

$$\mathbb{P}\left(\left|\widehat{Q}(B) - \widetilde{Q}(B)\right| > \frac{t}{2n^2} + \frac{2}{\kappa n}\right) \leqslant \mathbb{P}\left(\left|2|\widehat{E}| - n^2\kappa\right| > \kappa t + 4n\right)$$

$$\leqslant 2\exp\left(-\frac{\kappa^2 t^2}{n^2}\right). \quad (45)$$

Step 2. This step relies on McDiarmid's concentration inequality. Recall from Section 2.1 that $\widehat{X}(u,v)$ denotes the indicator of edge presence between nodes u and v. Note that node pairs have a natural, unique ordering along the upper-diagonal of the adjacency matrix. Define $ord\{u,v\} = 2(u-1) + (v-1)$, for $\{u,v\} \in [n]^2$ with $u < v$ (e.g. $ord\{1,2\} = 1$, $ord\{1,3\} = 2$, etc.). For all $n > 1$ and $i \leqslant n(n-1)/2$, define $\widehat{Z}(i) := \widehat{X}(u,v)$ such that $ord\{u,v\} = i$. If $ord\{u,v\} = i$, we call $\{u,v\}$ the "i-th ordered node pair". Define the set $\mathcal{I}(B) := \{i : \text{the } i\text{-th ordered node pair has at least one node in } B\}$ and let $\widehat{\mathcal{Z}}(B) := \{\widehat{Z}(i) : i \in I(B)\}$. Note that the proxy score $\widetilde{Q}(B)$ is a function $f(z_1, z_2, \ldots)$ of the indicators $\widehat{\mathcal{Z}}(B)$.

Consider a *fixed* indicator set $\mathcal{Z}(B)$. For each $j \in I(B)$, define $\mathcal{Z}^j(B) := \{Z^j(i) : i \in I(B)\}$ with

$$Z^j(B) := \begin{cases} Z^j(i) = 1 - Z(i), & i = j \\ Z^j(i) = Z(i), i \neq j \end{cases} \quad (46)$$

To apply McDiarmid's inequality, we must bound $\Delta(j) := |f(\mathcal{Z}(B)) - f(\mathcal{Z}^j(B))|$ uniformly over $j \in \mathcal{I}(B)$. Fix $j \in \mathcal{I}(B)$ and let $\{u', v'\}$ be the j-th ordered edge. Without loss of generality, we assume $Z(j) = 1$. Since $f(\mathcal{Z}(B)) = Q(B)$, $f(\mathcal{Z}(B))$ has a representation in terms of $Y(B)$ and $\widetilde{\mu}(B)$. We let $Y^j(B)$ and $\widetilde{\mu}^j(B)$ correspond to $f(\mathcal{Z}(B)^j)$. Notice that

$$n\binom{|B|}{2}^{1/2}\Delta(j) = \left|Y(B) - Y^j(B) - \left(\widetilde{\mu}(B) - \widetilde{\mu}^j(B)\right)\right|. \quad (47)$$

We bound the right hand side of equation (47) in two cases: (i) $u', v' \in B$, and (ii) $u' \notin B, v' \in B$. In case (i), $Y(B) - Y^j(B) = 1$, and

$$\widetilde{\mu}(B) - \widetilde{\mu}^i(B) = \frac{\sum_{u,v\in B;u\neq v} d(u)d(v) - d^j(u)d^j(v)}{n^2\kappa} = \frac{d(u')d(v') - d^j(u')d^j(v')}{n^2\kappa}$$

$$= \frac{d(u')d(v') - (d(u')-1)(d(v')-1)}{n^2\kappa} = \frac{d(u') + d(v') - 1}{n^2\kappa},$$

which is bounded in the interval $(0,1)$ for large enough n. Thus in case (i), $\Delta(j) \leqslant 2\binom{|B|}{2}^{-1/2}$ by the triangle inequality, for large enough n. In case (ii), $Y(B) - Y'(B) = 0$, and

$$\widetilde{\mu}(B) - \widetilde{\mu}^j(B) = \frac{\sum_{u,v\in B;u\neq v} d(u)d(v) - d^j(u)d^j(v)}{n^2\kappa} = \frac{\sum_{u\in B;u\neq v'} d(u)\left(d(v') - d^j(v')\right)}{n^2\kappa}$$

$$= \frac{\sum_{u\in B;u\neq v'} d(u)}{n^2\kappa} \leqslant \frac{n|B|}{n^2\kappa} \leqslant \kappa^{-1}.$$

Hence due to equation (47), we have for sufficiently large n that

$$\Delta(j) \leqslant n^{-1}\binom{|B|}{2}^{-1/2} \cdot \max\{2, \kappa^{-1}\} \leqslant n^{-1}\binom{|B|}{2}^{-1/2} \cdot 2 \cdot \kappa^{-1} \quad (48)$$

for all $j \in \mathcal{I}(B)$, as $\kappa \leqslant 1$. Since $|\mathcal{I}(B)| = \binom{|B|}{2} + |B||B^C| \leqslant n|B|$, McDiarmid's bounded-difference inequality implies that for sufficiently large n,

$$\mathbb{P}\left(\left|\widetilde{Q}(B) - \mathbb{E}\left(\widetilde{Q}(B)\right)\right| > \frac{t}{n}\right) = 2\exp\left(\frac{-t^2}{n|B|\Delta(j)}\right) \leqslant 2\exp\left(-\kappa^2\frac{n^2\binom{|B|}{2}t^2}{4n^3|B|}\right)$$

$$\leqslant 2\exp\left(-\kappa^2\frac{(|B|-1)t^2}{8n}\right) \leqslant 2\exp\left(-\kappa^2\frac{\alpha t^2}{16}\right)$$

for any $t > 0$. Replacing t by t/n gives

$$\mathbb{P}\left(\left|\widetilde{Q}(B) - \mathbb{E}\left(\widetilde{Q}(B)\right)\right| > \frac{t}{n^2}\right) \leqslant 2\exp\left(-\kappa^2\frac{\alpha t^2}{16n^2}\right). \quad (49)$$

Step 3. Turning our attention to $\mathbb{E}(\widetilde{Q}(B))$, recall that $n\binom{|B|}{2}^{1/2}\widetilde{Q}(B) = Y(B) - \widetilde{\mu}(B)$ and that $\widetilde{\mu}(B) := \sum_{u,v\in B;u<v} \widehat{d}(u)\widehat{d}(v)/(n^2\kappa)$. As in previous lemmas, we will shorthand the quantities $s(B), \rho(B)$, and $v(B)$, by s, ρ, and v (respectively). Note that

$$\mathbb{E}\left(2\cdot\sum_{u,v\in B;u<v} \widehat{d}(u)\widehat{d}(v)\right) = \mathbb{E}\left\{\left(\sum_{u\in B}\widehat{d}(u)\right)^2 - \sum_{u\in B}\widehat{d}^2(u)\right\}$$

$$= \mathrm{Var}\left(\sum_{u\in B}\widehat{d}(u)\right) + \mathbb{E}\left(\sum_{u\in B}\widehat{d}(u)\right)^2 - \sum_{u\in B}\mathbb{E}\left(\widehat{d}^2(u)\right). \quad (50)$$

Part 3 of Lemma 17 gives $\text{Var}\left(\sum_{u\in B}\widehat{d}(u)\right) \leqslant 9sn^2$. Furthermore, for $u \in C_i$ we have

$$\begin{aligned}\mathbb{E}\left(\widehat{d}^2(u)\right) &= \text{Var}\left(\widehat{d}(u)\right) + \mathbb{E}\left(\widehat{d}(u)\right)^2 \\ &= n\pi^T V(\cdot,i) - V(i,i) + n^2\left(\pi^T P(\cdot,i) - P(i,i)\right)^2,\end{aligned}$$

and therefore $\sum_{u\in B}\mathbb{E}\left(\widehat{d}^2(u)\right) \leqslant 2sn^3$. Finally, Part 2 of Lemma 17 gives $\left|\mathbb{E}\left(\sum_{u\in B}\widehat{d}(u)\right) - |B|nv^T P\pi\right| \leqslant |B|$. By expansion, this implies there exists a constant a with $|a| < 3$ such that for large enough n, $\mathbb{E}\left(\sum_{u\in B}\widehat{d}(u)\right)^2 = s^2n^4(v^tP\pi)^2 + as^2n^3$. Therefore overall, line (50) implies there exists a constant b with $|b| < 6$ such that for large enough n, $\mathbb{E}\left(2\cdot\sum_{u,v\in B;u<v}\widehat{d}(u)\widehat{d}(v)\right) = s^2n^4(v^TP\pi)^2 + bsn^3$. Therefore, using the definition of $\widetilde{\mu}(B)$,

$$\begin{aligned}\mathbb{E}\left(\widetilde{\mu}(B)\right) &= s^2n^4\frac{(v^tP\pi)^2 + b(sn)^{-1}}{2n^2\kappa} = \binom{sn}{2}\left(1+\frac{1}{sn-1}\right)\left(\frac{(v^tP\pi)^2}{\kappa} + \frac{b}{\kappa sn}\right) \\ &= \binom{sn}{2}\left(\frac{(v^tP\pi)^2}{\kappa} + \frac{b}{\kappa sn} + \frac{(v^tP\pi)^2}{\kappa(sn-1)} + \frac{b}{\kappa sn(sn-1)}\right) \\ &= \binom{sn}{2}\left(\frac{(v^tP\pi)^2}{\kappa} + \frac{1}{\kappa sn}\left(b + \frac{sn(v^tP\pi)^2 + b}{sn-1}\right)\right) \\ &= \binom{sn}{2}\left(\frac{(v^tP\pi)^2}{\kappa} + \frac{c_1}{\kappa sn}\right) \qquad (51)\end{aligned}$$

for a constant c_1 with $|c_1| < 8$, for large enough n. Now, part 1 of Lemma 17 gives that $\left|\mathbb{E}(Y(B)) - \binom{|B|}{2}v^tPv\right| \leqslant 3|B|/2$ for large enough n. Thus there exists a constant c_2 with $|c_2| < 3$ such that for large enough n, $\mathbb{E}(Y(B)) = \binom{|B|}{2}\left(v^tPv + \frac{c_2}{sn}\right)$. Thus

$$\begin{aligned}n\mathbb{E}\left(\widetilde{Q}(B)\right) &= \binom{|B|}{2}^{-1/2}\left(\mathbb{E}(Y(B)) - \mathbb{E}(\tilde{\mu}(B))\right) = \frac{sn}{\sqrt{2}}\left(v^tPv - \frac{(v^tP\pi)^2}{\kappa} + \frac{1}{sn}\left(c_1/\kappa + c_2\right)\right) \\ &\quad * \left(\sqrt{1-\frac{1}{sn}}\right) = \frac{sn}{\sqrt{2}}\left(v^tPv - \frac{(v^tP\pi)^2}{\kappa}\right) + \frac{c_1/\kappa + c_2}{\sqrt{2}}\left(\sqrt{1-\frac{1}{sn}}\right).\end{aligned}$$

Thus there exists a constant c with $|c| \leqslant |c_1|/\kappa + |c_2| < 8/\kappa + 3$ such that for large enough n, $\mathbb{E}(\widetilde{Q}(B)) = q(B) + c/n$. This completes Step 3.

Completion of the proof: We now recall the results of the three steps:

(i) For large enough n, we have $\mathbb{P}\left(\left|\widehat{Q}(B) - \widetilde{Q}(B)\right| > \frac{t}{2n^2} + \frac{2}{\kappa n}\right) \leqslant 2\exp\left(-\frac{\kappa^2t^2}{n^2}\right)$

(ii) $\mathbb{P}\left(\left|\widetilde{Q}(B) - \mathbb{E}\left(\widetilde{Q}(B)\right)\right| > \frac{t}{n^2}\right) \leqslant 2\exp\left(-\kappa^2\frac{\alpha t^2}{16n^2}\right)$

(iii) There exists c with $|c| < 8/\kappa + 3$ such that for large enough n, $\mathbb{E}\left(\widehat{Q}(B)\right) = q(B) + c/n$

Noting that $\alpha/16 < 1$, we apply a union bound to the results of steps (i) and (ii):

$$\mathbb{P}\left(\left|\widehat{Q}(B) - \mathbb{E}\left(\widetilde{Q}(B)\right)\right| > \frac{t}{n^2} + \frac{2}{\kappa n}\right) \leqslant 4\exp\left(-\frac{\kappa^2\alpha t^2}{16n^2}\right) \qquad (52)$$

Applying the inequality $|x-a| \geqslant |x| - |a|$ with (iii) and some algebra gives the result. ■

Appendix C. Competing Methods

In Sections 6 and 7, we compare and contrast the performance of Multilayer Extraction with the following methods:

Spectral clustering (Newman, 2006a): an iterative algorithm based on the spectral properties of the modularity matrix of an observed network. In the first step, the modularity matrix of the observed network is calculated and its leading eigenvector is identified. The graph is divided into two disjoint communities so that each vertex is assigned according to its sign in the leading eigenvector. Next, the modularity matrix is calculated for both of the subgraphs corresponding to the previous division. If the modularity of the partition increases, these communities are once again divided into two disjoint communities, and the procedure is repeated in this fashion until the modularity no longer increases. For the desired igraph object `graph`, the call for this in `R` was:

```
cluster_leading_eigen(graph, steps = -1, weights = NULL, start = NULL,
options = arpack_defaults, callback = NULL, extra = NULL, env = parent.frame())
```

Label Propagation (Raghavan et al., 2007): an iterative algorithm based on propagation through the network. At the first step, all vertices are randomly assigned a community label. Sequentially, the algorithm chooses a single vertex and updates the labels of its neighborhood to be the majority label of the neighborhood. The algorithm continues updating labels in this way until no updates are available. For the desired igraph object `graph`, the call for this in `R` was:

```
cluster_label_prop(graph, weights = E(graph)$weight, initial = NULL,
fixed = NULL)
```

Fast and greedy (Clauset et al., 2004): an iterative and greedy algorithm that seeks a partition of vertices with maximum modularity. The algorithm is an agglomerative approach that is a modification of the Kernighan-Lin algorithm commonly used in the identification of community structure in network. For the desired igraph object `graph`, the call for this in `R` was:

```
cluster_fast_greedy(graph, merges = TRUE, weights = E(graph)$weight,
modularity = TRUE, membership = TRUE, weights = NULL)
```

Walktrap (Pons and Latapy, 2005): an agglomerative algorithm that seeks a partition of vertices that minimizes the total length of a random walk within each community. At the first stage, each vertex of the network is placed in its own community. At each subsequent stage, the two closest communities (according to walk distance) are merged. This process is continued until all vertices have been merged into one large community, and a community dendrogram is formed. The partition with the smallest random walk distance is chosen as the final partition.

```
cluster_walktrap(graph, weights = E(graph)$weight, steps = 4,
 merges = TRUE, modularity = TRUE, membership = TRUE)
```

GenLouvain (Jutla et al., 2011): a multilayer generalization of the iterative GenLouvain algorithm. This algorithm seeks a partition of the vertices and layers that maximizes the multilayer modularity of the network, as described in (Mucha et al., 2010). We use the MATLAB implementation from (Jutla et al., 2011) of GenLouvain with resolution parameter set to 1, and argument `randmove = moverandw`.

Infomap (De Domenico et al., 2014): a multilayer generalization of the Infomap algorithm from Rosvall and Bergstrom (2008). This algorithm seeks to identify a partition of the vertices and layers that minimize the generalized map equation, which measures the description length of a random walk on the partition. We use the C++ multiplex implementation of Infomap provided at `http://www.mapequation.org/code.html`. In implementation, we set the arguments of the function to permit overlapping communities, and set the algorithm to ignore self-loops.

For the first four methods, we use the default settings from the *igraph* package version 0.7.1 set in `R`.

Appendix D. Extraction Simulations

D.1 Simulation

We now investigate several intrinsic properties of Multilayer Extraction by applying the method to multilayer networks with several types of community structure, including I) disjoint, II) overlapping, III) persistent, IV) non-persistent, and V) hierarchical structure. Figure 7 illustrates six multilayer networks that we analyze for this purpose. Each simulated network contains 1000 nodes and 90 layers. Embedded communities have inner connection probability 0.15; whereas, the remaining vertices independently connected to all other vertices with probability 0.05.

D.2 Results

In the disjoint, overlapping, persistent, and non-persistent networks (I, II, III, and IV, respectively), Multilayer Extraction identifies communities that perfectly match the true embedded communities. On the other hand, in the hierarchical community setting, Multilayer Extraction is unable to identify the full set of communities. In example V, Multilayer

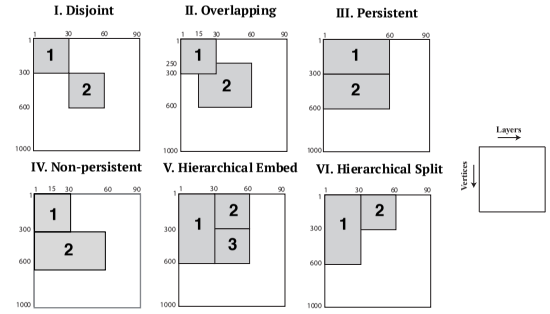

Figure 7: Simulation test bed for extraction procedures. Each graphic displays a multilayer network on 1000 nodes and 90 layers. In each plot, shaded rectangles are placed over the nodes (rows) and layers (columns) that are included in a multilayer community. Communities are labeled by number. Vertices within the same community are randomly connected with probability 0.15 while all other vertices have connection probability 0.05 to vertices in their respective layer.

Extraction does not identify community 1, and in example VI Extraction identifies a community with vertices 1 - 300 across layers 1 - 60, which combines community 1 and community 2.

Together, these results suggest two properties of the Multilayer Extraction procedure. First, the method can efficiently identify disjoint and overlapping community structure in multilayer networks with heterogeneous community structure. Second, Multilayer Extraction tends to disregard communities with a large number of vertices (e.g. communities that include over half of the vertices in a network). The inverse relationship between the score and the number of vertices in a community may provide some justification as to why this is the case. In networks with large communities, one can in principle modify the score by introducing a reward for large collections. We plan to pursue this further in future research.
